CONTRIBUTOR LIST

- ABDEL HADY, MAZEN**, *McMaster University, Hamilton, Ontario Canada*, Bladder Dysfunction, Neurostimulation of
- ABEL, L.A.**, *University of Melbourne, Melbourne, Australia*, Ocular Motility Recording and Nystagmus
- ABREU, BEATRIZ C.**, *Transitional Learning Center at Galveston, Galveston, Texas*, Rehabilitation, Computers in Cognitive
- ALEXANDER, A.L.**, *University of Wisconsin–Madison, Madison, Wisconsin*, Magnetic Resonance Imaging
- ALI, ABBAS**, *University of Illinois, at Urbana-Champaign, Bioinformatics*
- ALI, MÜFTÜ**, *School of Dental Medicine, Boston, Massachusetts*, Tooth and Jaw, Biomechanics of
- ALPERIN, NOAM**, *University of Illinois at Chicago, Chicago, Illinois*, Hydrocephalus, Tools for Diagnosis and Treatment of
- ANSON, DENIS**, *College Misericordia, Dallas, Pennsylvania*, Environmental Control
- ARENA, JOHN C.**, *VA Medical Center and Medical College of Georgia*, Biofeedback
- ARIEL, GIDEON**, *Ariel Dynamics, Canyon, California*, Biomechanics of Exercise Fitness
- ARMSTRONG, STEVE**, *University of Iowa, Iowa City, Iowa*, Biomaterials for Dentistry
- ASPDEN, R.M.**, *University of Aberdeen, Aberdeen, United Kingdom*, Ligament and Tendon, Properties of
- AUBIN, C.E.**, *Polytechnique Montreal, Montreal Quebec, Canada*, Scoliosis, Biomechanics of
- AYRES, VIRGINIA M.**, *Michigan State University, East Lansing, Michigan*, Microscopy, Scanning Tunneling
- AZANGWE, G.**, Ligament and Tendon, Properties of
- BACK, LLOYD H.**, *California Institute of Technology, Pasadena, California*, Coronary Angioplasty and Guidewire Diagnostics
- BADYLAK, STEPHEN F.**, *McGowan Institute for Regenerative Medicine, Pittsburgh, Pennsylvania*, Sterilization of Biologic Scaffold Materials
- BANDYOPADHYAY, AMIT**, *Washington State University, Pullman, Washington*, Orthopedic Devices, Materials and Design for
- BANERJEE, RUPAK K.**, *University of Cincinnati, Cincinnati, Ohio*, Coronary Angioplasty and Guidewire Diagnostics
- BARBOUR, RANDALL L.**, *State University of New York Downstate Medical Center, Brooklyn, New York*, Peripheral Vascular Noninvasive Measurements
- BARKER, STEVEN J.**, *University of Arizona, Tucson, Arizona*, Oxygen Monitoring
- BARTH, ROLF F.**, *The Ohio State University, Columbus, Ohio*, Boron Neutron Capture Therapy
- BECCHETTI, F.D.**, *University of Michigan, Ann Arbor, Michigan*, Radiotherapy, Heavy Ion
- BELFORTE, GUIDO**, *Politecnico di Torino – Department of Mechanics*, Laryngeal Prosthetic Devices
- BENKESER, PAUL**, *Georgia Institute of Technology, Atlanta, Georgia*, Biomedical Engineering Education
- BENNETT, JAMES R.**, *University of Iowa, Iowa City, Iowa*, Digital Angiography
- BERSANO-BEGEY, TOMMASO**, *University of Michigan, Ann Arbor, Michigan*, Microbioreactors
- BIGGS, PETER J.**, *Harvard Medical School, Boston, Massachusetts*, Radiotherapy, Intraoperative
- BIYANI, ASHOK**, *University of Toledo, and Medical College of Ohio, Toledo, Ohio*, Human Spine, Biomechanics of
- BLOCK, W.F.**, *University of Wisconsin–Madison, Madison, Wisconsin*, Magnetic Resonance Imaging
- BLUE, THOMAS E.**, *The Ohio State University, Columbus, Ohio*, Boron Neutron Capture Therapy
- BLUMSACK, JUDITH T.**, *Disorders Auburn University, Auburn, Alabama*, Audiometry
- BOGAN, RICHARD K.**, *University of South Carolina, Columbia, South Carolina*, Sleep Laboratory
- BOKROS, JACK C.**, *Medical Carbon Research Institute, Austin, Texas*, Biomaterials, Carbon
- BONGIOANNINI, GUIDO**, *ENT Division Mauriziano Hospital, Torino, Italy*, Laryngeal Prosthetic Devices
- BORAH, JOSHUA**, *Applied Science Laboratories, Bedford, Massachusetts*, Eye Movement, Measurement Techniques for
- BORDEN, MARK**, *Director of Biomaterials Research, Irvine, California*, Biomaterials, Absorbable
- BORTON, BETTIE B.**, *Auburn University Montgomery, Montgomery, Alabama*, Audiometry
- BORTON, THOMAS E.**, *Auburn University Montgomery, Montgomery, Alabama*, Audiometry
- BOSE SUSMITA.**, *Washington State University, Pullman, Washington*, Orthopedic Devices, Materials and Design for
- BOVA, FRANK J.**, *M. D. Anderson Cancer Center Orlando, Orlando, FL*, Radiosurgery, Stereotactic
- BRENNER, DAVID J.**, *Columbia University Medical Center, New York, New York*, Computed Tomography Screening
- BREWER, JOHN M.**, *University of Georgia*, Electrophoresis
- BRIAN, L. DAVIS**, *Lerner Research Institute, The Cleveland Clinic Foundation, Cleveland, Ohio*, Skin, Biomechanics of
- BRITT, L.D.**, *Eastern Virginia Medical School, Norfolk, Virginia*, Gastrointestinal Hemorrhage
- BRITT, R.C.**, *Eastern Virginia Medical School, Norfolk, Virginia*, Gastrointestinal Hemorrhage
- BROZIK, SUSAN M.**, *Sandia National Laboratories, Albuquerque, New Mexico*, Microbial Detection Systems
- BRUNER, JOSEPH P.**, *Vanderbilt University Medical Center, Nashville, Tennessee*, Intrauterine Surgical Techniques
- BRUNSWIG NEWRING, KIRK A.**, *University of Nevada, Reno, Nevada*, Sexual Instrumentation
- BRUYANT, PHILIPPE P.**, *University of Massachusetts, North Worcester, Massachusetts*, Nuclear Medicine, Computers in
- BUNNELL, BERT J.**, *Bunnell Inc., Salt Lake City, Utah*, High Frequency Ventilation
- CALKINS, JERRY M.**, *Defense Research Technologies, Inc., Rockville, Maryland*, Medical Gas Analyzers
- CANNON, MARK**, *Northwestern University, Chicago, Illinois*, Resin-Based Composites

- CAPPELLERI, JOSEPH C.**, *Pfizer Inc., Groton, Connecticut*, Quality-of-Life Measures, Clinical Significance of
- CARDOSO, JORGE**, *University of Madeira, Funchal, Portugal*, Office Automation Systems
- CARELLO, MASSIMILIANA**, *Politecnico di Torino – Department of Mechanics, Laryngeal Prosthetic Devices*
- CASKEY, THOMAS C.**, *Cogene Biotech Ventures, Houston, Texas*, Polymerase Chain Reaction
- CECCIO, STEVEN**, *University of Michigan, Ann Arbor, Michigan*, Heart Valve Prostheses, In Vitro Flow Dynamics of
- CHAN, JACKIE K.**, *Columbia University, New York, New York*, Photography, Medical
- CHANDRAN, K.B.**, *University of Iowa, Iowa City, Iowa*, Heart Valve Prostheses
- CHATZANDROULIS, S.**, *NTUA, Athens, Attiki, Greece*, Capacitive Microsensors for Biomedical Applications
- CHAVEZ, ELIANA**, *University of Pittsburgh, Pittsburgh, Pennsylvania*, Mobility Aids
- CHEN, HENRY**, *Stanford University, Palo Alto, California*, Exercise Stress Testing
- CHEN, JIANDE**, *University of Texas Medical Branch, Galveston, Texas*, Electrogastrogram
- CHEN, YAN**, *Lerner Research Institute, The Cleveland Clinic Foundation, Cleveland, Ohio*, Skin, Biomechanics of
- CHEYNE, DOUGLAS**, *Hospital for Sick Children Research Institute, Biomagnetism*
- CHUI, CHEN-SHOU**, *Memorial Sloan-Kettering Cancer Center, New York, New York*, Radiation Therapy Treatment Planning, Monte Carlo Calculations in
- CLAXTON, NATHAN S.**, *The Florida State University, Tallahassee, Florida*, Microscopy, Confocal
- CODERRE, JEFFREY A.**, *Massachusetts Institute of Technology, Cambridge, Massachusetts*, Boron Neutron Capture Therapy
- COLLINS, BETH**, *University of Mississippi Medical Center, Jackson, Mississippi*, Hyperbaric Medicine
- COLLINS, DIANE**, *University of Pittsburgh, Pittsburgh, Pennsylvania*, Mobility Aids
- CONSTANTINOU, C.**, *Columbia University Radiation Oncology, New York, New York*, Phantom Materials in Radiology
- COOK, ALBERT**, *University of Alberta, Edmonton, Alberta, Canada*, Communication Devices
- COOPER, RORY**, *University of Pittsburgh, Pittsburgh, Pennsylvania*, Mobility Aids
- CORK, RANDALL C.**, *Louisiana State University, Shreveport, Louisiana*, Monitoring, Umbilical Artery and Vein, Blood Gas Measurements; Transcutaneous Electrical Nerve Stimulation (TENS); Ambulatory Monitoring
- COX, JOSEPHINE H.**, *Walter Reed Army Institute of Research, Rockville, Maryland*, Blood Collection and Processing
- CRAIG, LEONARD**, *Feinberg School of Medicine of Northwestern University, Chicago, Illinois*, Ventilators, Acute Medical Care
- CRESS, CYNTHIA J.**, *University of Nebraska, Lincoln, Nebraska*, Communicative Disorders, Computer Applications for
- CUMMING, DAVID R.S.**, *University of Glasgow, Glasgow, United Kingdom*, Ion-Sensitive Field-Effect Transistors
- CUNNINGHAM, JOHN R.**, *Camrose, Alberta, Canada*, Cobalt 60 Units for Radiotherapy
- D'ALESSANDRO, DAVID**, *Montefiore Medical Center, Bronx, New York*, Heart-Lung Machines
- D'AMBRA, MICHAEL N.**, *Harvard Medical School, Cambridge, Massachusetts*, Cardiac Output, Thermodilution Measurement of
- DADSETAN, MAHROKH**, *Mayo Clinic, College of Medicine, Rochester, Minnesota*, Microscopy, Electron
- DALEY, MICHAEL L.**, *The University of Memphis, Memphis, Tennessee*, Monitoring, Intracranial Pressure
- DAN, LOYD**, *Linköping University, Linköping, Sweden*, Thermocouples
- DAS, RUPAK**, *University of Wisconsin, Madison, Wisconsin*, Brachytherapy, High Dosage Rate
- DATTAWADKAR, AMRUTA M.**, *University of Wisconsin, Madison, Madison, Wisconsin*, Ocular Fundus Reflectometry
- DAVIDSON, MICHAEL W.**, *The Florida State University, Tallahassee, Florida*, Microscopy, Confocal
- DE LUCA, CARLO**, *Boston University, Boston, Massachusetts*, Electromyography
- DE SALLES, ANTONIO A.F.**, *UCLA Medical School, Los Angeles, California*, Stereotactic Surgery
- DECAU, SABIN**, *University of Maryland, School of Medicine*, Shock, Treatment of
- DECHOW, PAUL C.**, *A & M University Health Science Center, Dallas, Texas*, Strain Gages
- DELBEKE, JEAN**, *Catholique University of Louvain, Brussels, Belgium*, Visual Prostheses
- DELL'OSSO, LOUIS F.**, *Case Western Reserve University, Cleveland, Ohio*, Ocular Motility Recording and Nystagmus
- DELORME, ARNAUD**, *University of San Diego, La Jolla, California*, Statistical Methods
- DEMENKOFF, JOHN**, *Mayo Clinic, Scottsdale, Arizona*, Pulmonary Physiology
- DEMIR, SEMAHAT S.**, *The University of Memphis and The University of Tennessee Health Science Center, Memphis, Tennessee*, Electrophysiology
- DEMLING, ROBERT H.**, *Harvard Medical School*, Skin Substitute for Burns, Bioactive
- DENNIS, MICHAEL J.**, *Medical University of Ohio, Toledo, Ohio*, Computed Tomography
- DESANTI, LESLIE**, *Harvard Medical School*, Skin Substitute for Burns, Bioactive
- DEUTSCH, STEVEN**, *Pennsylvania State University, University Park, Pennsylvania*, Flowmeters
- DEVINENI, TRISHUL**, *Conemaugh Health System*, Biofeedback
- DI BELLA EDWARD, V.R.**, *University of Utah*, Tracer Kinetics
- DI AKIDES, NICHOLAS A.**, *Advanced Concepts Analysis, Inc., Falls Church, Virginia*, Thermography
- DOLAN, PATRICIA L.**, *Sandia National Laboratories, Albuquerque, New Mexico*, Microbial Detection Systems
- DONOVAN, F.M.**, *University of South Alabama*, Cardiac Output, Indicator Dilution Measurement of
- DOUGLAS, WILSON R.**, *Children's Hospital of Philadelphia, Philadelphia, Pennsylvania*, Intrauterine Surgical Techniques
- DRAPER, CRISSA**, *University of Nevada, Reno, Nevada*, Sexual Instrumentation
- DRZEWIECKI, TADEUSZ M.**, *Defense Research Technologies, Inc., Rockville, Maryland*, Medical Gas Analyzers
- DURFEE, W.K.**, *University of Minnesota, Minneapolis, Minnesota*, Rehabilitation and Muscle Testing
- DYRO, JOSEPH F.**, *Setauket, New York*, Safety Program, Hospital

- DYSON, MARY**, *Herts, United Kingdom*, Heat and Cold, Therapeutic
- ECKERLE, JOSEPH S.**, *SRI International, Menlo Park, California*, Tonometry, Arterial
- EDWARDS, BENJAMIN**, *University of Wisconsin-Madison, Madison, Wisconsin*, Codes and Regulations: Radiation
- EDWARDS, THAYNE L.**, *University of Washington, Seattle, Washington*, Chromatography
- EKLUND, ANDERS**, *University of Illinois at Chicago, Chicago, Illinois*, Hydrocephalus, Tools for Diagnosis and Treatment of
- EL SOLH, ALI A.**, *Erie County Medical Center, Buffalo, New York*, Sleep Studies, Computer Analysis of
- ELMAYERGI, NADER**, *McMaster University, Hamilton, Ontario, Canada*, Bladder Dysfunction, Neurostimulation of
- ELSHARYDAH, AHMAD**, *Louisiana State University, Baton Rouge, Louisiana*, Ambulatory Monitoring; Monitoring, Umbilical Artery and Vein, Blood Gas Measurements
- FADDY, STEVEN C.**, *St. Vincents Hospital, Sydney, Darlinghurst, Australia*, Cardiac Output, Fick Technique for
- FAHEY, FREDERIC H.**, *Childrens Hospital Boston*, Computed Tomography, Single Photon Emission
- FAIN, S.B.**, *University of Wisconsin-Madison, Madison, Wisconsin*, Magnetic Resonance Imaging
- FELDMAN, JEFFREY**, *Childrens Hospital of Philadelphia, Philadelphia, Pennsylvania*, Anesthesia Machines
- FELLERS, THOMAS J.**, *The Florida State University, Tallahassee, Florida*, Microscopy, Confocal
- FERRARA, LISA**, *Cleveland Clinic Foundation, Cleveland, Ohio*, Human Spine, Biomechanics of
- FERRARI, MAURO**, *The Ohio State University, Columbus, Ohio*, Drug Delivery Systems
- FONTAINE, ARNOLD A.**, *Pennsylvania State University, University Park, Pennsylvania*, Flowmeters
- FOUST, MILTON J., JR.**, *Medical University of South Carolina Psychiatry and Behavioral Sciences, Charleston, South Carolina*, Electroconvulsive Therapy
- FRASCO, PETER**, *Mayo Clinic Scottsdale, Scottsdale, Arizona*, Temperature Monitoring
- FRAZIER, JAMES**, *Louisiana State University, Baton Rouge, Louisiana*, Ambulatory Monitoring
- FREISLEBEN DE BLASIO, BIRGITTE**, *University of Oslo, Oslo, Norway*, Impedance Spectroscopy
- FRESTA, MASSIMO**, *University of Catanzaro Magna Græcia, Germaneto (CZ), Italy*, Drug Delivery Systems
- FREYTES, DONALD O.**, *McGowan Institute for Regenerative Medicine, Pittsburgh Pennsylvania*, Sterilization of Biologic Scaffold Materials
- FROELICHER, VICTOR**, *VA Medical Center, Palo Alto, California*, Exercise Stress Testing
- FUNG, EDWARD K.**, *Columbia University, New York, New York*, Photography, Medical
- GAGE, ANDREW A.**, *State University of New York at Buffalo, Buffalo, New York*, Cryosurgery
- GAGLIO, PAUL J.**, *Columbia University College of Physicians and Surgeons*, Liver Transplantation
- GARDNER, REED M.**, *LDS Hospital and Utah University, Salt Lake City, Utah*, Monitoring, Hemodynamic
- GEJERMAN, GLEN**, *Hackensack University Medical, Hackensack, New Jersey*, Radiation Therapy, Quality Assurance in
- GEORGE, MARK S.**, *Medical University of South Carolina Psychiatry and Behavioral Sciences, Charleston, South Carolina*, Electroconvulsive Therapy
- GHARIEB, R.R.**, *Infinite Biomedical Technologies, Baltimore, Maryland*, Neurological Monitors
- GLASGOW, GLENN P.**, *Loyola University of Chicago, Maywood, Illinois*, Radiation Protection Instrumentation
- GLASGOW, GLENN**, *University of Wisconsin-Madison, Madison, Wisconsin*, Codes and Regulations: Radiation
- GOEL, VIJAY K.**, *University of Toledo, and Medical College of Ohio, Toledo, Ohio*, Human Spine, Biomechanics of
- GOETSCH, STEVEN J.**, *San Diego Gamma Knife Center, La Jolla, California*, Gamma Knife
- GOLDBERG, JAY R.**, *Marquette University Milwaukee, Wisconsin*, Minimally Invasive Surgery
- GOLDBERG, ZELENNA**, *Department of Radiation Oncology, Davis, California*, Ionizing Radiation, Biological Effects of
- GOPALAKRISHNAKONE, P.**, *National University of Singapore, Singapore*, Immunologically Sensitive Field-Effect Transistors
- GOPAS, JACOB**, *Ben Gurion University of the Negev, Beer Sheva, Israel*, Monoclonal Antibodies
- GORGULHO, ALESSANDRA**, *UCLA Medical School, Los Angeles, California*, Stereotactic Surgery
- GOUGH, DAVID A.**, *University of California, La Jolla, California*, Glucose Sensors
- GOUSTOURIDIS, D.**, *NTUA, Athens, Attiki, Greece*, Capacitive Microsensors for Biomedical Applications
- GRABER, HARRY L.**, *State University of New York Downstate Medical Center, Brooklyn, New York*, Peripheral Vascular Noninvasive Measurements
- GRACA, M.**, *Louisiana State University, Baton Rouge, Louisiana*, Boron Neutron Capture Therapy
- GRANT, WALTER III**, *Baylor College of Medicine, Houston, Texas*, Radiation Therapy, Intensity Modulated
- GRAYDEN, EDWARD**, *Mayo Health Center, Albertlea, Minnesota*, Cardiopulmonary Resuscitation
- GREEN, JORDAN R.**, *University of Nebraska, Lincoln, Nebraska*, Communicative Disorders, Computer Applications for
- HAEMMERICH, DIETER**, *Medical University of South Carolina, Charleston, South Carolina*, Tissue Ablation
- HAMAM, HABIB**, *Université de Moncton, Moncton New Brunswick, Canada*, Lenses, Intraocular
- HAMMOND, PAUL A.**, *University of Glasgow, Glasgow, United Kingdom*, Ion-Sensitive Field-Effect Transistors
- HANLEY, JOSEPH**, *Hackensack University Medical, Hackensack, New Jersey*, Radiation Therapy, Quality Assurance in
- HARLEY, BRENDAN A.**, *Massachusetts Institute of Technology*, Skin Tissue Engineering for Regeneration
- HARPER, JASON C.**, *Sandia National Laboratories, Albuquerque, New Mexico*, Microbial Detection Systems
- HASMAN, ARIE**, *Maastricht, The Netherlands*, Medical Education, Computers in
- HASSOUNA, MAGDY**, *Toronto Western Hospital, Toronto, Canada*, Bladder Dysfunction, Neurostimulation of
- HAYASHI, KOZABURO**, *Okayama University of Science, Okayama, Japan*, Arteries, Elastic Properties of

PREFACE

This six-volume work is an alphabetically organized compilation of almost 300 articles that describe critical aspects of medical devices and instrumentation.

It is comprehensive. The articles emphasize the contributions of engineering, physics, and computers to each of the general areas of anesthesiology, biomaterials, burns, cardiology, clinical chemistry, clinical engineering, communicative disorders, computers in medicine, critical care medicine, dermatology, dentistry, ear, nose, and throat, emergency medicine, endocrinology, gastroenterology, genetics, geriatrics, gynecology, hematology, hepatology, internal medicine, medical physics, microbiology, nephrology, neurology, nutrition, obstetrics, oncology, ophthalmology, orthopedics, pain, pediatrics, peripheral vascular disease, pharmacology, physical therapy, psychiatry, pulmonary medicine, radiology, rehabilitation, surgery, tissue engineering, transducers, and urology.

The discipline is defined through the synthesis of the core knowledge from all the fields encompassed by the application of engineering, physics, and computers to problems in medicine. The articles focus not only on what is now useful but also on what is likely to be useful in future medical applications.

These volumes answer the question, "What are the branches of medicine and how does technology assist each of them?" rather than "What are the branches of technology and how could each be used in medicine?" To keep this work to a manageable length, the practice of medicine that is unassisted by devices, such as the use of drugs to treat disease, has been excluded.

The articles are accessible to the user; each benefits from brevity of condensation instead of what could easily have been a book-length work. The articles are designed not for peers, but rather for workers from related fields who wish to take a first look at what is important in the subject.

The articles are readable. They do not presume a detailed background in the subject, but are designed for any person with a scientific background and an interest in technology. Rather than attempting to teach the basics of physiology or Ohm's law, the articles build on such basic concepts to show how the worlds of life science and physical science meld to produce improved systems. While the ideal reader might be a person with a Master's degree in biomedical engineering or medical physics or an M.D. with a physical science undergraduate degree, much of the material will be of value to others with an interest in this growing field. High school students and hospital patients can skip over more technical areas and still gain much from the descriptive presentations.

The *Encyclopedia of Medical Devices and Instrumentation* is excellent for browsing and searching for those new divergent associations that may advance work in a peripheral field. While it can be used as a reference for facts, the articles are long enough that they can serve as an educational instrument and provide genuine understanding of a subject.

One can use this work just as one would use a dictionary, since the articles are arranged alphabetically by topic. Cross references assist the reader looking for subjects listed under slightly different names. The index at the end leads the reader to all articles containing pertinent information on any subject. Listed on pages xxi to xxx are all the abbreviations and acronyms used in the *Encyclopedia*. Because of the increasing use of SI units in all branches of science, these units are provided throughout the *Encyclopedia* articles as well as on pages xxxi to xxxv in the section on conversion factors and unit symbols.

I owe a great debt to the many people who have contributed to the creation of this work. At John Wiley & Sons, Encyclopedia Editor George Telecki provided the idea and guiding influence to launch the project. Sean Pidgeon was Editorial Director of the project. Assistant Editors Roseann Zappia, Sarah Harrington, and Surlan Murrell handled the myriad details of communication between publisher, editor, authors, and reviewers and stimulated authors and reviewers to meet necessary deadlines.

My own background has been in the electrical aspects of biomedical engineering. I was delighted to have the assistance of the editorial board to develop a comprehensive encyclopedia. David J. Beebe suggested cellular topics such as microfluidics. Jerry M. Calkins assisted in defining the chemically related subjects, such as anesthesiology. Michael R. Neuman suggested subjects related to sensors, such as in his own work—neonatology. Joon B. Park has written extensively on biomaterials and suggested related subjects. Edward S. Sternick provided many suggestions from medical physics. The Editorial Board was instrumental both in defining the list of subjects and in suggesting authors.

This second edition brings the field up to date. It is available on the web at <http://www.mrw.interscience.wiley.com/emdi>, where articles can be searched simultaneously to provide rapid and comprehensive information on all aspects of medical devices and instrumentation.

JOHN G. WEBSTER
University of Wisconsin, Madison

LIST OF ARTICLES

ALLOYS, SHAPE MEMORY
AMBULATORY MONITORING
ANALYTICAL METHODS, AUTOMATED
ANESTHESIA MACHINES
ANESTHESIA, COMPUTERS IN
ANGER CAMERA
ANORECTAL MANOMETRY
ARRHYTHMIA ANALYSIS, AUTOMATED
ARTERIES, ELASTIC PROPERTIES OF
AUDIOMETRY
BIOCOMPATIBILITY OF MATERIALS
BIOELECTRODES
BIOFEEDBACK
BIOHEAT TRANSFER
BIOIMPEDANCE IN CARDIOVASCULAR MEDICINE
BIOINFORMATICS
BIOMAGNETISM
BIOMATERIALS, ABSORBABLE
BIOMATERIALS: AN OVERVIEW
BIOMATERIALS: BIOCERAMICS
BIOMATERIALS: CARBON
BIOMATERIALS, CORROSION AND WEAR OF

ABBREVIATIONS AND ACRONYMS

AAMI	Association for the Advancement of Medical Instrumentation	ALS	Advanced life support; Amyotropic lateral sclerosis
AAPM	American Association of Physicists in Medicine	ALT	Alanine aminotransferase
ABC	Automatic brightness control	ALU	Arithmetic and logic unit
ABET	Accreditation board for engineering training	AM	Amplitude modulation
ABG	Arterial blood gases	AMA	American Medical Association
ABLB	Alternative binaural loudness balance	amu	Atomic mass units
ABS	Acrylonitrile–butadiene–styrene	ANOVA	Analysis of variance
ac	Alternating current	ANSI	American National Standards Institute
AC	Abdominal circumference; Affinity chromatography	AP	Action potential; Alternative pathway; Anteroposterior
ACA	Automated clinical analyzer	APD	Anterioposterior diameter
ACES	Augmentative communication evaluation system	APL	Adjustable pressure limiting valve; Applied Physics Laboratory
ACL	Anterior chamber lens	APR	Anatomically programmed radiography
ACLS	Advanced cardiac life support	AR	Amplitude reduction; Aortic regurgitation; Autoregressive
ACOG	American College of Obstetrics and Gynecology	Ara-C	Arabinosylcytosine
ACR	American College of Radiology	ARD	Absorption rate density
ACS	American Cancer Society; American College of Surgeons	ARDS	Adult respiratory distress syndrome
A/D	Analog-to-digital	ARGUS	Arrhythmia guard system
ADC	Agar diffusion chambers; Analog-to-digital converter	ARMA	Autoregressive-moving-average model
ADCC	Antibody-dependent cellular cytotoxicity	ARMAX	Autoregressive-moving-average model with external inputs
ADCL	Accredited Dosimetry Calibration Laboratories	AS	Aortic stenosis
ADP	Adenosine diphosphate	ASA	American Standards Association
A-D-T	Admission, discharge, and transfer	ASCII	American standard code for information interchange
AE	Anion exchange; Auxiliary electrode	ASD	Antisiphon device
AEA	Articulation error analysis	ASHE	American Society for Hospital Engineering
AEB	Activation energy barrier	ASTM	American Society for Testing and Materials
AEC	Automatic exposure control	AT	Adenosine-thiamide; Anaerobic threshold; Antithrombin
AED	Automatic external defibrillator	ATA	Atmosphere absolute
AEMB	Alliance for Engineering in Medicine and Biology	ATLS	Advanced trauma life support
AES	Auger electron spectroscopy	ATN	Acute tubular necrosis
AESC	American Engineering Standards Committee	ATP	Adenosine triphosphate
AET	Automatic exposure termination	ATPD	Ambient temperature pressure dry
AFO	Ankle-foot orthosis	ATPS	Ambient temperature pressure saturated
AGC	Automatic gain control	ATR	Attenuated total reflection
AHA	American Heart Association	AUC	Area under curve
AI	Arterial insufficiency	AUMC	Area under moment curve
AICD	Automatic implantable cardiac defibrillator	AV	Atrioventricular
AID	Agency for International Development	AZT	Azido thymidine
AIDS	Acquired immune deficiency syndrome	BA	Biliary atresia
AL	Anterior leaflet	BAEP	Brainstem auditory evoked potential
ALG	Antilymphocyte globulin	BAPN	Beta-amino-propionitril
		BAS	Boston anesthesia system
		BASO	Basophil
		BB	Buffer base
		BBT	Basal body temperature

BCC	Body-centered cubic	CCTV	Closed circuit television system
BCD	Binary-coded decimal	CCU	Coronary care unit; Critical care unit
BCG	Ballistocardiogram	CD	Current density
BCLS	Basic cardiac life support	CDR	Complimentary determining region
BCRU	British Committee on Radiation Units and Measurements	CDRH	Center for Devices and Radiological Health
BDI	Beck depression inventory	CEA	Carcinoembryonic antigen
BE	Base excess; Binding energy	CF	Conversion factor; Cystic fibrosis
BET	Brunauer, Emmett, and Teller methods	CFC	Continuous flow cytometer
BH	His bundle	CFR	Code of Federal Regulations
BI	Biological indicators	CFU	Colony forming units
BIH	Beth Israel Hospital	CGA	Compressed Gas Association
BIPM	International Bureau of Weights and Measurements	CGPM	General Conference on Weights and Measures
BJT	Bipolar junction transistor	CHO	Carbohydrate
BMDP	Biomedical Programs	CHO	Chinese hamster ovary
BME	Biomedical engineering	CI	Combination index
BMET	Biomedical equipment technician	CICU	Cardiac intensive care unit
BMO	Biomechanically optimized	CIF	Contrast improvement factor
BMR	Basal metabolic rate	CIN	Cervical intraepithelial neoplasia
BOL	Beginning of life	CK	Creatine kinase
BP	Bereitschafts potential; Break point	CLAV	Clavicle
BR	Polybutadiene	CLSA	Computerized language sample analysis
BRM	Biological response modifier	CM	Cardiomyopathy; Code modulation
BRS	Bibliographic retrieval services	CMAD	Computer managed articulation diagnosis
BSS	Balanced salt solution	CMI	Computer-managed instruction
BTG	Beta thromboglobulin	CMRR	Common mode rejection ratio
BTPS	Body temperature pressure saturated	CMV	Conventional mechanical ventilation; Cytomegalovirus
BUN	Blood urea nitrogen	CNS	Central nervous system
BW	Body weight	CNV	Contingent negative variation
CA	Conductive adhesives	CO	Carbon monoxide; Cardiac output
CABG	Coronary artery by-pass grafting	COBAS	Comprehensive Bio-Analysis System
CAD/CAM	Computer-aided design/computer-aided manufacturing	COPD	Chronic obstructive pulmonary disease
CAD/D	Computer-aided drafting and design	COR	Center of rotation
CADD	Central axis depth dose	CP	Cerebral palsy; Closing pressure; Creatine phosphate
CAI	Computer assisted instruction; Computer-aided instruction	CPB	Cardiopulmonary bypass
CAM	Computer-assisted management	CPET	Cardiac pacemaker electrode tips
cAMP	Cyclic AMP	CPM	Computerized probe measurements
CAPD	Continuous ambulatory peritoneal dialysis	CPP	Cerebral perfusion pressure; Cryoprecipitated plasma
CAPP	Child amputee prosthetic project	CPR	Cardiopulmonary resuscitation
CAT	Computerized axial tomography	cps	Cycles per second
CATS	Computer-assisted teaching system; Computerized aphasia treatment system	CPU	Central Processing unit
CAVH	Continuous arteriovenous hemofiltration	CR	Center of resistance; Conditioned response; Conductive rubber; Creatinine
CB	Conjugated bilirubin; Coulomb barrier	CRBB	Complete right bundle branch block
CBC	Complete blood count	CRD	Completely randomized design
CBF	Cerebral blood flow	CRL	Crown rump length
CBM	Computer-based management	CRT	Cathode ray tube
CBV	Cerebral blood volume	CS	Conditioned stimulus; Contrast scale; Crown seat
CC	Closing capacity	CSA	Compressed spectral array
CCC	Computer Curriculum Company	CSF	Cerebrospinal fluid
CCD	Charge-coupled device	CSI	Chemical shift imaging
CCE	Capacitance contact electrode	CSM	Chemically sensitive membrane
CCF	Cross-correlation function	CT	Computed tomography; Computerized tomography
CCL	Cardiac catheterization laboratory	CTI	Cumulative toxicity response index
CCM	Critical care medical services	CV	Closing volume
CCPD	Continuous cycling peritoneal dialysis		

C.V.	Coefficient of variation	EBS	Early burn scar
CVA	Cerebral vascular accident	EBV	Epstein–Barr Virus
CVP	Central venous pressure	EC	Ethyl cellulose
CVR	Cardiovascular resistance	ECC	Emergency cardiac care; Extracorporeal circulation
CW	Continuous wave	ECCE	Extracapsular cataract extinction
CWE	Coated wire electrodes	ECD	Electron capture detector
CWRU	Case Western Reserve University	ECG	Electrocardiogram
DAC	Digital-to-analog converter	ECM	Electrochemical machining
DAS	Data acquisition system	ECMO	Extracorporeal membrane oxygenation
dB	Decibel	ECOD	Extracranial cerebrovascular occlusive disease
DB	Direct body	ECRI	Emergency Care Research Institute
DBMS	Data base management system	ECS	Exner's Comprehensive System
DBS	Deep brain stimulation	ECT	Electroconvulsive shock therapy; Electroconvulsive therapy; Emission computed tomography
dc	Direct current	EDD	Estimated date of delivery
DCCT	Diabetes control and complications trial	EDP	Aortic end diastolic pressure
DCP	Distal cavity pressure	EDTA	Ethylenediaminetetraacetic acid
DCS	Dorsal column stimulation	EDX	Energy dispersive X-ray analysis
DDC	Deck decompression chamber	EEG	Electroencephalogram
DDS	Deep diving system	EEI	Electrode electrolyte interface
DE	Dispersive electrode	EELV	End-expiratory lung volume
DEN	Device experience network	EER	Electrically evoked response
DERS	Drug exception ordering system	EF	Ejection fraction
DES	Diffuse esophageal spasm	EF	Electric field; Evoked magnetic fields
d.f.	Distribution function	EFA	Estimated fetal age
DHCP	Distributed Hospital Computer Program	EGF	Epidermal growth factor
DHE	Dihematoporphyrin ether	EGG	Electrogastrogram
DHEW	Department of Health Education and Welfare	EIA	Enzyme immunoassay
DHHS	Department of Health and Human Services	EIU	Electrode impedance unbalance
DHT	Duration of hypothermia	ELF	Extra low frequency
DI	Deionized water	ELGON	Electrical goniometer
DIC	Displacement current	ELISA	Enzyme-linked immunosorbent assay
DIS	Diagnostic interview schedule	ELS	Energy loss spectroscopy
DL	Double layer	ELV	Equivalent lung volume
DLI	Difference lumen for intensity	EM	Electromagnetic
DM	Delta modulation	EMBS	Engineering in Medicine and Biology Society
DME	Dropping mercury electrode	emf	Electromotive force
DN	Donation number	EMG	Electromyogram
DNA	Deoxyribonucleic acid	EMGE	Integrated electromyogram
DOF	Degree of freedom	EMI	Electromagnetic interference
DOS	Drug ordering system	EMS	Emergency medical services
DOT-NHTSA	Department of Transportation Highway Traffic Safety Administration	EMT	Emergency medical technician
DPB	Differential pencil beam	ENT	Ear, nose, and throat
DPG	Diphosphoglycerate	EO	Elbow orthosis
DQE	Detection quantum efficiency	EOG	Electrooculography
DRESS	Depth-resolved surface coil spectroscopy	EOL	End of life
DRG	Diagnosis-related group	EOS	Eosinophil
DSA	Digital subtraction angiography	EP	Elastoplastic; Evoked potentiate
DSAR	Differential scatter-air ratio	EPA	Environmental protection agency
DSB	Double strand breaks	ER	Evoked response
DSC	Differential scanning calorimetry	ERCP	Endoscopic retrograde cholangiopancreatography
D-T	Deuterium-on-tritium	ERG	Electron radiography; Electroretinogram
DTA	Differential thermal analysis	ERMF	Event-related magnetic field
d.u.	Density unit	ERP	Event-related potential
DUR	Duration	ERV	Expiratory reserve volume
DVT	Deep venous thrombosis		
EA	Esophageal accelerometer		
EB	Electron beam		
EBCDIC	Extended binary code decimal interchange code		

ESCA	Electron spectroscopy for chemical analysis	GC	Gas chromatography; Guanine-cytosine
ESI	Electrode skin impedance	GDT	Gas discharge tube
ESRD	End-stage renal disease	GFR	Glomerular filtration rate
esu	Electrostatic unit	GHb	Glycosylated hemoglobin
ESU	Electrosurgical unit	GI	Gastrointestinal
ESWL	Extracorporeal shock wave lithotripsy	GLC	Gas-liquid chromatography
ETO, Eto	Ethylene oxide	GMV	General minimum variance
ETT	Exercise tolerance testing	GNP	Gross national product
EVA	Ethylene vinyl acetate	GPC	Giant papillary conjunctivitis
EVR	Endocardial viability ratio	GPH	Gas-permeable hard
EW	Extended wear	GPH-EW	Gas-permeable hard lens extended wear
FAD	Flavin adenine dinucleotide	GPO	Government Printing Office
FARA	Flexible automation random analysis	GSC	Gas-solid chromatography
FBD	Fetal biparietal diameter	GSR	Galvanic skin response
FBS	Fetal bovine serum	GSWD	Generalized spike-wave discharge
fcc	Face centered cubic	HA	Hydroxyapatite
FCC	Federal Communications Commission	HAM	Helical axis of motion
Fct	Fluorocrit	Hb	Hemoglobin
FDA	Food and Drug Administration	HBE	His bundle electrogram
FDCA	Food, Drug, and Cosmetic Act	HBO	Hyperbaric oxygenation
FE	Finite element	HC	Head circumference
FECG	Fetal electrocardiogram	HCA	Hypothermic circulatory arrest
FEF	Forced expiratory flow	HCFA	Health care financing administration
FEL	Free electron lasers	HCL	Harvard Cyclotron Laboratory
FEM	Finite element method	hcp	Hexagonal close-packed
FEP	Fluorinated ethylene propylene	HCP	Half cell potential
FES	Functional electrical stimulation	HDPE	High density polyethylene
FET	Field-effect transistor	HECS	Hospital Equipment Control System
FEV	Forced expiratory volume	HEMS	Hospital Engineering Management System
FFD	Focal spot to film distance	HEPA	High efficiency particulate air filter
FFT	Fast Fourier transform	HES	Hydroxyethylstarch
FGF	Fresh gas flow	HETP	Height equivalent to a theoretical plate
FHR	Fetal heart rate	HF	High-frequency; Heating factor
FIC	Forced inspiratory capacity	HFCWO	High-frequency chest wall oscillation
FID	Flame ionization detector; Free-induction decay	HFER	High-frequency electromagnetic radiation
FIFO	First-in-first-out	HFJV	High-frequency jet ventilation
FITC	Fluorescent indicator tagged polymer	HFO	High-frequency oscillator
FL	Femur length	HFOV	High-frequency oscillatory ventilation
FM	Frequency modulation	HFPPV	High-frequency positive pressure ventilation
FNS	Functional neuromuscular stimulation	HFV	High-frequency ventilation
FO	Foramen ovale	HHS	Department of Health and Human Services
FO-CRT	Fiber optics cathode ray tube	HIBC	Health industry bar code
FP	Fluorescence polarization	HIMA	Health Industry Manufacturers Association
FPA	Fibrinopeptide A	HIP	Hydrostatic indifference point
FR	Federal Register	HIS	Hospital information system
FRC	Federal Radiation Council; Functional residual capacity	HK	Hexokinase
FSD	Focus-to-surface distance	HL	Hearing level
FTD	Focal spot to tissue-plane distance	HMBA	Hexamethylene bisacetamide
FTIR	Fourier transform infrared	HMO	Health maintenance organization
FTMS	Fourier transform mass spectrometer	HMWPE	High-molecular-weight polyethylene
FU	Fluorouracil	HOL	Higher-order languages
FUDR	Floxuridine	HP	Heating factor; His-Purkinje
FVC	Forced vital capacity	HpD	Hematoporphyrin derivative
FWHM	Full width at half maximum	HPLC	High-performance liquid chromatography
FWTM	Full width at tenth maximum	HPNS	High-pressure neurological syndrome
GABA	Gamma amino buteric acid	HPS	His-Purkinje system
GAG	Glycosaminoglycan	HPX	High peroxidase activity
GBE	Gas-bearing electrodyamometer		

HR	Heart rate; High-resolution	IMIA	International Medical Informatics Association
HRNB	Halstead-Reitan Neuropsychological Battery	IMS	Information management system
H/S	Hard/soft	IMV	Intermittent mandatory ventilation
HSA	Human serum albumin	INF	Interferon
HSG	Hysterosalpingogram	IOL	Intraocular lens
HTCA	Human tumor cloning assay	IPC	Ion-pair chromatography
HTLV	Human T cell lymphotropic virus	IPD	Intermittent peritoneal dialysis
HU	Heat unit; Houndsfield units; Hydroxyurea	IPG	Impedance plethysmography
HVL	Half value layer	IPI	Interpulse interval
HVR	Hypoxic ventilatory response	IPPB	Intermittent positive pressure breathing
HVT	Half-value thickness	IPTS	International practical temperature scale
IA	Image intensifier assembly; Inominate artery	IR	Polyisoprene rubber
IABP	Intraaortic balloon pumping	IRB	Institutional Review Board
IAEA	International Atomic Energy Agency	IRBBB	Incomplete right bundle branch block
IAIMS	Integrated Academic Information Management System	IRPA	International Radiation Protection Association
IASP	International Association for the Study of Pain	IRRAS	Infrared reflection-absorption spectroscopy
IC	Inspiratory capacity; Integrated circuit	IRRS	Infrared reflection spectroscopy
ICCE	Intracapsular cataract extraction	IRS	Internal reflection spectroscopy
ICD	Intracervical device	IRV	Inspiratory reserve capacity
ICDA	International classification of diagnoses	IS	Image size; Ion-selective
ICL	Ms-clip lens	ISC	Infant skin servo control
ICP	Inductively coupled plasma; Intracranial pressure	ISDA	Instantaneous screw displacement axis
ICPA	Intracranial pressure amplitude	ISE	Ion-selective electrode
ICRP	International Commission on Radiological Protection	ISFET	Ion-sensitive field effect transistor
ICRU	International Commission on Radiological Units and Measurements	ISIT	Intensified silicon-intensified target tube
ICU	Intensive care unit	ISO	International Organization for Standardization
ID	Inside diameter	ISS	Ion scattering spectroscopy
IDDM	Insulin dependent diabetes mellitus	IT	Intrathecal
IDE	Investigational device exemption	ITEP	Institute of Theoretical and Experimental Physics
IDI	Index of inspired gas distribution	ITEPI	Instantaneous trailing edge pulse impedance
I:E	Inspiratory: expiratory	ITLC	Instant thin-layer chromatography
IEC	International Electrotechnical Commission; Ion-exchange chromatography	IUD	Intrauterine device
IEEE	Institute of Electrical and Electronics Engineers	IV	Intravenous
IEP	Individual educational program	IVC	Inferior vena cava
BETS	Inelastic electron tunneling spectroscopy	IVP	Intraventricular pressure
IF	Immunofluorescent	JCAH	Joint Commission on the Accreditation of Hospitals
IFIP	International Federation for Information Processing	JND	Just noticeable difference
IFMBE	International Federation for Medical and Biological Engineering	JRP	Joint replacement prosthesis
IGFET	Insulated-gate field-effect transistor	KB	Kent bundle
IgG	Immunoglobulin G	Kerma	Kinetic energy released in unit mass
IgM	Immunoglobulin M	KO	Knee orthosis
IHP	Inner Helmholtz plane	KPM	Kilopond meter
IHSS	Idiopathic hypertrophic subaortic stenosis	KRPB	Krebs-Ringer physiological buffer
II	Image intensifier	LA	Left arm; Left atrium
IIIES	Image intensifier input-exposure sensitivity	LAD	Left anterior descending; Left axis deviation
IM	Intramuscular	LAE	Left atrial enlargement
IMFET	Immunologically sensitive field-effect transistor	LAK	Lymphokine activated killer
		LAL	Limulus amoebocyte lysate
		LAN	Local area network
		LAP	Left atrial pressure
		LAT	Left anterior temporalis
		LBBB	Left bundle branch block
		LC	Left carotid; Liquid chromatography

LCC	Left coronary cusp	MDP	Mean diastolic aortic pressure
LCD	Liquid crystal display	MDR	Medical device reporting
LDA	Laser Doppler anemometry	MDS	Multidimensional scaling
LDF	Laser Doppler flowmetry	ME	Myoelectric
LDH	Lactate dehydrogenase	MED	Minimum erythema dose
LDPE	Low density polyethylene	MEDPAR	Medicare provider analysis and review
LEBS	Low-energy brief stimulus	MEFV	Maximal expiratory flow volume
LED	Light-emitting diode	MEG	Magnetoencephalography
LEED	Low energy electron diffraction	MeSH	Medline subject heading
LES	Lower esophageal sphincter	METS	Metabolic equivalents
LESP	Lower esophageal sphincter pressure	MF	Melamine-formaldehyde
LET	Linear energy transfer	MFP	Magnetic field potential
LF	Low frequency	MGH	Massachusetts General Hospital
LH	Luteinizing hormone	MHV	Magnetic heart vector
LHT	Local hyperthermia	MI	Myocardial infarction
LL	Left leg	MIC	Minimum inhibitory concentration
LLDPE	Linear low density polyethylene	MIFR	Maximum inspiratory flow rate
LLPC	Liquid-liquid partition chromatography	MINET	Medical Information Network
LLW	Low-level waste	MIR	Mercury-in-rubber
LM	Left masseter	MIS	Medical information system; Metal-insulator-semiconductor
LNNB	Luria-Nebraska Neuropsychological Battery	MIT	Massachusetts Institute of Technology
LOS	Length of stay	MIT/BIH	Massachusetts Institute of Technology/ Beth Israel Hospital
LP	Late potential; Lumboperitoneal	MMA	Manual metal arc welding
LPA	Left pulmonary artery	MMA	Methyl methacrylate
LPC	Linear predictive coding	MMECT	Multiple-monitored ECT
LPT	Left posterior temporalis	MMFR	Maximum midexpiratory flow rate
LPV	Left pulmonary veins	mm Hg	Millimeters of mercury
LRP	Late receptor potential	MMPI	Minnesota Multiphasic Personality Inventory
LS	Left subclavian	MMSE	Minimum mean square error
LSC	Liquid-solid adsorption chromatography	MO	Membrane oxygenation
LSI	Large scale integrated	MONO	Monocyte
LSV	Low-amplitude shear-wave viscoelastometry	MOSFET	Metal oxide silicon field-effect transistor
LTI	Low temperature isotropic	MP	Mercaptopurine; Metacarpal-phalangeal
LUC	Large unstained cells	MPD	Maximal permissible dose
LV	Left ventricle	MR	Magnetic resonance
LVAD	Left ventricular assist device	MRG	Magnetoretinogram
LVDT	Linear variable differential transformer	MRI	Magnetic resonance imaging
LVEP	Left ventricular ejection period	MRS	Magnetic resonance spectroscopy
LVET	Left ventricular ejection time	MRT	Mean residence time
LVH	Left ventricular hypertrophy	MS	Mild steel; Multiple sclerosis
LYMPH	Lymphocyte	MSR	Magnetically shielded room
MAA	Macroaggregated albumin	MTBF	Mean time between failure
MAC	Minimal auditory capabilities	MTF	Modulation transfer function
MAN	Manubrium	MTTR	Mean time to repair
MAP	Mean airway pressure; Mean arterial pressure	MTX	Methotroxate
MAST	Military assistance to safety and traffic	MUA	Motor unit activity
MBA	Monoclonal antibody	MUAP	Motor unit action potential
MBV	Maximum breathing ventilation	MUAPT	Motor unit action potential train
MBX	Monitoring branch exchange	MUMPI	Missouri University Multi-Plane Imager
MCA	Methyl cryanoacrylate	MUMPS	Massachusetts General Hospital utility multiuser programming system
MCG	Magnetocardiogram	MV	Mitral valve
MCI	Motion Control Incorporated	MVO ₂	Maximal oxygen uptake
MCM1	Millon Clinical Multiaxial Inventory	MVTR	Moisture vapor transmission rate
MCT	Microcatheter transducer	MVV	Maximum voluntary ventilation
MCV	Mean corpuscular volume	MW	Molecular weight
MDC	Medical diagnostic categories		
MDI	Diphenylmethane diisocyanate; Medical Database Informatics		

NAA	Neutron activation analysis	OPG	Ocular pneumoplethysmography
NAD	Nicotinamide adenine dinucleotide	OR	Operating room
NADH	Nicotinamide adenine dinucleotide, reduced form	OS	Object of known size; Operating system
NADP	Nicotinamide adenine dinucleotide phosphate	OTC	Over the counter
NAF	Neutrophil activating factor	OV	Offset voltage
NARM	Naturally occurring and accelerator- produced radioactive materials	PA	Posteroanterior; Pulmonary artery; Pulse amplitude
NBB	Normal buffer base	PACS	Picture archiving and communications systems
NBD	Neuromuscular blocking drugs	PAD	Primary afferent depolarization
N-BPC	Normal bonded phase chromatography	PAM	Pulse amplitude modulation
NBS	National Bureau of Standards	PAN	Polyacrylonitrile
NCC	Noncoronary cusp	PAP	Pulmonary artery pressure
NCCLS	National Committee for Clinical Laboratory Standards; National Committee on Clinical Laboratory Standards	PAR	Photoactivation ratio
NCRP	National Council on Radiation Protection	PARFR	Program for Applied Research on Fertility Regulation
NCT	Neutron capture theory	PARR	Poetanesesthesia recovery room
NEEP	Negative end-expiratory pressure	PAS	Photoacoustic spectroscopy
NEMA	National Electrical Manufacturers Association	PASG	Pneumatic antishock garment
NEMR	Nonionizing electromagnetic radiation	PBI	Penile brachial index
NEQ	Noise equivalent quanta	PBL	Positive beam limitation
NET	Norethisterone	PBT	Polybutylene terephthalate
NEUT	Neutrophil	PC	Paper chromatography; Personal computer; Polycarbonate
NFPA	National Fire Protection Association	PCA	Patient controlled analgesia; Principal components factor analysis
NH	Neonatal hepatitis	PCG	Phonocardiogram
NHE	Normal hydrogen electrode	PCI	Physiological cost index
NHLBI	National Heart, Lung, and Blood Institute	PCL	Polycaprolactone; Posterior chamber lens
NIR	Nonionizing radiation	PCR	Percent regurgitation
NIRS	National Institute for Radiologic Science	PCRC	Perinatal Clinical Research Center
NK	Natural killer	PCS	Patient care system
NMJ	Neuromuscular junction	PCT	Porphyria cutanea tarda
NMOS	N-type metal oxide silicon	PCWP	Pulmonary capillary wedge pressure
NMR	Nuclear magnetic resonance	PD	Peritoneal dialysis; Poly-p-dioxanone; Potential difference; Proportional and derivative
NMS	Neuromuscular stimulation	PDD	Percent depth dose; Perinatal Data Directory
NPH	Normal pressure hydrocephalus	PDE	Pregelged disposable electrodes
NPL	National Physical Laboratory	p.d.f.	Probability density function
NR	Natural rubber	PDL	Periodontal ligament
NRC	Nuclear Regulatory Commission	PDM	Pulse duration modulation
NRZ	Non-return-to-zero	PDMSX	Polydimethyl siloxane
NTC	Negative temperature coefficient	PDS	Polydioxanone
NTIS	National Technical Information Service	PE	Polyethylene
NVT	Neutrons versus time	PEEP	Positive end-expiratory pressure
NYHA	New York Heart Association	PEFR	Peak expiratory now rate
ob/gyn	Obstetrics and gynecology	PEN	Parenteral and enteral nutrition
OCR	Off-center ratio; Optical character recognition	PEP	Preejection period
OCV	Open circuit voltage	PEPPER	Programs examine phonetic find phonological evaluation records
OD	Optical density; Outside diameter	PET	Polyethylene terephthalate; Positron-emission tomography
ODC	Oxyhemoglobin dissociation curve	PEU	Polyetherurethane
ODT	Oxygen delivery truck	PF	Platelet factor
ODU	Optical density unit	PFA	Phosphonoformic add
OER	Oxygen enhancement ratio	PFC	Petrofluorochemical
OFD	Object to film distance; Occiputo-frontal diameter	PFT	Pulmonary function testing
OHL	Outer Helmholtz layer	PG	Polyglycolide; Propylene glycol
OHP	Outer Helmholtz plane		
OIH	Orthoiodohippurate		

PGA	Polyglycolic add	PURA	Prolonged ultraviolet-A radiation
PHA	Phytohemagglutinin; Pulse-height analyzer	PUVA	Psoralens and longwave ultraviolet light photochemotherapy
PHEMA	Poly-2-hydroxyethyl methacrylate	P/V	Pressure/volume
PI	Propidium iodide	PVC	Polyvinyl chloride; Premature ventricular contraction
PID	Pelvic inflammatory disease; Proportional/integral/derivative	PVI	Pressure-volume index
PIP	Peak inspiratory pressure	PW	Pulse wave; Pulse width
PL	Posterior leaflet	PWM	Pulse width modulation
PLA	Polylactic acid	PXE	Pseudo-xanthoma elasticum
PLATO	Program Logic for Automated Teaching Operations	QA	Quality assurance
PLD	Potentially lethal damage	QC	Quality control
PLED	Periodic lateralized epileptiform discharge	R-BPC	Reverse bonded phase chromatography
PLT	Platelet	R/S	Radiopaque-spherical
PM	Papillary muscles; Preventive maintenance	RA	Respiratory amplitude; Right arm
PMA	Polymethyl acrylate	RAD	Right axis deviation
p.m.f.	Probability mass function	RAE	Right atrial enlargement
PMMA	Polymethyl methacrylate	RAM	Random access memory
PMOS	P-type metal oxide silicon	RAP	Right atrial pressure
PMP	Patient management problem; Poly(4-methylpentane)	RAT	Right anterior temporalis
PMT	Photomultiplier tube	RB	Right bundle
PO	Per os	RBBB	Right bundle branch block
P_{O_2}	Partial pressure of oxygen	RBC	Red blood cell
POBT	Polyoxybutylene terephthalate	RBE	Relative biologic effectiveness
POM	Polyoxymethylene	RBF	Rose bengal fecal excretion
POMC	Patient order management and communication system	RBI	Resting baseline impedance
POPRAS	Problem Oriented Perinatal Risk Assessment System	RCBD	Randomized complete block diagram
PP	Perfusion pressure; Polypropylene; Postprandial (after meals)	rCBF	Regional cerebral blood flow
PPA	Phonemic process analysis	RCC	Right coronary cusp
PPF	Plasma protein fraction	RCE	Resistive contact electrode
PPM	Pulse position modulation	R&D	Research and development
PPSFH	Polymerized phyridoxalated stroma-free hemoglobin	r.e.	Random experiment
PR	Pattern recognition; Pulse rate	RE	Reference electrode
PRBS	Pseudo-random binary signals	REM	Rapid eye movement; Return electrode monitor
PRP	Pulse repetition frequency	REMATE	Remote access and telecommunication system
PRO	Professional review organization	RES	Reticuloendothelial system
PROM	Programmable read only memory	RESNA	Rehabilitation Engineering Society of North America
PS	Polystyrene	RF	Radio frequency; Radiographic-nuoroscopic
PSA	Pressure-sensitive adhesive	RFI	Radio-frequency interference
PSF	Point spread function	RFP	Request for proposal
PSI	Primary skin irritation	RFQ	Request for quotation
PSP	Postsynaptic potential	RH	Relative humidity
PSR	Proton spin resonance	RHE	Reversible hydrogen electrode
PSS	Progressive systemic sclerosis	RIA	Radioimmunoassay
PT	Plasma thromboplastin	RM	Repetition maximum; Right masseter
PTB	Patellar tendon bearing orthosis	RMR	Resting metabolic rate
PTC	Plasma thromboplastin component; Positive temperature coefficient; Pressurized personal transfer capsule	RMS	Root mean square
PTCA	Percutaneous transluminal coronary angioplasty	RN	Radionuclide
PTFE	Polytetrafluoroethylene	RNCA	Radionuclide cineangiogram
PTT	Partial thromboplastin time	ROI	Regions of interest
PUL	Percutaneous ultrasonic lithotripsy	ROM	Range of motion; Read only memory
		RP	Retinitis pigmentosa
		RPA	Right pulmonary artery
		RPP	Rate pressure product
		RPT	Rapid pull-through technique
		RPV	Right pulmonary veins
		RQ	Respiratory quotient

RR	Recovery room	SEBS	Surgical isolation barrier system
RRT	Recovery room time; Right posterior temporalis	SID	Source to image reception distance
RT	Reaction time	SIMFU	Scanned intensity modulated focused ultrasound
RTD	Resistance temperature device	SIMS	Secondary ion mass spectroscopy; System for isometric muscle strength

CONVERSION FACTORS AND UNIT SYMBOLS

SI UNITS (ADOPTED 1960)

A new system of metric measurement, the International System of Units (abbreviated SI), is being implemented throughout the world. This system is a modernized version of the MKSA (meter, kilogram, second, ampere) system, and its details are published and controlled by an international treaty organization (The International Bureau of Weights and Measures).

SI units are divided into three classes:

Base Units	
length	meter [†] (m)
mass [‡]	kilogram (kg)
time	second (s)
electric current	ampere (A)
thermodynamic temperature§	kelvin (K)
amount of substance	mole (mol)
luminous intensity	candela (cd)
Supplementary Units	
plane angle	radian (rad)
solid angle	steradian (sr)

Derived Units and Other Acceptable Units

These units are formed by combining base units, supplementary units, and other derived units. Those derived units having special names and symbols are marked with an asterisk (*) in the list below:

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
*absorbed dose	gray	Gy	J/kg
acceleration	meter per second squared	m/s ²	
*activity (of ionizing radiation source)	becquerel	Bq	1/s
area	square kilometer	km ²	
	square hectometer	hm ²	ha (hectare)
	square meter	m ²	

[†]The spellings “metre” and “litre” are preferred by American Society for Testing and Materials (ASTM); however, “-er” will be used in the Encyclopedia.

[‡]“Weight” is the commonly used term for “mass.”

§Wide use is made of “Celsius temperature” (*t*) defined $t = T - T_0$ where *T* is the thermodynamic temperature, expressed in kelvins, and $T_0 = 273.15$ K by definition. A temperature interval may be expressed in degrees Celsius as well as in kelvins.

<i>Quantity equivalent</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable</i>
* capacitance	farad	F	C/V
concentration (of amount of substance)	mole per cubic meter	mol/m ³	
* conductance	siemens	S	A/V
current density	ampere per square meter	A/m ²	
density, mass density	kilogram per cubic meter	kg/m ³	g/L; mg/cm ³
dipole moment (quantity)	coulomb meter	C·m	
* electric charge, quantity of electricity	coulomb	C	A·s
electric charge density	coulomb per cubic meter	C/m ³	
electric field strength	volt per meter	V/m	
electric flux density	coulomb per square meter	C/m ²	
* electric potential, potential difference, electromotive force	volt	V	W/A
* electric resistance	ohm	Ω	V/A
* energy, work, quantity of heat	megajoule	MJ	
	kilojoule	kJ	
	joule	J	N·m
	electron volt [†]	eV [†]	
	kilowatt hour [†]	kW·h [†]	
energy density	joule per cubic meter	J/m ³	
* force	kilonewton	kN	
	newton	N	kg·m/s ²
* frequency	megahertz	MHz	
	hertz	Hz	1/s
heat capacity, entropy	joule per kelvin	J/K	
heat capacity (specific), specific entropy	joule per kilogram kelvin	J/(kg·K)	
heat transfer coefficient	watt per square meter kelvin	W/(m ² ·K)	
* illuminance	lux	lx	lm/m ²
* inductance	henry	H	Wb/A
linear density	kilogram per meter	kg/m	
luminance	candela per square meter	cd/m ²	
* luminous flux	lumen	lm	cd·sr
magnetic field strength	ampere per meter	A/m	
* magnetic flux	weber	Wb	V·s
* magnetic flux density	tesla	T	Wb/m ²
molar energy	joule per mole	J/mol	
molar entropy, molar heat capacity	joule per mole kelvin	J/(mol·K)	
moment of force, torque	newton meter	N·m	
momentum	kilogram meter per second	kg·m/s	
permeability	henry per meter	H/m	
permittivity	farad per meter	F/m	
* power, heat flow rate, radiant flux	kilowatt	kW	
	watt	W	J/s
power density, heat flux density, irradiance	watt per square meter	W/m ²	
* pressure, stress	megapascal	MPa	
	kilopascal	kPa	
	pascal	Pa	N/m ²
sound level	decibel	dB	
specific energy	joule per kilogram	J/kg	
specific volume	cubic meter per kilogram	m ³ /kg	
surface tension	newton per meter	N/m	
thermal conductivity	watt per meter kelvin	W/(m·K)	
velocity	meter per second	m/s	
	kilometer per hour	km/h	
viscosity, dynamic	pascal second	Pa·s	
	millipascal second	mPa·s	

[†]This non-SI unit is recognized as having to be retained because of practical importance or use in specialized fields.

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
viscosity, kinematic	square meter per second	m ² /s	
	square millimeter per second	mm ² /s	
	cubic meter	m ³	
	cubic decimeter	dm ³	L(liter)
	cubic centimeter	cm ³	mL
wave number	1 per meter	m ⁻¹	
	1 per centimeter	cm ⁻¹	

In addition, there are 16 prefixes used to indicate order of magnitude, as follows:

<i>Multiplication factor</i>	<i>Prefix</i>	<i>Symbol</i>	<i>Note</i>
10 ¹⁸	exa	E	
10 ¹⁵	peta	P	
10 ¹²	tera	T	
10 ⁹	giga	G	
10 ⁸	mega	M	
10 ³	kilo	k	
10 ²	hecto	h ^a	^a Although hecto, deka, deci, and centi are SI prefixes, their use should be avoided except for SI unit-multiples for area and volume and nontechnical use of centimeter, as for body and clothing measurement.
10	deka	da ^a	
10 ⁻¹	deci	d ^a	
10 ⁻²	centi	c ^a	
10 ⁻³	milli	m	
10 ⁻⁶	micro	μ	
10 ⁻⁹	nano	n	
10 ⁻¹²	pico	p	
10 ⁻¹⁵	femto	f	
10 ⁻¹⁸	atto	a	

For a complete description of SI and its use the reader is referred to ASTM E 380.

CONVERSION FACTORS TO SI UNITS

A representative list of conversion factors from non-SI to SI units is presented herewith. Factors are given to four significant figures. Exact relationships are followed by a dagger (†). A more complete list is given in ASTM E 380-76 and ANSI Z210.1-1976.

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
acre	square meter (m ²)	4.047 × 10 ³
angstrom	meter (m)	1.0 × 10 ^{-10†}
are	square meter (m ²)	1.0 × 10 ^{2†}
astronomical unit	meter (m)	1.496 × 10 ¹¹
atmosphere	pascal (Pa)	1.013 × 10 ⁵
bar	pascal (Pa)	1.0 × 10 ^{5†}
barrel (42 U.S. liquid gallons)	cubic meter (m ³)	0.1590
Btu (International Table)	joule (J)	1.055 × 10 ³
Btu (mean)	joule (J)	1.056 × 10 ³
Bt (thermochemical)	joule (J)	1.054 × 10 ³
bushel	cubic meter (m ³)	3.524 × 10 ⁻²
calorie (International Table)	joule (J)	4.187
calorie (mean)	joule (J)	4.190
calorie (thermochemical)	joule (J)	4.184 [†]
centimeters of water (39.2 °F)	pascal (Pa)	98.07
centipoise	pascal second (Pa·s)	1.0 × 10 ^{-3†}
centistokes	square millimeter per second (mm ² /s)	1.0 [†]

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
cfm (cubic foot per minute)	cubic meter per second (m ³ /s)	4.72 × 10 ⁻⁴

ALLOYS, SHAPE MEMORY

YOUNG KON KIM
Inje University
Kimhae City
Korea

INTRODUCTION

An alloy is defined as a substance with metallic properties that is composed of two or more chemical elements of which at least one is an elemental metal (1). The internal structure of most alloys starts to change only when it is no longer stable. When external influences, such as pressure and temperature, are varied, it will tend to transform spontaneously into a mixture of phases, the structures, compositions, and morphologies of which differ from the initial one. Such microstructural changes are known as phase transformation and may involve considerable atomic rearrangement and compositional change (2,3).

Shape memory alloys (SMAs) exhibit a unique mechanical “memory”, or restoration force characteristic, when heated above a certain phase-transformation temperature range (TTR), after having been deformed below the TTR. This thermally activated shape recovering behavior is called the shape memory effect (SME) (3–5). This particular effect is closely related to a martensitic phase transformation accompanied by subatomic shear deformation resulting from the diffusionless, cooperative movement of atoms (6,7). The name martensite was originally used to describe the very fine, hard microstructure found in quenched steels (8). The meaning of this word has been extended gradually to describe the microstructure of non-ferrous alloys that have similar characteristics.

SMAs have two stable phases: a high temperature stable phase, called the parent or austenite phase and a low temperature stable martensite phase. Martensite phases can be induced by cooling or stressing and are called thermally induced martensite (TIM) or stress induced martensite (SIM), respectively (8). The TIM forms and grows continuously as the temperature is lowered, and it shrinks and vanishes as the temperature is raised. The SIM is generated continuously with increasing applied stress on the alloy. On

removing the applied stress, SIM disappears gradually at a constant temperature. If the temperature is sufficiently low when stressing, however, the SIM cannot return to its initial structure when the stress is removed. When the temperature is increased above the TTR, the residual SIM restores the original structure, resulting in shape recovery (9). Surprisingly, this process can be reliably repeated millions of times, provided that the strain limits are not breached. If dislocations or slips intervene in this process, the shape memory becomes imperfect. When the applied stress on a SMA is too great, irreversible slip occurs, and the SMA cannot recover its original shape even after heating above TTR (10). However, it can remember this hot parent pattern. In the next cooling cycle, the SMA changes slightly and remembers the cool-martensite pattern. A SMA trained with this repeated cyclic treatment is called a two-way SMA (9). A schematic explanation of the SME related to the two-dimensional (2D) crystal structure (11) is shown in Fig. 1. When a SMA is cooled below its TTR, the parent phase begins to form TIM without an external shape change. This TIM can be changed into SIM easily by mechanical deformation below the TTR. When the deformed SMA is heated above its TTR, however, it cannot hold the deformed shape anymore, and the SMA returns to its original shape, resulting in a reverse martensitic phase transformation.

A SMA also shows rubber-like behavior at temperatures above its TTR. When a SMA is deformed isothermally above its TTR, only SIM is produced, until plastic deformation occurs. Then, the SIM disappears immediately after removing the applied load, resulting in a much greater amount of recovering strain, in excess of the elastic limit, compared to the conventional elastic strain of a metal. This rubber-like behavior at a constant temperature above TTR is called superelasticity (12). A schematic explanation of superelasticity is shown in Fig. 2.

These contrasting behaviors of superelasticity and SME are a function of the testing temperature. If a SMA is tested below its TTR, it shows SME, while a SMA that is deformed above its TTR shows superelasticity.

It is convenient to subdivide the superelastic behavior into two categories, “superelasticity” and “rubber-like behavior”, depending on the nature of the driving forces and mechanism involved. If it is triggered by SIM formation and subsequent reversion, the terminology superelasticity is used. By contrast, rubber-like behavior does not involve phase transformation, but involves deformation of the martensite itself. It is closely related to the reversible movement of deformed twin boundaries or martensite boundaries (10).

An example of SME in a shape-memory suture needle (13) is shown in Fig. 3. Figure 3a shows a curved needle with the shape preset by a heat-treatment process. When the shape-memory needle is cooled below its TTR, it is readily amenable to a change in shape with forceps (b). On heating it above TTR, thermal energy causes the needle to recover its original curved shape (c).

Figure 1. Schematic illustration of the shape memory effect. The parent phase is cooled below TTR to form a twinned (self-accommodated) martensite without an external shape change. Deformed martensite is produced with twin boundary movement and a change of shape by deformation below the TTR. Heating above the TTR results in reverse transformation and leads to shape recovery.

Figure 2. Schematic illustration of the superelasticity of a SMA above TTR. During the loading process, the applied load changes the parent phase into stress-induced martensite, which disappears instantly on unloading.

Figure 3. Shape-memory effect in a SMA suture needle. (a) Cooling the SMA suture needle below its TTR, (b) straightening the SMA suture needle below its TTR, (c) recovering the original shape of the SMA suture needle above its TTR.

HISTORY OF SHAPE MEMORY ALLOYS

The first observed shape memory phenomenon was pseudoelasticity. In 1932, Oelander observed it in a Au–Cd alloy and called it “rubber-like” behavior (14). Owing to the great amount of reversible strain, this effect is also called “superelasticity”. The SME was discovered in 1938 by Greninger and Mooradian (15), while observing the formation and disappearance of martensite with falling and rising temperature in a brass (Cu–Zn alloy) sample. The maximum amount of reversible strain was observed in a Cu–Al–Ni single crystal with a recoverable elastic strain of 24% (16). In 1949, Kurdjumov and Khandros (17), provided a theoretical explanation of the basic mechanism of SME, the thermoelastic behavior of the martensite phase in Au–Cd alloy. Numerous alloy systems have been found to exhibit shape memory behavior. However, the great breakthrough came in 1963, when Buehler et al. (4) at the U.S. Naval Ordnance Laboratory discovered the SME in an equiatomic alloy of Ni–Ti, since then popularized under the name nitinol (Nickel–Titanium Naval Ordnance Laboratory). Partial listings of SMAs include the alloy systems: Ag–Cd, Au–Cd, Au–Cu, Cu–Zn, Cu–Zn–X (X = Si, Sn, Al, Ga), Cu–Al–Ni, Cu–Au–Zn, Cu–Sn, Ni–Al, Ni–Nb, Ni–Ti, Ni–Ti–Cu, Ti–Pd–Ni, In–Tl, In–Cd, Mn–Cd, Fe–Ni, Fe–Mn, Fe–Pt, Fe–Pd, and Fe–Ni–Co–Ti (9). It took several years to understand the microscopic, crystallographic, and thermodynamic properties of these extraordinary metals (18–20). The aeronautical, mechanical, electrical, biomedical, and biological engineering communities, as well as the health professions, are making use of shape memory alloys for a wide range of applications (9). Several commercial applications of Ni–Ti and Cu–Zn–Al SMAs have been developed, such as tube-fitting systems, self-erectable structures, clamps, thermostatic devices, and biomedical applications (5,21–23).

Andreasen suggested the first clinical application of Ni–Ti SMA in 1971. He suggested that nitinol wire was useful for orthodontics by reason of its superelasticity and good corrosion resistance (24). Since then, Ni–Ti alloys have been used in a broad and continually expanding array of biomedical applications, including various prostheses and disposables used in vascular and orthopedic surgery. Medical interventions have themselves been driven toward minimally invasive procedures by the creation of new medical devices, such as guide wires, cardiovascular stents, filters, embolic coils, and endoscopic surgery devices. The Ni–Ti SMA stent was first introduced in 1983 when Dotter (25) and Cragg (26) simultaneously published the results of their experimental studies. However, their studies were unsuccessful because of the unstable introduction system and the intimal hyperplasia in the stent-implanted region (27). In 1990, Rauber et al. renewed the effort to use a Ni–Ti alloy as a stent, significantly reducing intimal hyperplasia by using a transcatheter insertion method (28). In 1992, Josef Rabkin reported successful results in the treatment of obstructions in vascular and nonvascular systems in 268 patients (29). In 1989, Kikuchi reported that a guidewire constructed from kink-resistant titanium–nickel alloy was helpful for angiography and interventional

procedures (30). Guidewires are used for needles, endoscopes, or catheters, to gain access to a desired location within the human body. In 1989, the U.S. Food and Drug Administration approved the use of a Mitek anchor constructed of nitinol for shoulder surgery (31). Since then, many devices and items have been developed with nickel–titanium SMAs.

NICKEL–TITANIUM SHAPE MEMORY ALLOY

Physical Properties

Some of the physical properties of 55-Nitinol are listed in Table 1 (32,33). Nitinol has good impact properties, low density, high fatigue strength, and a nonmagnetic nature. The excellent malleability and ductility of nitinol enable it to be manufactured in the form of wires, ribbons, tubes, sheets, or bars. It is particularly useful for very small devices.

Phase Diagram and Crystal Structures

A Ti–Ni equilibrium phase diagram (34) is very useful for understanding phase transformation and alloy design; a modified one is shown in Fig. 4 (35). There is a triangular region designated “TiNi” near the point of equiatomic composition. The left slope (solubility limit) is nearly vertical with temperature. This means that a precipitation-hardening process cannot be used on the Ti-rich side in bulk alloys. By contrast, the right slope is less steep than the left. Therefore, the precipitation-controlling process can adjust transformation temperatures for practical application of SMAs on the Ni-rich side. The crystal structure of the upper part of this triangle, $> 1090^\circ\text{C}$, is body centered cubic (bcc). The lower part is a CsCl-type ordered structure (B2) from 1090°C to room temperature. A schematic atomic configuration of the B2 structure is shown in Fig. 5 (36). In 1965, Wang determined the lattice constant of the B2 crystal as $a_0 = 3.01 \text{ \AA}$ (6). He proposed that the

^bRoom temperature = RT.

Ni–Ti crystal structure is not a simple CsCl-type structure, but has a disordered 9 Å superlattice and an ordered 3 Å CsCl-type sublattice. As the temperature is lowered, the ordered CsCl structure is slightly tilted instantaneously and cooperatively into a close-packed structure, called martensite, with a 2D dimensional close-packed plane (basal plane) (6,37). The martensite unit cell is described as a monoclinic (B19’) configuration, as shown in Fig. 6.

Figure 4. Phase diagram of a Ti–Ni alloy and details of the TiNi and TiNi₃ phases (35). (Reproduced with permission from Binary Alloy Phase Diagrams, 2nd ed., Vol. 3, 1990, Phase diagram of a Ti–Ni alloy on page 2874, T. B. Massalski, H. Okamoto, P. R. Subramanian, and L. Kacprzak, ASM International.)

Figure 5. Schematic 3D diagram of the Ni–Ti atomic model in the stable high temperature phase (CsCl-type structure; lattice constant; $a_0 = 3.01 \text{ \AA}$).

The twin-type stacking of the thermally induced martensite structure shown on the left (a) has a readily deformable crystalline arrangement, from the twin structure to the detwinned structure shown on the right (b) (9,38). Diagram (b) of the detwinned structure shows relatively planar atomic stacking layer by layer alternately along the $\{111\}$ basal plane of the deformed martensite crystal (39). Since martensitic transformation in Ni–Ti SMAs demonstrates an abnormal heat capacity change, it is regarded as a crystallographic distortion instead of a crystallographic transformation. The Ni–Ti martensite transformation is accompanied by a large latent heat of enthalpy ($\Delta H \sim 4,150 \text{ J/mol}$). This extraordinarily latent heat of transformation was considered to be owing to a portion of the electrons undergoing a “covalent-to-metallic” electron-state transformation (11).

Thermomechanical Properties

The mechanical properties of Ni–Ti SMAs are closely dependent on the testing temperature. If a mechanical stress is applied to the SMA below the TTR, then the metastable parent structure of the Ni–Ti alloy is susceptible to transformation into the martensite. However, if the testing temperature exceeds the TTR, then, in the absence of stress, the reverse transformation happens. Figure 7 shows an example of a uniaxial compressive stress-strain curve of a Ni–Ti alloy above its TTR, which shows its superelasticity (40).

Figure 6. Schematic 3D diagram of the Ni–Ti atomic stacking model of low temperature stable monoclinic structured martensite (a) twin-type stacking of martensite, (b) detwinned-type stacking of martensite).

Figure 7. Compressive stress–strain curve of a heat-treated 6-mm-diameter Ni–Ti rod at $4 \text{ }^\circ\text{C}$. Three distinct stages are observed on the stress–strain curve (σM_f : stress-induced martensite finishing stress, σM_s : stress-induced martensite starting stress, σA_s : parent phase starting stress, σA_f : parent phase finishing stress) (40).

With stress below the martensite starting stress (σM_s), the Ni–Ti alloy behaves in a purely elastic way, as shown in section AB. As soon as the critical stress is reached at point B, corresponding to stress level σM_s , forward transformation (parent phase-to-martensite) is initiated and SIM starts to form. The slope of section BC (upper plateau) reflects the ease with which the transformation proceeds to completion, generating large transformational strains. When the applied stress reaches the value of the martensite finishing stress (σM_f), the forward transformation is completed and the SMA is fully in the SIM phase. For further loading above σM_f , the elastic behavior of martensite is observed again until plastic deformation occurs, as represented in section CD. For stress beyond D, the material deforms plastically until fracture occurs. However, if the stress is released before reaching point D, the strain is recovered in several stages. The first stage is elastic unloading of the martensite, as shown in section DE. On arriving at stress σA_s , at E, the reverse martensite transformation starts and the fraction of martensite decreases until the parent phase is completely restored at F. Section FA represents the elastic unloading of the parent phase. If some irreversible deformation has taken place during either loading or unloading, the total strain may not be recovered completely. Owing to the stress differences between σM_f and σA_s and between σM_s and σA_f , a hysteresis loop is obtained in the loading–unloading stress–strain curve. Increasing the test temperature results in an increase in the values of the critical transformation stresses, while the general shape of the hysteresis loop remains the same. The area enclosed by the loading and unloading curves represents the energy dissipated during a stress cycle. As part of the hysteresis loop, both the loading and unloading curves show plateaus, at which point large strains are accommodated on loading, or recovered on unloading, with only a small change in stress (19). This behavior of Ni–Ti SMAs is much like that of natural tissues, such as hair and bone, and results in a “superelastic” ability to withstand and recover from large deforming stresses.

Figure 8. The effect of compressive (a) and tensile (b) loading on martensite formation and disappearance in 20.7% Ti–In alloy (19). (From J. Mat. Sci. Vol. 9, 1974, Figure 2 on page 1537, Krishnan R. V., Delaey L., Tas H. and Warlimont H., Kluwer Academic Publisher. Reproduced with kind permission of Springer Science and Business Media.)

In 1974, Krishnan argued that Burkart and Read had found the effects of compressive and tensile stress on martensite formation and disappearance in Ti–In SMAs (19). The transformation stresses σM_s and σA_s have a linear relation with testing temperature, as shown in Fig. 8 (41). They inferred that σM_s is a linear function of temperature, and the stresses σM_s and σA_s increase with temperature.

Another important thermomechanical property of SMAs is the relationship between the plateau stress of the martensite phase transformation and the enthalpy change of that reaction. As the stress-induced martensitic transformation is a second-order transformation, the amount of transformation depends on its temperature, so the high temperature state has a larger energy barrier of SIM and needs more energy to overcome this larger reverse martensitic transformation barrier. The enthalpy change of the parent phase to martensitic transformation (ΔH^{p-m}) can be calculated theoretically using the modified Clausius–Clapeyron equation (20), shown in Eq. 1.

$$\frac{\delta\sigma^{p-m}}{\delta T} = \frac{\rho\Delta H^{p-m}}{\varepsilon^{p-m}T_0} \quad (1)$$

Where ΔH^{p-m} is the enthalpy change of the parent phase to the martensite phase at T_0 ; σ^{p-m} is the stress at which stress-induced martensite is formed at the testing temperature, T ; ρ is the density of the SMA; and ε^{p-m} is the strain corresponding to complete transformation. $\delta\sigma^{p-m}$ and ε^{p-m} can be taken from the stress–strain curves. Kim compared the theoretically calculated ΔH^{p-m} of a Ni–Ti alloy using stress–strain curves and Eq. 1 with an experimentally acquired value (9). He reported that the theoretical value of ΔH^{p-m} for a Ni–Ti alloy calculated from the stress–strain curves was 6.24 cal/g. The experimental value of the enthalpy change (ΔH^{p-m}) of an 8% prestrained Ni–Ti wire sample from DSC measurement was 6.79 cal·g⁻¹. Based on this result, he inferred that Ni–Ti alloys undergo thermomechanical-phase transformation by exchanging thermal energy into mechanical energy and vice versa (9).

MANUFACTURING METHODS

Alloy Refining

The Ni–Ti SMAs can be refined using either the vacuum-induction melting method or the consumable arc melting technique. In vacuum-induction melting, a prerequisite in working with Ni–Ti is a high purity graphite crucible. To prevent impurities, the crucible should be connected to the pouring lip mechanically to keep the molten Ni–Ti compound from contacting anything, but the high density, low porosity graphite. Elemental carbon is very reactive with Ni or Ti alone and any contact with either will ruin the purity of the desired sample. However, there is very little reaction with the crucible in the consumable arc melting process. This method yields a product that is relatively free of impurities. Once the Ni–Ti alloy is cast using the melting technique, it is ready for hot or cold working into more practical forms and consecutive annealing treatment (42).

Mechanical Processing

When hot working a piece of Ni–Ti alloy, the temperature should be below that where incipient melting of the secondary phase can occur. This temperature should also be held constant for a period of time sufficient for certain nonequilibrium phases to return to solution, which makes the remaining alloy homogeneous. Andreasen suggested that the optimum hot working temperature is 700–800 °C for forging, extrusion, swaging, or rolling. If cold rolling is desired, then the alloy should be annealed before the oxide is removed (42). The most common form of Ni–Ti alloy is a wire. To make a wire, the Ni–Ti alloy ingot must be rolled into a bar at high temperature. Swaging the bar, followed by drawing, and a final annealing, reduce the alloy to wire form. To soften the wire, it should be annealed between 600 and 800 °C for a short period. When the Ni–Ti alloy is drawn down to 0.8 mm through a carbide die, the maximum reduction in area with each pass should be within 10%. Once this diameter is reached, a diamond die is used to draw the alloy with a 20% area reduction per die. The Ni–Ti alloy is annealed again at 700 °C and allowed to cool to room temperature between passes (42). By contrast, the extrusion method is used for the tube-making process, which enables a substantially greater reduction in cross-sectional area as compared to drawing wire. Laser cutting of Ni–Ti tubes has been used to make vascular stents (43). Most Ni–Ti alloys require a surface finishing procedure after the final machining process, such as chemical leaching, cleaning, rinsing, and surface modification.

Shape Memory Programming

There are two steps in the shape memory programming of a Ni–Ti alloy. First, the Ni–Ti alloy sample must be deformed to the desired shape and put into a constraining mold or fixture. The next step is shape memory heat treatment in a furnace at 400–600 °C. The shape recovery efficiency of a Ni–Ti alloy can be controlled by changing the heat treatment conditions or the degree of deformation. In general, there are three different ways to control the TTR of a Ni–Ti SMA: altering the chemical composition,

changing the heat treatment conditions, and varying the degree of deformation (13).

Chemical Composition Effect on TTR. The shape memory characteristic is limited to Ni–Ti alloys with near-equiatomic composition, as shown in Fig. 4. A pure stoichiometric (50 at%) Ni–Ti alloy will have a nickel content of ~ 55 wt%. Increasing the nickel concentration lowers the characteristic transformation temperature of the alloy. The limit of the nickel concentration for a SMA is ~ 56.5 wt%, owing to the formation of a detrimental second phase. In addition, the shape memory properties of a Ni–Ti alloy can be readily modified by adding ternary elements that are chemically similar to Ni or Ti. Adding a small amount of a transition metal such as Co, Fe, or Cr, instead of Ni, depresses the TTR, such that the SME occurs at well-below ambient temperature (44). When larger ions are substituted for smaller ions, the transformation temperature increases. Concerning ternary additions to alloys, Murakami et al. (45) proposed that the stability of the parent phase is controlled by ion–core repulsive interactions such that when larger ions are substituted for smaller ions, the transformation temperature increases. Based on this hypothesis, substitutions of Au and Zr should increase the recovery temperature of Ni–Ti alloys, Al and Mn should decrease it, and Co and Fe should cause little change. The effects of Au, Zr, Al, and Mn were predicted correctly, but those of Co and Fe were not. Similarly, Morberly suggested that if $> 7.5\%$ copper is added to a Ni–Ti alloy, up to 30%, the addition of Cu increases and narrows the TTR (46).

Mechanical Deformation Effect on the TTR. Many investigators have reviewed the effect of mechanical deformation on the TTR (5,36,47). They found that the degree of deformation affects the TTR of a SMA, and the stress slope (ds/dT) is a very important fundamental descriptor of SMAs. The residual stress from prior cold work can have a major effect on the transformation behavior. As a result, retention of the parent phase is a function of the stress and heat treatment history. Lee et al. reported that bending beyond the yielding point broadened the TTR and increased the stored internal energy (48). Figure 9 shows an example of transition temperature variation with respect to uniaxial prestrain of a Ni–Ti alloy wire (13). When the prestrain $> 8\%$, the shape recovery transition temperature (A_s) and the martensite starting temperature (M_s) are increased with increasing prestrain. However, the enthalpy change of the cooling cycle is almost the same because most stored internal energy in SIM is already liberated during the heating cycle (36).

Heat Treatment Effect on the TTR. The TTR of a Ni–Ti alloy can be controlled by the final annealing temperature and time. Kim insisted that a higher annealing temperature gives a lower transition temperature and a wider TTR (9). Moreover, he showed that a larger grain size has a lower transition temperature because the annealed large grains have much more transformable volume than smaller grains, so they need more energy for second-phase nucleation and growth inside the grain (49).

Figure 9. Transition temperatures of prestrained Ni–Ti alloy wire (13).

Figure 10 shows an example of the heat treatment temperature effect on SME (40). When a Ni–Ti rod is heat treated for 30 min at 600°C , the rod shows superelasticity at room temperature. This indicates that the TTR is lower than the testing temperature. By contrast, when a Ni–Ti rod is heat treated for 30 min at $< 500^\circ\text{C}$, the rod shows SME at room temperature, which suggests that the TTR is higher than the testing temperature. These results clearly show that the SME is closely related to the heat treatment temperature (9,50).

Methods of Measuring Transition Temperatures

There are many measurable parameters that accompany the shape memory transformation of a Ni–Ti alloy, for example, hardness, velocity of sound, damping characteristic, elastic modulus, thermal expansion, electrical resistivity, specific heat, latent heat of transformation, thermal conductivity, and lattice spacing. Of these, the electrical resistivity and latent heat of transformation are useful for measuring the TTR of a SMA.

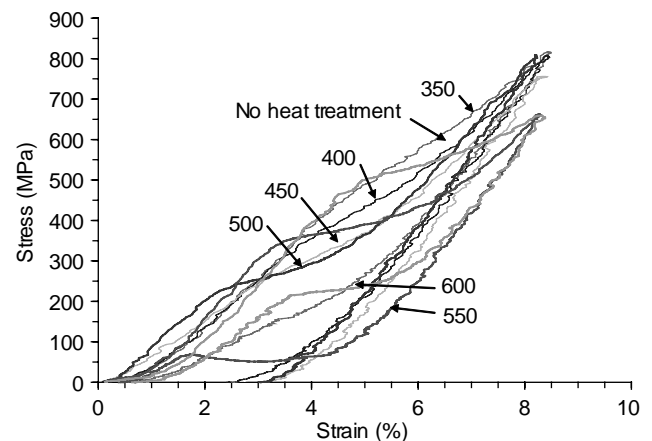

Figure 10. The room temperature compression stress–strain curves of heat-treated $\phi 6$ -mm Ni–Ti rods for 30 min at 350 – 600°C . The numbers pointing to the graphs are the annealing temperatures (40).

Figure 11. A cyclic DSC curve of the specific heat versus temperature for a Ni-Ti alloy wire from -70 to 70 °C. The lower and upper parts of the cyclic curve represent heating and cooling processes, respectively. (A_s : shape recovery starting temperature, A_f : shape recovery finishing temperature, M_s : martensitic transformation starting temperature, M_f : martensitic transformation finishing temperature, R_f : R phase transformation finishing temperature) (40).

DSC Measurement. Differential scanning calorimetry (DSC) is a thermal analysis technique that determines the specific heat, heat of fusion, heat of reaction, or heat of polymerization of materials. It is accomplished by heating or cooling a sample and reference under such conditions that they are always maintained at the same temperature. The additional heat required by the sample to maintain it at the same temperature is a function of the observed chemical or physical change (50). Figure 11 shows a typical DSC curve of the specific heat change of a Ni-Ti alloy (40). The lower curve is the heating curve and the upper one is the cooling curve. Each peak represents a phase transformation during the thermal cycle. The area under the curve represents the enthalpy change (ΔH) during the phase transformation. The arrows on Fig. 11 indicate the transition temperatures. The advantage of DSC measurement is that samples can be small and require minimal preparation. In addition, it can detect the residual strain energy, diffusing DSC peaks (51).

Electrical Resistivity Measurement. The shape memory transition temperature can also be determined from the curve of the electrical resistance versus temperature using a standard four-probe potentiometer within a thermal scanning chamber. In 1968, Wang reported the characteristic correlation between the shape memory phase transformations of a Ni-Ti alloy and the irreversible electrical resistivity curves (52). He proposed that the electrical resistivity curve in the same temperature range has a two-step process on cooling, that is, from the parent phase via R-phase to the final martensite phase, and a one-step process on heating, that is, from the martensite to the parent phase. Figure 12 plots the electrical resistivity versus temperature curves of a $\phi 1.89$ mm Ni-Ti alloy wire that was heat treated at 550 °C for 30 min. During the heating process, the electrical resistivity increases up to temperature A_s , and then it decreases until temperature A_f

Figure 12. The electrical resistivity versus temperature curve of a $\phi 1.89$ mm Ni-Ti alloy wire that was heat treated at 550 °C (53).

is reached. This suggests the restoration of the parent structure accompanying this resistivity change. During the cooling cycle, however, a triangular curve appears. The increasing part of this triangular curve from R_s to R_f represents the formation of an intermediate R phase resulting in a further increase in electrical resistivity. The decreasing part represents the thermal energy absorption of the martensitic phase transformation.

Corrosion Resistance

The Ni-Ti SMAs are an alloy of nickel, which is not corrosion resistant in saline solutions, such as seawater, and titanium, which has excellent corrosion resistance under the same conditions. The corrosion resistance of Ni-Ti alloys more closely resembles that of titanium than that of nickel. The corrosion resistance of Ni-Ti alloys is based mainly on the formation of a protective oxide layer, which is called passivation (9). If the alloy corrodes, then breakdown of the protective oxide film on the alloy's surface occurs locally or generally, and substantial quantities of metallic ions are released into the surrounding solution. Therefore, corrosion resistance is an important determinant of biocompatibility (54–56). The Pourbaix diagram is a useful means of measuring corrosion. It is a potential versus pH diagram of the redox and acid-base chemistry of an element in water. It is divided into regions where different forms of the metal predominate. The three regions of interest for conservation are corrosion, immunity, and passivity. The diagram may indicate the likelihood of passivation (or corrosion) behavior of a metallic implant *in vivo*, as the pH varies from 7.35 to 7.45 in normal extracellular fluid, but can reach as low as 3.5 around a wound site (57). An immersion test is also used for determining the concentration of released metallic ions, corrosion rates, corrosion types, and passive film thickness in saline, artificial saliva, Hank's solution, physiological fluids, and so on (58).

Some surface modifications have been introduced to improve the corrosion properties of Ni-Ti alloys, and prevent the dissolution of nickel. These include titanium

nitride coating of the Ni–Ti surface and chemical modification with coupling agents for improving corrosion resistance. However, when the coating on a Ni–Ti alloy is damaged, corrosion appears to increase in comparison with an uncoated alloy (56). Laser surface treatment of Ni–Ti leads to increases in the superficial titanium concentration and thickness of the oxide layer, improving its cytocompatibility up to the level of pure titanium (9). Electropolishing methods and nitric acid passivation techniques can improve the corrosion resistance of Ni–Ti alloys owing to the increased uniformity of the oxide layer (59).

Biocompatibility

Biocompatibility is the ability of a material or device to remain biologically inactive during the implantation period. The purpose of a biocompatibility test is to determine potential toxicity resulting from contact of the device with the body. The device materials should not produce adverse local or systemic effects, be carcinogenic, or produce adverse reproductive or developmental effects, neither directly nor through the release of their material constituents (60). Therefore, medical devices must be tested for cytotoxicity, toxicity, specific target-organ toxicity, irritation of the skin and mucosal surfaces, sensitization, hemocompatibility, short-term implantation effects, genotoxicity, carcinogenicity, and effects on reproduction.

The biocompatibility of a Ni–Ti alloy must include the biocompatibility of the alloy's constituents. As Ni–Ti alloys corrode, metallic ions are released into the adjacent tissues or fluids by some mechanisms other than corrosion (61). Although Ni–Ti alloys contain more nickel than 316L stainless steel, Ni–Ti alloys show good biocompatibility and high corrosion resistance because of the naturally formed homogeneous TiO₂ coating layer, which has a very low concentration of nickel. Although Ni–Ti alloys have the corrosion resistance of titanium, the passivated oxide film will dissolve at some rate; furthermore, the oxide layer does not provide a completely impervious barrier to the diffusion of nickel and titanium ions (62,63).

Many investigators have reported on the biocompatibility of Ni–Ti alloys. Comparing the corrosion resistance of common biomaterials, the biocompatibility of Ni–Ti ranks between that of 316L stainless steel and Ti6Al4V, even after sterilization. Some of these findings are listed here. Thierry found that electropolished Ni–Ti and 316L stainless steel alloys released similar amounts of nickel after a few days of immersion in Hank's solution (64). Trepanier reported that electropolishing improved the corrosion resistance of Ni–Ti stents because of the formation of a new homogeneous oxide layer (59). In a short-term biological safety study, Wever found that a Ni–Ti alloy had no cytotoxic, allergic, or genotoxic activity and was similar to the clinical reference control material AISI 316 LVM stainless steel (65). Motzkin showed that the biocompatibility of nitinol is well within the limits of acceptability in tissue culture studies using human fibroblasts and buffered fetal rat calvaria tissue (66). Ryhanen reported that nitinol is nontoxic, nonirritating, and very similar to stainless steel and Ti–6Al–4V alloy in an *in vivo* soft tissue and inflammatory response study (67). Castleman found no

significant histological compatibility differences between nitinol and Vitallium (Co–Cr alloy) (68). However, Shih reported that nitinol wire was toxic to primary cultured rat aortic smooth muscle cells in his cytotoxicity study using a supernatant and precipitate of the corrosion products (69). Moreover, he found that the corrosion products altered cell morphology, induced cell necrosis, and decreased cell numbers.

MEDICAL DEVICES

The Ni–Ti alloys have been used successfully for medical and dental devices because of their unique properties, such as SME, superelasticity, excellent mechanical flexibility, kink resistance, constancy of stress, good elastic deployment, thermal deployment, good corrosion resistance, and biocompatibility. Recently, Ni–Ti alloys have found use in specific devices that have complex and unusual functions, for example, self-locking, self-expanding, or compressing implants that are activated at body temperature (58). Some popular examples of Ni–Ti medical devices have been selected and are reviewed below.

Orthodontic Arch Wires

A commercially available medical application of nitinol is the orthodontic dental arch wire for straightening malpositioned teeth, marketed by Unitek Corporation under the name Nitinol Active-Arch (70). This type of arch wire, which is attached to bands on the teeth, is intended to replace the traditional stainless steel arch wire. Although efforts have been made to use the SME in orthodontic wires (71), the working principle of Nitinol Active-Arch wire is neither the SME nor pseudoelasticity, but the rubber-like behavior and relatively low Young's modulus (30 GPa) of nitinol in the martensitic condition. This modulus is very low in comparison with the modulus of stainless steel (200 GPa). Comparing the bending moment change of nitinol and stainless steel wire undergoing a constant change in deflection (72), stainless steel wire shows a much larger change in moment than the moment change of nitinol wire. Clinically, this means that for any given malocclusion nitinol wire will produce a lower, more constant force on the teeth than would a stainless steel wire of equivalent size. Figure 13 shows a clinical example of orthodontic treatment using a superelastic Ni–Ti arch wire (73). This wire showed faster movement of teeth and shorter chair time than conventional stainless steel wire.

Guidewires

One typical application of superelasticity is the guidewires that are used as guides for the safe introduction of various therapeutic and diagnostic devices. A guidewire is a long, thin metallic wire that is inserted into the body through a natural opening or a small incision. The advantages of using superelastic guide wire are the improvement in kink resistance and steerability. A kink in a guidewire creates a difficult situation when the time comes to remove it from a

Figure 13. Orthodontic treatment using a Ni-Ti superelastic arch wire. (a) Malaligned teeth before treatment and (b) normally aligned teeth after the first stage of treatment (73). complex vascular structure. The enhanced twist resistance and flexibility make it easier for the guidewire to pass to the desired location (74). Figure 14 shows the tip of a guidewire. The curved “J” tip of the guidewire makes it easy to select the desired blood vessel.

Figure 14. Photograph of the tip of a commercial Ni-Ti guidewire (FlexMedics, USA) (75).

Figure 15. Commercial Ni-Ti stents (a) Gianturco stent, (b) self-expanding nitinol stent with the Strecker stent design, (c) Wall stent (76).

Stents

A stent is a slender metal mesh tube that is inserted inside a luminal cavity to hold it open during and after surgical anastomosis. Superelastic nitinol stents are very useful for providing sufficient crush resistance and restoring lumen shape after deployment through a small catheter (25–27). Figure 15 shows three examples of commercial self-expandable Ni-Ti superelastic stents: a Gianturco stent for the venous system, a Strecker stent for a dialysis shunt, and a Wall stent for a hepatic vein. Figure 16 shows the moment of expansion of a Ni-Ti self-expandable stent being deployed from the introducer. The driving force of the self-expanding stent is provided by the superelasticity of the Ni-Ti alloy. Some clinical limitations of Ni-Ti stents remain unresolved and require further development; these are the problems of intimal hyperplastic and restenosis (78).

Orthopedic Applications

Dynamic compression bone plates exhibiting the SME are one of the most popular orthopedic applications of nitinol, followed by intramedullary fixation nails. Fracture healing

Figure 16. Deployment of a commercial Ni-Ti self-expandable stent (Taewoong Medical, Korea) (77).

in long bones can be accelerated when bone ends are held in position with compression between the bone fragments. Using this method, the undesirable surface damage and wear of the holes that occur in a conventional dynamic bone plate are avoided, while continuous compression is assured, even if bone resorption occurs at the fracture sites. The effect continues as long as the original shape is not reached (79).

Historically, the first orthopedic application of a SMA was a Nitinol Harrington instrument for scoliosis treatment that was introduced in 1976 by Schmerling (80), which enabled the surgeon to restore any relaxed corrective force postoperatively simply by the external application of heat. In addition, it could be used initially to apply a more appropriate set of corrective forces. Figure 17 shows an example of a Ni–Ti shape memory clamp in small bone surgery (81). Six months after surgery, a non-union was present, although the outcome in this patient was assessed as good.

CONCLUSIONS

A shape memory alloy is a metallic substance that has a memory for shape combined with superelasticity. The mechanisms of a nickel–titanium alloy's shape memory effect and superelasticity are described based on thermally induced or stress induced martensite phase transformations. Some of the physical properties of nickel–titanium alloys and a phase diagram are included for reference. The thermomechanical characteristics, corrosion properties, and biocompatibility of Ni–Ti shape memory alloys are reviewed for the design of shape memory devices. Manufacturing methods, including refining, processing, shape memory programming, and transformation temperature range measuring methods are summarized for practical applications. Finally, some applications in medical devices are reviewed as examples of current trends in the use of shape memory alloys. In conclusion, Ni–Ti shape memory alloys are a very useful biocompatible material because of

Figure 17. Failed arthrodesis of the carpometacarpal joint when only one titanium–nickel (TiNi) clamp was used (81). (From Arch. Orthop. Trauma Surg., Vol. 117, 1998. Figure 1 on page 342, Musialek J., Filip P. and Nieslanik J. Reproduced with kind permission of Springer Science and Business Media.)

their unique mechanical properties and good corrosion resistance. A better understanding of shape memory alloys should allow further developments in this area.

AMBULATORY MONITORING

HAIBO WANG
AHMAD ELSHARYDAH
RANDALL CORK
JAMES FRAZIER
Louisiana State University

INTRODUCTION

Due to advances in technology, especially computer sciences, ambulatory monitoring with medical instruments has increasingly become an important tool in the diagnosis of some diseases and medical conditions. Some devices used or in development for current clinical practice are shown in Table 1.

The ideal device for ambulatory monitoring should be consistently sensitive, accurate, lightweight, noninvasive, and easy to use. The Holter monitor is a popular device for ambulatory monitoring. Therefore, this article will start with a discussion of the Holter monitor.

AMBULATORY MONITORING WITH A HOLTER DEVICE

A Holter monitor is a continuous recording of a patient's ecocardiogram (ECG) for 24 h as shown in Fig. 1. It was named in honor of Norman J. Holter for his contribution in creating the world's first ambulatory ECG monitor in 1963 (1). Since it can be worn during the patient's regular daily activities, it helps the physician correlate symptoms of dizziness, palpitations, and syncope with intermittent

Table 1. Current Devices for Ambulatory Monitoring

Devices	Uses
Holter monitoring	Cardiac arrhythmia and ischemia
Ambulatory BP monitoring	Hypertension and hypotension
Ambulatory glucose monitoring	Hyperglycemia and hypoglycemia

Figure 1. Holter monitor.

cardiac arrhythmias. When compared with the ECG, which lasts < 1 min. The Holter monitor is more likely to detect abnormal heart rhythm. It can also help evaluate the patient's ECG during episodes of chest pain due to cardiac ischemia. The common clinical applications for Holter monitor are summarized in Table 2 (2,3).

The basic components of a Holter monitor include at least a portable ECG recorder and a Holter analyzer (scanner). Functional characteristics of both components have improved dramatically since the first Holter monitor was developed > 40 years ago.

Portable ECG Recorder

The recorder is a compact, light-weight device used to record an ambulatory patient's three or more ECG leads, typically for 24 h for dysrhythmia or ischemia detection. There are two types of the recorder available on the market: the classical cassette type (tape) or the newer digital type (flash memory card). The cassette recorder uses magnetic tape to record ECG information. The tape needs to be sent to the physician's office for analysis with a scanner to produce a patient's report. The problems with this type of recorder are its limited memory for ECG recording, its inability to transmit ECG information to the service center digitally, and its difficulty in processing the information with computer software. Therefore, it normally takes days to produce a monitoring report for a patient.

The newer digital recorder has an increased memory compared to the classical cassette type, making it possible

Table 2. Clinical Application of the Holter Monitor

1. Evaluation of symptomatic events: dizziness, syncope, heart palpitations, fatigue, chest pain, shortness of breath, episodic diaphoresis.
2. Detection of asymptomatic dysrhythmia: asymptomatic atrial fibrillation.
3. Evaluation of rate, rhythm or ECG interval changes during drug therapy.
4. Evaluation for specific clinical situations: postmyocardial infarction, postcoronary bypass surgery, postpercutaneous transluminal coronary angioplasty, postpacemaker implant, first or second degree heart block, possible pacemaker malfunction, automatic implanted defibrillator functions.
5. Evaluation of ECG changes during specific activities.

to extend the monitoring time beyond 24 h if indicated. More importantly, the recorded signs are digital, which can be transmitted to the service center or on-call physician by digital transmission system via a phone line, email, or wireless technology, and can be processed rapidly with computer software. Therefore, the patient's report will be available for the patient's physician much sooner. If indicated, treatment can be started without delay. Additionally, a patient event button has been incorporated in some of newer recorders to allow correlation of symptoms and activity with ECG changes to obtain more clinical data useful for making a correct clinical diagnosis.

Another new development is the Cardiac Event Monitoring (CEM), which is similar to Holter monitor for recording an ambulatory patient's ECG. The difference between them is that the CEM is an event-triggered device, only recording the patient's ECG when they experiences a detectable symptoms (4). As a result, the CEM makes prolonged monitoring possible even with a limited recorder memory.

Holter Analyzer (Scanner)

There are different types of Holter analyzer systems currently available. The original system for analyzing the Holter cassette was a scanner with manual observer detection. With manual observer detection, the trained technician watches for audiovisual clues of abnormal beats while playing the tape back at 60–120 times real time. The process is time consuming. It requires a skilled technician who can withstand high boredom and fatigue levels to minimize possible human error rate.

The modern Holter analyzer system has been revolutionized due to the application of computer technologies. It is available in a variety of options, such as auto analysis and complete editing capabilities. Some of the newer systems provide easy-to-use professional features that allow rapid review of recorded information, producing a fast, accurate report.

Future Development

Ambulatory Holter monitoring is a valuable tool in patient care and is becoming more and more popular. Integration of computer technology, digital technology, wireless technology, and nanotechnology may lead to an ideal Holter device, which is minimal in size and weight, user-friendly, noninvasive, sensitive and accurate, wirelessly connected to a physician on-call center, and with automatic data analysis capacity. Newer analysis techniques involving fuzzy logic, neural networks and genetic algorithms will also enhance automatic detection of abnormal ECG. Hopefully, such an ideal ambulatory Holter monitor will be available in the near future.

AMBULATORY BLOOD PRESSURE MONITORING

Introduction

An ambulatory blood pressure monitoring device is a non-invasive instrument used to measure a patient's 24 h ambulatory blood pressure as shown in Fig. 2. The first device was developed by Hinman in 1962 (5). He used a

Figure 2. Ambulatory blood pressure monitoring device.

microphone placed over the brachial artery distal to a compression cuff and a magnetic tape recorder for recording of onset and disappearance of Korotkoff sounds. It weighed ~ 2.5 kg and was obviously inconvenient for an ambulatory patient to use. The first fully automatic device was developed, using compressed carbon dioxide to inflate the cuff. An electronic pump was introduced later and automatic data recording systems have been used since 1979.

Since then, the techniques for ambulatory blood pressure monitoring have been improved significantly. The modern device is light-weighted, compact in size, accurate, and automated in nature. It can be belt-worn and battery powered. The newest generation available in the current market is fully automatic, microprocessor-controlled, digitalized in memory, and extremely light weight (< 500 g).

Basic Techniques

The techniques for ambulatory blood pressure monitoring include auscultation, cuff oscillometry, and volume oscillometry.

Auscultation is a technique based on detection of onset and disappearance of Korotkoff sounds via a piezoelectric microphone taped over an artery distal to a deflating compression cuff. The Korotkoff sound is produced by turbulent flow while arterial blood flows through a segment of artery narrowed by a blood pressure cuff. The pressure at the onset of sound corresponds to systolic blood pressure, and at the disappearance of the sound to diastolic pressure. The advantage of this technique is simplicity, but the device is sensitive to background noise. This technique may also underestimate systolic pressure due to its flow dependency.

Cuff oscillometry is a technique based on detection of cuff pressure oscillations or vibrations to calculate systolic and diastolic values using an algorithmic approach. The systolic pressure corresponds to the cuff pressure at which oscillations first increase, and the diastolic pressure corresponds to the cuff pressure at which oscillations cease to decrease. The endpoints are estimated by analysis of oscillation amplitudes and cuff pressures. Different algorithms are used by different manufacturers, which may result in variability among different devices. This technique is insensitive to background noise, but arm movement may cause an errant reading. It may overestimate

systolic pressure because of transmitted cuff pressure oscillations.

Volumetric oscillometry is a technique based on detection of finger volume pulsations under a cuff. The pressures are estimated as the cuff pressures at which finger volume oscillations begin (systolic pressure) and become maximal (mean pressure). Diastolic pressure is then derived from the known systolic and mean pressures. One problem with this technique is that this finger pressure may have a variable relationship to the brachial pressure. Another problem is that the technique cannot directly assess diastolic pressure.

Despite some problems associated with the mentioned techniques, their accuracy has been confirmed by validation testing using mercury sphygmomanometry and intraarterial measurement. The discrepancy is generally < 5 mmHg (0.399 kPa) between ambulatory devices and readings taken by trained professionals.

Patients are advised to wear the monitor for a period of 24 h, preferably during a normal working day. The monitor is preprogrammed to measure and record blood pressure at certain time intervals, preferably every 15–20 min during daytime hours and every 20–30 min during nighttime hours. Patients are also advised to document their activity during the testing period for assessment of any stress-related blood pressure.

The monitoring device consists of a small central unit and an attached cuff. The central unit contains a pump for cuff inflation and deflation, and the memory device, such as tape or digital chip, for recording. The time intervals between the measurements, maximal and minimal inflation pressures, and deflation rate are programmable according to the physician's order. The recording pressures can be retrieved from the tape or memory chip for analysis. Due to recent applications of digital technology and advanced software programs, a large amount of data can be stored in a small chip, and analysis can also be done automatically to generate a patient's report for the physician's use. A complete patient's report normally contains all blood pressure readings over a 24 h period, heart rates, mean arterial pressures, and statistic summaries for daytime, nighttime, and 24 h periods.

New Clinical Concepts Related to Ambulatory Blood Pressure Monitoring

A few new considerations related to ambulatory blood pressure monitoring have emerged. These include blood pressure load, pressure dipping, pressure variability, and white-coat hypertension. Health professionals need to understand these concepts in order to properly interpret or use data collected from monitoring.

Blood Pressure Load. This is defined as the proportion of the 24 h pressure recordings above the thresholds for waking and sleep blood pressure. The threshold commonly used for estimating the pressure load during waking hours is 140/90 and 120/80 mmHg (15.99/10.66 kPa) during sleep. Blood pressure load is helpful in the diagnosis of hypertension and in the prediction of end-organ damage. It has been considered closely correlated with left ventricle

hypertrophy. It has been reported that the incidence of left ventricular hypertrophy is ~ 90% in untreated patients with systolic blood pressure loads > 50%, and ~ 70% with diastolic blood pressure loads < 40% (6,7).

Dipping and Circadian Blood Pressure Variability. Dipping is a term used to describe the circadian blood pressure variation during 24 h ambulatory blood pressure monitoring. In normotensive patients there is circadian blood pressure variability. Typically, the peak blood pressures occur around 6 a.m., and then taper to lower levels during the evening hours and further at night with the lowest levels between 2 and 4 a.m.. A patient whose blood pressure drops by at least 10% during sleep is considered normal (a dipper), and by < 10% abnormal (nondipper). In comparison to dippers, nondippers have been reported associated with higher prevalence of left ventricular hypertrophy, albuminuria, peripheral arterial changes, and cerebral lacunae. Nondippers have also been reported to have increased cardiovascular mortality rates (8).

White-Coat Hypertension. This is a condition in which blood pressure is persistently elevated in the presence of a doctor, but falls to normal levels when the patient leaves the medical facilities. Measurement by a nurse or trained nonmedical staff may reduce this effect. Because decisions regarding treating hypertension are usually made on the basis of isolated office blood pressure reading, a doctor may incorrectly diagnose this group of patients as sustained hypertension and prematurely start the therapy. This phenomenon has been reported in 15–35% of patients currently diagnosed and treated as hypertensive. However, white-coat hypertension can be easily detected by either ambulatory blood pressure monitoring or self-monitoring at home. It may or may not be benign, requiring definitive outcome studies to rule out any end-organ damages. It also requires continued surveillance by self-monitoring at home and repeat ambulatory blood pressure monitoring every 1–2 years (9,10).

Interpretation of Ambulatory Blood Pressure Profile

Normal ambulatory blood pressure values for adults are currently defined to be < 135/85 mmHg (17.99/11.33 kPa) during the day, < 120/75 mmHg (15.99/9.99 kPa) during the night, and < 130/80 mmHg (17.33/10.66 kPa) over 24 h. Daytime and night time blood pressure loads should be less 20% above normal values. Mean day-time and nighttime (sleep) blood pressure measurements should differ by at least 10%. The ambulatory blood pressure profile should also be inspected in relation to diary data and time of drug therapy.

Indications of Ambulatory Blood Pressure Monitoring

Although ambulatory blood pressure monitoring was originally developed as a research tool, it has widely been applied in clinical practice to help diagnose and manage hypertensive patients. It is indicated to rule out white-coat hypertension, to evaluate drug-resistant hypertension, to assess symptomatic hypertension or hypotension, to diagnose hypertension in pregnancy, and to assess adequacy of

blood pressure control in patients at high risk of cardiovascular diseases.

White-Coat Hypertension. Office-based blood pressure measurement cannot differentiate sustained hypertension from white-coat hypertension. Historical appraisal and review of self-recorded blood pressures may aid in identification of patients with white-coat hypertension. However, ambulatory blood pressure monitoring is more effective in this clinical scenario to rule out white-coat hypertension. Recognition and proper management of patients with white-coat hypertension may result in a reduction in medication use and eliminate related cost and side effects. Although white coat hypertension may be a prehypertensive state and can eventually evolve to sustained hypertension, data collected from ambulatory blood pressure monitoring suggest, patients with white coat hypertension who maintain low ambulatory blood pressures (< 130–135/80 mmHg) have a low cardiovascular risk status and no demonstrable end-organ damage (11).

Drug-Resistant Hypertension. Drug resistant hypertension is defined as a condition when adequate blood pressure control (< 140/90 mmHg)(18.66/11.99 kPa) cannot be achieved despite the use of appropriately combined antihypertensive therapies in proper dosages for a sufficient duration. Ambulatory blood pressure monitoring helps evaluate whether additional therapy is needed. The causes include true drug-resistant hypertension as well as other conditions such as superimposition of white-coat hypertension on existing hypertension, patient's noncompliance, pseudohypertension secondary to brachial artery calcification, and sleep apnea and other sleep disorders. Ambulatory blood pressure monitoring can help differentiate the true drug resistant hypertension from the above-mentioned conditions (12).

Episodic Hypertension. A single office-based measurement of blood pressure may or may not detect episodic hypertension as in pheochromocytoma. In this clinical scenario the 24 h ambulatory blood pressure monitoring is a useful diagnostic tool. It is indicated if a patient's symptoms or signs are suggestive of episodic hypertension (13).

Borderline or Labile Hypertension. Patients with borderline hypertension often demonstrate only some (but not all) elevated blood pressure readings in office-based measurement, 24 h ambulatory blood pressure monitoring can benefit these patients and provide a useful diagnostic information for physician's use (14).

Hypertension with End-Organ Damage. Patients who exhibit worsening of end-organ damage may suggest inadequate 24 h blood pressure control. Occasionally, those patients may demonstrate adequate blood pressure control based on the office-based measurements. In this condition, a 24 h blood pressure monitoring is needed to rule out inadequate blood pressure control, which is associated with worsening of end-organ damage (15).

Hypertensive Patients with High Risk of Cardiovascular Events. Some hypertensive patients are at particularly high

risk of cardiovascular events, such as those with diabetes and/or past stroke. Those patients require rigorous blood pressure control over 24 h. Ambulatory blood pressure monitoring can be applied to assess the 24 h control (15).

Suspected Syncope or Orthostatic Hypotension. Transient hypotensive episodes and syncope are difficult to assess with the office-based blood pressure measurements, but are readily recorded with ambulatory blood pressure monitoring. Therefore, if symptoms and signs are suggestive of syncope or orthostatic hypertension, patients can benefit from 24 h blood pressure monitoring, especially in conjunction with Holter monitoring (15).

Hypertension in Pregnancy. About 10% of pregnancies may be complicated by hypertension. At the same time, white-coat hypertension may affect up to 30% of patients. It is important to differentiate true hypertension in pregnancy from white-coat hypertension, to avoid unwarranted hospitalizations or medication use. In this clinical scenario, ambulatory blood pressure monitoring would help to rule out white-coat hypertension and identify pregnancy-induced hypertension (16).

Clinical Research. Since ambulatory blood pressure monitoring can provide more samples of blood pressure measurements, data from this device is therefore much more statistically significant than a single isolated office-based reading. Therefore, statistical significance of clinical studies can possibly be achieved with smaller numbers of patients. This is very important for the efficient study of new therapeutic agents (17).

Limitations of Ambulatory Blood Pressure Monitoring

Although ambulatory blood pressure monitoring has been proved useful in the diagnosis and management of hypertension, the technology remains underused secondary to lack of experience in interpretation of results, unfamiliarity with devices, and some economic issues. Adequate staff training, regular calibration of devices, and good quality control are required. The patient's diary of daily activities and time of drug treatment are also needed for proper data analysis and interpretation.

Future Development

Like any other ambulatory device, an ideal noninvasive ambulatory blood pressure monitoring device should be user-friendly, light-weight, compact in size, digitalized for automated data management, and low in cost. Application of newer technologies will make such devices available, hopefully, in the near future.

AMBULATORY BLOOD GLUCOSE MONITORING

Introduction

Diabetes is one of most common diseases suffered by millions of people around the world. It is essential to monitor blood glucose to ensure overall adequate blood glucose control. Traditional standard blood glucose

Figure 3. Ambulatory glucose monitoring with guardian real time system (Medtronic MiniMed).

monitoring devices require invasive blood samplings and are therefore unsuitable for ambulatory blood glucose monitoring. Development of minimally invasive or noninvasive ambulatory glucose monitoring devices that provide accurate, near-continuous measurements of blood glucose level have the potential to improve diabetes care significantly. Such devices will provide information on blood glucose levels, as well as rate and direction of change, which can be displayed to patients in real-time and be stored for later analysis by physicians. Guardian RT system recently developed by Medtronic MiniMed is an example (Fig. 3). It provides continuous real-time glucose readings around the clock. Due to the huge market potential, many biomedical and medical instrument companies are developing similar devices for ambulatory glucose monitoring. Several innovative devices have recently been unveiled; many more are still in development. It is expected that some of them will be eventually U. S. Food and Drug Administration (FDA) approved as a replacement for standard blood glucose monitors, providing patients with a new option for long-term, daily monitors in the near future. The FDA is concerned about the accuracy of ambulatory continuous glucose monitoring devices when compared to the accuracy of standard monitoring devices. This issue will be eventually eliminated as related technologies become more and more mature. Technically, a typical ambulatory glucose monitoring device consists of a glucose sensor to measure glucose levels and a memory chip to record data information.

Glucose Sensors

The glucose sensors for ambulatory glucose monitoring devices are either minimally invasive or completely noninvasive. A variety of technologies have emerged over the past decade aiming at development of ideal glucose sensors suitable for ambulatory monitoring.

A typical minimally invasive ambulatory continuous glucose sensor is a subcutaneous device developed by MiniMed, Inc. (18). The sensor is designed to be inserted into a patient's abdominal subcutaneous tissue. It measures glucose levels every 10 s and records means > 5 min intervals. The technology involves measurement of glucose levels of

interstitial fluid via the subcutaneous sensor. The blood glucose levels are then derived from the measured interstitial fluid glucose levels. The detection mechanism involves use of a low fluorescence molecule. Electrons are transferred from one part of the molecule to another when excited by light. This prevents bright fluorescence from occurring (19). When bound to glucose, the molecule prevents the electrons from interfering with fluorescence, and the molecule becomes a bright fluorescent emitter. Therefore, the glucose levels can be determined based on the brightness of fluorescence. The glucose information will be transmitted from the sensor to a watch-like device worn on the wrist. Using this type of sensor, two devices have been developed by the company. One is a device that can be worn by the patient for a few days to record the glucose levels for the physician's analysis. The other is a device that can alert patients of impending hyperglycemia or hypoglycemia if the glucose levels go beyond the physician's predetermined upper and lower limits. The sensor can also work in conjunction with an implanted insulin pump, creating a "biomechanical" or artificial pancreas in response to the change at the glucose levels (20). It is predictable that such a biomechanical pancreas will eventually benefit millions of diabetic patients whose glucose control is dependant on insulin.

Complete noninvasive sensors for ambulatory glucose monitoring are even more attractive since they do not need any blood or interstitial samples to determine glucose levels. Several such sensors have recently been developed based on different technologies. For example, a glucose sensor that can be worn like a wristwatch has been developed by Pendragon Medical AG (Zurich, Switzerland). This sensor can continuously monitor blood glucose level without the need for a blood sample. It is based on impedance spectroscopy technology (21). The principle of this technology relates to the fact that blood glucose changes produce significant conductivity changes, causing electric polarization of cell membranes. At the same time, the sensor generates an electronic field that fluctuates according to the electrical conductivity of the body. A micro antenna in the sensor then detects these changes and correlates them with changes in serum glucose. With this technology, blood glucose levels can be monitored noninvasively in real time. Another promising noninvasive sensor is based on the possibility of measuring glucose by detecting small changes in the retinal capillaries. By scanning the retinal microvasculature, the sensor can directly measure glucose levels in aqueous humor using a reflectometer. Recently, a plastic thin sensor, which can be worn like a contact lens, has been innovated (22,23). The sensor changes its color based on the concentration of glucose, from red, which indicates dangerously low glucose levels, to violet, which indicates dangerously high glucose concentrations. When glucose concentration is normal, the sensor is green. Integration of the sensor material into commercial contact lenses may also be possible with this technology.

Memory Chips

Memory chips are used to record glucose data information for later use by the physician. The digital chips have many advantages, such as compact size, large memory, easy data transmission via wire or wireless, and possible

autoanalysis with computer software. Patients can also upload their glucose data from digital memory chips to web-based data management systems, allowing diabetic patients and their health care providers to analyze and communicate glucose information using the internet.

Significances of Ambulatory Glucose Monitoring

Ambulatory glucose monitoring can provide continuous data on blood glucose levels. Such data can improve diabetic care by enabling patients to adjust insulin delivery according to the rate and direction of blood glucose change, and by warning of impending hypoglycemia and hyperglycemia. Doctors can use ambulatory glucose monitoring to help diagnose problematic cases, fine-tune medications, and get tighter control of blood glucose levels for high risk patients. Obviously, the monitoring will improve overall blood glucose control, reducing short-term adverse complications and delaying onset of long-term serious complications, such as end-stage renal disease, heart attack, blindness, stroke, neuropathy, and lower extremity amputation.

In addition, continuous ambulatory glucose monitoring is a key step toward the development of artificial pancreas, which could deliver insulin automatically in response to blood glucose levels. It is expected that such an artificial pancreas would greatly benefit many diabetic patients and provide them new hope for better quality of life.

Future Development

Although many continuous ambulatory glucose monitoring devices are still in the stage of clinical trials, there is little doubt as to the value of the devices in management of diabetic patients. It is expected that millions of diabetic patients will be benefited once such devices are widely available. At the same time, introduction of more and more new devices highlights the need for careful evaluation to ensure accuracy and reliability. Cooperation between the manufacturers and physicians to fine-tune the technology will eventually lead to approval of the devices by the FDA to replace traditional invasive standard glucose monitoring. Technology for continuous ambulatory glucose monitoring is also required to make an artificial pancreas, which would offer great hope for millions of patients with diabetes.

CONCLUSION

Ambulatory monitoring has increasingly provided a powerful alternative tool to diagnose and manage some diseases. Continuous advancement in a variety of technologies provides more and more innovative ambulatory devices to serve the patients' need. Applications of information technology and specialized software tools make autotransmission and autoanalysis of ambulatory monitoring data possible. Clinicians will be able to monitor their ambulatory patients distantly without a hospital or office visits. In addition, integration of the technology of continuous ambulatory monitoring with an implantable automatic therapeutic pump may create a biomechanical system in response to specific abnormal changes. The artificial pancreas currently in development is a typical example for

such hybrid devices. Such devices will be available in the market in the near future.

ANALYTICAL METHODS, AUTOMATED

LAKSHMI RAMANATHAN

Mount Sinai Medical Center

LASZLO SARKOZI

Mount Sinai School of Medicine

INTRODUCTION

The chemical composition of blood, urine, spinal fluid, sweat, provides a wealth of information on the well being or illness of the individual. The presence, concentration, and activity of chemical constituents are indicators of various organ functions. Concentrations higher or lower than expected sometimes require immediate attention. Some of the reasons to analyze body fluids:

- Screening of an apparently healthy population for unsuspected abnormalities.
- Confirming or ruling out a diagnosis.
- Monitoring changes during treatment, improvement of condition or lack of improvement.
- Detecting or monitoring drug levels for diagnosis or maintenance of optimal therapeutic levels.

By the 1950s, demands of clinicians for laboratory tests increased rapidly. Classical methods of manual laboratory techniques could not keep up with these demands. The cost of performing large numbers of laboratory tests by manual methods became staggering and the response time was unacceptable.

The article in the first edition of this Encyclopedia published in 1988 describes the history of laboratory instrumentation during the previous three decades (1). Reviewing that long list of automated instruments, with the exception of a few, all became museum pieces. During the last 15 years the laboratory landscape changed drastically. In addition, new group of automated instruments were introduced during this period. They were developed to perform bedside or near patient testing, collectively called Point of Care Testing instruments. In this period in addition to new testing instruments, perianalytical instrumentation for specimen handling became available. Their combined result is increased productivity and reduction of manpower requirements, which became imperative due to increased cost of healthcare and dwindling resources.

This article will present some financial justification of these investments.

PATIENT PREPARATION, SPECIMEN COLLECTION, AND HANDLING

The prerequisites for accurate testing include proper patient preparation, specimen collection, and specimen handling. Blood specimens yield the most information about the clinical status of the patient though in many cases urine is the preferred sample. For specialized tests, other body fluids that include sweat and spinal fluid are used. When some tests, such as glucose and lipids, require fasting specimens, patients are prepared accordingly.

Common errors affecting all specimens include the following:

- Inaccurate and incomplete patient instructions prior to collection.
- Wrong container/tube used for the collection.
- Failure to label a specimen correctly.
- Insufficient amount of specimen to perform the test.
- Specimen leakage in transit due to failure to tighten specimen container lids.
- Interference by cellular elements of blood.

Phlebotomy techniques for blood collection have considerably improved with better gauge needles and vacuum tubes for collection. The collection tubes are color coded with different preservatives so that the proper container can be used for a particular analyte. The cells should be separated from the serum by centrifugation within 2 h of collection. Grossly or moderately hemolyzed specimens may be unsuitable for certain tests. If not separated from serum or plasma, blood cells metabolize glucose and produce a false decrease of ~5%/h in adults. The effect is much greater in neonates (2). If there is a delay in separating the cells from the serum, the blood should be collected in a gray top tube containing sodium fluoride as a preservative that inhibits glycolysis.

Urine collection is prone to errors as well, some of which include (3):

- Failure to obtain a clean catch specimen.
- Failure to obtain a complete 24 h collection/aliquot or other timed specimen.
- No preservative added if needed prior to the collection.

Once specimens are properly collected and received in the clinical laboratory, processing may include bar coding, centrifugation, aliquoting, testing and reporting of results.

AUTOMATED ANALYZERS

A large variety of instruments are available for the clinical chemistry laboratory. These may be classified in different ways based on the type of technology applied, the test menu, the manufacturer, and the intended application. Depending on the size of the laboratory, the level of

automation varies. Clinical chemistry analyzers can be grouped according to throughput of tests and diversity of tests performed and by function, such as immunoassay analyzers, critical care blood gas analyzers, and urinalysis testing systems. Point of Care analyzers vary in terms of accuracy, diversity and menu selection.

Some of the features to consider while evaluating low or high volume analyzers are listed below:

Test menu available on instrument:

- Number of different measured assays onboard simultaneously.
- Number of different assays programmed/calibrated at one time.
- Number of user-defined (open) channels.

Reagents:

- Preparation of reagents if any.
- Storage of reagents.
- On board stability.
- Bar-coding for inventory control.

Specimen volume:

- Minimum sample volume.
- Dead volume.

Instrument supplies:

- Use of disposable cuvettes.
- Washable/reusable cuvettes.

Clot detection features along with quantitation of hemolysis and turbidity detection.

- Auto dilution capabilities of analyzer.
- Frequency of calibration.
- Quality control requirements.
- Stat capability.
- LIS interface.
- Maintenance procedures on instrument; anticipated downtime.
- Analyzer costs expressed in cost per reportable test.

Our goal is not to review every analyzer available on the market. We have chosen a few of the instruments—vendors. This is by no means endorsing any particular vendor, but merely discussing some of the most frequently utilized features or describing our personal experiences. The College of American Pathologists has provided excellent surveys of instruments and the reader is referred to those articles for more complete details (4).

CHEMISTRY ANALYZERS

Routine chemistry analyzers have broad menus capable of performing an average of 45 (20 to >70) different on board tests simultaneously, selected from an available menu of 26

Table 1. Automated Analyzers from Different Manufacturers

Instrument Type	Generic Menu	Vendor
Routine chemistry	Electrolytes, BUN, Glucose, Creatinine, Protein, Albumin, Lipids, Iron, Drugs of abuse, Therapeutic drug monitoring, etc.	Abbott, Bayer, Beckman Dade, J&J, Olympus, Roche
Immunoassays	Tumor markers, Cardiac markers, Anemia, B12, Folate and misc. Endocrine tests	Abbott, Bayer, Beckman, DPL, J&J, Olympus, Roche
Critical Care	Blood gases, Cooximetry, Electrolytes Ionized calcium, Lactate, Hematocrit	Abbott, Bayer, Instrumentation Lab, Nova, Radiometer, Roche

to >100 different analytes (5,6). Selection is based on test menu, analytic performance, cost (reagents, consumables and labor), instrument reliability (downtime etc.), throughput, and ease of use, customer support and robotic connectivity, if needed. Some automated analyzers from different manufacturers are listed in Table 1.

General Chemistry

Virtually all automated chemistry analyzers offer random access testing, multiple tests can be performed simultaneously and continuously. This is different from batch-mode instruments that perform a single test on a batch of samples loaded on the instrument (Abbott TDX and COBAS Bio). Many analyzers are so-called “open systems” that use reagents from either the instrument manufacturer or different vendors. The advantage of these systems being that the customer has a choice of reagent vendors and the reagent can be selected based on performance and cost.

An example of a closed system is a line of analyzers manufactured by Ortho Clinical Diagnostics. The Vitros 950 and the analyzers in this category use a unique, dry chemistry film-based technology developed by Kodak. The slide is a dry, multilayer, analytical element coated on a polyester support. A 10 μ L drop of patient sample is deposited on the slide and is evenly distributed by the spreading layer to the underlying layers that contain the ingredients for a particular chemical reaction.

The reaction slide (Fig. 1.) for albumin shows the reactive ingredient is the dye (bromocresol green), which is in the reagent layer. The inactive ingredients that include polymeric beads, binders, buffer, and surfactants are in the spreading layer. When the specimen penetrates the reagent layer, the bromocresol green (BCG) diffuses to the spreading layer and binds to albumin from the sample. This binding results in a shift in wavelength of the reflectance maxima of the free dye. The color complex that forms is measured by reflectance spectrophotometry. The amount of albumin-bound dye is proportional to the concentration of albumin in the sample. Once the test is completed the slide is disposed into the waste container.

Some manufacturers close their system by labeling their individual reagent packs with unique barcodes, rejecting packs not distributed by them. Examples of “open systems” include analyzers manufactured by Olympus, Roche (Fig. 2.), Beckman, Dade and Abbott. Many instruments have both open and closed channels allowing greater flexibility in the use of reagents. In addition to diverse menus, open and closed channels, compatibility of analyzers

Figure 2. The Roche/Hitachi Modular™ analytic system has a theoretical throughput of 3500–5000 tests or 150–250 samples/h. They test 24 different analytes simultaneously with a total menu of > 140 available tests.

with perianalytical technology is becoming an important feature.

Perianalytical systems include front-end automation with specimen processing and aliquoting, track systems or other technologies to move specimens between instruments in the laboratory, and robots to place specimens on and remove them from the analyzers.

Immunoassay Analyzers

Immunoassay systems are presently the fastest growing areas of the clinical laboratory where advances in immunochemical methodology, signal detection systems, microcomputers and robotic processing are taking place at an accelerated pace (7). At present, manufacturers have high volume immunoassay analyzers that can be modularly integrated along with chemistry and hematology analyzers into fully automated laboratory systems. In addition, expanding menus of homogeneous immunoassays allow integration into many laboratories using "open reagent kits" designed for use on automated clinical chemistry analyzers.

One of the several analyzers in this category is the Bayer Advia Centaur (Fig. 3.)

Of the different enzyme immunoassays (EIA) available, only the two homogeneous methods, EMIT and CEDIA have been easily adapted to fully automated chemistry analyzers (8–11). The other EIAs require a separation step to remove excess reagent that will interfere with the quantitation of the analyte. Abbott uses a competitive assay involving a fluorescent-labeled antigen that competes for a limited number of sites on antigen specific antibody. The amount of analyte is inversely proportional

to the amount of fluorescence polarization. Chemiluminescence technology is used in the Bayer ACS and Roche Elecsys systems combines very high sensitivity with low levels of background interference. Essentially, it involves a sandwich immunoassay direct chemiluminometric technology, which uses constant amounts of two antibodies. The first antibody in the Lite Reagent is a polyclonal goat anticomponent antibody labelled with acridinium ester. The second antibody in the Solid Phase is a monoclonal mouse anticomponent antibody, which is covalently coupled to paramagnetic particles. A direct relationship exists between the amount of compound present and the amount of relative light units (RLU) detected by the system (Table 2).

Critical Care Analyzers

Blood gas measurements performed on arterial, venous, and capillary whole blood includes electrolytes and other tests in addition to the gases. These tests are listed in Table 3.

The Nova CCX series combines blood gas measurements with co-oximetry, electrolytes, a metabolic panel and hematology on 50 μ L of whole blood. Several blood gas analyzers are utilizing the concept of "Intelligent Quality Management" whereby the analyzers run controls automatically at specified time intervals set by the operator. If a particular analyte is not within the specified range, the analyzer will not report out any patient results on the questionable test. Selected blood gas and critical care analyzers are listed in Table 4.

The unique specimen and turnaround time requirements for blood gases have prevented the tests from

Figure 3. The Bayer Advia Centaur system has large on-board capacity for reagents and supplies combined with automated maintenance and monitoring features streamline operations. Categories such as fertility, therapeutic drug monitoring, infectious disease, allergy, cardiovascular, anemia, and oncology, therapeutic drug monitoring and thyroid tests are available. Up to 30 different reagent packs can be placed on the instrument. It has a throughput of 240 tests/h.

Category	Tests Included
Blood gases	pH, $p\text{CO}_2$, $p\text{O}_2$ and other calculated parameters
Electrolytes	Sodium, potassium, chloride, bicarbonate, ionized calcium
Co-oximetry	Carboxyhemoglobin, methemoglobin, total hemoglobin, O_2 saturation
Metabolic panel	Glucose, blood urea nitrogen, creatinine, lactate
Hematology	Hematocrit, hemoglobin, activated clotting time

being performed in combination with general chemistry tests.

Point of Care Testing

Point of care testing (POCT) is defined as laboratory diagnostic testing performed close to the location of the patient. Recent advances over the last decade have resulted in smaller, more accurate devices with a wide menu of tests (12,13). Today POCT can be found from competitive sports to the prison system, from psychiatric counseling to pre-employment and shopping mall health screening. Use of POCT devices can be found in mobile transport vehicles such as ambulances, helicopters cruise ships and even the space shuttle.

The advantage of POCT is the ability to obtain extremely rapid laboratory results. However, it is necessary to be aware of the limitations of POCT devices in clinical practice. Venous blood samples often have to be drawn and sent to the main laboratory for confirmation if the results

are not within a certain specified range. Another disadvantage of POCT is costs.

In compliance with the guidelines set by federal, state regulatory agencies and the College of American Pathologists (CAP), point of care testing programs are usually overseen by dedicated staff under the direction of the central laboratory. The responsibilities of the POCT staff include education and training of hospital staff, troubleshooting of equipment, maintaining quality control and

Table 4. Partial List of Critical Care Instruments

Urinalysis	Bayer (Multistix and Clintek)
	Roche (Chemstrip and CUA)

delivering specimens to the automated testing instruments, recapping and storing plays significant role in the modern clinical laboratory (14). Robotic systems that automate some or virtually all of the above functions are available. Automated laboratory and information systems offer benefits in terms of speed, operating efficiency, integrated information sharing and reduction of error.

However, the individual needs of each laboratory have to be considered in order to select the optimum combination of instrumentation and perianalytical automation. For small laboratories, front-end work cell automation may be applied economically. For large commercial reference labs and hospital labs, total laboratory automation (TLA) is appropriate where samples move around the whole lab, or from place to place (15).

Clinical laboratory automation evolved with the development of the hematology “Coulter Counter” and the chemistry “AutoAnalyzer” in the 1950s. Automated cell counting by the Coulter involved placing a sample of whole blood in a hemocytometer and using a microscope to count the serial passage of individual cells through an aperture. Likewise, the automated analysis of patient samples for several chemistries dramatically changed the testing process in the chemistry laboratory.

In the 1980s in Japan, Dr. Sasaki’s group developed a point-to-point laboratory system that was based on overhead conveyor transportation, delivering specimens placed in 10 position racks (16). These initial designs are the basis of several automation systems available today.

Automation Options and System Design

Available options for automation include the following:

- Interfaced instruments (some can be operated as stand alone analyzers and later linked to a modular system).
- Modular instruments (including, processing, and instrument work cells).
- Multidiscipline platforms (including multifunction instruments and multiwork cells).
- Total laboratory automation robotics system that automates virtually all routine functions in the laboratory.

Automation system design usually rests on the needs of the user. However, the following concepts should be considered:

- Modern information technology with hardware and operating systems that are vertically upgraded.
- Transportation system management at both the local level (device) and overall system level.
- Specimen tracking so that any specimen can be located in the automation system.
- Reflex testing where an additional test can be performed at the same instrument or the specimen can be retrieved to another instrument.
- Information systems agreement with the Laboratory Information System (LIS).

The ability to interface between the hospital LIS and the laboratory automation system (LAS) has been significantly

enhanced by the implementation of the HL7 system-to-system interface. The National Committee on Clinical Laboratory Standards (NCCLS) has issued a proposal level standard (Auto 3-P) that specifies the HLA interface as the system-to-system communications methodology for connecting an LIS and an LAS (17-21).

NCCLS Guidelines

Components of an optimized laboratory automation system per NCCLS may include:

- Preprocessing specimen sorting.
- Automated specimen centrifugation.
- Automated specimen aliquoting.
- Specimen-aliquot recapping/capping.
- Specimen integrity monitoring.
- Specimen transportation.
- Automated specimen sampling.
- Automated specimen storage and retrieval.

It is also recommended that process control software should support:

- Specimen routing.
- Reflex testing.
- Repeat testing.
- Rules based processing.
- Patient data integration.

Available Automation Systems

In the mid-1990s, several laboratory automation technologies implemented hardware-based automation solutions that were centered on defining a limited number of specimen containers compatible with the transportation system. By limiting the number of specimen containers, the hardware can be better defined and more efficient. The original Coulter IDS automation system and the original Hitachi CLAS were based on fixed, rigid or hard-coded hardware technologies.

In the Hitachi CLAS and modular systems, the automation transportation devices use the Hitachi 747 five-place specimen container rack. In order to move the specimen container rack from one analyzer to the next, the automation system must carry along four other patient specimens. The requirement to carry along additional specimens along with the target specimen creates significant mathematical complexity in routing and scheduling of tests. The use of a simple specimen container per specimen carrier model allows the routing of an individual specimen to a workstation without interrupting the flow of other individual specimens in the system.

Total laboratory automation is used to describe the Beckman Coulter IDS system (22). We have two parallel systems in our laboratory (Fig. 5). The basic components include the inlet module, where samples are placed, a centrifuge, serum level sensor, decapping unit, aliquoter-labeler units, outlet units, refrigerated storage unit

and a disposal unit. A line PC that interacts with the LIS and all the individual components of the automation system controls the entire system. Each of the automated instruments has their own individual attachment for the handling of specimens being received from the robotic system. View of our automated (perianalytical and analytical) clinical laboratory is shown on Fig. 6.

Work Cell Technologies

The work cell model can be divided into two basic approaches. The first includes all instruments from the same discipline (Chemistry). The second approach is the development of a platform that includes multiple disciplines. An example of this is the Bayer Advia work cell in which chemistry, hematology, immunoassay, and urinalysis processing can take place on one platform. However, this work cell does not have front-end specimen processing and handling capability. Several automated work cells are available in the market at the present time. They include Abbott (Abbott hematology work cell), Beckman-Coulter (Acel-Net work cell), Bayer (Advia work cell), Johnson and Johnson (lab interlink labframe select), and Roche (modular system). The work cell technology varies from simple specimen transportation to complex specimen management.

LABORATORY AUTOMATION-A FINANCIAL PERSPECTIVE

Several studies are being reported on the financial aspects of automation. The most significant impact has been the reduction in FTEs and improvement in turnaround time. A retrospective analysis of 36 years of the effects of initially automation followed by total laboratory automation in the clinical chemistry laboratory at Mount Sinai Medical Center indicated that workload was significantly increased with a reduction of personnel (23). We present these productivity changes in Table 6.

Increased productivity resulted in significant reduction of performing laboratory tests (Table 7).

The effect of increased productivity is illustrated by the drastic reduction of cost/test (Fig. 7)

CALCULATIONS FOR NET PRESENT VALUE OF THE MOUNT SINAI CHEMISTRY AUTOMATION PROJECT (FIG. 8)

Net Present Value

The Net Present Value (NPV) is the value of the net cash flows generated by the project in 1998 \$ (the year in which the project was initiated). The NPV is calculated by discounting the value of the annual cash flows [using values taken from the Present Value Interest Factor (PVIF) table for a given project length and cost of capital] to the purchasing value of the dollar at the date of inception of the project (1998). The length of the investment project is a conservative estimate of the useful economic lifetime of the investment project. In this case, we believe that after 8 years additional investments in upgrades

Figure 5. Floor plan of our Total Laboratory Automation. (a) Sample reception. Specimens are picked up, 5 at a time, from 50-position racks and loaded into individual tube holders. A bar-code verification unit determines the legibility of the labels, determines if the specimen is on the right processing location, rejects the suspect samples into a holding area and accepts the correct ones by a message to the Laboratory Information System: "Specimen Received". (b) Sample transport. The transport lanes are conveyor belts that move the samples about the system. (c) Centrifugation. Samples are loaded and unloaded automatically. The rotor has 50 positions. In our laboratory 350 specimens/h can be processed in these centrifuges. (d) Serum level detection. After centrifugation the samples are lowered into an optical well and based on the transmitted information the amount of the available serum is calculated. (e) Cap removal. A gentle rocking motion removes the cups without creating potentially hazardous aerosols. (f) Tube labeling and sample aliquoting. For each primary serum sample secondary aliquot tubes are prepared. The tube labeler prints a bar-code label and applies it to each aliquot tube. The number of aliquot tubes is defined by the system. Disposable pipette tips transfer the serum from the primary to the secondary (aliquot) tubes. The primary tubes are directed to a storage unit. (g) Instrument connections. Several instruments are connected to the transport system. Connection units load and unload samples. Samples not going to the analyzer can continue down the main line. (h) Cap replacement. When the testing of a secondary aliquot tube has been completed, the tube is directed toward an outlet unit, stockyard or storage locker. Before storage, the tube can receive a clean cap. (i) Refrigerated Sample storage. It holds up to 3000 tubes. Samples can be retrieved automatically through a request in the computer and sent to the location requested by the operator.

Figure 6. A portion of the Chemistry automated Core Laboratory at The Mount Sinai Hospital, New York.

beyond normal maintenance may be required. The cost of capital used was the interest rate of the lease taken out to finance the project. The relevant calculations are shown below:

1. Total cost of the lease (capital and interest):
2. Total interest paid over the life of the lease:
3. Annual interest payments:
4. Interest rate paid on lease:

Negative Cash Flows

Negative cash flows represent money spent on the project. This includes capital outlays, lease payments (\$3,140,000 or \$741,921/year for 5 years, represented the portion on chemistry automation), project-related expenses (annual maintenance contract, years 1999 and 2000 = \$74,240 annually, 2001–2005 = \$39,000 annually).

Table 6. Increased Productivity

Year	Tech Staff	Other Staff	Total Staff	No. of Tests/Tech	No. of Tests/tot. Staff	No. of Tests/Specimen	Total No. of Specimens
1965	19	6.00	24.00	14,000	10,600	4.2	2,560
1970	34	17.00	51.00	36,205	24,150	8.8	2,745
1980	39	22.00	61.00	82,359	53,732	10.0	5,268
1997	38	17.00	55.00	94,058	66,099	11.8	5,529
2000	29	13.00	42.00	151,190	104,558	10.4	10,066
2002	29	39.00	35.00	169,582	128,530	10.5	12,190

Table 7. Cost/Test Reduction

Year	Tech Salary, \$	Salary \$/Test	Supplies \$/Test	Total \$/Test	Salary 1965 \$/Test	Supplies 1965 \$/Test	Total 1965 \$/Test
1965	5,170	0.70	0.19	0.79	0.70	0.09	0.79
1970	9,114	0.38	0.17	0.55	0.31	0.14	0.45
1980	16,500	0.37	0.20	0.57	0.14	0.08	0.22
1997	38,000	0.66	0.41	1.07	0.13	0.08	0.21
2000	41,000	0.45	0.36	0.81	0.08	0.07	0.15
2002	44,000	0.38	0.34	0.72	0.07	0.06	0.13

Figure 7. Automation increased Productivity and reduced cost. While the number of specimens processed increased from 2,500 to 10,000 specimens/year the cost/test was reduced from \$0.79 to 0.15 (in 1965\$).

Positive Cash Flows

Positive cash flows are those that represent money saved and/or costs avoided as the result of the chemistry auto-

$\$121,963/\text{month} \times 60 \text{ months}$	=	\$7,318,480
$\$7,318,380 - \$6,194,650$	=	\$1,123,730
$\$1,123,730/5 \text{ years}$	=	\$224,730
$(\$224,746/\$6,194,650) \times 100$	=	3,628%

mation project. There are recurring positive cash flows, resulting from savings that are essentially perpetual, such as salaries and benefits of workers replaced permanently by the chemistry automation project. Savings realized in a given year that are not expected to be repeated in subsequent years are nonrecurring positive cash flows. Staff pay raises during the years 1998, 1999, 2000, and 2002 were

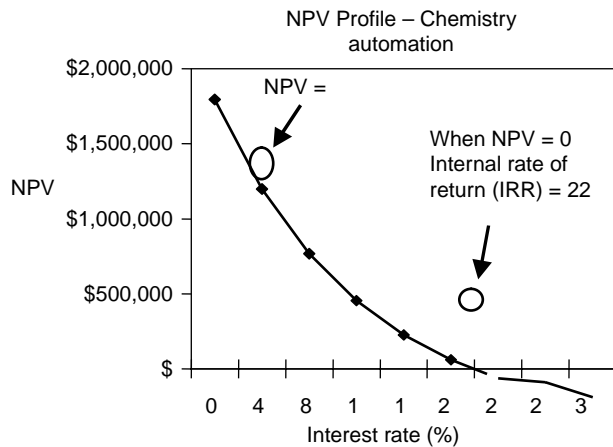

Figure 8. The Internal Rate of Return for the Chemistry Automation project was a remarkable 22%.

financed directly from chemistry automation project savings. These amounts are not reflected in the net salary and benefits savings. As such they are positive cash flow, since they represent costs covered by the automation savings that otherwise would have had to be financed through other sources.

The NPV Profile and Internal Rate of Return

The interest rate employed to discount the value of cash flows to the baseline year (1998) is the marginal cost of capital (the interest rate of the lease), which is 4%. The interest rate at which the NPV equals zero is especially interesting. This is called the internal rate of return (IRR) of the project. For all interest rates below the IRR, the NPV will generate positive values. In order to determine the IRR, we construct an NPV profile for different interest rates and locate the rate where the NPV crosses the X axis where the NPV = 0 (Fig. 8.). It shows that the chemistry automation project can tolerate interest rates up to 18.0% (the IRR) and still generate positive returns.

The Payback Period and Average Return on Investment

Although the NPV and IRR are vastly superior indicators of project profitability because of their use of discounted cash flows, the payback period and return on investment (ROI) are still key determinant of project viability by a majority of financial managers.

The Payback Period. After 8 years the raw dollar value of positive cash flows is \$5,371,743 versus negative cash flows of \$4,0053,085. The payback period therefore:

$$8 \text{ years} \times (\$4,053,085 / \$5,371,743)$$

$$8 \text{ years} \times 0.755 = 6.04 \text{ years}$$

Average ROI

Average Annual Cash Outlay: $\$4,053,085 / 8 \text{ years} = \$506,635 / \text{year}$

Average Annual Net Return: $(5,371,743 - \$4,053,085) / 8 \text{ years} = \$164,822$
 Average ROI: $(\$164,832 / \$506,635) \times 100 = 32.5\%$

CONCLUSIONS

Productivity is a key issue for labs.

The major financial benefit of automation is increased productivity.

Perianalytical automation increased our chemistry productivity by 120% (from 5,530 to 12,190 specs/tech/year).

Perianalytical automation reduced our chemistry labor cost/test by 42% (from 66¢ to 38¢/test).

Automation is a key solution for staff shortages.

Speedy implementation, speedy labor reductions and speedy revenue generation improve financial performance.

To achieve financial success, laboratorians must understand key financial principles.

ACKNOWLEDGMENTS

We thank E. Simson for practical advice on the financial perspective and M. Gannon for teaching us the meaning and calculation of the Net Present Value.

ANESTHESIA MACHINES

ROBERT LOEB
University of Arizona
Tucson, Arizona

JEFFREY FELDMAN
Children's Hospital of
Philadelphia
Philadelphia, Pennsylvania

INTRODUCTION

On October 16, 1846, W. T. G. Morton gave the first successful public demonstration of inhalational anesthesia. Using a hastily devised glass reservoir to deliver diethyl ether, he anesthetized a patient before an audience at the Massachusetts General Hospital (Fig. 1). This glass reservoir thus became the first, crude, anesthesia machine. The technology of anesthesia machines has advanced immeasurably in the ensuing 150 years. Modern anesthesia machines are used to administer inhalational anesthesia safely and precisely to patients of any age, in any state of health, for any duration of time, and in a wide range of operating environments.

Figure 1. A reproduction of the Morton Inhaler, ~1850. (Image © by the Wood Library-Museum of Anesthesiology, Park Ridge, Illinois.)

The term anesthesia machine colloquially refers to all of the medical equipment used to deliver inhalational anesthesia. Inhalational anesthetics are gases that, when inhaled, produce a state of general anesthesia, a drug-induced reversible loss of consciousness during which the patient is not arousable, even in response to painful stimulation. Inhalational anesthetics are supplied as either compressed gases (e.g., nitrous oxide), or volatile liquids (e.g., diethyl ether, sevoflurane, or desflurane). In recent years, the anesthesia machine has been renamed the anesthesia delivery system, or anesthesia workstation because modern devices do more than simply deliver inhalational anesthesia. Defined precisely, the term “anesthesia machine” specifically refers to that component of the anesthesia delivery system that precisely mixes the compressed and vaporized gases that are inhaled to produce anesthesia. Other components of the anesthesia delivery system include the ventilator, breathing circuit, and waste gas scavenger system. Anesthesia workstations are anesthesia delivery systems that also incorporate patient monitoring and information management functions (Fig. 2).

The most obvious goals of general anesthesia are to render a patient unaware and insensible to pain so that surgery or other medically necessary procedures can be performed. In the process of achieving these goals, potent medications are administered that interfere with normal body functions, most notably circulation of blood and the ability to breathe (see the text box Typical Process of Delivering General Anesthesia). The most important goal of anesthesia care is therefore to keep the patient safe and free from injury.

Patient safety is a major principle guiding the design of the anesthesia workstation. Precise control of the dose of anesthetic gases and vapors reduces the risk of administering an overdose. The ventilator and breathing circuit are fundamental components of the anesthesia delivery system designed to allow for continuous delivery of oxygen to the lungs and removal of exhaled gases. To fulfill national and international standards, anesthesia delivery systems must have essential safety features and meet specified minimum performance criteria (1–6)

Typical Process of Delivering General Anesthesia

Check the anesthesia delivery system for proper function:

At the start of each day, the anesthesia provider places disposable components on the breathing circuit and performs an equipment check to ensure proper function of the anesthesia workstation (7).

Identify the patient and confirm the surgical site:

Healthcare institutions are required to have formal procedures to identify patients and the site of surgery before the patient is anesthetized.

Establish venous access to administer medications and fluids:

Using this catheter, drugs can be administered intravenously and fluids can be given to replace loss of blood or other body fluids.

Attach physiologic monitors: Monitoring the effects of anesthesia on the body is of paramount importance to guide the dose of anesthetic given and to keep the patient safe. Typical monitors include a blood pressure cuff, electrocardiogram, and pulse oximeter. Standards require that additional monitors be used during most anesthesia care (8).

Have the patient breathe 100% oxygen through a mask and circuit attached to the anesthesia machine: A tightly fitting mask is held over the patient's face while 100% oxygen is administered using the anesthesia machine. The goal is to eliminate the nitrogen in the lungs and provide a reservoir of oxygen to sustain the patient from the time anesthesia is induced until mechanical ventilation is established.

Inject a rapidly acting sedative-hypnotic medicine into the patient's vein: This injection induces general anesthesia and often causes the patient to stop breathing. Typical induction medications (e.g., thiopental, propofol) are quickly redistributed and metabolized, so additional anesthetics must be administered shortly thereafter to maintain anesthesia.

Breathe for the patient: This is typically accomplished by holding a mask attached to the breathing circuit tightly over the patient's face and squeezing the bag on the anesthesia machine to deliver oxygen to the lungs. This process is also known as manual ventilation.

Inject a neuromuscular blocking drug to paralyze the patient's muscles: Profound muscle relaxation makes it easier for the anesthesia provider to insert a tracheal tube into the patient's trachea. Neuromuscular blockers are also often used to make it easier for the surgeon to perform the procedure.

Insert a tube into the patient's trachea: This step is called endotracheal intubation and is used to establish a secure path for delivering oxygen and inhaled anesthetics to the patient's lungs as well as eliminating carbon dioxide.

Confirm correct placement of the endotracheal tube: This step is fundamental to patient safety. Numerous methods to confirm correct placement have been described. Identifying the presence of carbon dioxide in the exhaled gas is considered the best method for

confirming tube placement. Continuous monitoring of carbon dioxide in the exhaled gases is considered a standard of care during general anesthesia.

Deliver anesthetic agents: General anesthesia is typically maintained with inhaled anesthetic gases. Dials are adjusted on the anesthesia machine to dispense a specified concentration of anesthetic vapor mixed with oxygen and air or nitrous oxide.

Begin mechanical ventilation: The anesthesia delivery system is switched from spontaneous to mechanical ventilation mode, and a ventilator, built into the anesthesia delivery system, is set to breathe for the patient. This frees the anesthesia provider's hands and ensures that the patient breathes adequately during deeper levels of anesthesia and while under the effect of neuromuscular blockers. The ability to deliver anesthetic gases while providing mechanical ventilation is a unique feature of the anesthesia machine.

Adjust ventilation and depth of anesthesia: During the case, the gas flows are reduced to minimize anesthetic usage. The inhaled anesthetic concentration is adjusted to optimize the depth of anesthesia in response to changing levels of surgical stimulus. The ventilator settings are tuned to optimize the patient's ventilation and oxygenation status. Information from the physiologic monitors helps to guide these adjustments.

Establish spontaneous ventilation: Toward the end of the operation, the magnitude of ventilation is decreased. The patient responds by starting to breathe spontaneously, at which time the anesthesia delivery system is switched from mechanical to spontaneous ventilation mode and the patient continues to breathe from the bag on the anesthesia machine.

Remove the endotracheal tube: At the end of the case, the anesthetic gases are turned off and the patient regains consciousness. The endotracheal tube is removed and the patient breathes oxygen from a cylinder while being transported to the recovery area.

System Overview

Anesthesia delivery systems allow anesthesia providers to achieve the following goals:

1. Precisely deliver a prescribed concentration of inhaled gases to the patient.
2. Support multiple modes of ventilation (i.e., spontaneous, manually assisted, and mechanically controlled).
3. Precisely deliver a wide variety of prescribed ventilator parameters.
4. Conserve the use of anesthetic vapors and gases.
5. Minimize contamination of the operating room atmosphere by anesthetic vapors and gases.
6. Minimize the chance of operator errors.
7. Minimize patient injury in the event of operator error or equipment malfunction.

Figure 2. Four contemporary anesthesia workstations. The top two are manufactured by GE Healthcare, and the bottom two by Draeger Medical.

These goals will be discussed further in the following section, which describes the major components of the anesthesia delivery system. The following overview of anesthesia delivery system function will refer to these goals.

The anesthesia delivery system consists of four components: a breathing circuit, an anesthesia machine, a waste gas scavenger system, and an anesthesia ventilator. The breathing circuit is the functional center of the system, since it is physically and functionally connected to each of the other components and to the patient's airway (Fig. 3). There is a one-way flow of gas from the anesthesia machine into the breathing circuit, and from the breathing circuit into the scavenger system. There is a bidirectional flow of gas between the breathing circuit and the patient's lungs, and between the breathing

circuit and the anesthesia ventilator or reservoir bag. The ventilator and the reservoir bag are functionally interchangeable units, which are used during different modes of ventilation (Goal 2). During spontaneous and manually assisted modes of ventilation, the elastic reservoir bag is used as a source of inspired gas and a low impedance reservoir for exhaled gas. The anesthesia ventilator is used during mechanically controlled ventilation to automatically inflate the lungs using prescribed parameters (Goal 3).

During inhalation, gas flows from the anesthesia ventilator or reservoir bag through the breathing circuit to the patient's lungs. The patient's bloodstream takes up a small portion of gas (e.g., oxygen and anesthetic agent) from the lungs and releases carbon dioxide (CO_2) into the lungs.

Figure 3. Block diagram of anesthesia delivery system components. The arrows show the direction of gas flow between components.

During exhalation, gas flows from the patient's lungs through the breathing circuit back to the anesthesia ventilator or reservoir bag. This bulk flow of gas, between the patient and the ventilator or reservoir bag, constitutes the patient's pulmonary ventilation; the volume of each breath is referred to as tidal volume, and the total volume exchanged during one minute is referred to as minute volume.

Over time, the patient absorbs oxygen and anesthetic agents from, and releases CO_2 to, the gas in the breathing circuit. Without intervention, the gas within the breathing circuit would progressively decrease in total volume, oxygen concentration, and anesthetic concentration. The anesthesia provider, therefore, dispenses fresh gas into the breathing circuit, replacing the gas absorbed by the patient. Using the anesthesia machine, the anesthesia provider precisely controls both the flow rate and the concentration of various gases in the fresh gas (Goal 1). The anesthesia machine is capable of delivering a total fresh gas flow that far exceeds the volume of gas absorbed by the patient. When higher fresh gas flows are used (for example, to rapidly change the concentration of gases in the breathing circuit), the excess gas is vented into the scavenger system to be evacuated from the operating room (Goal 5).

To conserve the use of anesthetic gases (Goal 4), the anesthesia provider will use a fresh gas flow rate that is significantly lower than the patient's minute volume. In this situation, the patient reinhales gas that they had previously exhaled into the breathing circuit (this is called rebreathing). Carbon dioxide absorbent contained within the breathing circuit prevents the patient from rebreathing CO_2 , which would be deleterious. All other gases (oxygen, nitrous oxide, nitrogen, and anesthetic vapors) can be rebreathed safely.

During the course of a typical anesthetic, the anesthesia provider will use a relatively high fresh gas flow at the beginning and end of the anesthetic when a rapid change in

anesthetic concentration is desired, and a lower fresh gas flow when little change in concentration is desired. The technique of closed circuit anesthesia refers to the process of adjusting the fresh gas flow to exactly match the amount of gas used by the patient so that no gas is vented to the scavenging system.

Because anesthesia delivery systems provide critical life support functions to unconscious patients, equipment malfunctions and user errors can have catastrophic consequences. In 1974, the American National Standards Institute published an anesthesia machine standard that specified minimum performance and safety requirements for anesthesia gas machines (Goals 6 and 7). That standard was a landmark one, in that it was the first systematic approach to standardize the safety requirements for a medical device. Similar standards have since been written for other medical equipment, and the anesthesia machine standards have been regularly updated.

Breathing Circuit (Semiclosed Circle System)

The semiclosed circle system is the most commonly used anesthesia breathing circuit, and the only type that will be discussed in this article. It is so named because expired gases can be returned to the patient in a circular fashion (Fig. 4). The components of the circle system include a carbon dioxide absorber canister, two one-way valves, a reservoir bag, an adjustable pressure-limiting valve, and tubes that connect to the patient, ventilator, anesthesia machine, and scavenger system.

During inspiration, the peak flow of gas exceeds $25 \text{ L}\cdot\text{min}^{-1}$, far in excess of the rate of fresh gas supply. As a result, the patient will inspire both fresh gas and gas stored in the reservoir bag or ventilator bellows. Inspired gas travels through the carbon dioxide absorber canister, past the one-way inspiratory valve, to the patient. During

Figure 4. This schematic of the circle breathing circuit shows the circular arrangement of components. The one-way valves permit flow in only one direction.

exhalation, gas travels from the patient, past the one-way expiratory valve, to the reservoir bag (or ventilator bellows, depending upon the position of the bag–ventilator selector switch). The one-way valves establish the direction of gas flow in the breathing circuit. Carbon dioxide is not rebreathed because exhaled gas is directed through the carbon dioxide absorber canister prior to being reinhaled. Fresh gas from the anesthesia machine flows continuously into the breathing circuit. During inhalation, this gas joins with the inspiratory flow and is directed toward the patient. During exhalation, the fresh gas enters the breathing circuit and travels retrograde through the carbon dioxide absorber canister toward the reservoir bag (it does not travel toward the patient because the inspiratory one-way valve is closed during exhalation). Thus, during exhalation, gas enters the reservoir bag from the expiratory limb and from the carbon dioxide absorber canister. Once the reservoir bag is full, excess returning gas is vented out the adjustable pressure-limiting (APL) valve to the scavenger system (when the ventilator is used, the excess gas is vented out the ventilator exhaust valve). The total fresh gas flow will therefore control the amount of gas that is rebreathed. At high fresh gas flows, the exhaled gases are washed out through the scavenging system between each inspiration. At low fresh gas flow, very little exhaled gas is

forced out to the scavenging system and most of the exhaled gas is reinhaled in subsequent breaths.

CIRCLE SYSTEM COMPONENTS

CO₂ Absorbents

Alkaline hydroxides of sodium, potassium, calcium, and barium in varying concentrations are most commonly used as carbon dioxide absorbents. These alkaline hydroxides irreversibly react with carbon dioxide to eventually form carbonates, releasing water and heat. Absorbent granules are 4- to 8-mesh in size (25–35 granules cm⁻³) to maximize the surface area available for chemical reaction and minimize the resistance to gas flow through the absorber canister. Ethyl violet is incorporated into the granules as a pH indicator; fresh granules are white, while a purple color indicates that the absorbent needs to be replaced. Absorbent canisters are constructed with transparent sides so that absorbent color can be easily monitored during use. Canisters have a typical capacity of 900–1200 cm³ and the absorbent is good for ~10–30 h of use, depending on the operating conditions.

Many of the absorbent materials have the potential to interact with anesthetic agents to degrade the anesthetics

and produce small amounts of potentially toxic gases, such as carbon monoxide. This is especially true if the absorbents are allowed to desiccate by exposure to high flows of dry gas (e.g., leaving the fresh gas flowing on the anesthesia machine over a weekend). Periodic replacement of absorbent, especially at the end of a weekend is therefore desirable. Newer absorbent materials, which are more costly, are designed to reduce or eliminate the potential for producing toxic gases by eliminating the hydroxides of sodium, barium, and potassium.

Unidirectional Valves

The inspiratory and expiratory one-way valves are simple, passive devices. Each has an inlet tube that is capped by a valve disk. When the pressure in the inlet tube exceeds that in the outlet tube, the valve opens to allow gas to flow downstream. The valve disks are light in weight to minimize gas flow resistance. Each valve has a clear dome to allow visual monitoring of valve function. Rarely, valves malfunction by failing to open or close properly. Carbon dioxide rebreathing can occur if either valve becomes incompetent (i.e., fails to close properly). This can occur if a valve disk becomes warped, sticks open due to humidity, or fails to seat properly.

Reservoir Bag

The reservoir bag is an elastic bag that serves three functions in the breathing circuit. First, it is a compliant element of an otherwise rigid breathing circuit that allows changes in breathing circuit gas volume without changes in breathing circuit pressure. Second, it provides a means for manually pressurizing the circuit to control or assist ventilation. Third, it provides a safety limit on the peak pressure that can be achieved in the breathing circuit. It acts as a pressure-limiting device in the event that fresh gas inflow exceeds APL valve outflow. Reservoir bags are designed such that, at fresh gas flow rates below $15 \text{ L}\cdot\text{min}^{-1}$, the breathing circuit pressure will remain $< 35 \text{ cm H}_2\text{O}$ (3.4 kPa) until the bag reaches more than twice its full capacity. Yet, inspiratory pressures up to $70 \text{ cm H}_2\text{O}$ (6.9 kPa) can be achieved by quickly compressing the reservoir bag.

APL Valve

The APL valve (euphemistically referred to as the pop-off valve) is a spring-loaded device that controls the flow of gas from the breathing circuit to the scavenger system. The valve opens when the pressure gradient from the circuit to the scavenger exceeds the force exerted by the spring (as discussed later, the pressure in the scavenger system is regulated to be equal to atmospheric pressure plus or minus a few $\text{cm H}_2\text{O}$). When the patient is breathing spontaneously, the anesthesia practitioner minimizes the spring tension allowing the valve to open with minimal end-expiratory pressure (typically $< 3 \text{ cm H}_2\text{O}$, or 0.3 kPa). When the anesthesia practitioner squeezes the reservoir bag to manually control or assist ventilation, the APL valve opens during inhalation. Part of the gas exiting the reservoir bag escapes to the scavenger system and the remainder is directed toward the patient. By turning a knob, the

anesthesia practitioner increases the pressure on the spring so that the APL valve remains closed until the pressure in the circuit achieves a level that is adequate to inflate the patient's lungs; the APL valve thus opens toward the end of inhalation, once the lungs are adequately inflated. Continual adjustment of the APL valve is sometimes needed to adapt to changing fresh gas flow rate, circuit leaks, pulmonary mechanics, and ventilation parameters.

Bag-Ventilator Selector Switch

During mechanical ventilation, the reservoir bag and APL valve are disconnected from the breathing circuit and an anesthesia ventilator is connected to the same spot. Modern breathing circuits have a selector switch that quickly toggles the connection to either the ventilator or the reservoir bag and APL valve.

VIRTUES AND LIMITATIONS OF THE CIRCLE BREATHING CIRCUIT

Primary advantages of the circle breathing system over other breathing circuits include conservation of anesthetic gases and vapors, ease of use, and humidification and heating of inspired gases.

As stated previously, anesthetic agents are conserved when very low fresh gas flows are used with the circle breathing system. The minimum adequate flow is one that just replaces the gases taken up by the patient; for a normal adult, flows below $0.5 \text{ L}\cdot\text{min}^{-1}$ can be achieved during anesthesia maintenance. It is customary to use higher fresh gas flow rates in the range of $1\text{--}2 \text{ L}\cdot\text{min}^{-1}$, but this is still well below typical minute ventilation rates of $5\text{--}10 \text{ L}\cdot\text{min}^{-1}$ which is the fresh gas flow that would be required for a nonbreathing ventilation system.

The circle breathing circuit is easy to use because the same fresh gas settings can be used with patients of various sizes. A 100 kg adult and a 1 kg infant can each be anesthetized with a circle breathing system and a fresh gas maintenance flow rate of $1\text{--}2 \text{ L}\cdot\text{min}^{-1}$. Since the larger patient would take up more anesthetic agent and more oxygen, and would give off more carbon dioxide, higher *minimal* flows would be required for the larger patient and the carbon dioxide absorbent would become exhausted quicker. Also, for convenience, a smaller reservoir bag and smaller bore breathing tubes would be selected for the smaller patient. But, otherwise, the system would function similarly for both patients.

Humidification and warming of inspired gases is another advantage of rebreathing. Fresh gas is mixed from compressed gases that contain zero water vapor, and breathing this dry gas can have detrimental effects on lung function. But, within the circle breathing system, inspired gas is humidified by the admixture of rebreathed gas, and by the water vapor that forms as a byproduct of carbon dioxide absorption. Both of these mechanisms also act to warm the inspired gas. By using low flows, enough heat and humidity is conserved to eliminate the need to actively heat and humidify inspired gas.

Most disadvantages of the circle breathing system are due to the large circuit volume. Internal volumes are primarily

Figure 5. Schematic showing the internal piping and placement of components within the anesthesia machine. Dark gray indicates oxygen (O₂) and light gray indicates nitrous oxide (N₂O).

determined by the sizes of the absorbent canister, reservoir bag, and breathing hoses; 3–6 L are typical. Large circuits are physically bulky. They also increase the time required to change inspired gas concentrations because the large reservoir of previously exhaled gas is continually added to fresh gas. Finally, large circuits are more compliant, which degrades the efficiency and accuracy of ventilation. This effect will be discussed further in the section on ventilators.

Anesthesia Machine

The anesthesia machine is used to accurately deliver into the breathing circuit a precise flow and concentration of gases and vapors. Anesthesia machines are manufactured to deliver various compressed gases; all deliver oxygen, most deliver nitrous oxide or air, some deliver helium or carbon dioxide. They have one or more vaporizers that convert liquid anesthetic agents into anesthetic vapors; currently used inhaled vapors include halothane, enflurane, isoflurane, sevoflurane, and desflurane. Anesthesia machines include numerous safety features that alert the anesthesia provider to malfunctions and avert use errors.

The anesthesia machine is a precision gas mixer (Fig. 5). Compressed gases enter the machine from the hospital's centralized pipeline supply or from compressed gas cylinders. The compressed gases are regulated to specified pressures, and each passes through its own flow controller and flow meter assembly. The compressed gases then are mixed together and may flow through a single vaporizer where anesthetic vapor is added. The final gas mixture then exits the common gas outlet (also called the fresh gas outlet) to enter the breathing circuit.

ANESTHESIA MACHINE COMPONENTS

Compressed Gas Inlets

Compressed gases from the hospital pipeline system or from large compressed gas cylinders enter the anesthesia machine through flexible hoses. The inlet connector for each gas is unique in shape to prevent the connection of the wrong supply hose to a given inlet. The standardized design of each hose-inlet connector pair conforms to the Diameter Indexed Safety System (DISS) (9).

Anesthesia machines also have inlet yokes that hold small compressed gas cylinders; these cylinders provide compressed gas for emergency backup and for use in locations without piped gases. Each yoke is designed to prevent incorrect placement of a cylinder containing another gas. Two pins located in the yoke must insert into corresponding holes on the cylinder valve stem. The standardized placement of these pins and corresponding holes, referred to as the Pin Indexed Safety System (PISS), is unique for each gas (10).

Pressure Regulators And Gauges

Gauges on the front panel of the anesthesia machine display the cylinder and pipeline inlet pressures of each gas. Gases from the pipeline inlets enter the anesthesia machine at pressures of 45–55 psig (310–380 kPa), whereas gases from the compressed gas cylinders enter at pressures up to 2000 psig (1379 kPa). (Pressure conversion factors: 1 psig = 0.068 atm = 51.7 mmHg = 70.3 cm H₂O = 6.89 kPa.) Pressure regulators on each cylinder gas inlet line reduce the pressure from each cylinder to ~ 45 psig (310 kPa). The pressure regulators provide a relatively constant outlet pressure in the presence of a variable inlet pressure, which is important since the pressure within a gas cylinder declines during use. Lines from the pipeline inlet and the cylinder inlet (downstream of the pressure regulator) join to form a common source line for each gas. Gases are preferentially used from the pipelines, since the pressure regulators are set to outlet pressures that are less than the usual pipeline pressures.

Flow Controllers And Meters

A separate needle-valve controls the flow rate of each compressed gas. Turning a knob on the front panel of the anesthesia machine counterclockwise opens the needle valve and increases the flow; turning it clockwise decreases or stops the flow. A flowmeter assembly, located above each flow-control knob, shows the resulting flow rate. The flowmeter consists of a tapered glass tube containing a movable float; the internal diameter of the tube is larger at the top than at the bottom. Gas flows up through the tube, which is vertically aligned, and in doing so blows the float higher in the tube. The float balances in midair partway up the tube when its weight equals the force of the gas traveling through the space between the float and the tube. Thus, the height to which the float rises within the tube is proportional to the flow rate of the gas. Flow rate is indicated by calibrated markings on the tube alongside the level of the float.

Each flowmeter assembly is calibrated for a specific gas. The density and viscosity of the gas significantly affects the force generated in traveling through the variable-sized annular orifice created by the outer edge of the float and the inner surface of the tube. Temperature and barometric pressure affect gas density, and major changes in either can alter flowmeter accuracy. Accuracy is also impaired by dirt or grease within the tube, static electricity between the float and the tube, and nonvertical alignment of the tube.

To increase precision and accuracy, some machines indicate gas flow rate past a single needle valve using two flowmeter assemblies, one for high flows and the other for low flows. These flowmeters are connected in series and the flow rate is indicated on one flowmeter or the other. A flow rate below the range of the high-flow meter shows an accurate flow rate on the low flow meter and an unreadable low flow rate on the high flow meter. While, a flow rate that exceeds the range of the low-flow meter shows an accurate flow rate on the high flow meter and an unreadable high flow rate on the low flow meter.

Each gas, having passed through its individual flow controller and meter assembly, passes into a common manifold before continuing on. Only the individual gas flow rates are indicated on the flowmeters; the user must calculate the total gas flow rate and the percent concentration of each gas in the mixture.

Vaporizers

Vaporizers are designed to add an accurate amount of volatilized anesthetic to the compressed gas mixture. Anesthetic vapors are pharmacologically potent, so low concentrations (generally < 5%) are typically needed. The volatilized gases contribute to the total gas flow rate and dilute the concentration of the other compressed gases. The user can calculate these effects since they are not displayed on the machine front panel; luckily, these are generally negligible and can be ignored. Even though most anesthesia machines have multiple vaporizers, only one is used at a time; interlock mechanisms prevent a vaporizer from being turned on when another vaporizer is in use. Vaporizers are anesthetic agent specific and keyed filling systems prevent filling a vaporizer with the wrong liquid anesthetic.

All current anesthesia machines have direct-setting vaporizers that add a specified concentration of a single anesthetic vapor to the compressed gas mixture. Variable-bypass vaporizers are the most common (Fig. 6). In these, the inflowing compressed gas mixture is split into two streams. One stream is directed through a bypass channel and the other is directed into a chamber within the vaporizer that contains liquid anesthetic agent. The gas entering the vaporizing chamber becomes saturated with anesthetic vapor at a concentration that depends on the vapor pressure of the particular liquid anesthetic. For example, sevoflurane has a vapor pressure of 157 mmHg (20.9 kPa) at 20 °C, so the gas within the vaporizing chamber is about 20% sevoflurane (at sea level). This highly concentrated anesthetic mixture exits the chamber (now, at a flow rate greater than that entering the chamber, due to the addition of anesthetic vapor) to join, and be diluted by, gas that traversed the bypass channel. A dial on the vaporizer controls the delivered anesthetic concentration by regulating the resistance to flow along each path. For example, setting a sevoflurane vaporizer to a dialed concentration of 1% splits the inflowing compressed gas mixture so that one-twenty-fourth of the total is directed through the vaporizing chamber and the remainder is directed through the bypass. Direct-reading variable-bypass vaporizers are calibrated for a specific agent, since each anesthetic liquid has a different vapor pressure. Vapor pressure varies with

Figure 6. Schematic of a variable-bypass vaporizer. Arrows indicate direction of gas flow; heavier arrows indicate larger flow rates. Gas enters the Inlet Port and is split at the Bypass Cone into two streams. One stream is directed through a bypass channel and the rest enters the Vaporizing Chamber. Gas entering the Vaporizing Chamber equilibrates with Liquid Anesthetic Agent to become saturated with Anesthetic Vapor. This concentrated anesthetic mixture exits the chamber to join, and be diluted by, gas that traversed the bypass channel. The Concentration Control Dial is attached to the Concentration Cone, which regulates resistance to flow exiting the Vaporizing Chamber and thus controls the anesthetic concentration dispensed from the Outlet Port.

temperature, so vaporizers are temperature compensated; at higher temperatures, a temperature sensitive valve diverts more gas through the bypass channel. Vaporizers are designed to ensure that the gas within the liquid-containing chamber is saturated with anesthetic vapor. A cotton wick within the chamber promotes saturation by increasing the surface area of the liquid. Thermal energy is required for liquid vaporization (heat of vaporization). To minimize cooling of the anesthetic liquid, vaporizers are constructed of metals with high specific heat and high thermal conductivity so that heat is transferred easily from the surroundings. The output of variable-bypass vaporizers varies with barometric pressure; delivered concentration increases as barometric pressure decreases.

Desflurane vaporizers are designed differently because desflurane has such a high vapor pressure (664 mmHg, or 88.5 kPa, at 20 °C) and low boiling point (22.8 °C). Uncontrollably high output concentrations could easily occur if desflurane were administered at room temperature from a variable-bypass vaporizer. In a desflurane vaporizer, the liquid desflurane is electrically heated to a controlled temperature of 39 °C within a pressure-tight chamber. At this temperature, the vapor pressure of desflurane is 1500 mmHg (200 kPa) and the anesthetic vapor above the liquid is a compressed gas. The concentration dial on the vaporizer regulates a computer-assisted flow proportioning mechanism

that meters pressurized desflurane into the incoming gas mixture to achieve a set output concentration of desflurane vapor. Room temperature does not affect the output concentration of the vaporizer, nor does barometric pressure. The vaporizer requires electrical power for the heater, the onboard computer, and two electronic valves.

Safety Systems

By written standard, the anesthesia machine has numerous safety systems designed to prevent use errors. Some of these, such as the DISS and PISS systems to prevent compressed gas misconnections, interlock mechanisms to prevent simultaneous use of multiple vaporizers, and keyed filler systems to prevent misfilling of vaporizers, have already been discussed. Others are presented, below.

Failsafe Mechanism And Oxygen Alarm. The anesthesia machine has a couple of safety systems that alert the user and stop the flow of other gases when the oxygen supply runs out (for example, when an oxygen tank becomes depleted). An auditory alarm sounds and a visual message appears to alert the user when the oxygen supply pressure falls below a predetermined threshold pressure of ~30 psig (207 kPa). A failsafe valve in the gas line supplying each flow controller-meter assembly, except oxygen, stops the

flow of other gases. The failsafe valve is either an on-off valve or a pressure-reducing valve that is controlled by the pressure within the oxygen line. When the oxygen supply pressure falls below the threshold level, the failsafe valves close to stop the flow, or proportionally reduce the supply pressure, of all the other gases. This prevents administration of hypoxic gases (e.g., nitrous oxide, helium, nitrogen, carbon dioxide) without oxygen, which could rapidly cause injury to the patient, but it also prevents administration of air without oxygen. The failsafe mechanisms do *not* prevent delivery of hypoxic gas mixtures in the presence of adequate oxygen supply pressure; the gas proportioning system, described below, prevents this.

Gas Proportioning System. Anesthesia machines are equipped with proportioning systems that prevent the delivery of high concentrations of nitrous oxide, the most commonly used non-oxygen containing gas. A mechanical or pneumatic link between the oxygen and nitrous oxide lines ensures that nitrous oxide does not flow without an adequate flow of oxygen. One such mechanism, the Datex-Ohmeda Link-25 system, is a chain linkage between sprockets on the nitrous oxide and oxygen flow needle valves. The linkage is engaged whenever the nitrous oxide is set to exceed three-times the oxygen flow, or when the oxygen flow is set to less than one-third of the nitrous oxide flow; this limits the nitrous oxide concentration to a maximum of 75% in oxygen. Another mechanism, the Draeger Oxygen Ratio Monitor Controller (ORMC), is a slave flow control valve on the nitrous oxide line that is pneumatically linked to the oxygen line. This system limits the flow of nitrous oxide to a maximum concentration of $72 \pm 3\%$ in oxygen. Both of the above systems control the ratios of nitrous oxide and oxygen, but do not compensate for other gases in the final mixture; a hypoxic mixture (oxygen concentration $< 21\%$) could be dispensed, therefore, if a third gas were added in significant concentrations.

Oxygen Flush. Each anesthesia machine has an oxygen flush system that can rapidly deliver $45\text{--}70\text{ L}\cdot\text{min}^{-1}$ of oxygen to the common gas outlet. The user presses the oxygen flush valve in situations where high flow oxygen is needed to flush anesthetic agents out of the breathing circuit, rapidly increase the inhaled oxygen concentration, or compensate for a large breathing circuit leak (for example, during positive pressure ventilation of the patient with a poorly fitted face mask). The oxygen flush system also serves as a safety system because it bypasses most of the internal plumbing of the anesthesia machine (e.g., safety control valves, flow controller-meter assemblies, and vaporizers) and because it is always operational, even when the anesthesia machine's master power switch is off.

Monitors and User-Interface Features. Written standards specify that all anesthesia machines must be equipped with essential safety monitors and user-interface features. To protect against hypoxia, each has an integrated oxygen analyzer that monitors the oxygen concentration in the breathing circuit whenever the anesthesia machine is powered on. The oxygen monitor must have an

audible alarm that sounds whenever the oxygen concentration falls below a preset threshold, which cannot be set $< 18\%$. To protect against dangerously high and low airway pressures, the breathing circuit pressure is continuously monitored by an integrated system that alarms in the event of sub-atmospheric airway pressure, sustained high airway pressure, or extremely high airway pressure. To protect against ventilator failure and breathing circuit disconnections, the breathing circuit pressure is monitored to ensure that adequate positive pressure is generated at least a few times a minute whenever the ventilator is powered on; a low airway pressure alarm (AKA disconnect alarm) is activated whenever the breathing circuit pressure does not reach a user-set threshold level over a 15 s interval. User-interface features protect against mistakes in gas flow settings. Oxygen controls are always positioned to the right of other gas flow controls. The oxygen flow control knob has a unique size and shape that is different from the other gas control knobs. The flow control knobs are protected against their being bumped to prevent accidental changes in gas flow rates. All gas flow knobs and vaporizer controls uniformly increase their settings when turned in a clockwise direction.

LIMITATIONS

Anesthesia machines are generally reliable and problem-free. Limitations include that they require a source of compressed gases, are heavy and bulky, are calibrated to be accurate at sea level, and are designed to function in an upright position within a gravitational field. Machine malfunctions are usually a result of misconnections or disconnections of internal components during servicing or transportation. Aside from interlock mechanisms that decrease the likelihood of wrong gas or wrong anesthetic agent problems, there are no integrated monitors to ensure that the vaporizers are filled with the correct agents and the flow meters are dispensing the correct gases. Likewise, except for oxygen, the gas supply pressures and anesthetic agent levels are not automatically monitored. Thus, problems can still result when the anesthesia provider fails to diagnose a problem with the compressed gas or liquid anesthetic supplies.

Ventilator

General anesthesia impairs breathing by two mechanisms, it decreases the impetus to breath (central respiratory depression), and it leads to upper airway obstruction. Additionally, neuromuscular blockers, which are often administered during general anesthesia, paralyze the muscles of respiration. For these reasons, breathing may be supported or controlled during anesthesia to ensure adequate minute ventilation. The anesthesia provider can create intermittent positive pressure in the breathing circuit by rhythmically squeezing the reservoir bag. Ventilatory support is often provided in this way for short periods of time, especially during the induction of anesthesia. During mechanical ventilation, a selector switch is toggled to disconnect the reservoir bag and APL valve from the breathing circuit and connect an anesthesia ventilator instead. Anesthesia

ventilators provide a means to mechanically control ventilation, delivering consistent respiratory support for extended periods of time and freeing the anesthesia provider's hands and attention for other tasks. Most surgical patients have normal pulmonary mechanics and can be adequately ventilated with an unsophisticated ventilator designed for ease of use. But, high performance anesthesia ventilators allow safe and effective ventilation of a wide variety of patients, including neonates and the critically ill.

Most anesthesia ventilators are pneumatically powered, electronically controlled, and time cycled. All can be set to deliver a constant tidal volume at a constant rate (volume control). Many can also be set to deliver a constant inspiratory pressure at a constant rate (pressure control). All anesthesia ventilators allow spontaneous patient breaths between ventilator breaths (intermittent mandatory ventilation, IMV), and all can provide PEEP during positive pressure ventilation (note that in some older systems PEEP is set using a PEEP-valve integrated into the expiratory limb of the breathing circuit, and is not actively controlled by the ventilator). In general, anesthesia ventilators do not sense patient effort, and thus do not provide synchronized modes of ventilation, pressure support, or continuous positive airway pressure (CPAP).

As explained above, the anesthesia delivery system conserves anesthetic gases by having the patient rebreathe previously exhaled gas. Unlike intensive care ventilators, which deliver new gas to the patient during every breath, anesthesia ventilators function as a component of the anesthesia delivery system and maintain rebreathing during mechanical ventilation. In most anesthesia ventilators, this is achieved by incorporating a bellows assembly (see Fig. 4). The bellows assembly consists of a distensible bellows that is housed in a clear rigid chamber. The bellows is functionally equivalent to the reservoir bag; it is attached to, and filled with gas from, the breathing circuit. During inspiration, the ventilator injects drive gas into the rigid chamber; this squeezes the bellows and directs gas from the bellows to the patient via the inspiratory limb of the breathing circuit. The drive gas, usually oxygen or air, remains outside of the bellows and never enters the breathing circuit. During exhalation, the drive gas within the rigid chamber is vented to the atmosphere, and the patient exhales into the bellows through the expiratory limb of the breathing circuit.

The bellows assembly also contains an exhaust valve that vents gas from the breathing circuit to the scavenger system. This ventilator exhaust valve serves the same function during mechanical ventilation that the APL valve serves during manual or spontaneous ventilation. However, unlike the APL valve, it is held closed during inspiration to ensure that the set tidal volume dispensed from the ventilator bellows is delivered to the patient. Excess gas then escapes from the breathing circuit through this valve during exhalation.

The tidal volume set on an anesthesia ventilator is not accurately delivered to the patient; it is augmented by fresh gas flow from the anesthesia machine, and reduced due to compression-loss within the breathing circuit. Fresh gas, flowing into the breathing circuit from the anesthesia machine, augments the tidal volume delivered from the

ventilator because the ventilator exhaust valve, which is the only route for gas to escape from the breathing circuit, is held closed during inspiration. For example, at a fresh gas flow rate of $3 \text{ L}\cdot\text{min}^{-1}$ ($50 \text{ mL}\cdot\text{s}^{-1}$), and ventilator settings of $10 \text{ breaths min}^{-1}$ and an I/E ratio of 1:2 (inspiratory time = 2 s), the delivered tidal volume is augmented by 100 mL per breath ($2 \text{ s per breath} \times 50 \text{ mL}\cdot\text{s}^{-1}$). Conversely, the delivered tidal volume is reduced due to compression loss within the breathing circuit. The magnitude of this loss depends on the compliance of the breathing circuit and the peak airway pressure. Circle breathing circuits typically have a compliance of $7\text{--}9 \text{ mL}\cdot\text{cm}^{-1} \text{ H}_2\text{O}$ ($70\text{--}90 \text{ mL}\cdot\text{kPa}^{-1}$), which is significantly higher than the typical $1\text{--}3 \text{ mL}\cdot\text{cm}^{-1} \text{ H}_2\text{O}$ ($10\text{--}30 \text{ mL}\cdot\text{kPa}^{-1}$) circuit compliance of intensive care ventilators, because of their large internal volume. For example, when ventilating a patient with a peak airway pressure of $20 \text{ cm H}_2\text{O}$ (2 kPa) using an anesthesia ventilator with a breathing circuit compliance of $10 \text{ mL}\cdot\text{cm H}_2\text{O}$, delivered tidal volume is reduced by 200 mL per breath.

LIMITATIONS

Until recently, anesthesia ventilators were simple devices designed to deliver breathing circuit gas in volume control mode. The few controls consisted of a power switch, and dials to set respiratory rate, inspiratory/expiratory (I/E) ratio, and tidal volume. While simple to operate, these ventilators had a number of limitations. As discussed above, delivered tidal volume was altered by peak airway pressure and fresh gas flow rate. Tidal volume augmentation was particularly hazardous with small patients, such as premature infants and neonates, since increasing the gas flow on the anesthesia machine could unintentionally generate dangerously high tidal volumes and airway pressures. Tidal volume reduction was particularly hazardous since dramatically lower than set tidal volumes could be delivered, unbeknown to the provider, to patients requiring high ventilating pressures (e.g., those with severe airway disease or respiratory distress syndrome). Worse yet, the pneumatic drive capabilities of these ventilators were sometimes insufficient to compensate for tidal volume losses due to compression within the breathing circuit; anesthesia ventilators were unable to adequately ventilate patients with high airway pressures ($> 45 \text{ cm H}_2\text{O}$) requiring large minute volumes ($> 10 \text{ L}\cdot\text{min}^{-1}$). Another imperfection of anesthesia ventilators is that they are pneumatically powered by compressed gases. The ventilator's rate of compressed gas consumption, which is approximately equal to the set minute volume ($5\text{--}10 \text{ L}\cdot\text{min}^{-1}$ in a normal size adult), is not a concern when central compressed gas supplies are being used. But the ventilator can rapidly deplete oxygen supplies when compressed gas is being dispensed from the emergency backup cylinders attached to the anesthesia machine (e.g., a backup cylinder could provide over 10 h of oxygen to a breathing circuit at low flow, but would last only one-hour if also powering the ventilator). Lastly, anesthesia ventilators that do not sense patient effort are unable to provide synchronized or supportive modes of ventilation. This limitation is most significant during spontaneous ventilation, since CPAP and pressure support cannot be provided to compensate

for the additional work of breathing imposed by the breathing circuit and endotracheal tube, or to prevent the low lung volumes and atelectasis that result from general anesthesia. New anesthesia ventilators, introduced in the past 10 years, address many of these limitations as discussed later in the section on New Technologies.

Scavenger System

Waste anesthetic gases are vented from the operating room to prevent potentially adverse effects on health care workers. High volatile anesthetic concentrations in the operating room atmosphere can cause problems such as headaches, dysphoria, and impaired psychomotor functioning; chronic exposure to trace levels has been implicated as a causative factor for cancer, spontaneous abortions, neurologic disease, and genetic malformations, although many studies have not borne out these effects. The National Institute for Occupational Safety and Health (NIOSH) recommends that operating room levels of halogenated anesthetics be < 2 parts per million (ppm) and that nitrous oxide levels be < 25 ppm. Waste gases can be evacuated from the room actively via a central vacuum system, or passively via a hose to the outside; alternatively, the waste gas can pass through a canister containing activated charcoal, which absorbs halogenated anesthetics.

The scavenger system is the interface between the evacuation systems described in the preceding sentence and the exhaust valves on the breathing circuit and ventilator (i.e., APL valve and ventilator exhaust valve). It functions as a reservoir that holds waste gas until it can vent to the evacuation system. This is necessary because gas exits the exhaust valves at a non-constant rate that may, at times, exceed the flow rate of the evacuation system. The scavenger system also ensures that the downstream pressure on the exhaust valves does not become too high or too negative. Excessive pressure at the exhaust valve outlet could cause sustained high airway pressure leading to barotrauma and cardiovascular collapse; whereas, excessive vacuum at the exhaust valve outlet could cause sustained negative airway pressure leading to apnea and pulmonary edema.

There are two categories of scavenger systems, open and closed. Open scavenger systems can only be used with a vacuum evacuation system. In an open scavenger system, waste gas enters the bottom of a rigid reservoir that is open to the atmosphere at the top, and gas is constantly evacuated from the bottom of the reservoir into the vacuum. Room air is entrained into the reservoir whenever the vacuum flow rate exceeds the waste gas flow rate, and gas spills out to the room through the openings in the reservoir whenever the waste gas flow rate exceeds the vacuum flow rate. The arrangement of the components prevents spillage of waste gas out of the reservoir openings unless the *average* vacuum flow rate is less than the *average* flow out of the exhaust valves.

Closed scavenger systems consist of a compliant reservoir bag with an inflow of waste gas from the exhaust valves of the breathing system and an outflow to the active or passive evacuation system. Two or more valves regulate the internal pressure of the closed scavenger system. A

negative pressure release valve opens to allow entry of room air whenever the pressure within the system becomes too negative, < -1.8 cm H₂O (-0.18 kPa) (i.e., in situations where the evacuation flow exceeds the exhaust flow and the reservoir bag is collapsed). A positive pressure release valve opens to allow venting of waste gas to the room whenever the pressure within the scavenger system becomes too high, > 5 cm H₂O (0.5 kPa) (i.e., in situations where the reservoir bag is full and the exhaust flow exceeds the evacuation flow). Thus, the pressure within the scavenger system is maintained between -1.8 and 5.0 cm H₂O.

Integrated Monitors

All anesthesia delivery systems have integrated electronic safety monitors intended to avert patient injuries. Included are (1) an oxygen analyzer, (2) an airway pressure monitor, and (3) a spirometer.

The oxygen analyzer measures oxygen concentration in the inspiratory limb of the breathing circuit to guard against the administration of dangerously low inhaled oxygen concentrations. Most analyzers use a polarographic or galvanic (fuel cell) probe that senses the rate of an oxygen-dependent electrochemical reaction. These analyzers are inexpensive and reliable, but are slow to equilibrate to changes in oxygen concentration (response times on the order of 30 s). They also require daily calibration. Standards stipulate that the oxygen analyzer be equipped with an alarm, and be powered-on whenever the anesthesia delivery system is in use.

The airway pressure monitor measures pressure within the breathing circuit, and warns of excessively high or negative pressures. It also guards against apnea during mechanical ventilation. Most anesthesia delivery systems have two pressure gauges: an analog Bourdon tube pressure gauge that displays instantaneous pressure on a mechanical dial, and an electronic strain-gauge monitor that displays a pressure waveform. Most electronic pressure monitors embody an alarm system with variable-threshold negative pressure, positive pressure, and sustained pressure alarms that can be adjusted by the user. An apnea alarm feature, which is enabled whenever the ventilator is powered-on, ensures that positive pressure is sensed within the breathing circuit at regular intervals. On some anesthesia delivery systems pressure is sensed within the circle system absorber canister; on other systems it is sensed on the patient side of the one-way valves; the latter gives a more accurate reflection of airway pressure.

The spirometer measures gas flow in the expiratory limb of the breathing circuit and guards against apnea and dangerously low or high respiratory volumes. A number of different techniques are commonly used to measure flow. These include spinning vanes, rotating sealed spirometers, ultrasonic, and variable orifice differential pressure. Respiratory rate, tidal volume, and minute volume are derived from the sensor signals and displayed to the user. Some machines also display a waveform of exhaled flow versus time. Most spirometers have an alarm system with variable-threshold alarms for low and high tidal volume, as well as an apnea alarm that is triggered if no flow is detected during a preset interval.

In addition to these standard monitors, some anesthesia workstations have integrated gas analyzers that measure inhaled and exhaled concentrations of oxygen, carbon dioxide, nitrous oxide, and volatile anesthetic agents. Although stand-alone gas analyzers are available, they are likely to be integrated into the anesthesia workstation because they monitor gas concentrations and respiratory parameters that are controlled by the anesthesia delivery system.

Other patient monitors, such as electrocardiography, pulse oximetry, invasive and noninvasive blood pressure, and thermometry may also be integrated into the anesthesia workstation; but often stand-alone monitors are placed on the shelves of the anesthesia delivery system. In either case, standard patient monitors must be used during the conduct of any anesthetic to evaluate the adequacy of the patient's oxygenation, ventilation, circulation, and body temperature. Monitoring standards, which have contributed to the dramatic increase in anesthesia safety, were initially published by the American Society of Anesthesiologists in 1986 and have been continually evaluated and updated (8).

New Technologies

The anesthesia delivery system as described thus far has evolved incrementally from a pneumatic device designed in 1917, by Henry Boyle for administration of anesthesia using oxygen, nitrous oxide and ether. The evolution of Boyle's machine has occurred in stages. In the 1950s and 1960s the failsafe devices and fluidic controlled ventilators were added. In the 1970s and early 1980s the focus was on improving safety with features, such as gas proportioning systems, safety alarms, electronically controlled ventilators, and standardization of the user interface to decrease errors. In the late 1980s and 1990s, monitors and electronic recordkeeping were integrated to create anesthesia workstations. Since 2000 the focus has been on improving ventilator performance, incorporating automated machine self-checks, and transitioning to electronically controlled and monitored flow meters and vaporizers. Some of the new technologies that have been introduced in the last few years are discussed, below.

BREATHING CIRCUIT

As discussed above, the tidal volume set on an anesthesia ventilator is not accurately delivered to the patient because of two breathing circuit effects. First, a portion of the volume delivered from the ventilator is compressed within the breathing circuit and does not reach the patient. Second, fresh gas flowing into the breathing circuit augments the delivered tidal volume. A number of techniques are used to minimize these effects in new anesthesia delivery systems.

Two techniques have been used to minimize the effect of gas compression. First, smaller, less compliant breathing circuits are being used. This has been achieved by minimizing the use of compliant hoses between the ventilator and breathing circuit and by decreasing the size of the absorber canister. A tradeoff is that the absorbent must be changed more frequently with a smaller canister, hence new breathing circuits are designed so that the carbon dioxide absorbent can be exchanged during use. Second, many new machines automatically measure breathing

circuit compliance during an automated preuse checkout procedure and then compensate for breathing circuit compliance during positive pressure ventilation; the ventilator continually senses airway pressure and delivers additional volume to make up for that lost to compression.

A number of techniques have also been used to eliminate augmentation of tidal volume by fresh gas flowing into the circuit. In one approach, the ventilator automatically adjusts its delivered volume to compensate for the influx of fresh gas into the breathing circuit. The ventilator either adjusts to maintain a set exhaled tidal volume as measured by a spirometer in the expiratory limb of the breathing circuit, or it responds to maintain a set inhaled tidal volume sensed in the inspiratory limb, or it modifies its delivered volume based on the total fresh gas flow as measured by electronic flowmeters in the anesthesia machine. None of the above methods requires redesign of the breathing circuit, except for the addition of flow sensors that communicate with the ventilator.

In a radically different approach, called fresh gas decoupling, the breathing circuit is redesigned so that fresh gas flow is channeled away from ventilator-delivered gas during inspiration, which removes the augmenting effect of fresh gas flow on tidal volume. An example of such a breathing circuit is illustrated in Fig. 7. In this circuit, during inhalation, gas dispensed from a piston driven ventilator travels directly to the patient's lungs; retrograde flow is blocked by a passive fresh gas decoupling valve, and expiratory flow is blocked by the ventilator-controlled expiratory valve, which is actively closed during the inspiratory phase. Fresh gas does not contribute to the delivered tidal volume; instead it flows retrograde into a nonpressurized portion of the breathing circuit. During exhalation, the ventilator-controlled expiratory valve opens, and the ventilator piston withdraws to actively fill with a mixture of fresh gas and gas from the reservoir bag. This design causes a number of other functional changes. First, the breathing circuit compliance is lower during positive pressure ventilation, since only part of the breathing circuit is pressurized during inspiration (the volume between the fresh gas decoupling valve and the ventilator-controlled expiratory valve). Second, the reservoir bag remains in the circuit during mechanical ventilation. As a result, it fills and empties with gas throughout the ventilator cycle, which is an obvious contrast to the absence of bag movement during mechanical ventilation with a conventional circle breathing circuit.

ANESTHESIA MACHINE

Many new anesthesia machines have electronic gas flow sensors instead of tapered glass tubes with internal floats. Advantages include (1) improved reliability and reduced maintenance; (2) improved precision and accuracy at low-flows; and (3) ability to automatically record and use gas flows (for instance to adjust the ventilator). The electronic sensors operate on the principle of heat transfer, measuring the energy required to maintain the temperature of a heated element in the gas flow pathway. Each sensor is calibrated for a particular gas, since every gas has a different specific heat index. Gas flows are shown on dedicated light-emitting diode (LED) displays or on the

Figure 7. Example of a breathing circuit with fresh gas decoupling. This breathing circuit is used in the Draeger Fabius anesthesia machine. It contains three passive one-way valves and two active valves that are controlled by the ventilator during mechanical ventilation.

main anesthesia machine flat panel display. Most anesthesia machines still regulate the flow of each gas using mechanical needle valves, but in some these have been replaced with electronically control valves. Electronically controlled valves provide a mechanism for computerized gas proportioning systems that limit the ratios of multiple gases. Some machines with electronic flow control valves allow the user to select the balance gas (i.e., air or nitrous oxide) and set a desired oxygen concentration and total flow, leaving the calculation of individual gas flow rates to the machine.

Most new anesthesia machines continue to use mechanical vaporizers as described above, but a few incorporate electronic vaporizers. These operate on one of two principles: either computer-controlled variable bypass, or computer-controlled liquid injection. Computerized variable bypass vaporizers control an electronic valve that regulates the flow of gas exiting from the liquid anesthetic containing chamber to join the bypass stream. The valve is adjusted to reach a target flow that is based upon the: (1) dial setting, (2) temperature in the vaporizing chamber, (3) total pressure in the vaporizing chamber, (4) bypass flow, and (5) liquid anesthetic identity. Computerized injectors

continuously add a measured amount liquid anesthetic directly into the mixed gas coming from the flowmeters based upon the: (1) dial setting, (2) mixed gas flow, and (3) liquid anesthetic identity. Electronic vaporizers offer a number of advantages. First, they provide a mechanism for vaporizer settings to be automatically recorded and controlled. Second, a number of different anesthetics can be dispensed (one at a time) using a single control unit, provided that the computer knows the identity of the anesthetic liquid.

VENTILATOR

Anesthesia ventilator technology has improved dramatically over the past 10 years and each new machine brings further advancements. As discussed above, most new ventilators compensate for the effects of circuit compliance and fresh gas flow, so that the set tidal volume is accurately delivered. Older style ventilators notoriously delivered low tidal volumes to patients requiring high airway pressures, but new ventilators overcome this problem with better flow generators, compliance compensation and feedback

control. Many new anesthesia ventilators offer multiple modes of ventilation (in addition to the traditional volume control), such as pressure control, pressure support, and synchronized intermittent mandatory ventilation. These modes assess patient effort using electronic flow and pressure sensors that are included in many new breathing circuits. Lastly, some anesthesia ventilators use an electronically controlled piston instead of the traditional pneumatically compressed bellows. Piston ventilators, which are electrically powered, dramatically decrease compressed gas consumption of the anesthesia delivery system. However, they actively draw gas out of the breathing circuit during the expiratory cycle (as opposed to bellows, which fill passively) so they cannot be used with a traditional circle system (see Fig. 7 for an example of a piston ventilator used with a fresh gas decoupled breathing circuit).

AUTOMATED CHECKOUT

Many new anesthesia delivery systems feature semiautomated preuse checkout procedures. These ensure that the machine is functioning properly prior to use by (1) testing electronic and computer performance, (2) calibrating flow sensors and oxygen monitors, (3) measuring breathing circuit compliance and leakage, and (4) testing the ventilator.

Future Challenges

The current trend is to design machines that provide advanced capabilities through the use of computerized electronic monitoring and controls. This provides the infrastructure for features such as closed-loop feedback, smart alarms, and information management that will be increasingly incorporated in the future. We can anticipate closed-loop controllers that automatically maintain a user-set exhaled anesthetic concentration (an indicator of anesthetic depth), or exhaled carbon dioxide concentration (an indicator of adequacy of ventilation). We can look forward to smart alarms that pinpoint the location of leaks or obstructions in the breathing circuit, alert the user and switch to a different anesthetic when a vaporizer becomes empty, or notify the user and switch to a backup cylinder if a pipeline failure or contamination event is detected. We can foresee information management systems that automatically incorporate anesthesia machine settings into a nationwide repository of anesthesia records that facilitate outcomes-guided medical practice, critical event investigations, and nationwide access to patient medical records. Anesthesia machine technology continues to evolve.

INTRODUCTION

Computer applications in anesthesia patient care have evolved with advancement of computer technology, information processing capability, and anesthesia devices and procedures.

Anesthesia is an integral part of most surgical operations. The objectives of anesthesia are to achieve hypnosis (consciousness control), analgesia (pain control), and immobility (body movement control) simultaneously throughout surgical operations, while maintaining the vital functions of the body. Vital functions, such as respiration and circulation of blood, are assessed by signs such as blood pressures, heart rate, end-tidal carbon dioxide (CO₂), oxygen saturation by pulse oximetry (SpO₂), and so on. These objectives are

Figure 1. Some anesthesia equipment in an operating room.

carefully balanced and maintained by a dedicated anesthesia provider using a combination of sedative agents, hypnotic drugs, narcotic drugs, and, in many surgeries, muscle relaxants. Anesthesia decisions and management are complicated tasks, in which anesthetic requirements and agent dosages depend critically on the surgical procedures, the patient's medical conditions, drug interactions, and coordinated levels of anesthesia depth and physiological variables. Anesthesia decisions impact significantly on surgery and patient outcomes, drug consumptions, hospital stays, and therefore quality of patient care and healthcare cost (Fig. 1).

Computer technologies have played essential roles in assisting and improving patient care in anesthesia. Development of computer technology started from its early stages of bulky computing machines, progressed to minicomputers and microcomputers, exploded with its storage capability and computational speed, and evolved into multiprocessor systems, distributed systems, computer networks, and multimedia systems. Computer applications in anesthesia have taken advantage of this technology advancement. Early computer applications in medicine date back to the late 1950s when some hospitals began to develop computer data processing systems to assist administration, such as storage, management, and analysis of patient and procedural data and records. The main goals were to reduce manpower in managing ever-growing patient data, patient and room scheduling, anesthesia supply tracking, and billing. During the past four decades computer utility in anesthesia has significantly progressed to include computer-controlled fluid administration and drug dispersing, advanced anesthesia monitoring, anesthesia information systems, computer-assisted anesthesia control, computer-assisted diagnosis and decisions, and telemedicine in anesthesia.

COMPUTER UTILITY IN ADVANCED ANESTHESIA MONITORING

The quality of anesthesia patient care has been greatly influenced by monitoring technology development. A

patient's state during a surgery is assessed using vital signs. In earlier days of anesthesiology, vital signs were limited to manual measurements of blood pressures, stethoscope auscultation of heart–lung sounds, and heart rates. These values were measured intermittently and as needed during surgery. Thanks to advancement of materials, sensing methods, and signal processing techniques, many vital signs can now be directly, accurately, and continuously measured. For example, since the invention of pulse oximetry in the early 1980s, this noninvasive method of continuously monitoring the arterial oxygen saturation level in a patient's blood (SpO_2) has become a standard method in the clinical environment, resulting in a significant improvement of patient safety. Before this invention, blood must be drawn from patients and analyzed using laboratory equipment.

Integrating these vital signs into a comprehensive anesthesia monitoring system has been achieved by computer data interfacing, multisignal processing, and computer graphics. Advanced anesthesia monitors are capable of acquiring multiple signals from many vital sign sensors and anesthesia machine itself, displaying current readings and historic trends, and providing audio and visual warning signals. At present, heart rate, electrocardiogram (ECG), arterial blood pressures, temperature, ventilation parameters (inspired–expired gas concentration, peak airway pressure, plateau airway pressure, inspired and expired volumes, etc.), end-tidal CO_2 concentrations, blood oxygen saturation (SpO_2), and so on, are routinely and reliably monitored (Figs. 2 and 3).

However, there are still many other variables reflecting a patient's state that must be inferred by the physician, such as anesthesia depth and pain intensity. Pursuit of new

Figure 3. An anesthesia monitor from GE Healthcare in 2005. (Courtesy of GE Healthcare.)

physiological monitoring devices for direct and reliable measurements of some of these variables is of great value and imposes great challenges at the same time (1). Anesthesia depth has become a main focus of research in the anesthesia field. At present, most methods rely in part or in whole on processing of the electroencephalogram (EEG) and frontalis electromyogram (FEMG) signals. Proposed methods include the median frequency, spectral edge frequency, visual evoked potential, auditory evoked potential, entropy, and bispectral index (2,3). Some of these technologies have been commercialized, leading to several anesthesia depth monitors for use in general anesthesia and sedation. Rather than using indirect implications from blood pressures, heart rate, and involuntary muscle movements to derive consciousness levels, these monitors purport to give a direct index of a patient's anesthesia depth. Consequently, combined effects of anesthesia drugs on the patient anesthesia depth can potentially be understood clearly and unambiguously. Currently (the year 2005), the BIS Monitor by Aspect Medical Systems, Inc. (www.aspectmedical.com), Entropy Monitor by GE Healthcare (www.gehealthcare.com), and Patient State Analyzer (PSA) by Hospira, Inc. (www.hospira.com) are three FDA (U.S. Food and Drug Administration) approved commercial monitors for anesthesia depth.

Availability of commercialized anesthesia depth monitors has prompted a burst of research activity on computerized depth control. Improvement of their reliability remains a research frontier. Artifacts have fundamental impact on reliability of EEG signals. In particular, muscle movements, eye blinks, and other neural stimulation effects corrupt EEG signals, challenging all the methods that rely on EEG to derive anesthesia depth. As a result, reliability of these devices in intensive care units (ICU) and emergency medicine remains to be improved.

Another area of research is pain-intensity measurement and monitoring. Despite a long history of research and development, pain intensity is still evaluated by subjective assessment and patient self-scoring. The main thrust is to establish the relation between subjective pain scores, such as the visual analog scale (VAS) system, and objective measures of vital signs. Computer-generated objective and continuous monitoring of pain will be a significant advance in anesthesia pain control. This remains an open and active area of research and development (R&D). As an intermediate step, patient-controlled analgesia (PCA) devices have been developed (see, e.g., LifeCare PCA systems from Hospira, Inc., which is a 2003 spin-off of Abbott Laboratories) that allow a patient to assess his/her pain intensity and control analgesia as needed.

Currently, anesthesia monitors are limited to data recording and patient state display. Also, their basic functions do not offer substantial interaction with human and environment. Future monitors must enhance fundamentally human-factors design: Intelligent human-machine interface and integrated human-machine-environment systems (4). Ideally, a monitor will intelligently organize observation data into useful information, adapt its functions according to surgical and anesthesia events, select the most relevant information to display, modify its display layouts to reduce distraction and amplify essential

information, tune safety boundaries for its warning systems on the basis of the individual medical conditions of the patient, analyze data to help diagnosis and treatment, and allow user-friendly interactive navigation of the monitor system. Such a monitor will eventually become an extension of a physician's senses and an assistant of decision-making processes.

COMPUTER INFORMATION TECHNOLOGY IN ANESTHESIA

Anesthesia Information Systems

Patient information processing systems have undergone a long history of evolution. Starting in the 1960s, some computer programming software and languages were introduced to construct patient information systems. One example is MUMPS (Massachusetts General Hospital Utility Multi-Programming System), which was developed in Massachusetts General Hospital and used by other hospitals, as well as the U.S. Department of Defense and the U.S. Veteran's Administration. During the same period, Duke University's GEMISCH, a multi-user database programming language, was created to streamline data sharing and retrieval capabilities.

Currently, a typical anesthesia information system (AIS) consists of a central computer station or a server that is interconnected via wired or wireless data communication networks to many subsystems. Subsystems include anesthesia monitors and record-keeping systems in operating rooms, preoperative areas, postanesthesia care units (PACU), ICUs; data entry and record systems of hospital testing labs; office computers of anesthesiologists. The system also communicates with hospital mainframe information systems to further exchange information with in- and out-patient care services, patient database, and billing systems.

Information from an operating room is first collected by medical devices and anesthesia monitors and locally sorted and recorded in the record-keeping system. Selected data are then transmitted to the mainframe server through the data network. Anesthesia events, procedures, physician observations and diagnosis, patient care plans, testing results, drug and fluid data can also be entered into the record-keeping system, and broadcast to the main server and/or other related subsystems.

The main server and observation station provide a center in which patient status in many operating rooms, preoperative area and PACUs can be simultaneously monitored in real time. More importantly, the central anesthesia information system keeps accurately patient data and makes them promptly accessible to many important functions, including patient care assessment, quality assurance, room scheduling, physician assignment, clinical studies, medical billing, regulation compliance, equipment and personnel utility, drug and blood inventory, postoperative in-patient and out-patient service, to name just a few examples (Fig. 4).

One example of AIS is the automation software system CareSuite of PICIS, Inc. (www.picis.com). The system delivers comprehensive perioperative automation. It provides surgical

Figure 4. An illustration of a surgical/anesthesia information management system from surgical information systems, Inc. (www.orsoftware.com).

and anesthesia supply management, intraoperative nursing notes, surgical infection control monitoring, adverse event tracking and intervention, patient tracking, resource tracking, outlier alerts, anesthesia record, anesthesia times, case compliance, and so on. Similarly, the surgical and anesthesia management software by Surgical Information Systems (SIS), Inc. (www.orsoftware.com) streamlines patient care and facilitates analysis and performance improvement.

Anesthesia information systems are part of an emerging discipline called medical informatics, which studies clinical information and clinical decision support systems. Although technology maturity of computer hardware and software has made medical information systems highly feasible, creating seamless exchange of information among disparate systems remain a difficult task. This presents new opportunities and challenges for broader application of medical informatics in anesthesia practice.

Computer Simulation: Human Patient Simulators

Human patient simulators (HPS) are computerized mannequins whose integrated mechanical systems and computer hardware, and sophisticated computer software mimic authentically many related physiological, pathological, and pharmacological aspects of the human patient during a surgery or a medical procedure (Fig. 5). The mannequins are designed to simulate an adult or pediatric patient of either gender under a medical stress condition. They are accommodated in a clinical setting, such as an operating room, a trauma site, an emergence suite, or an ICU. Infusion pumps use clean liquid (usually water) through bar-coded syringes, whose barcodes are read by the HPS code recognition system to identify the drugs, to administer the simulated drugs, infusion liquids, or transfused blood during an anesthesia administration. The HPS allows invasive procedures such as intubation.

The HPS responds comprehensively to administered drugs, surgical events, patient conditions, and medical crisis; and displays on standard anesthesia monitors most

related physiological vital signs, including blood pressures, heart rate, EKG, and oxygen saturations. They also generate normal and adventurous heart and lung sounds for auscultation. All these characteristics are internally generated by the computer software that utilizes mathematics models of typical human patients to simulate the human responses. The patient's physical parameters (age, weight, smoker, etc.), preexisting medical conditions (high blood pressure, asthma, diabetic, etc.), surgical procedures, clinical events, and critical conditions are easily programmed by a computer Scenario Editor with a user-friendly graphical interface. The Scenario Editor also allows interactive reprogramming of scenarios during an operation. This on-the-fly function of scenario generation is especially useful for training. It gives the instructor great flexibility to create new scenarios according to the trainee's reactions to previous scenarios.

The HPS is a great educational tool that has been used extensively in training medical students, nurse anesthetists, anesthesia residents, emergency, and battlefield

Figure 5. Human patient simulator complex at Wayne State University.

Figure 6. Anesthesia resident training on an HPS manufactured by METI, Inc. (Used with permission.)

medics. Its preliminary development can be traced back to the 1950s, with limited computer hardware or software. Its more comprehensive improvement occurred in pace with computer technology in the late 1960s when highly computerized models were incorporated into high fidelity HPS systems with interfaces to external computers.

Due to rareness of anesthesia crisis, student and resident training on frequent and repeated critical medical conditions and scenarios is not possible in operating rooms. The HPS permits the trainee to practice clinical skills and manage complex and critical clinical conditions by generating and repeating difficult medical scenarios. The instructor can design individualized programs to evaluate and improve trainees' crisis management skills. For invasive skills, such as intubation, practice

on simulators is not harmful to human patients. Catastrophic or basic events are presented with many variations so that trainees can recognize their symptoms, diagnose their occurrences, treat them according to established guidelines, and avert disasters. For those students who have difficulties to transform classroom knowledge to clinical hands-on skills, the HPS training is a comfortable bridge for them to rehearse in simulated clinical environments (5) (Fig. 6).

There are several models of HPSs on market. For example, the MedSim-Eagle Patient Simulator (Fig. 7) is a realistic, hands-on simulator of the anesthetized or critically ill patient, developed at Stanford University and manufactured by Eagle Simulation, Inc. METI (Medical Education Technologies, Inc.) (www.meti.com) manufactures adult HPS (Stan), pediatric HPS (PediaSim), emergency care simulator (ECS), pediatric emergency simulator (PediaSim-ECS), and related simulation suites such as airway tools (AirSim), surgical training tools (SurgicalSim). Laerdal Medical AS (www.laerdal.com) has developed a comprehensive portable HPS that can be operated without the usual operating room settings for HPS operations.

Human simulations, however, are not a total reality. Regardless how comprehensive the HPS has become, real environments are far more complex. There are many complications that cannot be easily simulated. Consequences of overly aggressive handling of certain medical catastrophic events may not be fully represented. Issues like these have prompted further efforts in improving HPS technologies and enhancing their utilities in anesthesia education, training, and research.

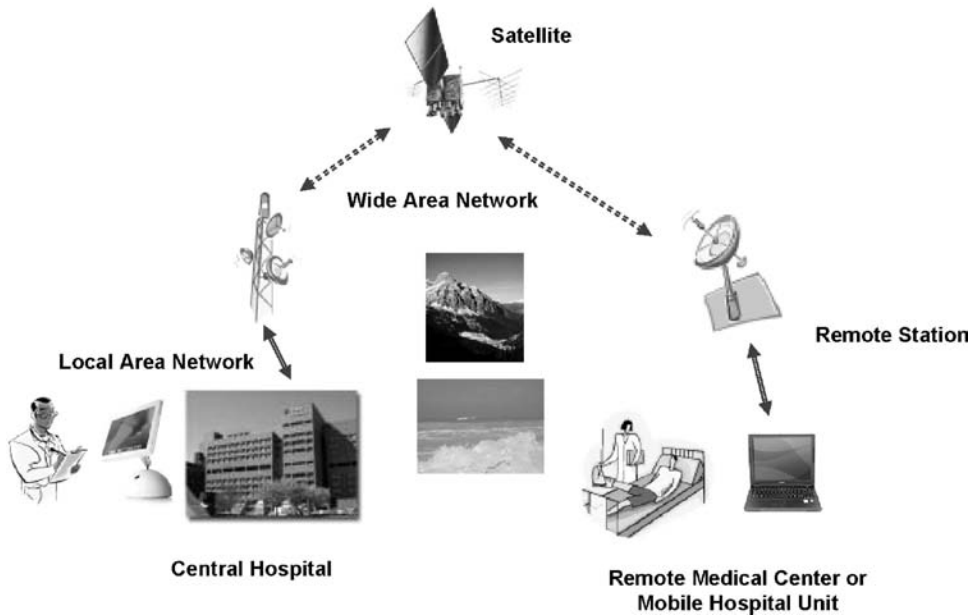

Figure 8. Telemedicine connects remote medical centers for patient care.

Large Area Computer Networks: Telemedicine in Anesthesia

Telemedicine can be used to deliver healthcare over geographically separated locations. High speed telecommunication systems allow interactive video-mediated clinical consultation, and the possibility in the future of remote anesthesia administration. Wide availability of high speed computer and wireless network systems have made telemedicine a viable area for computer applications. Telemedicine could enable the delivery of specialized anesthesia care to remote locations that may not be accessible to high quality anesthesia services and knowledge, may reduce significantly travel costs, and expand the supervision capability of highly trained anesthesiologists.

In a typical telemedicine anesthesia consultation, an anesthesiologist in the consultation center communicates by a high speed network with the patient and the local anesthesia care provider, such as a nurse, at the remote location (Fig. 8). Data, audio and video connections enable the parties to transfer data, conduct conversations on medical history and other consultation routines, share graphs, discuss diagnosis, and examine the patient by cameras. The anesthesiologist can evaluate the airway management, ventilation systems, anesthesia monitor, and cardiovascular systems. Heart and lung sound auscultation can be remotely performed. Airway can be visually examined. The anesthesiologist can then provide consultation and instructions to the remote anesthesia provider on anesthesia management.

Although telemedicine is a technology-ready field of computer applications and has been used in many medicine specialties, at present its usage for systematic anesthesia consultation remains at its infancy. One study reports a case of telemedicine anesthesia between the Amazonian rainforests of Ecuador and Virginia Commonwealth University, via a commercially developed telemedicine system (6). In another pilot study, the University Health Network in Toronto utilized Northern Ontario Remote Telecommunication Health (NORTH) Network to provide telemedicine

clinical consultations to residents of central and northern Ontario in Canada (7).

COMPUTER-AIDED ANESTHESIA CONTROL

The heart of most medical decisions is a clear understanding of the outcome from drug administration or from specific procedures performed on the patient. To achieve a satisfactory decision, one needs to characterize outcomes (outputs), establish causal links between drugs and procedures (inputs) and the outcomes, define classes of decisions in consideration (classes of possible actions and controllers), and design actions (decisions and control). Anesthesia providers perform these cognitive tasks on the basis of their expertise, experience, knowledge of guidelines, and their own subjective judgments. It has long been perceived in the field of anesthesiology that computers may help in this decision and control process.

At a relatively low level of control and decision assistance, there has been routine use by anesthesia providers of computers to supply comprehensive and accurate information about anesthesia drugs, procedures, and guidelines in relation to individual patient care. Thanks to miniaturization and internets, there are now commonly and commercially available digital reference databases on anesthesia drugs, their detailed user manuals, and anesthesia procedures. With a palm-held device, all information becomes readily available to anesthesia providers in operating rooms, and other clinical settings. New data can be routinely downloaded to keep information up-to-date.

More challenging aspects of computer applications are those involving uncertainty, control, and intelligence that are the core of medical decision processes. These include individualized models of human patients, outcome prediction, computer-assisted control, diagnosis, and decision assistance. Such tools need to be further developed and commercialized for anesthesia use.

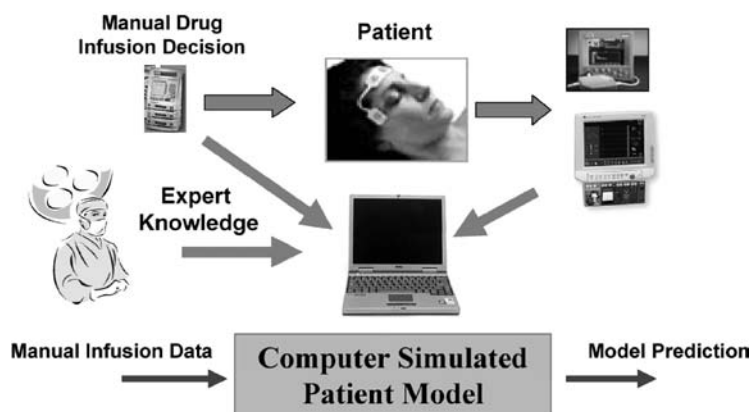

Figure 9. Utility of patient models to predict outcomes of drug infusion.

Patient Modeling and Outcome Prediction

Response of a patient's physiological and pathological state to drugs and procedures is the key information that an anesthesiologist uses in their management. The response, that is, the outcome, can be represented by either the values of the patient vital signs such as anesthesia depth and blood pressures, or consequence values such as length of ICU stay, hospital stay, complications. Usually, drug impact on patient outcomes is evaluated in clinical trials on a large and representative population and by subsequent statistical analysis. These population-based models (average responses of the selected population) link drug and procedural inputs to their effects on the patient state. These models can then be used to develop anesthesia management guidelines (Fig. 9).

For real-time anesthesia control in operating rooms, the patient model also must represent dynamic aspects of the patient response to drugs and procedures (8). This real-time dynamic outcome prediction requires a higher level of modeling accuracy, and is more challenging than off-line statistical analysis of drug impact. Real-time anesthesia control problems are broadly exemplified by anesthesia drug infusion, fluid resuscitation, pain management, sedation control, automated drug rates for diabetics, and so on.

There have been substantial modeling efforts to capture pharmacokinetic and pharmacodynamic aspects of drug impact as well as their control applications (9). These are mostly physiology-based and compartment-modeling approaches. By modeling each process of infusion pump dynamics, drug propagation, concentration of drugs on various target sites, effect of drug concentration on nerve systems, physiological response to nerve stimulations, and sensor dynamics, an overall patient response model can be established. Verification of such models has been performed by comparing model-predicted responses to measured drug concentration and physiological variables. These models have been used in evaluating drug impact, decision assistance and control designs.

Computer Automation: Anesthesia Control Systems

At present, an anesthesiologist decides on an initial drug control strategy by reviewing the patient's medical conditions, then adapts the strategy after observing the patient's actual response to the drug infusion. The strategy is

further tuned under different surgical events, such as incision, operation, and closing. Difficulties in maintaining smooth and accurate anesthesia control can have dire consequences, from increased drug consumption, side effects, short- and long-term impairments, and even death. Real-time and computer-assisted information processing can play a pivotal role in extracting critical information, deriving accurate drug outcome predictions, and assisting anesthesia control.

Research efforts to develop computer-assisted anesthesia control systems have been ongoing since the early 1950s (10–14). The recent surge of interest in computer-assisted anesthesia diagnosis, prediction, and controls is partly driven by the advances in anesthesia monitoring technologies, such as depth measurements, computer-programmable infusion pumps, and multisignal real-time data acquisition capabilities. These signals provide fast and more accurate information on the patient state, making computer-aided control a viable possibility. Research findings from computer simulations, animal studies, and limited human trials, have demonstrated that many standard control techniques, such as proportional-integral-derivative (PID) controllers, nonlinear control techniques, fuzzy logic, model predictive control, can potentially provide better performance under routine anesthesia conditions in operating rooms (Fig. 10).

Target Concentration and Effect Control. Target concentration or drug effect control is an open-loop control strategy. It relies on computer models that relate drug infusion rates to drug concentrations on certain target sites or to drug effects on physiological or nerve systems. Since at present drug concentration or drug effects are not directly measured in real-time, feedback control is often not possible. Implementation of this control strategy can be briefly described as follows. For a prespecified time interval, the desired drug concentration profile is defined. This profile is usually determined *a priori* by expert knowledge, safety mandates, and smooth control requirements. A performance index is then devised that includes terms for control accuracy (to follow the desired profiles closely), drug consumption, constraints on physiological variables (safety constraints), and so on. Then, an optimal control is derived by optimizing the performance index under the given constraints and the dynamic

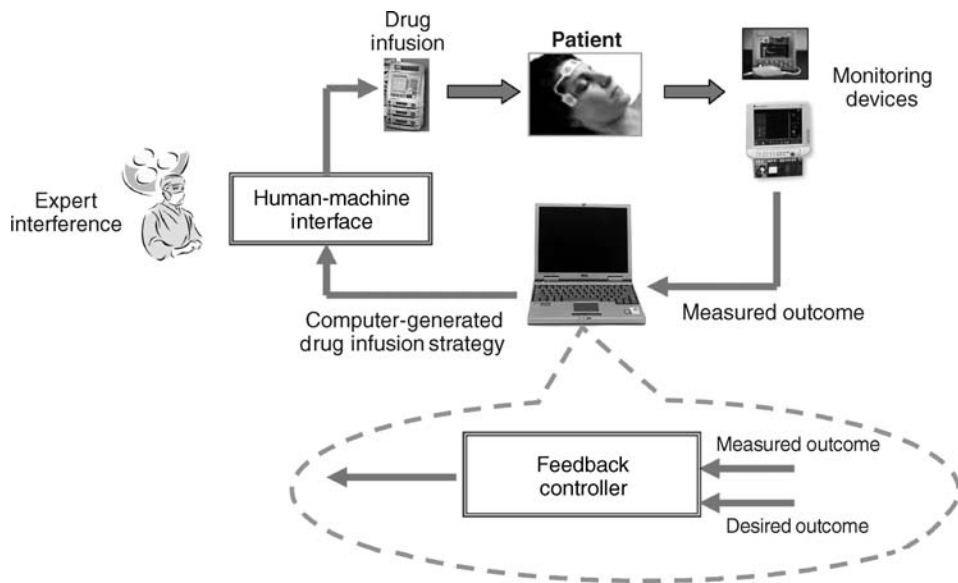

Figure 10. Computer-assisted drug infusion control (a) without expert interference: automated anesthesia feedback control. (b) With expert interference: anesthesia decision assistance systems.

models of the patient. One common method of designing optimal control strategies is dynamic programming, although many other optimal or suboptimal control design methodologies for nonlinear control systems are also available in the control field. Due to lack of feedback correction in target concentration control, optimality and accuracy of control actions may be compromised. However, even this open-loop control has seen many successful applications, such as glucose level control. Feedback control may become feasible in the future when new sensors become available to measure directly drug concentration.

Automatic Feedback Control. Computer-assisted anesthesia control has been frequently compared to autopilot systems in aviation. The autopilot system controls flying trajectories, altitude and position, airplane stability and smoothness, automatically with minimum human supervision. Success of such systems has resulted in their ubiquitous applications in most airplanes. It was speculated that an anesthesia provider's routine control tasks during a surgery may be taken over by a computer that adjusts automatically drug infusions to maintain desirable patient states. Potential and speculated advantages of such systems may include less reliance on experience, avoidance of fatigue-related medical mistakes, smoother control outcomes, reduced drug consumptions, and consequently faster recovery. So far, these aspects have been demonstrated only in a few selective cases of research subjects.

System Identification and Adaptive Control for Individualized Control Strategies. One possible remedy for compensating variations in surgical procedures and patient conditions in control design is to use real-time data to adjust patient models that are used in either target concentration control or feedback control. Successful implementation of this idea will generate individualized models that will capture the unique characteristics of the patient. This real-time patient model can then be used to tune

the controllers that will deliver best performance for the patient. This control tuning is the core idea of adaptive control systems: Modifying control strategies on the basis of individually identified patient models. Adaptive control has been successfully applied to a vast array of industrial systems. The main methods of model reference adaptive control, gain scheduling, self-tuning regulators, and machine learning are potentially applicable in anesthesia control. This is especially appealing since variations and uncertainties in patient conditions and surgical events and procedures are far more complicated than industrial systems.

Most control algorithms that have been employed in anesthesia control are standard. The main difficulties in applying automated anesthesia control are not the main control methodologies, but rather an integrated system with high reliability and robustness, and well-designed human-machine interaction and navigation. Unlike an airplane in midair or industrial systems, anesthesia patients vary vastly in their responses to drugs and procedures. Control strategies devised for a patient population may not work well in individual patients. Real-time, on-site, and automatic calibration of control strategies are far more difficult than designing an initial control strategy for a patient population. Adaptation adds a layer of nonlinear feedback over the underlying control, leading to adaptive PID, tuned fuzzy, adaptive neural frameworks, and so on. Stability, accuracy, and robustness of such control structures are more difficult to establish. Furthermore, human interference must be integrated into anesthesia control systems to permit doctors to give guidelines and sometimes take control. Due to high standard in patient safety, at present automated anesthesia control remains largely in a phase of research, and in a very limited sense, toward technology transfer to medical devices. It will require a major commercialization effort and large clinical studies to transform research findings into product development of anesthesia controllers.

Moreover, medical complications occur routinely, which cannot be completely modeled or represented in control

strategies. Since such events usually are not automatically measured, it is strenuous to compensate their impact quickly. In addition, medical liability issues have raised the bar of applying automated systems. These concerns have curtailed a widespread realization of automated anesthesia control systems, despite a history of active research over four decades on anesthesia control systems.

COMPUTER INTELLIGENCE: DIAGNOSIS AND DECISION ASSISTANCE

In parallel to development of automatic anesthesia control systems, a broader application of computers in anesthesia management is computer-aided anesthesia diagnosis, decision assistance, and expert systems. Surveys of anesthesia providers have indicated that the field of anesthesiology favors system features that advise or guide rather than control (15). Direct interventions, closed-loop control, lock-out systems, or any other coercive method draw more concerns. In this aspect, it seems that anesthesia expert decision support systems may be an important milestone to achieve before automated systems.

Anesthesia Diagnosis and Decision Assistance

Computer-aided diagnosis will extract useful information from patient data and vital-sign measurements, apply computerized logic and rigorous evaluations of the data, provide diagnosis on probable causes, and suggest guideline-driven remedy solutions. The outcome of the analysis and diagnosis can be presented to the anesthesia care provider with graphical displays, interactive user interfaces, and audio and visual warnings.

Decision assistance systems provide decision suggestions, rather direct and automatic decision implementations. Such systems provide a menu of possible actions for an event, or dosage suggestions for control purposes, and potential consequences of selected decisions. Diagnosis of possible causes can remind the anesthesiologist what might be overlooked in a crisis situation. The system can have interactive interfaces to allow the physician to discuss further actions and the corresponding outcomes with the computer. This idea of physician-assistant systems aims to provide concise, timely, and accurate references to the anesthesiologist for improved decisions. Since the physician remains as the ultimate decision maker, their management will be enhanced by the available information and diagnosis, but not taken over.

Suggested remedies of undesirable events are essentially recommendations from anesthesia management guidelines, brought out electronically to the anesthesiologist. Some computer simulators for anesthesia education are developed on the basis of this idea. For example, Anesthesia Simulator by Anesoft Corporation (www.anesoft.com) contains a software module of expert consultation that incorporates anesthesia emergency scenarios and suggests expert advices. Utility of expert systems in resident training has been widely accepted. However, decision support systems in the operating rooms are slow in development and acceptance. Generally speaking, a decision support system must interact with the compli-

cated cognitive environment of the operating rooms. To make such systems a useful tool, they must be designed to accommodate the common practice in which the anesthesiologist thinks, sees, and reasons, rather than imposing a complicated new monitoring mode for the clinician to be retrained. This is again an issue of human-factors design.

Dosage recommendations for anesthesia drugs are internally derived from embedded modeling and control strategies. In principle, the control strategies discussed in the previous sections can support the decision assistance system. By including the physician in the decision loop, some issues associated with automated control systems can be alleviated. Reliability of such control strategies, user interfaces, and clinical evidence of cost-effectiveness of the decision support system will be the key steps toward successful clinical applications of such systems.

FUTURE UTILITY OF COMPUTER TECHNOLOGY IN ANESTHESIA

The discussions in the previous sections outline briefly critical roles that computers have played in improving anesthesia management. New development in computer-related technologies are of much larger potential.

Micro-Electro-Mechanical Systems (MEMS) is a technology that integrates electrical and mechanical elements on a common silicon material. This technology has been used in developing miniature sensors and actuators, such as micro infusion pumps and *in vivo* sensors. Integrated with computing and communication capabilities, these devices become smart sensors and smart actuators. The MEMS technology has reached its maturity. Further into the realms of fabrication technology at atom levels, emergence of nanotechnology holds even further potential of new generations of medical devices and technologies. There are many exciting possibilities for utility of these technologies in anesthesia: *In vitro* sensors based on nano-devices can potentially pinpoint drug concentrations at specific target sites, providing more accurate values for automated anesthesia drug control; Microactuators can directly deliver drugs to the target locations promptly and accurately, reducing drastically reliance on trial-and-error and sharpened experience in anesthesia drug infusion control; MEMS and nanosensors together with computer graphical tools will allow two-dimensional (2D) or three-dimensional (3D) visual displays of drug propagation, drug concentration, distributed blood pressures, heart and lung functions, brain functions, consequently assisting anesthesiologists in making better decisions about drug delivery for optimal patient care.

On another frontier of technology advancement, computer parallel computing (many computers working in symphony to solve complicated problems), computer imaging processing, data mining (extracting useful information from large amount of data), machine intelligence, wireless communication technologies, and human-factors science and design provide a vast opportunity and a promising horizon in advancing anesthesia management.

Advanced anesthesia control systems will manage routine drug infusion with their control actions tuned to

individual patients' conditions and surgical procedures, relieving anesthesiologists from stressful and strenuous routine tasks to concentrate on higher level decisions in patient care.

Patient physiological conditions can be more accurately and objectively measured by computer-processed sensor and imaging information.

Computer-added imaging processing will make it possible to consolidate information from CT-Scan (Computed Tomography), TEE (Transesophageal Echocardiography), MRI (Magnetic Resonance Imaging), and fMRI (Functional Magnetic Resonance Imaging) into regular anesthesia monitoring.

Anesthesia decisions will be assisted by computer database systems and diagnosis functions.

Anesthesia monitoring devices will become wireless, eliminating the typical spaghetti conditions of monitoring cables in operating rooms.

Anesthesia information systems will become highly connected and standard in anesthesia services, automating and streamlining the total patient care system: From patient admission to patient discharge, as well as follow-up services.

ANGER CAMERA

MARK T. MADSEN
University of Iowa

INTRODUCTION

In nuclear medicine, radioactive tracers are used to provide diagnostic information for a wide range of medical indications. Gamma-ray emitting radionuclides are nearly ideal tracers, because they can be administered in small quantities and yet can still be externally detected. When the radionuclides are attached to diagnostically useful compounds (1), the internal distribution of these compounds provides crucial information about organ function and physiology that is not available from other imaging modalities. The Anger camera provides the means for generating images of the radiopharmaceuticals within the body. Example images of some common studies are shown in Figs. 1 and 2.

Initially, nonimaging detectors were used to monitor the presence or absence of the radiotracer. However, it was clear that mapping the internal distribution of the radiotracers would provide additional diagnostic information. In 1950, Benedict Cassen introduced the rectilinear scanner. The rectilinear scanner generated images of radionuclide distributions by moving a collimated sodium iodide detector over the patient in a rectilinear fashion. The detected count rate modulated the intensity of a masked light bulb that scanned a film in an associated rectilinear pattern. While this device did produce images, it was very slow and had no capability for imaging rapidly changing distributions. The rectilinear scanner was used into the 1970s, but was finally supplanted by the Anger camera (2–5).

The Anger camera, also referred to as the scintillation camera (or gamma camera), is a radionuclide imaging device that was invented by Hal O. Anger. It is the predominant imaging system in nuclear medicine and is responsible for the growth and wide applicability of nuclear medicine. Anger was born in 1920. He received his BS degree in electric engineering from the University of California at Berkeley in 1943 and in 1946 he began working at the Donner Laboratories, where he developed a large number of innovative detectors and imaging devices including the scintillation well counter and a whole body rectilinear scanner using 10 individual sodium iodide probes. In 1957, he completed his first gamma

Figure 1. Anger camera clinical images. A. Lung ventilation and perfusion images are used to diagnose pulmonary emboli. B. Renal function images are used to diagnose a variety of problems including renal hypertension and obstruction. C. Gated blood pool studies permit evaluation of heart wall motion and ejection fraction.

imaging camera that he called a scintillation camera and is often referred to as the Anger camera (6). Anger's scintillation camera established the basic design that is still in use today. The first Anger camera had a 10 cm circular field of view, seven photomultiplier tubes, pinhole collimation, and could only be oriented in one direction. A picture of this initial scintillation camera is shown in Fig. 3 and a schematic drawing of the electronics is shown in Fig. 4. In 1959, Anger adapted the scintillation camera for imaging positron emitting radionuclides without collimation using coincidence between the camera and a sodium iodide detector. He also continued improving the scintillation camera for conventional gamma emitting radionuclides. By 1963, he had a system with a 28 cm field of view and 19 photomultiplier tubes (7). This device became commercialized as the nuclear Chicago scintillation camera. Throughout the 1960s, 1970s, and 1980s Anger remained active at Donner labs developing numerous other radionuclide imaging devices. He has received many prestigious awards including the John Scott Award (1964), a Guggenheim fellowship (1966), an honorary Doctor of Science degree from Ohio State University (1972), the Society of Nuclear

Medicine Nuclear Pioneer Citation (1974), and the Society of Nuclear Medicine Benedict Cassen Award (1994) (8-10).

About the same time that the Anger camera was introduced, the molybdenum-99/technetium-99m radionuclide generator became available. This finding is mentioned because the advantages offered by this convenient source of ^{99m}Tc had a large influence on the development of the Anger camera. Technetium-99m emits a single gamma ray at 140 keV, has a 6 h half-life and can be attached to a large number of diagnostically useful compounds. Because it is available from a generator, it also has a long shelf life. The ^{99m}Tc is used in > 80% of nuclear medicine imaging studies. As a result, both the collimation and detector design of the Anger camera has been optimized to perform well at 140 keV (1).

SYSTEM DESCRIPTION

The Anger camera is a position sensitive gamma-ray imaging device with a large field of view. It uses one

Figure 2. Anger camera clinical images. A. Bone scans are used to evaluate trauma and metastatic spread of cancer. B. Myocardial perfusion studies are used to evaluate coronary artery disease.

large, thin sodium iodide crystal for absorbing gamma-ray energy and converting that into visible light. The light signal is sampled by an array of photomultiplier tubes that convert the light signal into an electronic pulse. The pulses from individual PMTs are combined in two ways. An energy pulse is derived from the simple summation of the PMT signals. The *X* and *Y* locations of the event are calculated from the sum of the PMT signals after position-dependent weighting factors have been applied. When a signal from a detected event falls within a preselected energy range, the *X* and *Y* locations are recorded in either list or frame modes. The components that make up the Anger camera are shown in Fig. 5 and are described in detail in the following section (11,12).

Sodium Iodide Crystal

Sodium iodide activated with thallium, NaI(Tl), is the detecting material used throughout nuclear medicine. Sodium iodide is a scintillator giving off visible light when it absorbs X- or gamma-ray energy. At room temperature, pure NaI has very low light emission, however, when small amounts (parts per million, ppm) of thallium are added, the

efficiency for light emission is greatly enhanced. This is an especially important aspect for its application in the Anger camera since the light signal is used to determine both the energy and location of the gamma-ray interaction with the detector. In addition to its high light output, NaI(Tl) has several other desirable properties. It has a relatively high effective atomic number ($Z_{\text{eff}} = 50$) and the density is $3.67 \text{ g}\cdot\text{cm}^{-3}$. This results in a high detection efficiency for gamma rays under 200 keV with relatively thin crystals (8,12–15).

Sodium iodide is grown as a crystal in large ingots at high temperatures ($> 650 \text{ }^\circ\text{C}$). The crystals are cut, polished, and trimmed to the required size. For Anger cameras, the crystals are typically $40 \times 55 \text{ cm}$ and 9.5 mm thick. Because NaI(Tl) absorbs moisture from the air (hygroscopic), it must be hermetically sealed. Any compromise of this seal often results in the yellowing of the crystal and its irreversible destruction.

In addition to the need to keep the crystal hermetically sealed, the temperature of the detector must be kept relatively constant. Temperature changes $> 2 \text{ }^\circ\text{C}\cdot\text{h}^{-1}$ will often shatter the detector.

Figure 5. Anger camera components.

Light Pipe

The scintillation light generated in the crystal is turned into electronic signals by an array of photomultiplier tubes (PMTs). These signals provide both event energy and localization information. It is desirable that the magnitude of the signal from the photomultiplier tube be linearly related to the event location as shown in Fig. 6. However, when the PMTs are in close proximity to the crystal, the relationship between the signal magnitude and the event location is very nonlinear. In early designs of the Anger camera, a thick transparent material referred to as a light pipe was coupled to the crystals to improve spatial linearity and uniformity. Glass, lucite, and quartz have been used for this purpose. Design enhancement of the light pipe included sculptured contouring to improve light collection and scattering patterns at the PMT interface to reduce positional nonlinearities (Fig. 7). In the past decade, many of the spatial nonlinearities have been corrected algorithmically operating on digitized PMT signals. This has allowed manufacturers to either reduce the thickness of the light pipe or completely eliminate it (2,16,17).

PMT Array

The visible light generated by the absorption of a gamma ray in the NaI(Tl) crystal carries location and energy information. The intensity of the scintillation is directly proportional to the energy absorbed in the event. To use this information, the scintillation must be converted into an electronic signal. This is accomplished by photomultiplier tubes. In a PMT, the scintillation light liberates electrons at the photocathode and these electrons are amplified through a series of dynodes. The overall gain available from a photomultiplier tube is on the order 10^6 .

Photomultiplier tubes are manufactured in a wide variety of shapes and sizes. Those with circular, hexagonal, and square photocathodes have all been used in Anger cameras. Hexagonal and square PMTs offer some advantages for

Figure 6. Photomultiplier tube response with source position. The ideal response can be approximated by interposing a light pipe between the crystal and photomultiplier tube.

close packing the PMTs over the surface of the detector. However, the sensitivity of all PMTs falls off near the edge of the field, so that “dead” space between the PMTs is unavoidable.

It is important to determine the energy of the detected event. Gamma rays that are totally absorbed produce a scintillation signal that is directly proportional to the gamma-ray energy. Thus, the signal resulting from the unweighted sum of the PMTs represents gamma-ray energy. This signal is sent to a pulse height analyzer. Scattered radiation from within the patient can be rejected by setting an energy window to select events that have resulted from the total absorption of the primary gamma ray. Gamma rays that have been scattered in the patient necessarily lose energy and are (largely) not included.

The position of the gamma-ray event on the detector is determined by summing weighted signals from the PMTs (2,6,7,12,16,18,19). Each PMT contributes to four signals:

X^+, X^-, Y^+, Y^- . The magnitude of the contribution is determined both by the amount of light collected by the PMT and its weighting factor. For the tube located exactly at the center of the detector, the four weighting factors are equal. A tube located along the x axis on the left side (e.g., tube 5 in Fig. 4) contributes equally to Y^+ and Y^- , has a large contribution to X^- , and a small contribution to X^+ . In Anger’s original design, the weighting factors were provided by capacitors with different levels of capacitance (Fig. 4). In commercial units, the capacitor network was replaced by resistors (Fig. 8). In the past decades, the resistor weighting matrix has been largely supplanted by digital processing where nonlinear weighting factors can be assigned in software (Fig. 9).

It is clear that PMTs located near the event collect most of the scintillation light while those far away get relatively little. Because each PMT has an unavoidable noise component, the PMTs that receive the least light increase the error associated with the event localization. Initially, all the PMTs were included. Later, in order to eliminate PMTs that have little real signal, diodes were used to set current thresholds. In digital Anger cameras, the PMT thresholds are set in software (20–22).

The weighted signals from the PMTs are summed together to generate four position signals: X^+, X^-, Y^+ , and Y^- . The X and Y locations are determined from: $(X^+ - X^-)/Z$ and $(Y^+ - Y^-)/Z$, where Z is the energy signal found from the unweighted sum of the PMT signals discussed above. This energy normalization is necessary to remove the size dependence associated with the intensity of the scintillation. This is not only important for imaging radionuclides with different gamma-ray energies, but it also improves the spatial resolution with a single gamma ray energy because of the finite energy resolution of the system. The energy signal is also sent to a pulse height analyzer where an energy window can be selected to include only those events associated with total absorption of the primary gamma.

Figure 7. The light pipe is a transparent light conductor between the crystal and the photomultiplier tubes. The sculpturing grooves and black dot pattern spread the light to improve the positioning response of the photomultiplier tube.

Image Generation

Anger camera images are generated in the following way (see Fig. 10). A gamma ray is absorbed in the NaI(Tl)

Figure 8. The Anger camera of the 1980s used resistors to provide position weighting factors. The energy signal was used both for normalization and scatter discrimination.

crystal and the resulting scintillation light is sampled by the PMT array to determine the event energy and location. The energy signal is sent to a pulse height analyzer and if the signal falls within the selected energy window, a logic pulse is generated. At the same time, the *X* and *Y* coordinates of the event are determined and the logic pulse from the PHA enables the processing of this information. For many years, Anger camera images were generated photographically with the enabled *X* and *Y* signals intensifying a dot on a cathode ray tube (CRT) viewed by a camera. In modern Anger cameras, the CRT has been replaced with computer memory and the location information is digital. The *X* and *Y* coordinate values, still enabled by the PHA, point to a memory element in a computer matrix. The contents of that memory element are incremented by 1. Information continues to accrue in the computer matrix until the count or time stopping criteria are met.

The image generation described in the previous paragraph is referred to as frame or matrix mode. The information can also be stored in list mode where the *X* and *Y* coordinate of each event is stored sequentially along with a time marker. The list mode data can then be reconstructed at a later time to any desired time or spatial resolution.

Collimation

In order to produce an image of a radionuclide distribution, it has to be projected onto the detector. In a conventional camera, image projection is accomplished by the camera lens. However, gamma rays are too energetic to be focused with optics or other materials. The first solution to projecting gamma-ray images was the pinhole collimator. The pinhole collimator on an Anger camera is conceptually identical to a conventional pinhole camera. There is an inversion of the object and the image is magnified or minified depending on the ratio of the pinhole to detector distance and the object to pinhole distance. Pinhole collimators are typically constructed out of tungsten and require lead shielding around the “cone”. Because the amount of magnification depends on the source to pinhole distance, pinhole images of large, three-dimensional (3D) distributions are often distorted. In addition, the count sensitivity falls off rapidly for off-axis activity. A better solution for most imaging situations is a multiholed parallel collimator (Fig. 11). As the name implies, the parallel collimator consists of a large number of holes with (typically) lead septae. Most parallel collimators have hexagonal holes that are ~ 1.5 mm across and are 20–30 mm long. The septal walls are typically 0.2 mm thick. The parallel hole collimator produces projections with no magnification by brute force. Gamma rays whose trajectories go through the holes reach the detector while those with trajectories that intersect the septae are absorbed. Less than 1 out of 5000 gamma rays that hit the front surface of the collimator are transmitted through to the detector to form the image (2,7,11,12,20,23,24).

Figure 9. Digital Anger camera electronics. The photomultiplier tube signals are digitized so that signal weighting, energy and position determination are performed in software rather than with digital electronics.

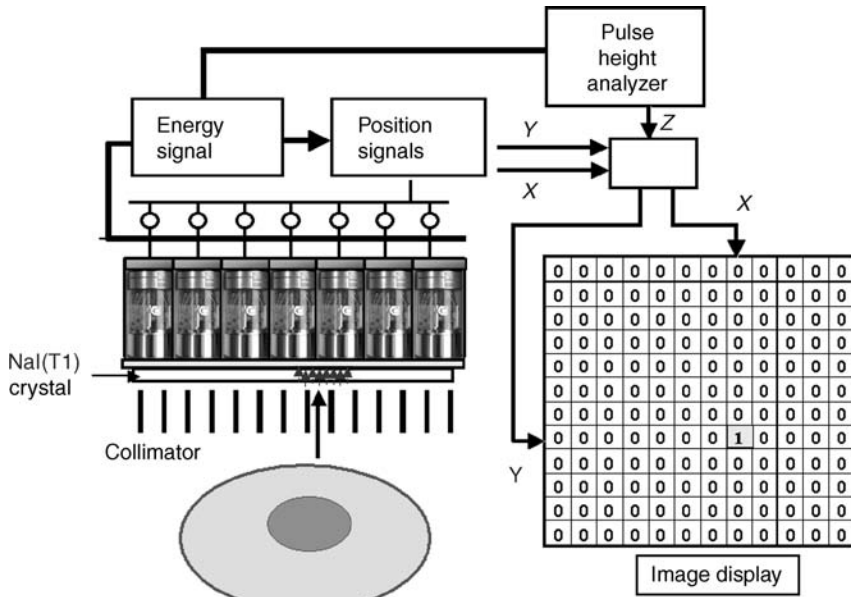

Figure 10. Schematic of Anger camera showing how image information is acquired.

Figure 11. Collimation. Collimators are the image forming aperture of the Anger Camera, but are also the limiting component in spatial resolution and count sensitivity.

The spatial resolution of the collimator, R_{col} , is determined by the hole size (d), hole length (L), and the source to collimator distance (D): $R_{col} = d(L + D)/L$. The efficiency of a parallel hole collimator is expressed as $K^2(d/L)^2 (d/d + t)^2$, where K is a shape factor constant equal to 0.26 and t is the septal wall thickness. Collimation design is an optimization problem since alterations in d and L to improve resolution will decrease count sensitivity. Collimator spatial resolution has a strong dependence on the source to collimator distance. As shown in Fig. 12, the spatial resolution rapidly falls with distance. However, the count sensitivity of a parallel hole collimator is *not* affected by the source distance because the parallel hole geometry removes the divergent rays that are associated with the inverse square loss. Another factor that influences collimator design is the energy of the gamma ray being imaged. Higher energy gamma rays require thicker septae and

Figure 12. Spatial resolution dependence on source to collimator distance.

larger holes resulting in poorer resolution and count sensitivity (2,7,25).

CORRECTIONS

The analog Anger camera had a number of limitations because of nonlinearities in the position signals and because of the uneven light collection over the NaI(Tl) crystal. As digital approaches became viable over the last two decades, a number of corrections to improve energy, spatial, and temporal resolution have evolved. All of these corrections, and particular those involving spatial and energy resolution, require system stability. This challenge was significant because of the variation in PMT output associated with environmental conditions and aging. In order for corrections to be valid over an extended period of time, a method to insure PMT stability has to be implemented. Several different approaches have evolved. In one method, PMT gains are dynamically adjusted to maintain consistent output signals in response to stabilized light emitting diodes (LEDs). An LED is located beneath each PMT where its light is sampled 10–100 times·s⁻¹. Gains and offsets on the PMTs are adjusted so that the resulting signal is held close to its reference value. Another approach uses the ratio of photopeak/Compton plateau counts from a ^{99m}Tc or ⁵⁷Co source as the reference.

Flood Field Image

When the Anger camera is exposed to a uniform flux of gamma rays, the resulting image is called a flood field image. Flood field images are useful for identifying non-uniform count densities and may be acquired in two different ways. An intrinsic flood field is obtained by removing the collimation and placing a point source of activity 1.5–2 m from the detector. An extrinsic flood field is obtained with the collimator in place and with a large, distributed source (often called a flood source) placed directly on the collimator. Flood field sources using ⁵⁷Co are commercially available. Alternatively, water-filled flood phantoms are available into which ^{99m}Tc or other radionuclide can be injected and mixed.

Energy Correction

The energy signal represents the total energy absorbed in a gamma-ray interaction with the detector. This signal is determined by the intensity of the scintillation and by how much of the scintillation light is captured by the PMTs. Because the efficiency for sampling the scintillation is position dependent, there are fluctuations in the energy signals across the detector as shown in Fig. 13. These variations degrade energy resolution and have a significant effect on the performance of the scintillation camera that limit corrections for nonuniformity. The idea of using a reference flood field image to correct nonuniformities has been around for a long time. However, if the reference flood field image is acquired with little or no scattered radiation (as it often is), the correction factors are not appropriate during patient imaging. The reason is that scattered radiation and the amount of scatter entering the selected energy

Figure 13. Energy correction. Local spectral gain shifts are evident across the crystal because of the variable sampling imposed by the photomultiplier tube array.

window will be position dependent. Energy correction electronics was introduced in the late 1970s that essentially generated an array of energy windows that are adjusted for the local energy spectra. Typically, the detector field of view is sampled in a 64 × 64 matrix and a unique energy window is determined for each matrix element. With the energy windows adjusted on the local photopeaks, the variations in the scatter component are greatly reduced. As shown in Fig. 13, energy correction does not significantly improve intrinsic field uniformity. Its role is to reduce the influence of source scatter on the other correction factors (11,20,26–28).

Spatial Linearity Correction

The nonlinearities in the PMT output with respect to source location causes a miss-positioning of events when Anger logic is used. This finding can be demonstrated by acquiring an image of a straight line distribution or a grid pattern. The line image will have a “wavy” appearance (Fig. 14). In the early 1980s, a method to improve the spatial linearity was developed. An imaging phantom array of precisely located holes in a sheet of lead is placed on the uncollimated detector and is exposed to a point source of ^{99m}Tc located 1–2 m away. The image of the hole pattern is used to calculate corrective *x* and *y* offsets for each point in the field of view. These correction factors are stored in a ROM. When an event is detected and the Anger logic produces *x* and *y* coordinates, the offsets associated with these coordinates are automatically added generating the new, accurate event location. Improving the spatial linearity has a profound affect on field uniformity as can be seen in Fig. 14 (17,28–31).

Uniformity Correction

After the energy and spatial linearity corrections have been made, there are still residual nonuniformities that are present in a flood field image. Typically, these will vary < 10% from the mean count value for the entire field. A high count reference flood field image can be acquired and

Figure 14. Spatial linearity correction. Accurate correction for inaccurate event localization has a profound effect on field uniformity.

this image is then used to generate regional flood correction factors that are then applied to subsequent acquisitions (Fig. 15) (17,29,32).

Pulse Pileup Correction

An Anger camera processes each detected event sequentially. Because the scintillation persists with a decay time of 230 ns, pulses from events occurring closely in time are distorted from summation of the light. This distortion is referred to as pulse pileup. As the count rate to the detector increases, the amount of pulse pileup also increases and becomes significant at count rates > 30,000 cps. For much of conventional nuclear medicine imaging, this is not a

Figure 15. Uniformity correction. Residual non-uniformities can be reduced by skimming counts based on a reference flood field image.

problem since the count rate is typically well below that level. There are certain applications such as coincidence positron emission tomography (PET) imaging where the detectors are exposed to event rates that can exceed 1,000,000 cps. Because the Anger logic used to establish the event location is essentially a centroid method, pulse pileup causes errors. An example of this is shown in Fig. 16, which shows an Anger camera image of four high-count rate sources. In addition to the actual sources, false images of source activity between the sources are also observed (33,34). The effects of pulse pileup can be minimized by electronic pulse clipping, where the pulse is forced to the baseline before all the light has been emitted and processed. While this increases the count rate capability, it compromises both spatial and energy resolution, which are optimal when the whole pulse can be sampled and integrated. One approach to reduce losses in spatial and energy resolution is to alter the integration time event-by-event, based on count rate demands. In addition, algorithms have been developed that can extrapolate the pulse to correct for

Figure 16. Pulse pileup correction. Pulse pileup correction improves the count rate capability and reduces the spurious placement of events.

its contribution to a second pileup pulse. This process can be repeated if a third pileup is also encountered. When this correction is performed at the PMT level, it reduces the “false” source images discussed above (35).

PERFORMANCE

Uniformity

When the Anger camera is exposed to a uniform flux of gamma rays, the image from that exposure should have a uniform count density. Anger cameras with energy, spatial linearity, and uniformity correction are uniform to within 2.5% of the mean counts.

Intrinsic Spatial Resolution

The intrinsic spatial resolution refers to the amount of blurring associated with the Anger camera independent of the collimation. It is quantified by measuring the full width at half-maximum (fwhm) of the line spread response function. The intrinsic spatial resolution for Anger cameras varies from 3 to 4.5 mm depending on the crystal thickness and the size of the PMTs. Another way of evaluating intrinsic spatial resolution for gamma-ray energies < 200 keV is with a quadrant bar phantom consisting of increasingly finer lead bar patterns where the bar width is equal to the bar spacing (Fig. 17). Typically an Anger camera can resolve a 2 mm bar pattern.

Extrinsic Spatial Resolution

The extrinsic spatial resolution, also referred to as the system spatial resolution, refers to the amount of blurring associated with Anger camera imaging. It depends on the collimation, gamma-ray energy, and the source to collimator distance. The standard method for determining the extrinsic resolution is from the fwhm of the line spread response function generated from the image of a line source positioned 10 cm from the collimator. Typical values for the extrinsic spatial resolution range from 8 to 12 mm.

Figure 17. Intrinsic spatial resolution is routinely assessed with bar pattern images. An Anger camera can typically resolve the 2 mm bar pattern.

Energy Resolution

The energy signal generated from gamma-ray absorption in the detector has statistical fluctuations that broaden the apparent energy peaks of the gamma rays. Energy resolution is determined from $100\% \times \text{fwhm}/E_\gamma$, where fwhm is of energy peak and E_γ is the gamma-ray energy. At 140 keV the energy resolution of an Anger camera is 10%. Good energy resolution is important because it permits the discrimination of scattered radiation from the patient. Gamma rays that are scattered in the patient necessarily lose energy and these scattered photons degrade image quality.

Spatial Linearity

Spatial linearity refers to the accurate positioning of detected events. On an Anger camera with spatial linearity correction, the misplacement of events is < 0.5 mm.

Multindow Spatial Registration

Because the Anger camera has energy resolution, it can acquire images from radionuclides that emit more than one gamma ray or from two radionuclides. However, the images from different energy gamma rays may have slightly different magnifications or have offsets because of imperfections in the energy normalization. The multiwindow spatial registration parameters quantifies the misalignment between different energy gamma rays (Fig. 18). For Anger cameras, the multiwindow spatial registration is < 2 mm, which is well below the system spatial resolution and therefore is not perceptible.

Count Rate Performance

The count rate capability of Anger camera ranges from 100,000 to 2,000,000 cps depending on the sophistication of the pulse handling technology as discussed above. Anger cameras that are used for conventional nuclear medicine imaging are designed to operate with maximum count rates of 200,000–400,000 cps range, whereas Anger cameras that are used for coincidence imaging require count rate capabilities that exceed 1,000,000 cps (25,28,30,32,36–41).

Figure 18. Multi-window spatial registration refers to ability to accurately image different gamma ray energies simultaneously. The figure on the right is an example of poor multi-window spatial registration.

SUMMARY

The Anger camera has been the primary imaging device in nuclear medicine for > 30 years and is likely to remain in that role for at least the next decade. Although it has evolved with the development of digital electronics, the basic design is essentially that promulgated by H.O. Anger. Special purpose imaging instruments based on semiconductor cadmium zinc telluride detectors are actively being pursued as imaging devices for ^{99m}Tc and other low energy gamma emitters. Their pixilated design removes the need for Anger logic position determination and the direct conversion of the absorbed energy into an electronic signal removes the need for photomultiplier tubes allowing compact packaging. However, over the range of gamma-ray energies encountered in nuclear medicine, NaI(Tl) still provides the best efficiency at a reasonable cost.

INTRODUCTION

The most commonly performed test is the evaluation of anorectal function. These tests can provide useful information regarding the pathophysiology of disorders that affect defecation, continence, or anorectal pain. Anorectal manometry quantifies anal sphincter tone and assesses anorectal sensory response, recto anal reflexes, and rectal compliance. Sensory testing is usually performed along with anorectal manometry and is generally considered a part of the manometry.

The functional anatomy of the anorectum, the equipment, and the technique used for performing anorectal manometry and the parameters for measuring and interpreting the test are described in this article. The indications for anorectal manometry are shown in Table 1.

FUNCTIONAL ANATOMY AND PHYSIOLOGY OF THE ANORECTUM

The neuromuscular integrity of the rectum, anus, and the pelvic floor musculature help to maintain normal fecal continence and evacuation. The rectum is an S-shaped muscular tube, which serves as a reservoir and as a pump for emptying stool. The anus is a 2–4 cm long muscular cylinder, which at rest forms an angle with the axis of the rectum of $\sim 90^\circ$. During voluntary squeeze the angle becomes more acute, $\sim 70^\circ$, and during defecation, the

angle becomes more obtuse, $\sim 110\text{--}130^\circ$ (1,2). The puborectalis muscle, one of the pelvic floor muscles, is responsible for these changes. The anal canal is surrounded by specialized muscles that form the anal sphincters [internal anal sphincter (IAS) and the external anal sphincter (EAS)]. The IAS is 0.5 cm thick and is an expansion of circular smooth muscle layer of the colon. It is an involuntary muscle innervated by fibers of the autonomic nervous system. The EAS is composed of striated muscle, is 0.6–1 cm thick, and is under voluntary control (3). The anus is normally closed by the tonic activity of the IAS. This barrier is reinforced during voluntary squeeze by the EAS. The IAS contributes $\sim 70\text{--}85\%$ of the resting anal pressure. The IAS does not completely seal the anal canal and requires the endo-anal cushions to interlock and seal the canal. The anal mucosal folds, together with the expansive anal vascular cushions, provide a tight seal. These barriers are further augmented by the puborectalis muscle, which forms a flap-like valve that creates a forward pull and reinforces the anorectal angle to prevent fecal incontinence (3,4). The rectum and the IAS are innervated by the autonomic nervous system. The EAS and the anoderm are supplied by somatic nerves. The mucosa of the rectum and proximal anal canal is lack of somatic sensory innervation. The pudendal nerve, arising from second, third, and fourth sacral nerves is the principal somatic nerve and innervates the EAS, the puborectalis muscle, and the anal mucosa (5).

EQUIPMENT FOR ANORECTAL MANOMETRY

The manometric system has two major components: the manometric probe and the pressure recording apparatus. Several types of probes and pressure recorders are available. Each system has distinct advantages and disadvantages. The most commonly used probes and recording devices are reviewed here (6).

Water-Perfused Catheter

This catheter has multiple canals through which water is perfused slowly using a pneumohydraulic pump (Arndorfer, Milwaukee, WI; MUI Scientific Ltd., Toronto, Canada). The infusion rate is $0.5 \text{ mL} \cdot \text{canal}^{-1} \cdot \text{min}^{-1}$. In the catheter with helicoidal configuration the side holes of the canals are arranged radially and spaced 1, 2, 3, 4, 5, and 8 cm from the "0" reference point. A compliant balloon is tied to one end of the probe, which has a 200 mL capacity. The catheter is placed inside the anorectum, but the pressure transducers are located outside the body and across the flow of water. Resistance generated to the flow of water by luminal contractile activity is quantified as intraluminal pressure. The transducers located on the perfusion pump and the perfusion ports must be at the same level during calibration and when performing the study. The maintenance of the water perfused system requires relatively skilled personnel and air bubbles in the water tubing can affect the pressure recordings. The probe and the recording system are inexpensive and versatile. The closely spaced pressure sensors along the probe can record rectal and anal canal pressures and discriminate between EAS and IAS activity (7).

Table 1. Indications for Anorectal Manometry

Rectal prolapse
Functional anorectal pain
Neurological diagnostic investigations
Biofeedback training
Pre- and Postsurgery (pouch)

Solid-State Probe

This system has pressure sensors (microtransducers) that are mounted on the probe. This allows more accurate measurement by placing the pressure sensors directly at the source of pressure activity. The transducers are true strain gauge, that is, they consist of a pressure sensitive diaphragm with semiconductor strain gauges that are mounted on its inner surface. Currently, this is the most accurate catheter system for performing manometry (8). It is user friendly, offers higher fidelity, and is free of limitations imposed by the perfused system. However, it is expensive.

Amplifier–Recorder

The pressure signals that are obtained from the transducer are amplified and recorded on computerized small size amplifiers and recorders (e.g., Polygraph-Medronics/Functional Diagnostics, Minneapolis, MN; Insight, Sandhill Scientific Ltd. Littleton, CO; 7-MPR, Gaeltec, Isle of Sky, UK, and others). They are small, compact, and not only serve as amplifiers and recorders, but also facilitate analysis of data and provide convenient storage for future retrieval of data or for generating a database. No one system is ideal, although each has its strengths and weakness.

STUDY PROTOCOL

General Instructions for Patients Undergoing Anorectal Manometry

In order to maximize uniformity, the manometry should be accomplished with the rectum emptied of feces. The preparation cannot be indispensable for incontinent patients. Constipated patients must be examined several hours after a 500 mL tap water enema or a single Fleets phospho-soda enema. Patients may continue with their routine medications, but the medications should be documented to facilitate interpretation of the data. Patients may eat or drink normally up to the time of the test. Upon arrival at the motility laboratory, the patient may be asked to change into a hospital gown.

The duration of the test is ~ 1 h. The manometry catheter is inserted into the rectum while patients lie on their left side. Patients will feel movement of the catheter and distension of the balloon. After the test, patients can drive home and resume their usual work and diet. It is a safe procedure. There should be little, if any, discomfort during manometry. No anesthetic is used. Absolute contraindication to manometry is recent surgery of the rectum and anal canal, relative contraindication is a poorly compliant patient and rectum loaded with stool.

Patient Position and Digital Examination

It is recommended that the patient is placed in the left lateral position with knees and hips bent to 90°. After explaining the procedure, a digital rectal examination is performed using a lubricated gloved finger. The presence of tenderness, stool, or blood on the finger glove should be noted.

Probe Placement

Next, the lubricated manometry probe is gently inserted into the rectum and oriented such that the most distal sensor (1 cm level) is located posteriorly at 1 cm from anal verge. The markings on the shaft of the probe should aid this orientation.

Run-in Time

After probe placement, a rest (run-in) period should be allowed (~ 5 min) to give the subject time to relax and allow the sphincter tone to return to basal levels.

Resting Anal Pressure

Currently, two methods are available for assessing this function (9). *Station pull-through*: In this technique, the most distal sensor of a multiport catheter assembly is placed 5 cm above the anal margin. At every 30 s intervals, the catheter is withdrawn by 0.5 cm either manually or with a probe withdrawal device (10). As the sensors straddle the high pressure zone, there is a step up of pressure. The length and the highest pressure of the anal sphincter is then measured. Because pull-through excites anal contraction and the individual is conscious of these movements, the recorded pressure is high (10). For the same reason, a rapid pull through is not an accurate method and is not advisable for measuring anal sphincter function. *Stationary method*: Uses radially arranged multiport catheter, at least three sensors, 1 cm apart that is placed in the anal sphincter zone, that is, 0–3 cm from the anal verge (11). After allowing the tracings to stabilize, the highest sphincter pressure that is observed at any level in the anal canal is taken as the maximum resting sphincter pressure. Resting pressures can be expressed as the average obtained from each transducer or as a range to identify asymmetry of anal canal pressures (12).

Normal anal canal pressures vary according to sex, age, and techniques used (10). Normal values for anorectal manometry are shown in Table 2. There are normal variations in external sphincter pressures both radially and longitudinally (12,14). Anterior quadrant pressures are lower in the oral part of anal canal while posterior quadrant pressures are lower in the distal part of the anal canal. In the mid-anal canal, pressures are equal in all four quadrants. Manometry also enables routine calculation

Table 2. Suggested List of Tests/Maneuver Based on Indication (s)^a

Test	Indications for maneuver	
	Incontinence	Constipation
Resting pressure	Yes	Yes
Squeeze pressure/duration	Yes	No
Cough reflex	Yes	No
Attempted defecation	No	Yes
RAIR	No	Yes
Rectal sensation	Yes	Yes
Rectal compliance	Optional	Optional

^aFrom Ref. 13 with permission.

of anal canal length. Overall pressures are higher in men and younger persons and men have longer anal canals than women. But there is considerable overlap in values and disagreement among various studies about the effect of age and gender on anal canal pressures (10–12,15). Furthermore, subjects with values outside the normal range may not have clinical symptoms and patients with clinical symptoms may exhibit normal values (16).

Squeeze Sphincter Pressure

This pressure can be measured with either the station pull-through or the alternative technique. In the station pull-through technique; after placing the multiport assembly as describe above, at each level the subject is asked to squeeze and to maintain the squeeze for as long as possible (at least 30 s). Alternatively, with a multiport catheter in place, the subject is instructed to squeeze on three separate occasions, with a minutes' rest between each squeeze to allow for recovery from fatigue. The average of the three highest sphincter pressures recorded at any level in the anal canal is taken as the maximum anal squeeze pressure (13). The duration of maximum sustained squeeze should also be determined and is defined as the time interval in seconds during which the subject can maintain a squeeze pressure at or above 50% of the maximum pressure.

Weak squeeze pressures may be a sign of external sphincter damage, neurological damage of the motor pathways, or a poorly compliant patient. Squeeze pressures should be evaluated together with response to cough reflex (16).

Response to Increases in Intraabdominal Pressure

An increase in intraabdominal pressure brought about by asking the subject to blow up a party balloon or by coughing is associated with a reflex increase in the activity of the EAS (11); also called the cough reflex. This reflex response causes the anal sphincter pressure to rise above that of the rectal pressure so that continence is maintained. The response may be triggered by receptors in the pelvic floor and mediated through a spinal reflex arc. In patients with complete supra conal spinal cord lesions, this reflex response is present, but the voluntary squeeze may be absent whereas in patients with lesions of the cauda equina or of the sacral plexus, both the reflex response and the voluntary squeeze are absent.

Rectoanal Pressure Changes During Attempted Defecation

In this maneuver, the subject is asked to bear down, and simulate the act of defecation. The side holes of catheter are located within the anal canal and the rectal balloon is kept inflated. The normal response consists of an increase in rectal pressure coordinated with a relaxation of the intra-anal pressure. Alternatively, there may be a paradoxical increase in anal canal pressures, or absent relaxation or incomplete relaxation of the anal sphincter (Fig. 1) (17). It must be appreciated that laboratory conditions may induce artifactual changes, which is a learned response and is under voluntary control.

Figure 1. Structures of the anorectum: Reprinted from Ref. 17 with permission from American Gastroenterological Association.

Rectoanal Inhibitory Reflex

This consists of reflex relaxation of the IAS in response to rectal distension. The catheter is positioned with its side holes within the anal canal. Volumes of air are rapidly inflated in the rectal balloon and removed. The inflated time is 10 mL · s. The reflux is evoked with 10, 20, 40, 60, 80, 140, and 200 mL. As the volume of rectal distension is increased, the amplitude and duration of IAS relaxation increases (7). The absolute or relative amplitude of the IAS relaxation depends on the preexisting tone of the IAS and the magnitude of its contribution to the basal anal tone. This reflex may facilitate sampling of rectal contents by the sensory receptors in the upper anal canal and may also help to discriminate flatus, from liquid or solid stools. This reflex is regulated by the intrinsic myenteric plexus. In patients with Hirschsprung's disease and in those with a history of rectal resection and colo- or ileo-anal anastomosis, this reflex is absent. However, in patients with spinal cord injury and in patients with transaction of the hypogastric nerves or lesions of the sacral spinal cord, it is present (18).

Sensory Testing

Rectal Sensory Function. In this technique, the rectal sensory threshold for three common sensations (first detectable sensation, the sensation of urgency to defecate, and the sensation of pain or maximum tolerable volume) is assessed. This can be assessed either by the intermittent rectal distension or by the ramp inflation method.

Intermittent Rectal Distension. This technique is performed by inflating a balloon in the rectum using a handheld syringe. After each inflation, the balloon is deflated completely and after a rest period it is reinflated to the next volume (19).

Ramp Inflation. In this method, the rectum is progressively distended without deflation. This is performed by continuously inflating the balloon at a constant rate with a peristaltic pump or a syringe using increasing volumes of air or fluid or in a stepwise fashion, with a 1 min interval between each incremental inflation of 10–30 cm³. It is known that the type of inflation (phasic vs. continuous) and the speed of continuous inflation affect the threshold

Figure 2. Normal squeeze profile.

volume required for healthy control subjects to perceive distension (20). Also the size and shape of the balloon will affect the threshold volume. Some of this variability can be reduced by using a high compliance balloon and a continuous-infusion pump or a barostat (21).

The maximum tolerable volume or pain threshold may be reduced in patients with a noncompliant rectum (e.g., proctitis) abdominoperineal pull-through, and rectal ischemia (9). Pain threshold also may be reduced in patients with irritable bowel syndrome (22). Higher sensory threshold is seen in autonomic neuropathy, congenital neurogenic anorectal malformations (spinal bifida, Hirschprung's disease, meningocele) and with somatic alteration in rectal reservoir (megarectum, descending perineum syndrome) (20,23). Rectal sensory threshold is altered by change in rectal wall compliance and sensory data should be interpreted along with measurement of rectal compliance (24).

Anal Sensation. At present, assessment of anal canal sensation is not of established value for the diagnosis and treatment of patients with constipation or fecal incontinence (9).

Rectal Compliance

The capacity and distensibility of the rectum are reflected by its compliance. It is a measure of the rectal reservoir function and is defined as the change in rectal volume per unit change in rectal pressure (11). The rectal compliance can be measured by the balloon distension method or more accurately by using a computerized barostat. The higher the compliance, the lower the resistance to distension and vice versa. Low rectal compliance is also seen in patients with acute ulcerative colitis, radiation proctitis, and low spinal cord lesions (20). High compliance is seen in patients with megarectum. Decreased rectal compliance can result in decreased rectal capacity, fecal urgency, and may contribute to fecal incontinence (25).

MANOMETRIC FEATURES OF FECAL INCONTINENCE AND CONSTIPATION

Fecal Incontinence

Anorectal manometry can provide useful information regarding the pathophysiology and management of fecal

incontinence (26). Anal sphincter pressures may be decreased in patients with fecal incontinence; either circumferentially or in one quadrant of the anal canal (Fig. 2). Manometry can also determine if compensatory squeeze pressure can be activated. A reduced resting pressure correlate with predominant weakness of IAS and decreased squeeze pressures correlate with EAS defects (27). Two large studies have reported that maximum squeeze pressure has the greatest sensitivity and specificity in discriminating fecal incontinence from continent and healthy controls (28,29). The ability of the EAS to contract reflexly can also be assessed during abrupt increases of intra-abdominal pressure (e.g., when coughing). This reflex response causes the anal sphincter pressure to rise above that of the intrarectal pressure to preserve continence. This reflex response is absent in patients with lesions of the cauda equina or the sacral plexus (18,30). On sensory testing, both hyper- and hyposensitivity can be seen. Assessment of rectal sensation is useful in patients with fecal incontinence associated with neurogenic problems, such as diabetes mellitus (decrease in rectal sensations) or multiple sclerosis (increase in rectal sensation) (31). In some patients, rectal sensory thresholds may be altered because of changes in the compliance of the rectal wall. Patients with megarectum have decreased rectal sensation; and can present with fecal incontinence. Patients with incontinence often have lower rectal compliance (i.e., chronic rectal ischemia, proctitis).

Because of the wide range of normal values in anorectal physiologic testing, no single test can predict fecal incontinence. However, a combination of the tests with clinical evaluation is helpful in assessment of patients with fecal incontinence (32). Anorectal manometry is also useful in evaluating the responses to biofeedback training as well as assessing objective improvement following drug therapy or surgery.

Constipation

Anorectal manometry is useful in the diagnosis of dyssynergic defecation. Manometry helps to detect abnormalities during attempted defecation. Normally, when subjects bear down or attempt to defecate, there is a rise in rectal pressure, which is synchronized with a relaxation of the EAS (Fig. 3). The inability to perform this coordinated

Figure 3. Strain maneuver: A normal coordinated response of the anorectum during attempted defecation shows a rise in rectal pressure associated with a decrease in anal sphincter pressure.

movement represents the chief pathophysiologic abnormality in patients with dyssynergic defecation (17). This inability may be due to impaired rectal contraction, paradoxical anal contraction, impaired anal relaxation, or a combination of these mechanisms (Fig. 4) (Fig. 5). Anorectal manometry also helps to exclude the possibility of Hirschsprung's disease. The absence of the rectoanal inhibitory reflex accompanied by a normal intrarectal pressure increase during distension of the intrarectal balloon is evidence of denervation of the intrinsic plexus at the recto-anal level. Megarectum can cause a falsely negative reflex. In this condition, there is hypotonia of the rectal wall due to a deficiency of viscoelastic properties of the rectum and high degrees of rectal distension are necessary to produce the reflex. In addition to the motor abnormalities, sensory dysfunction may be present. The rectal sensations are reduced in patients with megarectum. The first sensation and the threshold for a desire to defecate may be higher in ~ 60% of patients with dyssynergic defecation (33). The threshold for urge to defecate may be absent or elevated in patients with chronic constipation. Maximum tolerable volume can also be elevated (34). But is not clear whether these findings are the cause or secondary to constipation. When rectal sensation is impaired, neuromuscular conditioning using biofeedback technique can be effective in improving the dysfunction.

Select Appropriate Test/Maneuver

Because anorectal manometry consists of several maneuvers, it is important to determine whether a patient needs all of the maneuvers or only a selection from the array of tests described below. The patient's symptoms and the reason for referral are helpful in choosing the appropriate list. A suggested list is given in Table 3.

Prolonged Anorectal Manometry. It is now feasible to perform anorectal manometry for prolonged periods of time outside the laboratory setting. With the use of this technique, it is possible to measure physiologic functions of the anal sphincter while the person is mobile and free (35). This technique shows promise as an investigational procedure, but its clinical applicability has not been established.

Clinical Utility and Problems with Anorectal Manometry. A systematic and careful appraisal of anorectal function can provide valuable information that can guide treatment of patients with anorectal disorders. Prospective studies have shown that manometric tests of anorectal function provide not only an objective diagnosis, but also a better understanding of the underlying pathophysiology. In

Figure 4. Weak resting and squeeze anal sphincter pressure in a patient with fecal incontinence.

Figure 5. Dyssynergic defecation. During strain maneuver there is rise in intrarectal pressure together with a paradoxical rise in anal sphincter pressure.

addition, it provides new information that could influence the management and outcome of patients with disorder of defecation (36,37).

Anorectal manometry has gained wide acceptance as a useful method to objectively assess the physiology of defecation. However, there are some problems with anorectal physiologic testing. There is a lack of uniformity with regards to the anorectal manometry equipments, methods of performance, and interpretation of the tests. A multiplicity of catheter designs exists, including water-perfused catheters, microtransducers, and microballoons. The techniques of manometric measurement are variable. The catheter can be left at one position (stationary technique), it can be manually moved from one position to another (manual pull through technique), or it can be automatically delivered from one position to another (automatic pull-through technique). If the automated technique is selected, pressure can be recorded while the catheter is at rest or in motion. Pressure can be recorded in centimeters of H₂O, millimeters of mercury (mmHg), or kilopascals (kPa). There is also a relative lack of normative data stratified for age and gender. A more uniform method of performing

these tests and interpreting the results is needed to facilitate a wider use of this technology for the assessment of patients with anorectal disorders. Recently, experts from the American and European Motility Society have described a consensus document, where minimum standards for performing ARM have been described (13). By adopting such standards it is possible to standardize the technique globally that should help diagnosis and interpretation.

Medical Terms:

- Compliance:** It is defined as the capacity of the organ to stretch (expand) in response to an imposed force.
- Defecation:** The discharge of feces from the rectum.
- Distal:** Situated away from the center of the body, or from the point of origin, in contrast to proximal.

Table 3. Normal Manometric Data During Anorectal Manometry^{a,b}

	All (n = 45)	Male (N = 18)	Female (N = 22)
Length of anal sphincter, cm	3.7 (3.6–3.8)	4.0 (3.8–4.2)	3.6 (3.4–3.8)
Maximum anal rest pressure, mmHg	67 (59–74)	71 (52–90)	64 (53–75)
Sustained squeeze pressure, mmHg	138 (124–152)	163 (126–200)	117 (100–134)
Squeeze duration, s	28 (25–31)	32 (26–38)	24 (20–28)
% increase in anal sphincter pressure during squeeze	126 (89–163)	158 (114–202)	103 (70–136)
Rectal pressure when squeezing, mmHg	19 (14–23)	24 (15–33)	16 (11–21)
Anal pressure during party balloon inflation, mmHg	127 (113–141)	154 (138–170)	106 (89–123)
Rectal pressure during party balloon inflation, mmHg	63 (54–72)	66 (51–81)	62 (51–73)

^aMean 95% cl.

^bFrom Ref. 11 with permission.

Dyssynergia:	When an act is not performed smoothly or accurately because of lack of harmonious association of its various components; when there is lack of coordination or dyssynergia of the abdominal and pelvic floor muscles that are involved in defecation it is called dyssynergic defecation
ENS:	Abbreviation for enteric nervous system.
Endoanal Cushion:	Within the anus. Anal mucosal folds together with anal vascular cushion.
High pressure zone:	Intense compression area.
Intrinsic Plexus:	A network or inter-joining of nerves and blood vessels or of lymphatic vessels belonging entirely to a part.
Myenteric Plexus:	A plexus of unmyelinated fibers and postganglionic autonomic cell bodies lying in the muscular coat of the esophagus, stomach, and intestines; it communicates with the subserous and submucous plexuses, all subdivisions of the enteric plexus.
Orad:	In a direction toward the mouth.
Phasic:	In stages, in reference to rectal balloon distension for sensory testing.
Proctalgia:	Pain in the anus, or in the rectum.
Proximal:	Nearest the trunk or the point of origin, in contrast to distal.
Supraconal:	Above a condyle.
Tone:	Normal tension or resistance to stretch.

INTRODUCTION

Sudden cardiac death is estimated to affect ~ 400,000 people annually (1). Most of these cases are precipitated by ventricular fibrillation (VF), a chaotic abnormal electrical activation of the heart. Ventricular fibrillation disturbs systemic blood circulation and causes immediate death if therapy in the form of an electrical shock is not immediately applied. In fact, survival depends dramatically on the time it takes for therapy to arrive (2). Automated arrhythmia

detection is a key component for speeding up defibrillation therapy through medical devices that detect arrhythmia and provide treatment automatically without human oversight. Examples of devices include implantable defibrillators, public access automated external defibrillators, and more.

Arrhythmias generally are an abnormal electrical activation of the heart. These abnormalities can occur in the atrial chambers, ventricular chambers, or both. Since the ventricles are the chambers responsible for providing blood to the body and lungs, disruptions in the electrical system that stimulates the mechanical contraction of the heart can be life threatening. Examples of ventricular arrhythmias include VF and ventricular tachycardia (VT), as seen in Fig. 1. Atrial arrhythmias including atrial fibrillation (AF), atrial flutter (AFL), and supraventricular tachycardia (SVT) are not immediately life threatening, but can cause uncomfortable symptoms and complications over the long term.

Automated arrhythmia analysis is the detection of arrhythmias through the use of a computer. This article focuses on arrhythmia detection performed *without human oversight*. The primary focus will be algorithms developed for the implantable cardioverter defibrillator (ICD). An implantable cardioverter defibrillator is a device that provides an electrical shock to ventricular fibrillation and tachycardia to terminate it and restart NSR. The implantable cardioverter defibrillator was developed in the late 1970s and FDA-approved in the mid-1980s (4–7). A

VT/VF	True positive	False positive
All others	False negative	True negative

catheter placed in the right ventricle is used for both sensing and therapy. This device has a long history of arrhythmia detection algorithms developed in research laboratories and brought to the marketplace. Other medical devices that use purely automated arrhythmia detection include the automatic external defibrillator and the implantable atrial defibrillator. Semiautomated arrhythmia detection is used in ambulatory and bedside monitoring. These topics will be touched on briefly.

It is important to consider the measurements used to assess the performance of automated arrhythmia analysis. Sensitivity is defined as the percent correct detection of disease, while specificity is the percent correct detection of not disease. Take the case of an implantable defibrillator that detects ventricular tachycardia and ventricular fibrillation. Consider the truth table in Table 1.

$$\text{Sensitivity} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Negatives}}$$

$$\text{Specificity} = \frac{\text{True Negatives}}{\text{True Negatives} + \text{False Positives}}$$

A false positive is one minus the specificity, while a false negative is one minus the sensitivity.

Early Work

The earliest examples of computer-based arrhythmia analysis are semiautomated approaches for bedside and ambulatory monitoring. Ambulatory monitoring typically uses a 24 or 48 h, three-lead, portable electrocardiogram (ECG) recorder that the patient wears to diagnosis arrhythmias. Arrhythmia analysis is done in an off-line fashion with technician oversight, such that it is not purely automated (8). Other ambulatory monitors include loop recorders or implanted monitors like Medtronic Reveal Insertable Loop Recorder that permanently records with patient interaction. Clinical bedside monitors typically are also not fully automated, but are used as initial alarms, which is then over read by clinical staff.

In ambulatory monitoring, in addition to detection of arrhythmias, it is typical to also detect premature ventricular contractions (PVCs). These PVCs are beats that form ectopically in the ventricle and result in an early, wide ECG beat and occur alone or in small groups of two or more. They are considered a potential sign of susceptibility to arrhythmias.

Use of correlation is a common tool in surface arrhythmia analysis (9–18). Correlation waveform analysis (CWA) uses the correlation coefficient between a previously stored template of sinus rhythm and the unknown cycle under analysis. The correlation coefficient, used by CWA, is

computed as

$$\rho = \frac{\sum_{i=1}^{i=N} (t_i - \bar{t})(s_i - \bar{s})}{\sqrt{\sum_{i=1}^{i=N} (t_i - \bar{t})^2 \sum_{i=1}^{i=N} (s_i - \bar{s})^2}}$$

where ρ = the correlation coefficient, N = the number of template points, t_i = the template points, s_i = the signal points under analysis, \bar{t} = the average of the template points, and \bar{s} = the average of the signal points. The correlation coefficient falls within a range $-1 < \rho < +1$, where $+1$ indicates a perfectly matched signal and template.

To compute CWA, a beat detector (described in more detail in the section implantable cardioverter defibrillators) finds the location of each beat. From the location of each beat, the template is aligned with the beat under analysis, typically using the peak, and the correlation coefficient is calculated. Often, the template is shifted and the procedure is repeated to determine the best alignment indicated by the highest correlation coefficient. An example of CWA is shown in Fig. 2. Sustained high correlation indicates normal sinus rhythm and low indicates an arrhythmia.

Examples of other features used in PVC and arrhythmia detection include timing, width, height, area, offset, first spectral moment (5–25 Hz), T-wave slope, and others (9,13,14,17,20–24). Another early approach was to develop a database of electrocardiogram templates grouping similar shaped complexes based on shape, width, and prematurity (17,25–28).

Some of the earliest algorithms for *purely automated* arrhythmia detection involved algorithms for newly developing implantable devices for SVT termination and the developing implantable defibrillator (29,30). With problems of inducing ventricular arrhythmias in the devices for SVT termination, focus shifted to the implantable

Figure 2. Example of use of correlation waveform analysis. The first electrogram is the stored normal sinus rhythm template, the second is a NSR beat with correlation equal to 0.999 and the third is a ventricular tachycardia with correlation equal to 0.535. (Used with permission from Ref. 19.)

defibrillator (31,32). In the early 1980s, Furman (29) proposed that two sensors (atrial and ventricular) be required for automatic diagnosis of tachycardia (with even a possible refinement of a third sensor for hestidine (His) bundle detection). He also suggested examining the QRS configuration for a match with sinus rhythm as a schema for diagnosing supraventricular tachycardia. Other early work included the development of algorithms for surface electrocardiography that used an esophageal electrode for analysis of atrial information (33,34).

The original detection mechanism in the first implantable defibrillator, the AICD, was the probability density function (PDF). This algorithm utilized the derivative of the signal to define the duration of time that the signal departed from baseline (31,32) and was empirically based upon the observation that the ventricular fibrillation signal spends the majority of its time away from the electrocardiographic isoelectric baseline when compared to sinus rhythm or supraventricular rhythms (Fig. 1). The PDF was supplanted at a very early stage by intrinsic heart rate measures.

The need to identify and cardiovert ventricular tachycardia in addition to detecting and defibrillating ventricular fibrillation, and the recognition that sufficiently slow VT might have rates similar to those that may occur during sinus rhythm or supraventricular tachycardias resulted in several changes being incorporated into the second generation of devices. An alternative time-domain method called temporal electrogram analysis was incorporated into some second-generation devices (35). This algorithm employed positive and negative thresholds, or rails, placed upon electrograms sensed during sinus rhythm. A change in electrogram morphology was identified when the order of the excursion of future electrograms crossed the predetermined thresholds established during sinus rhythm. The combination of this morphologic method with ventricular rate was intended to differentiate ventricular tachycardia from other supraventricular tachycardias including sinus tachycardia.

Experience with probability density function and temporal electrogram analysis in first- and second-generation devices was disappointing. Probability density function was found to be unable to differentiate sinus tachycardia, supraventricular tachycardia, ventricular tachycardia, and ventricular fibrillation whose respective rates exceeded programmed device thresholds for tachycardia identification (36). A similar experience was encountered with temporal electrogram analysis. As a result, these criteria were utilized less and less frequently as increasing numbers of second-generation devices were implanted. By 1992, < 15% of all ICDs implanted worldwide utilized either algorithm for tachycardia discrimination (37).

IMPLANTABLE CARIOVERTER DEFIBRILLATORS

Over time, the implantable cardioverter defibrillator added capabilities to pace terminate and cardiovert ventricular tachycardia and provide pacemaker functions, single and dual chamber. Early reviews of automated algorithms particularly for implantable defibrillators are given in Refs. 38–40. More recent reviews of automated arrhythmia

detection algorithms include a thorough review by Jenkins and the author in 1996 (41) and reviews incorporating recent developments in dual chamber algorithms in 1998 and 2004 (42,43).

Rate-Based Analysis

The main method for detection of arrhythmias after initial use of PDA and TEA was the use of intrinsic heart rate for detection of ventricular tachycardia and ventricular fibrillation. To this day, all algorithms in ICDs have rate as a fundamental component for detection of arrhythmias. Since implantable defibrillators have a stable catheter screwed in the apex of right ventricle, the rate of the ventricles can be determined with little of the noise that is present at the surface of the body, like motion artifact and electromyogram noise. Ventricular tachycardia and ventricular fibrillation have rates of ~ 120–240 beats per minute and > 240 beats per minute, respectively.

Many approaches abound for arrhythmia detection using rate, but the general procedure is the same (Fig. 3). First, each ECG beat must be detected. Second, the time between beats (or the cycle length) is determined. Most algorithms rely on cycle length (CL) values over beats per minute. The value of the CL determines the zone it falls into: Normal, VT, or VF. In some cases, zones may be further divided depending on the device and therapy options. The thresholds that define the zones are programmable. Each zone has a programmable counter that will determine when therapy will need to be considered. In addition, each zone has a reset mechanism that may be different depending on the zone. For example, typical VT zones require X consecutive beats within the zone or the counter is reset. While VF often has an X of Y criteria, for example, 12 of 16 beats. This flexibility is due to the fact that VF is of varying amplitude, morphology, and rate, such that each beat may not be detected reliably and/or may not be in the VF zone. The CL thresholds, counters, and associated therapies are all programmable.

The fundamental basis of automated rate algorithms is the detection of each beat. Many approaches have been suggested and utilized including fixed thresholds, exponentially varying thresholds, amplitude gain control, and

Figure 3. Typical rate-based arrhythmia detection scheme for implantable cardioverter defibrillators. First, each beat is detected and the cycle length between beats determined. A counter is incremented in the zone that the CL falls and therapy is delivered when the counter reaches a programmed threshold.

Figure 4. Example of beat detector that utilizes an exponentially decaying threshold. After a beat is detected, a blanking period prevents detection of the same beat twice. Then, the threshold (dotted line) for determination of the next beat is calculated as a percentage of the peak amplitude of the previous beat. This threshold exponentially decays, such that beats that are smaller than the currently detected beat will not be missed (47).

others (9,44–46). In implantable devices, most are hardware-based and beyond the scope of this article. For example, one software method relies on an exponentially varying threshold (Fig. 4) (47). After a beat is detected, there is first a blanking period to prevent a beat from being detected more than once. After the blanking period, the threshold for detection of the next beat is set as a percentage of the previous beat. This threshold then decays exponentially such that subsequent beats that have a smaller peak amplitude will be detected. Most beat detectors also have a floor for the threshold, that is, the smallest amplitude by which a beat can be detected to prevent detection of noise as a beat.

An example of one rate-based algorithm is given in Fig. 5 (40). This algorithm uses three CL thresholds, fibrillation detection interval (FDI), fast tachycardia interval (FTI), and tachycardia detection interval (TDI), and two counters, VF counter (VFCNT) and VT counter (VTCNT). These are combined to result in three zones, VF, fast VT, and slow VT, which can have different therapeutic settings, utilizing defibrillation shock, cardioversion, and antitachycardia pacing. Therapy for ventricular fibrillation is given when 18 of 24 beats are shorter than the FDI. Therapy for slow ventricular tachycardia is delivered when 16 beats counted by the VTCNT are between the FDI and TDI thresholds. The VTCNT will be reset by one long CL greater than TDI. The fast VT zone is a combination of these techniques.

A thorough description of the rate-based algorithms is given in Ref. 40. While many additional features have been added to refine the decision, the main structure of auto-

mated arrhythmia detection algorithms still rely on this fundamental approach (42).

As can be seen from Fig. 1, heart rate in VT and VF increase substantially over normal sinus rhythm. This is a reliable means of detecting VT and VF for implantable devices, resulting in high sensitivity. Unfortunately, while providing high sensitivity, heart rate also increases for normal reasons, exercise, stress, resulting in sinus tachycardia or for nonventricular-based arrhythmias like atrial fibrillation, supraventricular tachycardia, atrial flutter, and so on, which do not require therapy from the ICD. Thus, rate-based algorithms have low specificity. False therapies have been estimated in as much as 10–40% in the early devices (48–50). Morphology and other extended algorithmic approaches have long been suggested as a means to increase specificity.

Early rate-based algorithms to prevent false therapies, due to sinus tachycardia, atrial fibrillation, and so on, include onset and rate stability. Rate-based methods were chosen initially over morphology due to the simplicity of calculations in battery operated devices.

Onset is the difference between the rate changes during the onset of sinus tachycardia compared to those of VT, since the onset of VT is typically sudden compared to sinus tachycardia. False therapies due to sinus tachycardia are determined by onset. Figure 6a shows the sudden onset of ventricular tachycardia.

Rate stability is used to prevent false therapies due to AF. In AF, it is common for the ventricle to respond to the atrium at a fast rate. This response is typically irregular since atrial fibrillation, by definition has an irregular rate,

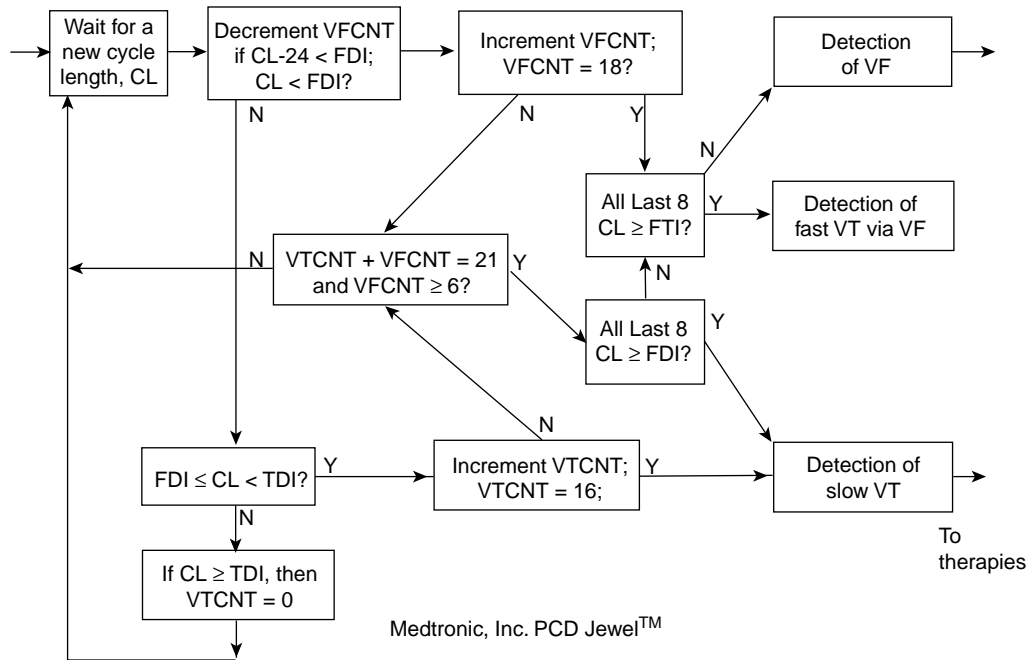

Figure 5. Example of rate-based algorithm for the Medtronic PCD Jewel. The VFCNT is the VF counter, FDI is the fibrillation detection interval, FTI is the fast tachycardia interval, VTCNT is the VT counter, and TDI is the tachycardia detection interval. This algorithm has three zones that has associated programmable therapies including defibrillation shock, cardioversion, and antitachycardia pacing (40).

and since not every beat is conducted from the atrium to the ventricle. Rate stability considers the stability of the ventricular rate, since VT typically has a stable rate compared to the ventricular response to atrial fibrillation. Figure 6b shows an irregular ventricular response to atrial flutter.

Rate and rate-derived measures that measure onset and stability (based on cycle-by-cycle interval measurements) include average or median cycle length, rapid deviation in cycle length (onset), minimal deviation of cycle length (stability), and relative timing measures in one or both chambers or from multiple electrodes within one or more chambers. Among the methods most widely used for detection of VT in commercially available single chamber antitachycardia devices have been combinations of rate, rate stability, and sudden onset (51–56). Pless and Sweeney published an algorithm for (1) sudden onset, (2) rate stability, and (3) sustained high rate (57). This schema among others (58,59) was a forerunner of many

of the methods introduced into tachycardia detection by ICDs (60).

Morphological Pattern Recognition

Instead of relying purely on rate, it has been suggested that morphology may provide the means for automated arrhythmia detection to separate VT and VF from rhythms with fast rates that do not need therapy. Morphology in this context refers to characteristics of the electrogram waveform itself, which are easily identifiable and measurable. Such features might include peak-to-peak amplitude, slew rate (a measure of waveform), sequence of slope patterns, sequence of amplitude threshold crossings, statistical pattern recognition of total waveform shape by correlation coefficient measures, and others (61,62). Figure 1 shows an example of distinctly different waveforms recorded from the right ventricular apex during SR, VT, and VF (3). Furthermore, morphology in the ventricle appears normal

Figure 6. Atrial (top) and ventricular (bottom) electrograms. (a) Sudden onset of VT with normal atrial electrogram, (b) irregular response of ventricular to atrial flutter, (c) simultaneous atrial flutter and ventricular tachycardia, and (d) sudden onset of supraventricular tachycardia with ventricular response.

even during supraventricular arrhythmias since the rhythm typically is conducted normally in the ventricles.

The ICDs often have two channels of electrograms. The first channel is typically bipolar, which is associated with two electrodes on the lead, or an electrode–coil combination, both located within the ventricle. This channel provides a near-field electrical view of the ventricle and is usually used for beat detection because the electrogram typically has a narrow QRS (the main depolarization of the electrogram). The second electrode configuration is far-field which, for example, may use an electrode in the ventricle versus the implantable device casing. The far-field electrode combination is used primarily for giving the electrical shock. However, this far-field view typically has a more global perspective of the electrogram depolarization and is helpful in differentiating the morphology changes between normal beats and ventricular abnormalities.

Template-Based Algorithms

Correlation Waveform Analysis. Lin et al. (19,62,63) investigated three techniques for morphologic analysis of VT: correlation waveform analysis, amplitude distribution analysis, and spectral analysis. Correlation waveform analysis (CWA) is a classic method of pattern recognition applied to the surface electrocardiogram, described earlier, but was first applied to intracardiac signals in this study. Correlation waveform analysis was shown to be superior and has the advantage of being independent of amplitude and baseline fluctuations. However, it requires heavy computational demands. Less computationally demanding algorithms based on the same principle have been developed and are described in the next section.

Less Computationally Demanding Template-Based Algorithms. Another template matching algorithm based on raw signal analysis measured the area of difference between electrograms, that is, adding absolute values of the algebraic differences between each point on the electrogram and corresponding point on the SR template (64,65). The area of difference was expressed as a percentage of the total area of the template. The measurement of an area of difference is simple computationally, but has the disadvantage of producing erroneous results in the face of baseline and amplitude fluctuations, and this method fails to produce a bounded measure. An improvement on this technique by signal normalization and scaling to create a metric bounded by ± 1 was utilized by Throne et al. (66).

Steinhaus et al. (67) modified correlation analysis of electrograms to address computational demand by applying data compression to filtered data (1–11 Hz) by retaining only samples with maximum excursion from the last saved sample. The average squared correlation coefficient (ρ^2) was used for separation of SR and VT. Comparison with noncompressed correlations demonstrated that data compression had negligible effects on the results.

Throne et al. (66) designed four fast algorithms and compared discrimination results to CWA performance. These morphological methods were the bin area method (BAM); derivative area method (DAM); accumulated difference of slopes (ADIOS); and normalized area of difference (NAD). All four techniques are independent of ampli-

tude fluctuations and three of the four are independent of baseline changes.

The bin area method is a template matching algorithm that compares corresponding area segments or bins of the template with the signal to be analyzed. Each bin (average of three consecutive points) is adjusted for baseline fluctuations by subtracting the average of the bins over one cycle and normalized to eliminate amplitude variations. This BAM equation is given in the following equation:

$$\rho = 1 - \sum_{i=1}^{i=M} \left| \frac{T_i - \bar{T}}{\sum_{k=1}^{k=M} |T_k - \bar{T}|} - \frac{S_i - \bar{S}}{\sum_{k=1}^{k=M} |S_k - \bar{S}|} \right|$$

where the bins are $S_1 = s_1 + s_2 + s_3$, $S_2 = s_4 + s_5 + s_6, \dots$, $S_M = s_{N-2} + s_{N-1} + s_N$ and the average of M bins is calculated similarly for the template. The BAM metric falls between -1 and $+1$, allowing a comparison to CWA.

Normalized area of difference is identical to BAM except that the average bin value is not removed. By not removing the average value the algorithm avoids one division that would otherwise increase computational demand each time the BAM algorithm is applied. The NAD is independent of amplitude changes.

The DAM uses the first derivative of the template and the signal under analysis. The method creates segments from zero crossings of the derivative of the template. It imposes the same segmentation for analysis of the derivative of the signal to be compared. The segments are normalized, but are not adjusted for baseline variations since derivatives are by their nature baseline independent. The DAM metric is calculated as follows:

$$\rho = 1 - \sum_{i=1}^{i=M} \left| \frac{\dot{T}_i}{\sum_{k=1}^{k=M} |\dot{T}_k|} - \frac{\dot{S}_i}{\sum_{k=1}^{k=M} |\dot{S}_k|} \right|$$

where \dot{T}_k represents the k th bin of the first derivative of the template. The DAM metric falls between -1 and $+1$.

The ADIOS is similar to DAM in that it also employs the first derivative of the waveforms. A template is constructed of the sign of the derivative of the ventricular depolarization template. This template of signs is then compared to the signs of the derivative for subsequent depolarizations. The total number of sign differences between the template and the current ventricular depolarization is then computed as

$$\rho = \sum_{i=1}^{i=N} \text{sign}(\dot{t}_i) \oplus \text{sign}(\dot{s}_i)$$

where \oplus is the exclusive or operator. The number of sign changes is bounded by 0 and the maximum number of points in the template (N), that is, $\rho \in \{0, \dots, N\}$.

Evaluation of these four algorithms was performed on 19 patients with 31 distinct ventricular tachycardia morphologies. Three of the algorithms (BAM, DAM, and

NAD) performed as well or better than correlation waveform analysis, but with one-half to one-tenth the computational demands.

A morphological scheme for analysis of ventricular electrograms (SIG) was devised for minimal computation (68) and compared to NAD. The SIG is a template-based method that creates a boundary window enclosing all template points that form a signature of the waveform to be compared. Equivalent results of VT separation were seen in the two techniques at two thresholds, but at an increased safety margin of separation SIG outperformed NAD and yielded a fourfold reduction in computation.

Another simplified correlation-type algorithm has been designed using electrogram vector timing and correlation, developed for the Guidant ICD (69). In this algorithm, the rate (near-field) channel is used for determining the location of each beat. The peak of the near-field electrogram or fiducial point is used for alignment of the template with the beat under analysis. From this fiducial point, eight specific points are chosen on the shock (far-field) electrogram. The amplitude of the shock channel at the rate-channel fiducial point is one point. In addition, amplitudes at the turning point, intermediate, and baseline values on the shock channel are selected as shown in Fig. 7. This provides an eight-point template that is compared to subsequent beats using the square of the correlation coefficient, as follows:

$$FCC = \frac{(8 \sum t_i s_i - (\sum t_i)(\sum s_i))^2}{(8 \sum t_i^2 - (\sum t_i)^2)(8 \sum s_i^2 - (\sum s_i)^2)}$$

where each summation is $i = 1-8$.

When an unknown beat is analyzed, the exact same timing relative to the fiducial point as the template is used for selecting the amplitudes of the unknown beat. For beats that have a different morphology, those points will not be associated with the same amplitudes as the normal template beat and, thus, the correlation coefficient will be low. To incorporate this into an overall scheme to detect

an arrhythmia, morphology was calculated for a sliding window of 10 beats. If 8 or more beats were detected as abnormal, a VT was detected.

Another algorithm that reduces computational complexity of the standard correlation algorithm uses the wavelet transform of the sinus beat for the template (70). Wavelets can reduce the number of coefficients needed to characterize a beat while still retaining the important morphologic information. The sinus electrogram is transformed using the Haar (square) wavelet, considering a family of 48 wavelets over 187.5 ms window aligned by the fiducial point of the QRS. The wavelet transform is simplified by removing the standard factor of square root of 2. In addition, wavelet coefficients that do not carry much information, defined by a threshold, are set to zero. The remaining coefficients are normalized. This gives a variable template size, depending on the electrogram, but typically between 8 and 20 coefficients. To analyze an unknown electrogram, the electrogram is aligned using the peak (negative or positive) point. The wavelet transform is computed for the unknown electrogram and each coefficient is compared using the absolute difference in wavelet coefficients (c_i) between the template and unknown beat. A match is determined by the following equation:

$$\text{Match}\% = \left| 1 - \frac{\sum |c_i^{\text{template}} - c_i^{\text{unknown}}|}{\sum |c_i^{\text{template}}|} \right| * 100$$

The nominal threshold used in this study is 70%. This morphology algorithm is incorporated into an overall rate scheme by remaining inactive until a ventricular tachycardia has been detected by the rate algorithm. Then, the morphology is calculated for the preceding eight beats. A VT is detected if six or more beats are detected as abnormal.

A novel way of testing this algorithm was used. Instead of, as in most tests, using data prerecorded in laboratory conditions, this algorithm was downloaded to the Medtronic clinical ICDs and tested off-line, while the device functioned with its regular algorithm.

Figure 7. Example for vector timing and correlation algorithm. Alignment of the template is based on the peak of the rate electrogram channel. From the peak, eight specific points on the shock channel are automatically selected for the template (left). These exact points in time relative to the fiducial point selected from the template are applied to the “unknown” beat (right). (Used with permission from Ref. 69.)

Another algorithm that utilizes morphology is termed morphology discrimination (MD) in St. Jude implantable cardioverter defibrillators (71,72). This algorithm uses an area-based approach. First, the template is defined based on the three consecutive peaks with the largest area. The area under each peak is normalized by the maximum peak area. When analyzing an unknown beat, the beat is aligned with the template using the dominant peak of the unknown beat. If this peak does not have same polarity, the second largest peak is used. If this also does not have the same polarity, a nonmatch is declared. Once the unknown beat and template are aligned, the morphology score is determined by the following:

$$\text{Score} = (1 - \frac{|N\text{Area}A - N\text{Area}A'| + |N\text{Area}B - N\text{Area}B'|}{|N\text{Area}C - N\text{Area}C'|}) * 100$$

where $N\text{Area}$ stands for the normalized area of the three corresponding peaks of the template (A , B , C) and test complexes (A' , B' , C'). For arrhythmia diagnosis, once the rate criteria is met, the algorithm determines the number of matching complexes in the morphology window. If the number of matching complexes equals or exceeds a programmed number of matching complexes, VT is not confirmed and therapy is not delivered. This is repeated for as long as the rate criteria has been met or VT is confirmed.

Template matching by CWA was further examined for distinction of multiple VTs of unique morphologies in the same patient (73,74). It was hypothesized that, in addition to a SR template, a second template acquired from the clinical VT could provide confirmation of a later recurrence of the same VT. The recognition of two or more different VTs within the same patient could play an important role in future devices in the selection of therapy to be delivered to hemodynamically stable versus unstable VTs.

Considerations for Template Analysis. While template-based algorithms appear the most promising, several issues need to be addressed. The first is that it is necessary that the normal sinus rhythm beat or template remain stable, that is, does not change over time or due to position or activity. Several studies using temporary electrodes saw changes in the morphology of normal rhythm due to increase in rate or positional changes (75–78) but further studies with fixed electrodes showed no changes in morphology due to heart rate or position, with some changes in amplitude (76,79). A second consideration is that paroxysmal (sudden) bundle branch block (BBB) may be misdiagnosed as ventricular tachycardia (80). While this may result in a false therapy, it does not result in withholding of therapy during life-threatening arrhythmias (the more critical mistake).

Feature-Based Algorithms

Depolarization Width for Detection of Ventricular Tachycardia. Depolarization width (i.e., duration) in ventricular electrograms has been used as a discriminant of supraventricular rhythm (SR) from VT (81,82). Electrogram width is available in the Medtronic single chamber ICDs. This criterion uses a slew threshold to find the

beginning and end of the QRS. Analysis of electrogram width compared to a patient-specific width threshold is performed using the previous eight beats after a VT detected by the rate component of the algorithm. If a minimum of six complexes are greater than the width, then a VT is detected. Otherwise, the counter is reset. This algorithm is not appropriate in patients with BBB that have a wider width for normal beats. Exercise induced variation should be considered in programming (83). Electrogram width has been shown to be sensitive to body position and changes over longer periods of time (6 months in this study) (84).

Amplitude and Frequency Analysis. Amplitude and frequency are distinguishing characteristics of arrhythmia. Amplitude during ventricular tachycardia is typically higher and during ventricular fibrillation is lower than normal sinus rhythm (85,86). These differences have not been considered pronounced and consistent enough, such that a classifier could be based on them.

Frequency-domain analysis is often proposed for classification of rhythms (87) but little success has been solidly demonstrated for the recognition of VT (63). Distinctly different morphological waveforms (SR vs VT), which are easily classified in the time domain, can exhibit similar or identical frequency components if one focuses on the depolarization component alone. Examination of longer segments of 1000–15,000 ms yields the same phenomenon because the power present in small visually distinctive high frequency notches is insignificant compared to the remainder of the signal, and changes in polarity of the waveform, easily recognized in the time domain, are simply not revealed by frequency analysis (63). Frequency-domain recognition of AF (88) and VF (89,90) is perhaps more promising. However, frequency has not been applied in commercial applications given the success of rate and time-domain morphology approaches.

Other Morphologic Approaches. Other approaches that have been suggested in the literature include use of neural networks (91–97). Neural network approaches utilize either features, the time-series, or frequency components as inputs to the neural network. The network is trained on one dataset and tested on a second. Limitations with the approaches developed thus far are related to the fact that there is only limited data for development of the neural network. One problem is that in some studies the training set and test set both include samples from the same patient. Thus, these networks cannot be considered a general classifier for all patients, since it did not have a valid test set for assessing results on unseen patients. Ideally, three sets should be utilized: training, validation, and testing. The purpose of the validation set is to test the generalization of the network, such that it is not overtrained. Plus, it is typical practice to retrain neural networks until good results are achieved on the validation set. A separate testing set verifies that success on the validation set was not just by chance. Until large datasets are available for development of the algorithms, neural networks will not be considered for clinical use. Furthermore, neural networks generally have not achieved much

acceptance by the clinical community who prefer methods that are tied to underlying physiologic understanding.

Dual-Chamber Arrhythmia Detection

Since dual-chamber pacemakers have been combined into ICDs, the possibility of the use of information from the atrial electrogram for arrhythmia diagnosis has opened up. The most prevalent cause of delivery of false therapy is AF, which accounts for > 60% of all false shocks according to the literature. The simple addition of an atrial sensing lead can dramatically change the false detection statistics.

The first two-channel algorithm for intracardiac analysis incorporated timing of atrial activation as well as ventricular into the diagnostic logic of arrhythmia classification (98,99). This scheme was based on earlier work in which an esophageal pill electrode (33) provided P-wave identification as an adjunct to surface leads in coronary care and Holter monitoring (34). The early argument for adding atrial sensing for improvement of ICD tachycardia detection was advanced conceptually by Furman in 1982 (29), was demonstrated algorithmically by Arzbaeher et al. in 1984 (58), and was further confirmed by Schuger (100). This simple two-channel analysis offers a first-pass method for confirming a VT diagnosis when the ventricular rate exceeds the atrial (Fig. 8). Recognition of a run of short intervals was followed by a comparison of atrial versus ventricular rate. With both chambers (atrial and ventricular) under analysis, most supraventricular arrhythmias could be detected by an $N : 1$ ($A : V$) relationship, and most ventricular arrhythmias could be detected by a $1 : N$ ($A : V$) relationship. Ambiguity occurred in tachycardias characterized by a $1 : 1$ relationship, where SVT with $1 : 1$ ventricular conduction could be confounded with ventricular tachycardia with retrograde $1 : 1$ atrial conduction. In addition, an $N : 1$ ($A : V$) relationship should not be an automatic detection of atrial arrhythmia, since a concurrent ventricular arrhythmia could be masked by a faster atrial arrhythmia, as seen in Fig. 6c. Thus the limitations of two-channel timing analysis, although powerful, needs to be addressed by more advanced logical relationships.

A system designed for two-channel analysis using rate in both chambers plus three supplemental time features (onset derived by median filtering, regularity, and multiplicity) was designed for real-time diagnosis (101) of spontaneous rhythms. This system was an integration of previously tested stand-alone timing schemes (102,103). The combined system is able to recognize competing atrial and ventricular tachycardias and produces joint diagnoses of the concurrent rhythms. Simultaneous VT and atrial flutter is classified via atrial rate, ventricular rate, and a lack of multiplicity. Fast ventricular response in AF is detected via the regularity criterion. Onset (employed in 1:1 tachycardias) utilizes a median filter technique (102).

Commercially, each manufacturer now has available algorithms that utilize information from both chambers for making the diagnosis, particularly for improving specificity. These algorithms are implemented in commercial devices and continually updated and improved. Examples of the algorithms are in the following paragraphs. Reviews are given in Refs. 42,43 along with a thorough comparison of clinical results of the various commercial dual-chamber algorithms (43). Other comparisons include Refs. 104,105.

The first actual realization of a two-channel ICD appeared with the introduction into clinical trials (1995) of the ELA *Defender*, a dual chamber sensing and pacing ICD that uses both atrial and ventricular signals for its tachycardia diagnoses (106) (Fig. 9). The first step after a fast rate is detected is to consider stability of the ventricular rate. If the rhythm is not stable, atrial fibrillation is detected and no therapy delivered. The next consideration is the association between the A and V. For $A : V$ association of $1 : N$ or no association, a VT is detected. For $N : 1$ association, atrial arrhythmia is detected and no therapy delivered. For 1:1 association, the last step is consideration of chamber of onset, ventricular acceleration will result in VT therapy, while no acceleration or atrial acceleration will result in no therapy. An example of a sudden onset in the atrium due to SVT is seen in Fig. 6d. The most recent algorithm, PARAD+ incorporates additional features after the association criteria (second step) (107). If there is no PR association, a second criteria is considered where a single

Figure 8. Basic dual chamber arrhythmia detection algorithm. For a sequence of intervals, the number of atrial (A) intervals is compared to the number of ventricular (V) intervals. If there are more V than A, a diagnosis of ventricular fibrillation (VF), ventricular flutter (VFI), or ventricular tachycardia (VT) is made based on the rate. If there are more V than A beats, a diagnosis of atrial fibrillation (AF), atrial flutter (AFI), or atrial tachycardia is made (AT) (58).

Figure 9. Flowchart of dual-chamber arrhythmia detection algorithm using simple rate-based features. For unstable RR interval (time between beats), atrial fibrillation is detected. For stable RR and no association between the atrium (A) and ventricle (V), ventricular tachycardia (VT) is detected. For $N : 1$ (A : V) association, atrial flutter (AFL) is detected. For $1 : 1$ (A : V) association with no acceleration (Accel), sinus tachycardia (ST) is detected. Last, with a ventricular acceleration, VT is detected and with atrial acceleration (Aaccel) supraventricular tachycardia (SVT) is detected (106).

long ventricular cycle will result in the diagnosis of atrial fibrillation (for the next 24 consecutive cycles) while no long ventricular cycles will result in VT detection.

The Guidant Ventak AV III DR algorithm uses the following scheme, shown in Fig. 10 (104). First, it checks if the ventricular rate is greater than the atrial rate (by 10 bpm). If yes, then VT is detected. If no, then more analysis is performed. If the atrial rate is greater than the atrial fibrillation threshold and the RR intervals are not stable, then supraventricular rhythm is classified. If the RR intervals are stable, VT is detected. If the atrial rate is not greater than the atrial fibrillation threshold, then ventricular tachycardia is detected if the RR intervals are stable and there is a sudden onset of ventricular rate. An updated algorithm from Guidant is described in the next section.

Figure 10. Algorithm for Guidant Ventak AV III DR, using comparison of the rate of A and V, stability and onset. (Used with permission from Ref. 104.)

Perhaps the most complex of the dual chamber algorithms rests with the PR Logic algorithm, by Medtronic (42). This algorithm uses a series of measurements from the timing of the atrial ventricular depolarizations to create a code (1 of 19 possible). These codes are then used for ultimate diagnosis. The main component of the algorithm is the timing between the atrial and ventricular beat to determine if the conduction was antegrade or retrograde. For a given ventricular RR interval, if the atrial beat falls 80 ms before or 50 ms after the ventricular beat, the rhythm is considered junctional. Outside of this, if the atrial beat (P-wave) falls within the first one-half of the RR interval, it is considered retrograde conduction. If the atrial beat falls in the second half of the RR interval it is considered antegrade. This is performed for the previous two beats and incorporated in the code. There are only a few programmable components in the algorithm. The first is the type of SVT for which rejection rules apply (AF/AFL, ST, SVT). The second is the SVT limit. The rest are not programmable.

Dual-Chamber with Ventricular Morphological Analysis

The Photon DR from St. Jude incorporates morphology in its dual chamber defibrillator algorithm. The MD in the ventricular chamber described earlier is incorporated in the full algorithm as follows (108). For $V > A$, ventricular tachycardia is detected. For $V < A$, a combination of morphology discrimination and interval stability is used to inhibit therapy for atrial fibrillation/flutter and SVT. For the branch $V = A$, morphology discrimination and sudden onset is used to inhibit therapy for ST and SVT. This algorithm has an automatic template feature update (ATU) for real-time calibration of the sinus template.

A new dual chamber algorithm from Guidant uses the vector timing and correlation (VTC) algorithm, described earlier (69). If the V rate exceeds A rate by > 10 bpm, a VT is detected. Otherwise, VTC algorithm is implemented. If the atrial rate does not exceed the AF threshold, then VTC will be used for diagnosis. Otherwise, stability will be used for diagnosis. Therapy would be inhibited for an unstable ventricular rhythm.

Two-Channel Morphological Analysis. An early algorithm that uses morphological analysis of both the intraatrial signal and the intraventricular signal (109,110) is based on strategy developed previously for surface and esophageal signals (111). A five-feature vector was derived for each cycle containing an atrial and a ventricular waveform metric (ρ_a, ρ_v), where ρ is the correlation coefficient for each depolarization, and AA, AV, and VV interval classifiers (short, normal, and long). Single-cycle codes were mapped to 122 diagnostic statements. The eight most current cycles were employed for a contextual interpretation of the underlying rhythm. This addition of morphological analysis of both atrial and ventricular channels combined with rate determination in each channel on a cycle-by-cycle basis, dramatically demonstrated the power of modern signal processing in the interpretation of arrhythmias.

One aspect in which analysis of the atrial morphology would be very useful in ICDs is the separation of antegrade versus retrograde atrial conduction. During a 1:1 tachycardia, it is difficult to separate an SVT with 1:1

anterograde conduction (forward conduction from the sinus node through the atrium and AV node to the ventricle) versus a ventricular arrhythmia with retrograde conduction (retrograde conduction from the ventricle through the AV node to the atrium). To differentiate these cases, morphology differences in the atrial electrogram could be utilized, where abnormal morphology would indicate retrograde conduction. Various methods have been described in the literature which use similar approaches as ventricular morphology (112–118).

Distinction of Ventricular Tachycardia and Ventricular Fibrillation

Discriminating between VT and VF might be useful to allow unique zone settings for choice of therapy. Antitachycardia pacing is a lower energy therapy used to treat VT, which is not painful to the patient. Currently, there is difficulty in detecting each VF cycle, leading to electrogram dropout, which leads physicians to expand the VF detection zone to eliminate the possibility of misdiagnosing VF (119,120). Therefore, many VTs are detected as VF and given shock therapy directly. While these are typically fast VTs, there is a possibility that fast VTs can be terminated using anti-tachycardia pacing protocols, with only limited delay of shock therapy, if fast VTs and VF could be differentiated (121). In one study, 76% of fast VTs would have received shock therapy if programmed traditionally (121). However, by expanding the fast VT zone, 81% diagnosed as fast VT were effectively pace-terminated. More sophisticated digital signal processing techniques could be applied to ensure proper separation of VT and VF by methods more intelligent than counting alone.

For separation of VT and VF, CWA using a sinus rhythm template was tested on a passage of monomorphic ventricular tachycardia and a subsequent passage of ventricular fibrillation in each patient (122–124). The standard deviation of the correlation coefficient (ρ) of each class (VT and VF) was used as a discriminant function. This scheme was based upon the empiric knowledge that correlation values are more tightly clustered in the cycle-by-cycle analysis of monomorphic VT and more broadly distributed in the dissimilar waveforms in VF. Results showed easy separation of sinus rhythm from VT and VF; however in the VT/VF separation, standard deviation only achieved limited success. Standard deviation requires patient-specific thresholds, may not hold for all template-based algorithms, and adds further computational requirements to the algorithm; therefore, it is not a promising algorithm in its present form for discrimination of VT from VF.

Throne et al. (125) addressed the problem of separating monomorphic and polymorphic VT/VF by using scatter diagram analysis. A moving average filter was applied to rate and morphology channels and plotted as corresponding pairs of points on a scatter diagram with a 15×15 grid. The percentage of grid blocks occupied by at least one sample point was determined. Investigators found that monomorphic VTs trace nearly the same path in two-dimensional space and occupy a smaller percentage of the graph than nonregular rhythms such as polymorphic VT or VF.

Figure 11. Basic algorithm for separation of VT and VF using PSC. Once a fast rate is detected, VT and VF are detected for slow fast rates and very fast rates, respectively. Only in the overlap between fast VT and VF rates, is the morphology algorithm implemented. Interquartile range (IQR) of the paired signal concordance over a passage is used.

A magnitude-squared coherence function was developed by Ropella et al. (126), which utilizes filtering and Fourier transformation of intraventricular electrograms derived from two leads with a sliding window to distinguish monomorphic ventricular tachycardia from polymorphic ventricular tachycardia and ventricular fibrillation. This method, while elegant, requires multiple electrode sites and is at present too computationally demanding for consideration in battery operated devices. As technology advances, the possibility of hardware implementation of frequency-based methods such as magnitude-squared coherence and time-domain CWA may become feasible.

A similar algorithm uses two “unipolar” ventricular electrograms, 1 cm apart, to compare the paired signal concordance (PSC) between the electrograms using correlation analysis (127). During normal rhythms and VT, the two closely spaced electrograms will exhibit high correlation, while during VF, the two electrograms will experience low correlation. Considering only rhythms that have a fast rate in the overlap between fast VT and VF rates, the variability of the correlation, measured by interquartile range, over a passage distinguishes VT from VF (Fig. 11).

Complexity measurements have also been utilized for distinction of ventricular tachycardia and fibrillation, including approximate entropy (128), Lempel–Ziv complexity (129), least-squares prony modeling algorithm (130).

OTHER DEVICES THAT USE AUTOMATED ARRHYTHMIA DETECTION

Other commercially available devices that use automated arrhythmia detection algorithms include the automatic external defibrillator and the implantable atrial defibrillator.

Automatic External Defibrillators

Recently, automatic external defibrillators (AEDs) have become widespread and available. The AED is able to determine if the rhythm for an unresponsive, pulseless patient is shockable or unshockable and is able to apply therapy automatically or to inform the user to deliver the

therapy (131–133). The AEDs are available on location for large organizations, such as airports, airplanes, businesses, sporting events, schools, and malls (134). This expanded availability dramatically increases the possibility that victims of ventricular fibrillation could receive defibrillation in a timely manner, thus, improving survival rates (135).

The AEDs, operating in a truly automated mode, must be exquisitely accurate in their interpretation of the ECG signal (136,137). In an AED, shockable rhythms are rhythms that will result in death if not treated immediately and include coarse ventricular fibrillation and ventricular tachycardia. Nonshockable rhythms are rhythms where no benefit and even possible harm may result from therapy and include supraventricular tachycardia, atrial fibrillation normal sinus rhythm, and asystole. Asystole is not considered shockable for these devices since the leads may be misplaced and no signal captured. Intermediate rhythms are rhythms that may or may not receive benefit from therapy and include fine VF and VT. Ventricular tachycardia is an intermediate rhythm because often it is hemodynamically tolerated in the patient. A rate threshold is usually programmed in the device (even though there is still no universally accepted or obvious delineation in rate for hemodynamic tolerance in the literature).

Contrary to the ICD, AEDs have an extremely necessary requirement for accurate specificity (shocks when not needed) since these devices are expected to be used by untrained personnel. Algorithms must consider large variations in cardiac rhythms and artifact from CPR or patient movement. The risk to the patient and the technician is too great to allow public use for devices with decreased specificity. Given that a bystander is on the scene and that trained help may soon be available, specificity is more important for the first, or immediate response. However, sensitivity must be considered to ensure the AEDs potential to save lives is maximized. In the AED, more battery power can be utilized (since the device is not implanted), and therefore more sophisticated schemes borrowed from ICD technology have been considered.

Current devices use numerous schemes for determining if the patient is in ventricular fibrillation. Common components include isoelectric content (like PDF algorithm of the ICD), zero crossings, rate, variability, slope, amplitude and frequency (138), all similar techniques to those described in the ICD literature. A review of AED algorithms is given in Ref. 138.

One example of a recent algorithm described in the literature is for a programmable automatic external defibrillator designed to be used in the hospital setting for monitoring and automatic defibrillation, if needed (139). This device uses a programmable rate criterion to detect shockable rhythms. In addition, the device has an algorithm which distinguishes VT and SVT rhythms below a SVT threshold. The algorithm uses three features to discriminate between SVT and VT. The first is the modulation domain function that uses amplitude and frequency characteristics. The second, called waveform factor (WF), provides a running average of the electrocardio-

gram signal amplitude normalized by the R-wave amplitude. The WF for one beat is as follows:

$$WF_i = \frac{100 \times \sum_1^N \text{abs}(A_n)}{N \times \text{abs}(A_r)}$$

where N is the total number of samples between the previous and current beat, A_n is the n th amplitude of the signal, and A_r is the peak. The algorithm uses an eight beat running average. The SVT rhythms would have a small WF value, while VT (which has a wide QRS complex on the surface of the body) would have a high WF value. This algorithm should not be used with patients who have bundle branch block, chronic or paroxysmal. The third feature is called amplitude variability analysis factor, which uses distribution of the average derivative. The measurement is found by calculating the number of derivatives which fall into the baseline bin as a percentage of the total number of sample points. Amplitude variability analysis (AVA) is calculated as follows:

$$AVA = \frac{100 \times \sum n(i)}{N}$$

where the summation is performed across the baseline bins and $n(i)$ is the number of samples for the i th bin. The baseline bins are defined as 25% of the total bins centered at $n(i)_{\max}$. Exact use of these features in the AED algorithm are not described.

Implantable Atrial Defibrillators

Implantable atrial defibrillators are used in patients with paroxysmal or persistent atrial fibrillation, particularly those which are symptomatic and drug refractory (140,141). Goals in atrial defibrillators are different than ICDs since atrial tachyarrhythmias are typically hemodynamically tolerable, therefore, more time and care can be used to make the decision. The challenge is that the device must sense low, variable amplitude atrial signals, while not sensing far-field ventricular waves. Furthermore, there are also multiple therapies available, antitachycardia pacing for atrial tachycardia, and cardioversion for atrial fibrillation. Lastly, some atrial defibrillators have been combined with ICDs such that back-up ventricular defibrillation therapy is available in this susceptible population (140,142).

A review of algorithms used in atrial defibrillators is given in Ref. 143. For example, Medtronic has a dual-chamber defibrillator that has both atrial and ventricular therapies (140,142). The algorithm for detection uses the same algorithm as the dual-chamber ventricular (only) defibrillator, PR Logic. In addition to this algorithm, there are two zones used for detection of atrial tachycardia and of atrial fibrillation. If the zones overlap, AT is detected if it is regular and AF if it is irregular. The purpose of multiple zones is similar to ventricular devices, in that a variety of therapies can be selected and utilized for each zone. For this device, this includes pacing algorithms for prevention, pacing therapies for termination, and high voltage shocks.

CONCLUSION

This article focuses on the overall approaches used for automated arrhythmia detection. However, this review did not delve into the specifics of comparisons of sensitivity and specificity results for the various algorithms. While, each paper referenced gives performance for a specific test database, it is difficult to compare the results from one study to another. There have been some attempts to develop standardized datasets, including surface electrocardiograms from Physionet (including the MIT-BIH databases) (144) and American Heart Association (145), and intracardiac electrograms, in addition to surface, from Ann Arbor Electrogram Libraries (3). Use of these datasets allows for comparisons, but does not address the differences between performance at the system level that incorporates the hardware components of the specific device. A comprehensive description of the pitfalls in comparing results from one study to another is given in (43). These include limitations of (1) benchtesting that does not incorporate specific ICD-system differences and spontaneous arrhythmias, (2) limited storage in the ICD making gold standard clinical diagnosis difficult, (3) great variations in settings of rate based thresholds and zones, (4) variability of types of rhythms included in the study, among others.

In conclusion, examples from the long history of automated arrhythmia detection for implantable cardioverter defibrillators is given with a brief mention of automated external defibrillators and implantable atrial defibrillators. The ICDs are beginning to reach maturity in terms of addressing both sensitivity and specificity in performance of the algorithms to achieve close to perfect detection of life-threatening arrhythmias, with greatly reduced false therapies. In the meantime, automated external defibrillators and implantable atrial defibrillators have learned many lessons from the ICD experience to provide accurate arrhythmia diagnosis. Devices on the horizon incorporating automated arrhythmia detection may include wearable external defibrillators (146,147), wearable wireless monitors, and beyond. This rich area of devices that detect and treat life-threatening arrhythmias shall reduce the risk of sudden cardiac death.

ARTERIES, ELASTIC PROPERTIES OF

KOZABURO HAYASHI
Okayama University of Science
Okayama, Japan

INTRODUCTION

The elastic properties of the arterial wall are very important because they are closely related to arterial physiology and pathology, especially via effects on blood flow and arterial mass transport. Furthermore, stresses and strains in the arterial wall are prerequisite for the understanding of the pathophysiology and mechanics of the cardiovascular system. Stresses and strains cannot be analyzed without exact knowledge of the arterial elasticity.

STRUCTURE OF ARTERIAL WALL AND BASIC CHARACTERISTICS

Arteries become smaller in diameter with increasing distance from the heart, depending on functional demands (1). In concert with this reduction in size, their structure, chemical composition, and wall thickness-inner diameter ratio gradually change in a way that leads to a progressive increase both in stiffness and in their ability to change their inner diameter in response to a variety of chemical and neurological control signals.

Arterial wall is inhomogeneous not only structurally, but also histologically. It is composed of three layers (intima, media, and adventitia), which are separated by elastic membranes. Because the media is much thicker than the other two layers and supports load induced by blood pressure, its mechanical properties represent the properties of arterial wall. The media is mainly composed of elastin, collagen, and cells (smooth muscle cell and fibroblast). Roughly speaking, elastin gives an artery its elasticity, while collagen resists tensile forces and gives the artery its burst strength. Smooth muscle cells contract or relax in response to mechanical, chemical, and the other stimuli, which alters the deformed configuration of arteries. The wall compositions vary at different locations depending on required functions. For example, collagen

and smooth muscle increase and elastin decreases at more distal sites in conduit arteries; the ratio of collagen to elastin increases in more distally located arteries. Collagen and elastin are essentially similar proteins, but collagen is very much stronger and stiffer than elastin. Therefore, the change of arterial diameter developed by blood pressure pulsation depends on the arterial site; it is larger in more proximal arteries.

Like most biological soft tissues, arteries undergo large deformation when they are subjected to physiological loading, and their force-deformation and stress-strain relations are nonlinear partly because of the above-mentioned inhomogeneous structure and partly because of the nonlinear characteristics of each component itself. Since collagen is a long-chained high polymer, it is intrinsically anisotropic. Moreover, not only collagen and elastin fibers, but also cells, are oriented in tissues and organs in order so that their functions be most effective. Inevitably, the arterial wall is mechanically anisotropic like many other biological tissues. Biological soft tissues including arterial wall demonstrate opened hysteresis loops in their force-deformation and stress-strain curves, which means that those tissues are viscoelastic. In such materials, the stress state is not uniquely determined by current strain, but depends also on the history of deformation. When a viscoelastic tissue is elongated and maintained at some length, load does not stay at a specific level, but decreases rather rapidly at first and then gradually (relaxation). If some constant load is applied to the tissue, it is elongated with time rather rapidly at first and then gradually (creep). Viscoelastic materials generally show different stress-strain properties under different strain rates. It is true, and higher strain rates give higher stresses. However, such a strain rate effect is not so much in biological soft tissues like arteries, namely, their elastic properties are not more sensitive to strain rate. Therefore, it is not always necessary to consider viscoelasticity for arterial mechanics; it is very often enough to assume wall material to be elastic. Many biological soft tissues contain water of > 70%. Therefore, they hardly change their volume even if load is applied, and they are almost incompressible. The incompressibility assumption is very important in the formulation of constitutive laws of soft tissues, because it imposes a constraint on the strains and they are not independent.

MEASUREMENT OF ARTERIAL ELASTICITY

In Vitro Tests

It is widely recognized that the mechanical properties of blood vessels do not change for up to 48 h if tissues are stored at $\sim 4^\circ\text{C}$ (1). One of the basic methods for the determination of the mechanical properties of biological tissues is uniaxial tensile testing on excised specimens. In this test, an increasing force is steadily applied to the longitudinal direction of a specimen, and the resulting specimen deformation is measured, which gives relations between stress (force divided by specimen cross-sectional area) and strain (specimen elongation divided by reference specimen length). This *in vitro* test is simple but, nevertheless, provides us with basic and useful information on

Figure 1. An *in vitro* experimental setup for the pressure-diameter-axial force test of a tubular arterial specimen. Internal pressure or outer diameter can be controlled with a feedback system (2).

the mechanical properties of tissues. Dumbbell-shape specimens, helically stripped specimens, and ring specimens are commonly used for arterial walls.

Under *in vivo* conditions, arteries are tethered to or constrained by perivascular connective tissues and side branches, and pressurized by blood from inside. These forces develop multiaxial stresses in the wall. For the determination of the mechanical characteristics of arteries under multiaxial conditions, biaxial tensile tests on flat specimens are utilized to simultaneously apply forces in the circumferential and longitudinal directions; however, the effect of wall radial stress is ignored in this case.

Although stress-strain data obtained from the above-mentioned uniaxial and biaxial tests on flat, strip, and ring specimens are often used to represent the elastic properties of arterial walls, the data obtained from pressure-diameter tests on the tubular segments of blood vessels are more important and realistic. An example of the test devices is shown in Fig. 1 (2). A tubular specimen is mounted in the bath filled with Krebs-Ringer solution, which is kept at 37 °C and aerated with 95% O₂ and 5% CO₂ gas mixture. Then, it is extended to the *in vivo* length to mimic the *in vivo* condition, because arteries inside the body are tethered to the surrounding tissues as mentioned above and, therefore, they are extended in the axial direction. A diaphragm-type actuator, which is controlled with a sequencer, is incorporated in the device for the application of internal pressure to the specimen. The internal pressure or specimen diameter can be controlled with the sequencer during pressure-diameter tests. The pressure is measured with a fluid-filled pressure transducer, while the outer diameter of the specimen is determined with a video dimension analyzer combined with a CCD camera. If the measurements of axial force are required in order to obtain pressure-diameter-axial force relations for the purpose of determining multiaxial constitutive laws, a load cell attached to one end of the vessel can be used.

In Vivo Measurements

It may be more realistic to obtain data from *in vivo* experiments under *in situ* conditions rather than to get data from *in vitro* biomechanical tests. As a result of recent progress

in ultrasonic techniques, arterial diameter and even arterial wall thickness can be measured noninvasively with fairly good precision. These methods are being used not only for *in vivo* animal experiments, but also for clinical diagnosis of vascular diseases. It is true that the data obtained from these experiments and clinical cases are very useful, and provide important information concerning arterial mechanics. On the other hand, it is also true that many factors considerably affect the results obtained. These include physiological reactions to momentary changes in body and ambient conditions as well as the effects of anesthesia and respiration. In addition, since there has been some difficulty in applying the methods to small-diameter blood vessels, accurate measurements of vascular diameter and wall thickness with current techniques have been mostly limited to aortas and large arteries.

Before noninvasive ultrasonic techniques were developed, *in vivo* measurements of vascular diameter were invasively performed following surgical exposure of blood vessels, using strain gauge-mounted cantilevers, strain gauge-pasted calipers, and sonomicrometers. For example, a pair of miniature ultrasonic sensors may be used for the measurement of the outer diameter of a blood vessel (3). They are attached to the adventitial surface of a blood vessel so as to face each other across the vascular diameter. The diameter is determined from the transit time of the pulses between the two sensors. Similar sonomicrometers have been used for the measurement of arterial diameter not only in anesthetized, but also in conscious animals.

The noninvasive measurement of the elastic properties of arteries offers several significant advantages over invasive techniques. First, the nontraumatic character of the measurement guarantees a physiological state of the arterial wall, whereas such key functional elements of the wall as endothelium and smooth muscle might be affected in certain invasive measurement techniques. Second, it is of great clinical interest because it allows the monitoring of many outpatients and, therefore, it is well adapted for epidemiological or cross-sectional studies.

Noninvasive measurement of the arterial diameter can be done with ultrasonic echo-tracking techniques; recent improvements of the original technique have been proposed, which include digital tracking, prior inverse filtering, and coupling with B-mode imaging (1).

There exist no direct ways to measure pressure noninvasively in large central arteries, such as the aorta. Thus, regardless of the progress of ultrasonic and magnetic resonance imaging techniques which allow for the noninvasive measurement of vascular diameter, mechanical properties, such as compliance and elastic modulus cannot be derived from first principles. Therefore, primarily for clinical use, as an indirect, but noninvasive way of estimating the mechanical properties, the pulse wave velocity, c (see the next section), is often obtained from the measurements of pulsation at two distinct points along the vessel. One of the major drawbacks of this technique is low accuracy. The other one is that it yields a single value for the wave velocity. Because of the nonlinear elastic properties of the arterial wall, the pulse wave velocity sensitively changes depending on blood pressure. Therefore, the determination of a single value or a typical value of the arterial stiffness

estimated from the pulsation does not provide a full description of the mechanical properties of the arterial wall.

MATHEMATICAL EXPRESSION OF ARTERIAL ELASTICITY

Uniaxial Tensile Behavior

There are many tensile test data from arterial walls in humans and animals (4). Arterial walls exhibit nonlinear force-deformation or stress-strain behavior, having higher distensibility in the low force or stress range and losing it at higher force or stress. To represent strain in such biological soft tissues that deform largely and nonlinearly, we commonly use extension ratio, λ , which is defined by the ratio of the current length of a specimen (L) to its initial length (L_0). If we plot a stress/extension ratio curve as the slope of a stress/extension ratio curve versus stress, we can see that the relation is composed of one or two straight lines (1). Each line is described by

$$dT/d\lambda = BT + C \quad (1)$$

where T is Lagrangian stress defined by F/A_0 (F , force; A_0 , cross-sectional area of an undeformed specimen), and B and C are constants. This is also expressed by

$$T = A[\exp B(\lambda - 1) - 1] \quad (2)$$

where A is equal to C/B . This type of exponential formulation is applicable to the description of the elastic behavior of many other biological soft tissues (5).

Pressure-Diameter Relations

For practical purposes, it is convenient to use a single parameter that expresses the arterial elasticity under living conditions. In particular, for noninvasive diagnosis in clinical medicine, material characterization should be simple, yet quantitative. For this purpose, several parameters have been proposed and commonly utilized (1). These include pressure-strain elastic modulus, E_p and vascular compliance, C_v . Pulse wave velocity, c , which was mentioned above, is also used to express elastic properties of the arterial wall. These parameters are described by

$$E_p = \Delta P / (\Delta D_o / D_o) \quad (3)$$

$$C_v = (\Delta V / V) / \Delta P \quad (4)$$

and

$$c^2 = (S/\rho)(\Delta P/\Delta S) = (V/\rho)(\Delta P/\Delta V) \quad (5)$$

where D_o , V , and S are the outer diameter, volume, and luminal area of a blood vessel at pressure P , respectively, and ΔD_o , ΔV , and ΔS are their increments for the pressure increment, ΔP . The parameter ρ is the density of the blood.

To calculate these parameters, we do not need to measure the wall thickness; for E_p and C_v , we need to know only pressure-diameter and pressure-volume data, respectively, at a specific pressure level. However, we should remember that these parameters express the stiffness or distensibility of a blood vessel. Therefore, they are

structural parameters, and do not rigorously represent the inherent elastic properties of the wall material; in this sense, they are different from the elastic modulus which is explained below. In addition, these parameters are defined at specific pressures, and give different values at different pressure levels because the pressure-diameter relations of arteries are nonlinear.

To overcome this shortcoming, several functions have been proposed to mathematically describe pressure-diameter, pressure-volume, and pressure-luminal area data, and one or several parameters included in these equations have been used for the expression of the elastic characteristics of arteries. Among these functions, the following equation is one of the simplest and most reliable for the description of pressure-diameter relations of arteries in the physiological pressure range (6):

$$\ln(P/P_s) = \beta(D_o/D_s - 1) \quad (6)$$

where P_s is a standard pressure and D_s is the wall diameter at pressure P_s . A physiologically normal blood pressure like 100 mmHg (13.3 kPa) is recommended for the standard pressure, P_s . As an example, Fig. 2 shows the pressure-diameter relationships of a human femoral artery under normal and active conditions of vascular smooth muscle and the relations between the logarithm of pressure ratio, P/P_s , and distension ratio, D_o/D_s . Figure 2a demonstrates nonlinear behavior of the artery under both conditions, while Fig. 2b shows the close fit of the data to Eq. 6 over a rather wide pressure range. The coefficient, β , called the stiffness parameter, represents the structural stiffness of a vascular wall; it does not depend upon pressure. This parameter has been used for the evaluation of the stiffness of arteries not only in basic investigations, but also in clinical studies (1).

As can be seen from Fig. 2a, under the normal condition, arteries greatly increase the diameter with pressure under a low pressure range, say < 60 mmHg (8 kPa), and then gradually lose the distensibility at higher pressures. When vascular smooth muscle cells are activated by stimuli, arteries are contracted and their diameter decreases in a

Figure 2. Pressure-diameter (a) and pressure ratio-distension ratio (b) relations of a human femoral artery under normal and active conditions (*in vitro* study) (1,7).

physiological pressure range and below the range [< 200 mmHg (26.6 kPa) in Fig. 2], and their pressure–diameter curves become greatly different from those observed under the normal condition.

To express the elastic properties of wall material, it is necessary to use a material parameter such as elastic modulus or Young's modulus, which is the slope of a linear stress–strain relation. For arterial walls that have non-linear stress–strain relations, the following incremental elastic modulus has been often used for this purpose (8):

$$H_{\theta\theta} = 2D_i^2 D_o (\Delta P / \Delta D_o) / (D_o^2 - D_i^2) + 2PD_o^2 / (D_o^2 - D_i^2) \quad (7)$$

where D_i is the internal diameter of a vessel. This equation was derived using the theory of small elastic deformation superposed on finite deformation in the case of a pressurized orthotropic cylindrical tube.

To calculate this modulus, it is necessary to know the thickness or internal diameter of a vessel. In *in vitro* experiments, we can calculate them from D_o , the internal and external diameters under no-load conditions measured after pressure–diameter testing, the *in vivo* axial extension ratio, and assuming the incompressibility of wall material. Noninvasive measurement of wall thickness or internal diameter on intact vessels has been rather difficult compared with the measurement of external diameter; however, it is now possible with high accuracy ultrasonic echo systems as mentioned above.

Constitutive Laws

Mathematical description of the mechanical behavior of a material in a general form is called a constitutive law or constitutive equation. We cannot perform any mechanical analyses without knowledge of constitutive laws of materials. Strain energy functions are commonly utilized for formulating constitutive laws of biological soft tissues that undergo large deformation (5). Let W be the strain energy per unit mass of a tissue, and ρ_0 be the density in the zero-stress state. Then, $\rho_0 W$ is the strain energy per unit volume of the tissue in the zero-stress state, and this is called the strain energy density function. Because arterial tissue is considered as an elastic solid, a strain energy function exists, and the strain energy W is a function solely of the Green strains:

$$W = W(E_{ij}) \quad (8)$$

where E_{ij} are the components of the Green strain tensor with respect to a local rectangular Cartesian coordinate system.

Under physiological conditions, arteries are subjected to axisymmetrical loads, and the axes of the principal stresses and strains coincide with the axes of mechanical orthotropy. Moreover, the condition of incompressibility is used to eliminate the radial strain E_{rr} , and therefore the strain energy function becomes a function of the circumferential and axial strains $E_{\theta\theta}$ and E_{zz} . Then, the constitutive equations for arteries are

$$\sigma_{\theta\theta} - \sigma_{rr} = (1 + 2E_{\theta\theta}) \partial(\rho_0 W) / \partial E_{\theta\theta} \quad (9)$$

and

$$\sigma_{zz} - \sigma_{rr} = (1 + 2E_{zz}) \partial(\rho_0 W) / \partial E_{zz} \quad (10)$$

where $\sigma_{\theta\theta}$, σ_{zz} , and σ_{rr} are Cauchy stresses in the circumferential, axial, and radial directions, respectively. Thus, we need to know the details of the strain energy function to describe stress–strain relations.

Three major equations have so far been proposed for the strain energy function of arterial wall. Vaishnav et al. (9) advocated the following equation:

$$\rho_0 W = (c/2) \exp(b_1 E_{rr}^2 + b_2 E_{\theta\theta}^2 + b_3 E_{zz}^2 + 2b_4 E_{rr} E_{\theta\theta} + 2b_5 E_{\theta\theta} E_{zz} + 2b_6 E_{zz} E_{rr}) \quad (11)$$

where $E_{\theta\theta}$ and E_{zz} are Green strains in the circumferential and axial directions, respectively, and A , B , and so on, are constants.

Chuong and Fung (10) proposed another form with an exponential function:

$$\rho_0 W = (c/2) \exp(b_1 E_{rr}^2 + b_2 E_{\theta\theta}^2 + b_3 E_{zz}^2 + 2b_4 E_{rr} E_{\theta\theta} + 2b_5 E_{\theta\theta} E_{zz} + 2b_6 E_{zz} E_{rr}) \quad (12)$$

where c , b_1 , b_2 , and so on, are material constants.

Later, Takamizawa and Hayashi (11) proposed a logarithmic form of the function described by

$$\rho_0 W = -C \ln(1 - a_{\theta\theta} E_{\theta\theta}^2 / 2 - a_{zz} E_{zz}^2 / 2 - a_{\theta z} E_{\theta\theta} E_{zz}) \quad (13)$$

where C , $a_{\theta\theta}$, a_{zz} , and $a_{\theta z}$ characterize the elastic properties of a material.

By using one of these strain energy equations or another type of equation for W in Eqs. 9 and 10, and applying the equations of equilibrium and boundary conditions, we determine the values of material constants. Although all of the proposed formulations describe quite well the elastic behavior of arterial walls, we prefer to reduce the number of constants included in the equations in order to handle them more easily, as well as to give physical meanings to the constants. For this reason, the logarithmic expression (Eq. 13) may be advantageous.

ELASTIC PROPERTIES OF NORMAL ARTERIES

Figure 3 shows β values of common carotid arteries, intracranial vertebral arteries, and coronary arteries obtained from autopsied human subjects of different ages (7). Note that arterial stiffness is much larger in the coronary arteries than in the other arteries, and also that intracranial vertebral arteries are considerably stiffer than extracranially located common carotid arteries. As can be seen from this figure, almost all the data obtained from normal human aortas and conduit arteries show that the structural stiffness of wall (e.g., E_p and β) increases with age rather gradually until the age of 40 years, and rapidly thereafter; on the other hand, the wall compliance (C_v) decreases with age. The stiffness of intracranial arteries like the intracranial vertebral artery progressively increases until 20 years, and then more slowly (6). There seems to be almost no age-related change in the human coronary artery (12).

Figure 3. Age-related changes in the wall stiffness of human arteries. (*In vitro* studies, reproduced from Ref. 7.)

Most of the data obtained from arteries in animals indicated that the incremental elastic modulus or the slope of stress–strain curve increases with age, although there are several opposite data (13).

ELASTIC PROPERTIES OF DISEASED ARTERIES

Hypertension

Hypertension is recognized as one of the important risk factors for many cardiovascular diseases, including atherosclerosis and stroke. Elevated blood pressure exerts influences on the synthetic activity of vascular smooth muscle cells, and is believed to induce changes in structure and morphology of the arterial wall, its mechanical properties, and vascular contractility. It is therefore very important to understand arterial mechanics in hypertension. However, results from the extensive literature concerning the elastic properties of hypertensive arteries are contradictory and inconclusive (1,7,13,14). As mentioned above, when we analyze the reported data, we should remember that the values of such parameters as E_p (Eq. 3) and C_v (Eq. 4) are dependent on pressure. Without this consideration, com-

Figure 4. Structural stiffness of thoracic aortas in normotensive and hypertensive rats (7).

parisons between the results from different studies have little meaning.

Several studies have been performed to determine the pressure–diameter or pressure–volume relationships of aortas and arteries in hypertensive animals and humans. For example, comparison of hypertensive rats to normotensive controls has shown that at 100 mmHg (13.3 kPa) and also at the working pressure (systolic blood pressure before sacrifice, P_{sys}) of each group, the pressure strain elastic modulus, E_p of the thoracic aorta is greater in hypertensives than in normals; whereas at 200 mmHg (26.6 kPa) the E_p values in the hypertensive animals are slightly lower than those of the normals (Fig. 4) (7). These results do not depend on the duration of hypertension for 2–16 weeks.

With regard to the inherent elastic modulus of wall material calculated from pressure–diameter data, it has been shown that the incremental elastic moduli of the rat thoracic aorta ($H_{\theta\theta}$ in Eq. 7) at systolic blood pressure levels have significant correlations with blood pressure until 8 weeks after the induction of hypertension; at 16 weeks, however, the correlation disappears and the elastic modulus tends to be at the same level as that in control, normotensive rats (Fig. 5) (7). There are no significant differences in the incremental elastic modulus at

Figure 5. Incremental elastic modulus versus blood pressure in the rat aorta at 2, 4, 8, and 16 weeks after the treatment for hypertension (7).

100 mmHg (13.3 kPa) regardless of the period of hypertension. The aortic wall in hypertensive rats seems to restore the *in vivo* elastic properties to a normal level in 16 weeks due to the functional adaptation and remodeling of the wall.

In connection with the elastic properties of wall, many data have shown that the arterial wall is thickened by hypertension and hypertrophy occurs (14). Wall thickness critically depends on pressure level and, therefore, we have to pay attention to the pressure for the thickness measurement when we interpret the results. If the thickness of wall at the *in vivo* blood pressure level is used to calculate *in vivo* wall stress in the circumferential direction (hoop stress), the stress is independent of the degree of hypertension and is always maintained at a control, normal level even at 2 weeks after the induction of hypertension. This phenomenon is attributable to a functional adaptation and remodeling of the arterial wall (15).

Atherosclerosis

Effects of flow dynamics and wall shear stress on the initiation and development of atherosclerosis have been studied extensively. However, less attention has been paid to the mechanical properties of atherosclerotic wall tissue. Does atherosclerosis stiffen the arterial wall or increase the elastic modulus of wall? The results obtained have been conflicting and inconclusive, as shown in Table 1 (7). One of the reasons for this is that the structural stiffness of arterial wall and the elasticity of wall material have been confusingly used for the expression of the elastic properties of atherosclerotic wall. In this table, the elastic modulus represents the elasticity of wall material, which corresponds to the slope of stress-strain curve and is given by, for example, the incremental elastic modulus, H_{00} ; the stiffness is the structural stiffness expressed by, for example, the stiffness parameter, β .

Several studies have shown that the arterial wall is stiffened by the development of atherosclerosis. However, others have presented different results. Thus it has not been clear whether atherosclerosis increases the elastic modulus of arterial wall. We can see from Table 1 that atherosclerosis is mostly accompanied by wall thickening. This might be a reason why there are no data indicating a decrease in the structural stiffness associated with atherosclerosis. The structural stiffness is determined not only by the elastic modulus of wall material, but also by wall dimensions such as wall thickness.

A detailed and systematic study on the mechanical properties and morphology of atherosclerotic aortas in the rabbit has shown that the changes in the wall stiffness (β) and the elastic modulus (H_{00}) are not always correlated

Table 1. Distributions of Reported Data of the Elasticity, Stiffness, and Thickness of Atherosclerotic Wall^a

	No. of Data	Increase, %	No Change, %	Decrease, %
Elastic modulus	17	29	47	24
Stiffness	17	71	29	0
Wall thickness	12	67	25	8

^aSee Ref. 7

Figure 6. Area fraction of intimal hyperplasia in atherosclerotic thoracic aortas in the rabbit (7). Atherosclerosis was induced by the combination of denudation of endothelial cells and cholesterol diet.

with the time of cholesterol diet feeding (16). Thus, the grade of atherosclerosis was defined from the percent fraction of the luminal surface area stained with Sudan IV as well as from wall stiffening. The area fraction of intimal hyperplasia increases with the grade (Fig. 6). Likewise, wall thickness steadily increases with the progression

Figure 7. Elasticity, wall thickness, and calcification of atherosclerotic thoracic aortas in the rabbit (7).

of atherosclerosis (Fig. 7). However, the elastic modulus is not significantly different from the control artery until the highest grade of atherosclerosis. On the other hand, there appears a significant increase in the arterial stiffness in the grade II atherosclerosis, which is attributable to the wall thickening. Significantly increased calcification and intimal hyperplasia are observed in the wall of the grade III atherosclerosis. From these results, it is concluded that the progression of atherosclerosis induces wall thickening, followed by wall stiffening. However, even if atherosclerosis is advanced, there is essentially no change in the elastic modulus of wall material unless considerable calcification occurs in the wall. Calcified aortas have high elastic moduli. At the most advanced stage of atherosclerosis, the arterial wall has high structural and material stiffness due to calcification and wall hypertrophy (16).

INTRODUCTION

Audiology is, literally, the science of hearing. In many countries around the world, audiology is a scientific discipline practiced by audiologists. According to the American Academy of Audiology, “an audiologist is a person who, by virtue of academic degree, clinical training, and license to practice and/or professional credential, is uniquely qualified to provide a comprehensive array of professional services related to the prevention of hearing loss and the audiologic identification, assessment, diagnosis, and treatment of persons with impairment of auditory and vestibular function, as well as the prevention of impairments associated with them. Audiologists serve in a number of roles including clinician, therapist, teacher, consultant, researcher and administrator” (1).

An important tool in the practice of audiology is audiometry, which is the measurement of hearing. In general, audiometry entails one or more procedures wherein precisely defined auditory stimuli are presented to the listener in order to elicit a measurable behavioral or physiologic response. Frequently, the term audiometry refers to procedures used in the assessment of an individual’s threshold of hearing for sinusoidal (pure tones) or speech stimuli (2). So-called conventional audiometry is conducted with a calibrated piece of electronic instrumentation called an audiometer to deliver controlled auditory signals to a listener. Currently, however, an expanded definition of audiometry also includes procedures for measuring various physiological and behavioral responses to the presentation

of auditory stimuli, whether or not the response involves cognition. More sophisticated procedures and equipment are increasingly used to look beyond peripheral auditory structures in order to assess sound processing activity in the neuroauditory system.

Today, audiologists employ audiometric procedures and equipment to assess the function of the auditory system from external ear to brain cortex and serve as consultants to medical practitioners, education systems, the corporate and legal sectors, and government institutions such as the Department of Veterans Affairs. Audiologists also use audiometric procedures to identify and define auditory system function as a basis for nonmedical intervention with newborns, young children with auditory processing disorders, and adults who may require sophisticated amplification systems to develop or maintain their communication abilities and quality of life.

The purpose of this chapter is to acquaint the reader with the basic anatomy of the auditory system, describe some of the instrumentation and procedures currently used for audiometry, and briefly discuss the application of audiometric procedures for the assessment of hearing.

AUDIOMETRY AND ITS ORIGINS

Audiometry refers broadly to qualitative and quantitative measures of auditory function/dysfunction, often with an emphasis on the assessment of hearing loss. It is an important tool in the practice of audiology, a healthcare specialty concerned with the study of hearing, and the functional assessment, diagnosis, and (re)habilitation of hearing impairment. The profession sprang from otology and speech pathology in the 1920s, about the same time that instrumentation for audiometry was being developed. Audiometry grew rapidly in the 1940s when World War II veterans returned home with hearing impairment related to military service (3). Hearing evaluation, the provision of hearing aids, and auditory rehabilitation were pioneered in the Department of Veterans Affairs and, subsequently, universities began programs to educate and train audiologists for service to children and adults in clinics, hospitals, research laboratories and academic settings, and private practice. Audiometry is now a fundamental component of assessing and treating persons with hearing impairment.

Audiometers

Audiometers are electroacoustic instruments designed to meet internationally accepted audiometric performance standards for valid and reliable assessment of hearing sensitivity and auditory processing capability under controlled acoustic conditions. The audiometer was first described around the turn of the twentieth century (4) and was used mainly in laboratory research at the University of Iowa. A laboratory assistant at the university, C. C. Bunch, would later publish a classic textbook describing audiometric test results in patients with a variety of hearing disorders (5). The first commercial audiometer, called the Western Electric 1A, was developed in the early 1920s by the Bell Telephone Laboratories in the United States, and was described by Fowler and Wegel in 1922 (6). More

than 20 years elapsed before the use of audiometers for hearing assessment was widely recognized (7), and it was not until the early 1950s (8) that audiometry became an accepted clinical practice. Since that time, electroacoustic instrumentation for audiometry has been described in standards written by scientists and experts designed to introduce uniformity and facilitate the international exchange of data and test results. The American National Standards Institute (ANSI), the International Standards Organization (ISO), and the International Electrotechnical Commission (IEC) are recognized bodies that have developed accepted standards for equipment used in audiometry and in psychophysical measurement, acoustics, and research. In the present day, audiometric procedures are routinely used throughout the world for identifying auditory dysfunction in newborns, assessing hearing disorders associated with ear disease, and monitoring the hearing of patients at risk for damage to the auditory system (e.g., because of exposure to hazardous noise, toxic substances).

Types of Audiometers

In the United States, ANSI (9) classifies audiometers according to several criteria, including the use for which they are designed, how they are operated, the signals they produce, their portability, and other factors.

In general, Type IV screening audiometers (designed to differentiate those with normal hearing sensitivity from those with hearing impairment) are of simpler design than those instruments used for in-depth diagnostic evaluation for medical purposes (Type I audiometers). There are automatic and computer-processor audiometers (Bekey or self-recording types), extended high-frequency (Type HF), free-field equivalent audiometers (Type E), speech audiometers (Types A, B, and C depending on available features), and others for specific purposes.

Audiometers possess one or more oscillation networks to generate pure tones of differing frequencies, switching networks to interrupt and direct stimuli, and attenuating systems calibrated in decibels (dB) relative to audiometric zero. The intensity range for most attenuation networks usually approximates 100 dB, typically graduated in steps of 5 dB. The "zero dB" level represents normal hearing sensitivity across the test frequency range for young adults under favorable, noise-free laboratory conditions. Collection of these hearing level reference data from different countries began in the 1950s and 1960s. These reference levels have been accepted by internationally recognized standards organizations. Audiometers also include various types of output transducers for presentation of signals to the listener, including earphones, bone-conduction vibrators, and loudspeakers. As the audiometrically generated signals are affected substantially by the electroacoustic characteristics of these devices (e.g., frequency response), versatile audiometers have multiple calibrated output networks to facilitate switching between transducers depending on the clinical application of interest.

Figure 1 shows the general layout of a Type I diagnostic audiometer. Such instruments are required by standards governing them to produce a stable output at a range of

Figure 1. Typical diagnostic audiometer.

operating temperatures and humidity and meet a wide variety of electrical and other safety standards, in addition to precise electroacoustic standards for frequency, intensity, spectral purity, maximum output sound pressure level (SPL), and harmonic distortion. Type II audiometers have fewer required features and less flexibility, and Type IV audiometers have even more limitations.

Audiometric Calibration

To ensure that an audiometer is performing in accordance with the relevant standard, the instrument’s electroacoustic characteristics are checked and adjusted as necessary, usually following a routine procedure. These calibration activities may be conducted at the manufacturing facility or an outside laboratory, but are most often accomplished on site at least annually. Calibration of speakers in a sound field is typically conducted on site because the unique acoustic characteristics of a specific field cannot easily be reproduced in a remote calibration facility.

Calibration of audiometers is routinely checked using instruments such as oscilloscopes, multimeters, spectrometers, and sound-level meters to verify frequency, intensity, and temporal characteristics of the equipment. Output transducers such as earphones and bone stimulators can be calibrated in two ways: (1) using “real ear” methods, involving individuals or groups of persons free from ear pathology and who meet other criteria, or (2) using hard-walled couplers (artificial ears) and pressure transducers specified by the relevant standard.

Audiometric Standards

Electroacoustic instrumentation for audiometry has been described in national and international standards written by scientists and experts designed to introduce uniformity and facilitate the international exchange of data and test results. ANSI, ISO, and IEC are recognized bodies that have developed accepted standards for equipment used in audiometry and acoustics. Some standards relate to equipment, others to audiometric procedures, and still others to

the environment and conditions in which audiometry should be conducted (10).

The aim of standards for audiometric equipment and procedures is to assure precision of equipment functions to help ensure that test results can be interpreted meaningfully and reliably within and between clinics and laboratories using different equipment and personnel in various geographical locations. The results of audiometry often help to provide a basis for decisions regarding intervention strategies, such as medical or surgical intervention, referral for cochlear implantation, hearing aid selection and fitting, application of assistive listening devices, or selection of appropriate educational or vocational placement. As in any measurement scheme, audiometric test results can be no more precise than the function of the equipment and the procedures with which those measurements are made.

PURE TONE AUDIOMETRY

Psychophysical Methods

Audiometry may be conducted with a variety of methodologies depending on the goal of the procedure and subject variables such as age, mental status, and motivation. For example, the hearing sensitivity of very young children may be estimated by assessing the effects of auditory stimuli presented in a sound field on startle-type reflexes, level of arousal, and localization. Patients who are developmentally delayed may be taught with reinforcement to push a button upon presentation of a test stimulus. Children of preschool age may be taught to make a motor response to auditory test stimuli using play audiometric techniques.

In conventional audiometry, auditory stimuli are presented through special insert or supra-aural earphones, or a bone oscillator worn by the patient. When indicated, a sound field around the listener may be created by presenting stimuli through strategically placed loudspeakers. Most threshold audiometric tests in school-aged children and adults can be conducted using one of two psychophysical methods originally developed by Gustav Fechner: (1) the method of adjustment, or (2) the method of limits (11). In the method of adjustment, the intensity of an auditory stimulus is adjusted by the listener according to some criterion (just audible or just inaudible), usually across a range of continuously or discretely adjusted frequencies. Nobel Prize Laureate Georg von Bekesy initially introduced this methodology into the practice of audiometry in 1947 (12). With this approach, listeners heard sinusoidal stimuli that changed from lower to higher test frequencies, and adjusted the intensity of continuous and interrupted tones from “just inaudible” to “just audible”. As shown in Fig. 2, this methodology yielded information about the listener’s auditory threshold throughout the test frequency range. The relationship of threshold tracings for the pulsed and continuous stimuli added additional information about the site of lesion causing the hearing loss (13,14).

Later, it was found that the tracing patterns tracked by hearing-impaired patients at their most comfortable loudness levels, instead of their threshold levels, yielded additional useful diagnostic information (15). A myriad of

Figure 2. Bekesy audiometric tracing of continuous and interrupted tones around auditory threshold.

factors associated with this psychophysical measurement method, including the age of the listener, learning effects, and the length of time required to obtain stable test results, make these methods unsuitable for routine diagnostic purposes, especially in young children. Nevertheless, audiometers incorporating this methodology are manufactured to precise specifications (9) and are routinely used in hearing conservation programs to record the auditory sensitivity of large numbers of employees working in industrial or military settings.

In most clinical situations today, routine threshold audiometry is conducted using the method of limits. In this approach, the examiner adjusts the intensity of the auditory stimuli of various frequencies according to a predetermined schema, and the listener responds with a gross motor act (such as pushing a button or raising a hand) when the stimulus is detected. Although auditory threshold may be estimated using a variety of procedural variants (ascending, descending, mixed, adaptive), research has established (16) that an ascending approach in which tonal stimuli are presented to the listener from inaudible intensity to a just audible level is a valid and reliable approach for cooperative and motivated listeners, and the technique most parsimonious with clinical time and effort. In this approach, tonal stimuli are presented at intensity levels below the listener's threshold of audibility and raised in increments until a response is obtained. At this point, the intensity is lowered below the response level and increased incrementally until a response is obtained. When the method of limits is used, auditory threshold is typically defined as the lowest intensity level that elicits a reliable response from the patient on approximately 50% or more of these "ascending" trials.

Sound Pathways of the Auditory System

The fundamental anatomy of the ear is depicted in Fig. 3. Sound enters the auditory mechanism by two main routes, air conduction and bone conduction. Most speech and other sounds in the ambient environment enter the ear by air conduction. The outer ear collects and funnels sound waves into the ear canal, provides a small amount of amplification

Figure 3. Anatomy of the peripheral auditory mechanism. Adapted from medical illustrations by NIH, Medical Arts & Photography Branch.

to auditory signals, and conducts sound to the tympanic membrane (eardrum). Acoustic energy strikes the tympanic membrane, where it is converted to mechanical energy in the form of vibrations to be conducted by small bones across the middle ear space to the inner ear. These mechanical vibrations are then converted to hydraulic energy in the fluid-filled inner ear (cochlea). This hydrodynamic form of energy results in traveling waves on cochlear membranous tissues. Small sensory hair cells are triggered by these waves to release neurotransmitters, resulting in the production of neural action potentials that are conducted through the auditory nerve (N. VIII) via central auditory structures in the brainstem to the auditory cortex of the brain, where sound is experienced.

Disorders affecting different sections of the ear depicted in Fig. 3 produce different types of hearing impairment. The outer ear, external auditory canal, and ossicles of the middle ear are collectively considered as the conductive system of the ear, and disorders affecting these structures produce a conductive loss of hearing. For example, perforation of the tympanic membrane, presence of fluid (effusion) in the middle ear due to infection, and the disarticulation of one or more bones in the middle ear all produce conductive hearing loss. This type of hearing loss is characterized by attenuation of sounds transmitted to the inner ear, and medical/surgical treatment often fully restores hearing. In a small percentage of cases, the conductive disorder may be permanent, but the use of a hearing aid or other amplification device can deliver an adequate signal to the inner ear that usually permits excellent auditory communication.

The inner ear and auditory nerve comprise the sensorineural mechanism of the ear, and a disorder of this apparatus often results in a permanent sensorineural hearing loss. Sensorineural disorders impair both perceived sound audibility and sound quality typically because of impaired frequency selectivity and other effects. Thus, in sensorineural-type impairments, sounds become difficult to detect, and they are also unclear, leading to poor understanding of speech. In some cases, conductive and sensorineural disorders simultaneously co-exist to produce

a mixed-type hearing impairment. Listeners with this disorder experience the effects of conductive and sensorineural deficits in combination.

Finally, the central auditory system begins at the point the auditory nerve enters the brainstem, and comprises the central nerve tracts and nuclear centers from the lower brainstem to the auditory cortex of the brain. Disorders of the central auditory nervous system produce deficits in the ability to adequately process auditory signals transmitted from the outer, middle, and inner ears. The resulting hearing impairment is characterized not by a loss of sensitivity to sound, but rather difficulties in identifying, decoding, and analyzing auditory signals, especially in difficult listening environments with background noise present. Auditory processing disorders require sophisticated test paradigms to identify and diagnose.

The Audiogram

The results of basic audiometry may be displayed in numeric form or on a graph called an audiogram, as shown in Fig. 4. As can be seen, frequency in hertz (Hz) is depicted on the abscissa, and hearing level (HL) in dB is displayed on the ordinate. Although the normal human ear can detect frequencies below 100 Hz and as high as 20,000 Hz, the audible frequency range most important for human communication lies between 125 and 8000 Hz, and the audiogram usually depicts this more restricted range. For special diagnostic purposes, extended high frequency audiometers produce stimuli between 8000 and 20,000 Hz, but specialty audiometers and earphones must be used to obtain thresholds at these frequencies. A few commercially available audiometers produce sound pressure levels as high as 120 dB HL, but such levels are potentially hazardous to the human ear and hearing thresholds poorer than 110 dB do not represent "useful" hearing for purposes of communication.

Figure 4. Graphic audiogram for a normal hearing listener. Bone conduction, right ear = <; Bone conduction, left ear = >; Air conduction, right ear = O; Air conduction, left ear = X.

Figure 5. Graphic audiogram for a listener with conductive hearing loss. Bone conduction, right ear = [; Bone conduction, left ear =]; Air conduction, right ear = O; Air conduction, left ear = X.

The dashed line across the audiogram in Fig. 4 at 25 dB HL represents a common depiction of the boundary between normal hearing levels and the region of hearing loss (below the line) in adults. The recorded findings on this audiogram represent normal test results from an individual with no measurable loss of hearing sensitivity.

Figure 5 displays test results for a listener with a middle ear disorder in both ears and a bilateral conductive loss of hearing, which is moderate in degree, and similar in each ear. Bone conduction responses for the two ears are within normal limits (between 0 and 25 dB HL), suggesting normal sensitivity of the inner ear and auditory nerve, while air conduction thresholds are depressed below normal, suggesting obstruction of the air conduction pathway to the inner ear. Thus, conductive hearing losses are characterized on the audiogram by normal bone conduction responses and depressed air conduction responses. In

Figure 6. Graphic audiogram. Bone conduction, right ear = <; Bone conduction, left ear = >; Air conduction, right ear = O; Air conduction, left ear = X.

Figure 7. Graphic audiogram for a listener with mixed hearing loss. Masked bone conduction, right ear = [; Masked bone conduction, left ear =]; Unmasked bone conduction, right ear = <; Unmasked bone conduction, left ear = >; Air conduction, right ear = O; Air conduction, left ear = X.

sensorineural-type hearing losses, air conduction and bone conduction responses in each ear are equally depressed on the audiogram. Figure 6 shows a high frequency loss of hearing in both ears, falling in pattern and sensorineural in type. Air and bone conduction hearing sensitivity is similar in both ears, suggesting that the cause of the hearing loss is not in the conductive mechanism (outer and middle ears).

The audiogram shown in Fig. 7 depicts a mixed-type loss of hearing in both ears. The gap between air and bone conduction thresholds in the two ears at the lower frequencies suggests a conductive disorder affecting the outer or middle ears. However, at frequencies above 500 Hz, hearing sensitivity via both air and bone conduction pathways in the two ears is nearly identical, which points to a disorder affecting the inner ear or auditory nerve.

In summary, an audiogram displays the results of basic audiometry in a stylized “shorthand”, so that the hearing impairment can be readily characterized according to type of loss, degree of deficit, configuration (shape) of loss, and the degree of symmetry between the two ears. Such findings constitute the basis for first-order description of a listener’s hearing sensitivity across the audible frequency range and provide important clues about the cause of hearing loss, the effects of the impairment on auditory communication ability, and the prognosis for treatment and rehabilitation.

SPEECH AUDIOMETRY

The first attempts to categorize hearing impairment on the basis of tests using speech stimuli were made in the early 1800s, when sounds were ranked according to their intensity and used to estimate the degree of hearing loss (17). Throughout the 1800s, refinements were introduced in

methodologies for using speech stimuli to evaluate hearing. These improvements included the control of word intensities by varying distance between speaker and listener, the introduction of whispered speech to reduce differences in audibility between words, recording speech stimuli on the phonograph devised by Edison in 1877, and standardizing words lists in English and other languages (17). Most of the early research on speech perception focused on the sensitivity of the auditory system to speech, but progress in this area accelerated in the early 1900s because of work at the Bell Telephone Laboratories centered on the discrimination of speech sounds from each other. This emphasis led to the development of modern materials for assessing speech recognition at the Harvard Psychoacoustic Laboratories (18), which have been refined and augmented since that time.

Although pure tone audiometry provides important information about hearing sensitivity, as well as the degree, configuration, and type of hearing loss in each ear, it provides little information about a listener’s auditory communication status and the ability to hear and understand speech in quiet as well as difficult listening situations. Attempts to predict speech recognition ability from the pure tone audiogram, even with normal hearing listeners, have met with only partial success, and the task is particularly complicated when listeners have a hearing impairment.

Instrumentation

Speech audiometry is conducted in the “speech mode” setting of a clinical audiometer. Speech stimuli are presented through the same types of transducers as those used for pure tone audiometry. Live speech stimuli via microphone and monitored with a VU meter can be used for speech audiometry, or recorded speech materials can be presented by CD or tape and routed through the audiometer to either one ear or both ears simultaneously by earphone or loudspeaker. Recorded speech materials typically include a calibration tone, and the input level is adjusted for individual recordings to a specified intensity level. Many different speech audiometric tests have been developed, and most currently in use are available in recorded form. Monitored live-voice presentation enables greater flexibility, but recorded speech materials enhance consistency across test conditions and avoid performance differences related to talker speech and vocal eccentricities.

In general, speech audiometry is conducted with the examiner in one room and the listener in another. With this arrangement, the examiner is able to observe the listener and maintain easy communication through microphones in both rooms, but the speech stimuli can be presented under carefully controlled conditions.

Speech Recognition Threshold

Speech recognition threshold (SRT) testing typically entails presentation of spondees (two-syllable, compound words), spoken with equal stress on each syllable (e.g., baseball, toothbrush, airplane). The use of these words for audiometric purposes has been investigated extensively, especially with respect to similarity in audibility (19).

Audiologists now generally select stimulus words from a list of commonly accepted spondees, and the words are presented at varying intensities using protocols similar to those used for pure tone audiometry. The speech recognition threshold (SRT) is the lowest intensity level at which the patient correctly responds to (repeats, writes down, points to) approximately 50% of the words, with the goal of determining the threshold of hearing for speech. The relationship between thresholds for speech and pure tone was identified in the early part of the twentieth century (20) and later described in detail (21,22). For purposes of clinical speech audiometry, speech recognition thresholds are expected to be within ± 6 dB of the average of the patient's pure tone air conduction thresholds at 500, 1000, and 2000. However, if the pure tone air conduction thresholds slope steeply, the speech recognition threshold is expected to agree with the average of the two best pure tone thresholds in the range of 500–2000 Hz.

The expected agreement between pure tone thresholds and speech recognition thresholds enables audiologists to use the SRT as a cross-check of pure tone air conduction threshold values. Disagreement between SRTs and pure tone threshold averages occurs for a variety of reasons. For example, poor agreement may exist between pure tone thresholds and SRTs in each ear if the patient misunderstands instructions regarding the test procedure for pure tone audiometry, or if the patient attempts to deceive the audiologist regarding actual hearing sensitivity.

SRTs can also be used to estimate/predict pure tone air conduction thresholds in the so-called speech frequency range of 500–2000 Hz in patients who are difficult to test with pure tones. Young children, for example, may reliably repeat or point to pictures of spondees (baseball, toothbrush) while exhibiting inconsistent responses to more abstract pure tones. Speech recognition thresholds have also been used as a basis for predetermining the presentation level for suprathreshold speech stimuli.

Speech Detection Threshold

Whereas the SRT represents the least intensity at which 50% of the speech stimuli presented to the listener can be recognized, the Speech Detection Threshold (SDT), sometimes called the Speech Awareness Threshold (SAT), represents the lowest intensity at which the patient exhibits an awareness of the presence of speech stimuli. If thresholds for spondaic words cannot be established, because of language impairment or other limitations such as young age or inability to speak because of injury, the SDT may represent a useful estimate of the level at which the patient indicates awareness of the presence of speech. In this type of speech threshold testing, the patient is not required to repeat the speech stimulus, which may be just a simple word or nonsense sound, but, instead, the patient simply responds with a hand movement or other gesture to indicate that a sound was detected. The SDT is obtained with protocols similar to those used for speech recognition measurement, and it is expected to be approximately 7–9 dB less intense than the value that would be obtained for the SRT (23,24).

Suprathreshold Speech Audiometry

In suprathreshold speech audiometry, speech stimuli (live-voice or recorded) are presented at levels well above the speech threshold in order to assess the listener's ability to understand speech. Depending on the purpose of the evaluation, the stimuli may be presented in quiet or in the presence of noise (e.g., speech babble, speech-spectrum noise), and the stimuli may be single nonsense syllables, monosyllabic words, nonsense sentences, or sentences. For some purposes, the stimuli are intentionally degraded by filtering or mixing them with noise, and depending on the purpose of suprathreshold evaluation, stimuli may be presented to one ear only (monaurally) or to both ears (binaurally). When stimuli are presented binaurally (both ears simultaneously), they may be identical (diotic) or different (dichotic). Stimuli may be presented at a specified level greater than speech recognition threshold or at varying intensity levels to establish a performance-intensity function. In suprathreshold testing, patient performance is often characterized in terms of percent correct, and standardized norms are used to interpret results.

Purposes for assessment of speech understanding include assessing auditory communication impairment, evaluating effectiveness of a hearing aid fitting, facilitating a comparison between hearing aids, and detecting possible VIIIth nerve or central auditory processing disorder. Suprathreshold stimuli may also be used to determine most comfortable and uncomfortable listening levels for purposes related to hearing aid fitting.

ELECTROPHYSIOLOGIC AUDIOMETRY

Auditory Evoked Potentials—Introduction

The electrophysiological response of the auditory system is often used by audiologists to evaluate auditory function. The techniques are derived from electroencephalography (EEG), which is the measurement of ongoing neural activity and has long been used to monitor brain function. The EEG can be recorded with surface electrodes attached to the scalp and connected to instrumentation that amplifies and records neural activity. Embedded in ongoing EEG activity is the brain's specific response to sensory stimulation. Auditory nervous system responses can be intentionally evoked with an auditory stimulus (such as an acoustic click) presented via an earphone (or other transducer) coupled to the ear. Neural responses that are time-linked to the stimulus can be recorded and differentiated from background EEG activity and other electrical noise sources (e.g., muscle artifact, 60 Hz electrical line noise).

Auditory Evoked Potentials—Clinical Applications

Auditory evoked response recording is an important tool for estimation of auditory sensitivity, particularly when conventional audiometry cannot be used. Evoked auditory potentials are also used routinely to assess the integrity of the auditory system (e.g., in tumor detection, auditory processing assessment, intra-operative monitoring),

but the following discussion will focus on threshold estimation/prediction.

Auditory evoked responses are used in place of conventional audiometry primarily in (1) infant hearing screening and assessment, (2) auditory evaluation of noncooperative children and adults, and (3) threshold estimation for people whose neurological status precludes use of conventional techniques. Although evoked potentials are not true measures of hearing, evoked potentials can be used in conjunction with other tests and information to estimate or predict hearing sensitivity. The capacity to make such estimates has important implications for early identification and rehabilitation of hearing impairment in newborns and young children, provision of auditory rehabilitation to people who have neurological problems, and even evaluation of nonorganic hearing impairment.

Historical Perspective

Early work indicated that ongoing EEG activity can be modified by sensory input (25). In order for a response specific to sensory stimulation to be observed, however, it was necessary to develop techniques to extract the sensory response from the ongoing EEG voltages. One important extraction technique that was developed involved algebraic summation (often called averaging) of responses that are linked in time to the sensory stimulus (26). When a bioelectric potential that is time-locked to a stimulus is recorded repeatedly and added to itself, the amplitude of the observed response will gradually increase with each stimulus repetition. In contrast, as EEG voltages during the same recording period are random, EEG voltages, when repeatedly summed, will gradually diminish or average out. Signal averaging was a critical advancement toward the clinical use of auditory evoked potentials. Other developments followed, and clinical applications of auditory potentials have now been investigated extensively. Measurement and assessment of evoked potentials are currently standard components of audiological practice.

Instrumentation

Many systems for recording auditory evoked potentials are now commercially available and are used widely. Components of the recording equipment typically include a stimulus generator capable of generating a variety of stimuli (e.g., clicks, tone bursts, tones), an attenuator, transducers for stimulus presentation (e.g., insert earphones, standard earphones, bone oscillator), surface electrodes, a differential amplifier, amplifier, filters, analog-to-digital converter, a signal averaging computer, data storage, display monitor, and printer. A simplified schematic diagram of a typical instrument is shown in Fig. 8.

In preparation for a typical single-channel recording, three electrodes are placed on the scalp. The electrodes often are called noninverting, inverting, and ground, but other terminology may be used (e.g., positive/negative or active/passive). A typical electrode montage is shown in Fig. 8, but electrode placements may vary depending on the potentials being recorded and the judgment of the clinician. Unwanted electrical or physiologic noise that may distort or obscure features of the response is reduced

Figure 8. Simple block diagram of an auditory evoked response audiometry system.

by the use of differential amplifiers with high common mode rejection ratios and filters. It is important to note that electrode placement, stimulus polarity, stimulus presentation rate, number of signal presentations, signal repetition rate, filter characteristics, stimulus characteristics, and sampling rate during analog-to-digital conversion all affect the recording, and so must be controlled by the clinician.

Classification of Evoked Auditory Potentials

After the onset of an auditory stimulus, neural activity in the form of a sequence of waveforms can be recorded. The amount of time between the onset of the stimulus and the occurrence of a designated peak or trough in the waveform is called the latency. The latency of some auditory evoked potentials can be as short as a few thousandths of a second, and other latencies can be 400 ms or longer. Auditory evoked potentials are often classified on the basis of their latencies. For example, a system of classification can divide the auditory evoked potentials into “early” [< 15 ms (e.g., electrocochleogram and auditory brainstem response)], “middle” [15–80 ms (e.g., Pa, Nb, and Pb)], and “late” [> 80 ms (e.g., P300)] categories. Various classification systems based on latencies have been described, and other forms of classification systems based on the neural sites presumed to be generating the potentials (e.g., brainstem, cortex) are also sometimes used.

It is important to note that recording most bioelectric potentials requires only passive cooperation from the patient, but for some electrical potentials originating in the cortex of the brain, patients must provide active, cognitive participation. In addition, certain potentials are affected by level of consciousness. These factors, combined with the purpose of the evaluation, are important in the selection of the waveforms to be recorded.

Auditory Threshold Estimation/Prediction with AEPs

Auditory threshold estimations/predictions have been made on the basis of early, middle, and late potentials, but the evoked potentials most widely used for this purpose are those recorded within the first 10–15 ms after stimulus onset, particularly the so-called auditory brainstem response (ABR). An ABR evoked by a click consists of 5–7 peaks that normally appear in this time frame (27–29). Typical responses are shown in Fig. 9. The figure depicts three complete ABRs, and each represents the algebraic average of 2048 responses to a train of acoustic transient stimuli. The ABR is said to be time-locked such that each of the prominent peaks occurs in the normal listener at

Figure 9. Normal auditory brainstem response; three complete responses.

predictable time periods after stimulation. Reliability is a hallmark of the ABR, and helps assure the audiologist that a valid estimation of conduction time through auditory brainstem structures has been made. A brief, gated, square-wave signal (click) stimulus is often used to generate the response, and stimulus intensity is reduced until the amplitude of the most robust peak (Wave V) is indistinguishable from the baseline voltage.

The response amplitude and latency (which lengthens as stimulus intensity decreases) are used to estimate behavioral auditory thresholds. In some equipment arrangements, computer software is used to statistically analyze the potentials for threshold determination purposes. ABR thresholds obtained with click stimuli correlate highly with behavioral thresholds at 2000–4000 Hz when hearing sensitivity ranges from normal to the severe range hearing impairment. Click stimuli are commonly used in clinical situations because their transient characteristics can excite many neurons synchronously, and thus a large amplitude response is evoked. However, variability limits the usefulness of click-evoked thresholds for prediction/estimation of auditory sensitivity of any particular patient (30), and the frequency specificity desired for audiometric purposes may not be obtained. As a result, gated tone bursts of differing frequencies are often used to estimate hearing sensitivity across the frequency range. These tonal stimuli can be embedded in bursts of noise to sharpen the frequency sensitivity and specificity of the test procedure.

In recent years, another evoked potential technique similar to the ABR has been developed to improve frequency specificity in threshold estimation while maintaining good neural synchronization. This technique, the auditory steady-state response (ASSR), uses rapidly (amplitude or frequency) modulated pure tone carrier stimuli (see Fig. 10). Evidence suggests that the ASSR is particularly useful when hearing sensitivity is severely impaired because high intensity stimuli can be used

Figure 10. Auditory steady-state response.

(31). Research on the ASSR is ongoing, and this technique currently is considered to be a complement to click and tonal ABR in threshold estimation/prediction.

ACOUSTIC IMMITTANCE MEASUREMENT

Introduction

One procedure that helps audiologists interpret the results of conventional audiometry and other audiological tests is a measure of the ease with which energy can flow through the ear. Heaviside (1850–1925) coined the term impedance, as applied to electrical circuitry, and these principles were later applied in the United States during 1920s to acoustical systems (32). Mechanical impedance-measuring devices were initially designed for laboratory use, but electroacoustic measuring instruments were introduced for clinical use in the late 1950s (33). As acoustic impedance is difficult and expensive to measure accurately, measuring instruments using units of acoustic admittance are now widely used. The term used to describe measures incorporating the principles of both acoustic impedance and its reciprocal (acoustic admittance) is acoustic immittance. Modern instrumentation permits an estimate of ear canal and middle ear acoustic immittance (including resistive and reactive components).

Instrumentation

Commonly available immittance measuring devices (see Fig. 11) employ a probe-tone delivered to the tympanic membrane through the external ear canal. Sinusoids of differing frequencies are presented through a tube encased in a soft probe fitted snugly in the ear canal. The probe also contains a microphone and tubing connected to an air pump so that air pressure in the external ear canal can be varied from – 400 to + 400 mmH₂O.

Immittance devices also typically have a signal generator and transducers that can be used to deliver high intensity tones at various frequencies for the purpose of acoustic reflex testing. The American National Standards Institute (ANSI) has published a standard (S3.39-1987) for immittance instruments (34).

Immittance Measurement Procedures

As mentioned earlier in this chapter, the middle ear transduces acoustic energy into mechanical form. The transfer function of the middle ear can be estimated by measuring acoustic immittance at the plane of the tympanic membrane. These measures are often considered (in conjunction with the results of other audiological tests) in determining the site of lesion of an auditory disorder.

Static Acoustic Immittance

The acoustic immittance of the middle ear system is usually estimated by subtracting the acoustic immittance of the ear canal. This value is termed the compensated static acoustic immittance and is measured in acoustic mhos (reciprocal of acoustic ohms). The peak compensated

Figure 11. Block diagram of an acoustic immittance measuring device.

static acoustic immittance is obtained by adjusting the air pressure in the external ear canal so that a peak in the tympanogram exists. The magnitude of this peak, relative to the uncompensated immittance value, is clinically useful, because it can be compared with norms (e.g., 0.3 to 1.6 mmho) to determine the presence of middle ear pathology. It is important to note that at ear canal pressures of + 200 daPa or more, the sound pressure level (SPL) in the ear canal is directly related to the volume of air in the external ear canal, because the contribution of the middle ear system is insignificant at that pressure. A measure of the external ear canal volume is a valuable measure that can be used to detect tympanic membrane perforations otherwise difficult to detect visually. That is, a large ear canal volume (i.e., a value considerably greater than 1.5 mL) indicates a measurement of both the external ear canal and the middle ear as a result of a perforation in the tympanic membrane.

Dynamic Acoustic Immittance (Tympanometry)

The sound pressure of the probe-tone directed at the eardrum is maintained at a constant level and the volume velocity is measured by the instrumentation while positive and negative air pressure changes are induced in the external ear canal.

Figure 12. Tympanogram of a normal ear.

The procedure is called tympanometry and the resulting changes in immittance are recorded graphically as a tympanogram. A typical tracing is seen in Fig. 12.

Admittance is at its maximum when the pressures on both sides of the tympanic membrane are equal. Sound transmission decreases when pressure in the ear canal is greater or less than the pressure at which maximum admittance occurs. As a result, in a normal ear, the shape of the tympanogram has a characteristic peaked shape (see Fig. 13) with the peak of admittance occurring at an air pressure of 0 decapascals (daPa).

Tympanograms are sometimes classified according to shape (Fig. 13) (35).

The Type A tympanogram shown in Fig. 13, so-called because of its resemblance to the letter “A”, is seen in normal ears. When middle ear effusion is present, the fluid contributes to a decrease in admittance, regardless of the changes of pressure in the external ear canal. As a result, a characteristically flat or slightly rounded Type B tympanogram is typical. When the Eustachian tube malfunctions, the pressure in the middle ear can become negative relative to the air pressure in the external auditory canal. As energy flow through the ear is maximal when the pressure differential across the tympanic membrane is zero, tympanometry reveals maximum admittance when the pressure being

Figure 13. Tympanogram types (see text for descriptions).

varied in the external ear canal matches the negative pressure in the middle ear. At that pressure, the peak admittance will be normal but will occur at an abnormal negative pressure value. This tympanogram type is termed a Type C. It is important to note that variations exist of the type A tympanogram associated with specific pathophysiology affecting the middle ear. For example, if the middle ear is unusually stiffened by ear disease, the height of the peak may be reduced (Type A_s). Similarly, if middle ear pathology such as a break in the ossicular chain occurs, the energy flow may be enhanced, which is reflected in the Type A_d tympanogram depicted in Fig. 13.

Multifrequency Tympanometry

Under certain circumstances, particularly during middle ear testing of newborns and in certain stages of effusion in the middle ear, responses to the 226 Hz probe-tone typically used in tympanometry may fail to reveal immittance changes caused by disorders of the middle ear. In these circumstances, tympanometry with probe-tone frequencies above 226 Hz may be very useful in the detection of middle ear dysfunction. With probe-tone frequencies above 226 Hz, tympanometric shapes are more complex. More specifically, multifrequency tympanometric tracings normally progress through an expected sequence of shapes as probe frequency increases (36), and deviations from the expected progression are associated with certain pathologies.

Acoustic Reflex Measurement

In humans, a sufficiently intense sound causes a reflexive contraction of the middle ear muscles in both ears, acoustically stiffening the middle ear systems in each ear, called the acoustic reflex and is a useful tool in the audiometric test battery. When the reflex occurs, energy flow through both middle ears is reduced, and the resulting change in immittance can be detected in the probe ear by an immittance measuring device. Intense tones can be introduced to the probe ear (ipsilateral stimulation) or by earphone to the ear opposite the probe ear (contralateral stimulation).

One acoustic reflex measure is the minimum sound intensity necessary to elicit the reflex. The minimum sound pressure level necessary to elicit the reflex is called the acoustic reflex threshold. Acoustic reflex thresholds that are from 70 to 100 dBHL are generally considered to be in the normal range when pure tone stimuli are used. In general, the acoustic reflex thresholds in response to broadband noise stimuli tend to be lower than those for pure tones. Reduced or elevated thresholds, as well as unusual acoustic reflex patterns, are used by audiologists to localize the site of lesion and as one method of predicting auditory sensitivity.

OTOACOUSTIC EMISSIONS

When sound is introduced to the ear, the ear not only is stimulated by sound, it can also generate sounds that can be detected in the ear canal. The generated sounds, so-

called otoacoustic emissions, have become the basis for the development of another tool that audiologists can use to assess the auditory system. In the following section, otoacoustic emissions will be described, and their relationship to conventional audiometry will be discussed.

Otoacoustic Emissions—Historical Perspective

Until relatively recently, the cochlea was viewed as a structure that converted mechanical energy from the middle ear into neural impulses that could be transmitted to and used by the auditory nervous system. This conceptual role of the cochlea was supported by the work on human cadavers of Georg von Békésy during the early and middle 1900s, and summarized in 1960 (37). In Nobel Prize-winning research, von Békésy developed theories to account for the auditory system's remarkable frequency sensitivity, and his views were widely accepted. However, a different view of the cochlea was proposed by one of von Békésy's contemporaries, Thomas Gold, who suggested that processing in the cochlea includes an active process, a mechanical resonator (38). This view, although useful in explaining cochlear frequency selectivity, was not widely embraced at the time it was proposed.

In later years, evidence in support of Gold's idea of active processing in the cochlea accumulated. Particularly significant were direct observations of outer hair cell motility (39). In addition, observed differences in inner hair cell and outer hair cell innervation such as direct efferent innervation of outer but not inner hair cells (40) suggested functional differences in the two cell types. Most relevant to the present discussion were reports of the sounds that were recorded in the ear canal (41) and attributed to a mechanical process occurring in the cochlea, which are now known as otoacoustic emissions.

Otoacoustic Emissions—Description

Initially, otoacoustic emissions (OAEs) were thought to originate from a single mechanism, and emissions were classified on the basis of the stimulus conditions under which they were observed. For example, spontaneous otoacoustic emissions (SOAEs) are sounds that occur spontaneously without stimulation of the hearing mechanism. Two categories of otoacoustic emissions that are most widely used clinically by audiologists are (1) transient otoacoustic emissions (TOAEs), which are elicited by a brief stimulus such as an acoustic click or a tone burst, and (2) distortion product otoacoustic emissions (DPOAEs), which are elicited by two tones (called primaries) that are similar, but not identical, in frequency. A third category of otoacoustic emissions that may prove helpful to audiologists in the future is the stimulus frequency otoacoustic emission (SFOAE), which is elicited with a pure tone. Currently, SFOAEs are used by researchers studying cochlear function, but they are not used widely in clinical settings.

Recent research indicates that, contrary to initial thinking, otoacoustic emissions are generated by at least two mechanisms, and a separate classification system has been proposed to reflect improved understanding of the physical basis of the emissions. Specifically, it is believed that the

mechanisms that give rise to evoked otoacoustic emissions include (1) a nonlinear distortion source mechanism and (2) a reflection source that involves energy reflected from irregularities within the cochlea such as variations in the number of outer hair cell motor proteins or spatial variations in the number and geometry of hair cell distribution (42). Emissions currently recorded in the ear canal for clinical purposes are thought to be mixtures of sounds generated by these two mechanisms.

Instrumentation

Improved understanding of the mechanisms that generate otoacoustic emissions may lead to new instrumentation that can “unmix” evoked emissions. Currently, commercially available clinical equipment records “mixed” emissions and includes a probe placed in the external ear canal that both delivers stimuli (i.e., pairs of primary tonal stimuli across a broad range of frequencies, clicks or tone-bursts) and records resulting acoustic signals in the ear canal. The microphone in the probe equipment is used in (1) the verification of probe fit, (2) monitoring probe status (e.g., for cerumen occlusion), (3) measuring noise levels, (4) verifying stimulus characteristics, and (5) detecting emissions. Otoacoustic measurement recording entails use of probe tips of various sizes to seal the probe in the external ear canal and hardware/software that control stimulus parameters and protocols for stimulus presentation. The computer equipment performs averaging of responses time-locked to stimulus presentation, noise measurement, artifact rejection, data storage, and so on, and can provide stored normative data and generate printable reports. An example of a typical DPOAE data display is shown in Fig. 14.

It is important to note that outer or middle ear pathology can interfere with transmission of emissions from the cochlea to the ear canal, and thus the external ear canal and middle ear status are important factors in data interpretation. Also, although otoacoustic emissions ordinarily are not difficult to record and interpret, uncooperative

Figure 14. DPAOE responses from 1000 to 6,000 Hz from the left ear of a normal listener. X = DPOAE response amplitudes; squares = physiologic noise floor; bold curves = 95% confidence limits for normal ears.

patient behavior and high noise levels can hamper or even preclude measurement of accurate responses.

Otoacoustic Emissions—Clinical Applications

Measurement of otoacoustic emissions is used routinely as a test battery component of audiometric evaluations in children and adults, and it is particularly useful for monitoring cochlear function (e.g., in cases of noise exposure and during exposure to ototoxic medication) as well as differentiating cochlear from neural pathology. Currently, otoacoustic emission evaluation is also useful, either alone or in combination with evoked potential recording, in newborn hearing screening. In addition, OAE assessment is sometimes used in preschool and school-age hearing screening, as well as with patients who may be unwilling to cooperate during audiometry.

Otoacoustic Emissions and Audiometric Threshold Prediction/Estimation

Audiologists do not use otoacoustic emissions as a measure of “hearing” because OAEs constitute an index of cell activity in the inner ear, not “hearing.” Research suggests, however, that otoacoustic emissions may become an important indicator for predicting/estimating auditory thresholds when conventional audiometry cannot be conducted (42).

Many sources of variability exist that affect DPOAE use in audiometric threshold prediction/estimation, including variability with respect to etiology of the hearing loss, age, gender, and uncertainty regarding locations of DPOAE generation and their relationship to audiometric test frequencies. Individual DPOAE amplitude variation, intra- and inter-subject variations occurring at different frequencies and at different stimulus levels, and the mixing of emissions from at least two different regions of the cochlea (as described above) can reduce frequency selectivity and specificity in DPOAE measurement.

It has been suggested that developing methods to “unmix” the emissions associated with different generators (e.g., through the use of suppressor tones to reduce or eliminate one source component or with the use of Fourier analysis to analyze the emissions) may reduce variability and improve specificity in threshold prediction/estimation and determination of etiology (41). It is likely that future commercial otoacoustic measurement instruments will enable the user to differentiate distortion source emissions from reflection source emissions and that this improvement will lead to more widespread use of otoacoustic emissions in audiometric threshold estimation and prediction.

BIOCOMPATIBILITY OF MATERIALS

ZHOU XIANG
MYRON SPECTOR
Brigham and Women's Hospital
Boston, Massachusetts

INTRODUCTION

Most surgical specialties have been revolutionized by the introduction of implantable devices. These advances have been founded, in large part, on biomaterials science and engineering. One of the critical determinants of the performance of the device relates to its compatibility with the structure and function of the tissue or organ (a structure comprised of two or more tissues) in which it is implanted. Moreover, the tissue response to the implant should not impede the required function of the device. This article will deal with the response to biomaterials implanted into solid tissues. Biocompatibility issues related to blood-contacting applications will be outside the scope of this discussion.

Implantation of the device requires the production of a surgical wound, and in this respect the tissue response to the implant may be looked upon as the modification of the wound healing response by the very presence of the implant. In vascularized tissues, the creation of a surgical wound elicits an inflammatory process that can be considered part of the natural course of healing. The end result of the healing process is tissue similar to that naturally occurring at the site (the process of "regeneration") or scar tissue (the process of "repair"), which in many tissues and organs comprises fibrous tissue. Infectious organisms (viz., bacteria) when present serve as a persistent injurious agent that prolongs and can further incite the inflammatory process, not only jeopardizing the performance of the implant, but threatening the life of the individual. The principles of biocompatibility including the mechanisms underlying inflammatory and infectious processes apply regardless of the type of material of fabrication of the implant. There are, however, features of the biomaterials that can affect certain aspects of these processes. It can

therefore be instructive to also consider issues of biocompatibility in the context of the various classes of materials: metals, ceramics, and polymers.

CLASSES OF MATERIALS

The term "biomaterials" generally refers to synthetic materials and treated natural materials that are employed for the fabrication of implantable devices that are to replace or augment tissue or organ function. An understanding of the chemical makeup of biomaterials can provide insights into their biocompatibility for selected applications. Generally, biomaterials may be considered "inert" or "reactive" with the biological milieu. In the latter case, the reactivity could relate to the release of moieties or the adsorption of biological molecules. Inert materials may also release small amounts of ions and molecules or nonspecifically bind biomolecules. The feature that distinguishes inert from reactive biomaterials is the degree to which the interactions of the implant with the biological environment affects the tissue response and device performance. Those materials designed to effect specific tissue responses through their reactivity may also be referred to as "bioactive".

This article provides a brief description of materials used for the fabrication of implantable devices relative to issues related to biocompatibility. A more comprehensive discussion of biomaterials can be found elsewhere in this encyclopedia.

Metals

In metals, closely packed arrays of positively charged atoms are held together in a loosely associated "cloud" of free electrons. The essential features of the metallic bond are that it is nondirectional and the electrons are freely mobile. The metals most often used for the fabrication of implantable devices are stainless steel, cobalt-chromium alloys, and titanium and titanium alloy. The specific members of these families used as biomaterials are usually identified by a designation provided by the American Society for Testing and Materials (ASTM). Metallic materials have certain properties that make them ideal for load-bearing applications; in particular, they can maintain very high strength under the aggressive aqueous environment in the body.

The biocompatibility of the implantable metallic materials is related to their corrosion resistance, in that they can generally be considered as inert. While they release detectable levels of metal ions (1,2), these ions have not yet been found to significantly affect tissue or organ function or cause pathological changes. One conundrum related to biomaterials is that while the ions released from certain metallic devices are known to be carcinogenic when administered to certain animals models (3,4) and when encountered by humans in certain circumstances (1), there have not yet been definitive studies relating the incidence of

various cancers to the ions released by metallic implants (see later section).

The following sections provide a brief description of three metal systems most frequently used for the fabrication of implantable devices.

Stainless Steels. The stainless steels, like all steels, are iron-based alloys. Chromium is added to improve the corrosion resistance through the formation of a chromium-oxide surface layer; at least 17% chromium is required for the term “stainless” to be used. Carbon and nickel are employed as alloying elements to increase strength. The most common type of stainless steel used for implants is 316L (American Iron and Steel Institute designation; ASTM F-138), containing 17–19% chromium, 13–15.5% nickel, and <0.03% carbon. Despite their very good corrosion resistance, stainless steels are subject to several types of corrosion processes, including crevice, pitting, intergranular, and stress corrosion. These processes can profoundly degrade the mechanical strength of the alloy and can lead to the elevated release of metallic ions into the surrounding tissue with undesirable biological consequences.

Alloying with chromium generates a protective, self-regenerating oxide film that resists perforation, has a high degree of electrical resistivity, and, thus, provides a major protection against corrosion; formation of the chromium oxide “passivation” layer is facilitated by immersion of the alloy in a strong nitric acid solution. The nickel imparts more corrosion resistance and ease of fabrication. The molybdenum addition provides resistance to pitting corrosion. Other alloying elements facilitate manufacturing processes.

Cobalt–Chromium Alloys. Surgical cobalt–chromium alloy is a cobalt-based system with chromium added for increased corrosion resistance. Its composition contains 27–30% chromium and 5–7% molybdenum. Tungsten is added to the wrought alloy to enhance ductility. As with stainless steels, the chromium content of this alloy generates a highly resistive passive film that contributes substantially to corrosion resistance. The Co–Cr Mo (F-75) alloy has superior corrosion resistance to the F-138 stainless steel, particularly in crevice corrosion. There is an extensive, decades-long history of biocompatibility in human implantation. The Co–Cr Mo devices are currently produced by a process referred to as hot isostatic pressing that results in parts with more favorable strength characteristics than results from casting processes. The Co–Cr Tn–Ni Alloy (ASTM F90) is very different from the F-75 alloy with which it is often confused. Parts can be fabricated from this alloy by hot forging and cold drawing; it is not used in the cast form. In clinical practice, F90 is used to make wire and internal fixation devices (e.g., plates, intramedullary rods, and screws).

Unalloyed Titanium (ASTM F-67) and Titanium Alloy (ASTM F-136). Titanium and its alloy with 6% aluminum and 4% vanadium, Ti-6Al-4V, are used for their excellent corrosion resistance and their modulus of elasticity that is approximately one-half that of stainless steel and cobalt–chromium alloys. This lower modulus results in devices

with lower stiffness that may be advantageous in certain applications such as implants in bone as they will result in less stress-shielding of bone. The alloy of titanium has much better material properties than the pure titanium. Problems with titanium are its severe notch sensitivity and poor wear resistance.

Titanium and its alloys are of particular interest for biomedical applications due to their outstanding biocompatibility. In general, their corrosion resistance significantly exceeds that of the stainless steels and the cobalt–chromium alloys. In saline solutions near neutral pH, the corrosion rate is extremely small, and there is no evidence of pitting, intergranular, or crevice corrosion. Unalloyed titanium is used less frequently than the alloy for the fabrication of implants. It is, however, available in various configurations, such as plain wire for manufacturing purposes. In addition, it is used to produce porous coatings for certain designs of total joint replacement prostheses.

ASTM F-136 specifies a titanium alloy with a content of 5.5–6.5% Al, 3.5–4.5% V, 0.25% Fe (maximum), 0.05% N (maximum) and 0.08% C (maximum), 0.0125% H (maximum), and other 0.1% (maximum 0.4% total). Developed by the aircraft industry as one of a number of high strength titanium alloys, this particular formulation has a yield strength reaching 1110 MPa. The ASTM F-136 specification limits the oxygen to an especially low level of 0.13% maximum. This is also known in the industry as the ELI (extra low interstitial) grade. Limiting the level of oxygen improves the mechanical properties of the material, particularly increasing its fatigue life. One interesting feature of titanium and its alloys is the low modulus of elasticity of 100 GPa as compared to 200 GPa for the cobalt–chromium alloys. This feature leads to their use in plates for internal fixation of fractures. Some have found that the lower stiffness of these plates may decrease the severity of bone stress-shielding that results in osteopenia under these devices.

One of the weaknesses of titanium is its poor wear resistance. It appears that this problem relates to the mechanical stability of the passive film covering the surface of the alloy. On a carefully polished surface, the film is highly passive but mechanically weak. The poor wear resistance of titanium can result in the release of particulate wear debris if the material is not judiciously employed in the fabrication of implants (5). While the metal in bulk form may be biocompatible adverse cell and tissue responses may be elicited by titanium particles (5–8).

Permanent and Absorbable Synthetic and Natural Polymers

Polymers consist of long chains of covalently bonded molecules characterized by the repeated appearance of a monomeric molecular unit. They can be produced *de novo* by the polymerization of synthetic monomers or prepared from natural polymers isolated from tissues. Most synthetic and natural polymers have a carbon backbone. Bonding among polymer chains results from much weaker secondary forces—hydrogen bonds or van der Waal’s forces. Covalent bonding among chains, referred to as cross-linking, can be produced in certain polymer systems. Physical

entanglements of the long polymer chains, the degree of crystallinity, and chemical cross-linking among chains play important roles in determining polymer properties. The molecular bonding of the backbone of the polymer can be designed to undergo hydrolysis or enzymatic breakdown thus allowing for the synthesis of absorbable, as well as permanent, devices.

Polymeric materials are generally employed for the fabrication of implants for soft tissue applications that require a greater degree of compliance than can be achieved with metals. However, they have also been shown to be of value as implants in bone for indications that would also benefit from their lower modulus of elasticity, and the ability of some to be polymerized *in vivo* so as to adapt to defects of complex shape. For some indications, the radiolucency of polymeric materials may be an important benefit. Because of the limited strength and wear resistance of polymers, care must be given to the load-bearing requirements of the applications in which they are used.

The following sections provide a summary of a few of the most frequently used polymers.

Polymethyl Methacrylate (PMMA). Polymethyl methacrylate (9) is used in a self-curing form as a filling material for defects in bone and as a grouting agent for joint replacement prostheses. It can be shaped *in vivo* while in a dough stage prior to complete polymerization and thus makes a custom implant for each use. Its purpose is the redistribution of stress in a more even pattern to the surrounding bone. Often referred to as “bone cement”, when PMMA is employed for joint arthroplasty it acts as a grout to support the prosthesis rather than a glue; it has minimal adhesive properties. The time-dependent properties of PMMA during curing require an understanding of its handling characteristics. Immediately after mixing, the low viscosity permits interdigitation with cancellous bone. Viscosity rises quickly once the chemical setting reaction begins requiring that the prosthesis be accurately positioned and stationary to achieve maximum fixation.

The chemical toxicity of the methyl methacrylate monomer and the heat generated during the polymerization exothermic reaction need be considered when using PMMA. While the toxicity of the monomer has not prevented the material from being employed successfully for a wide array of applications, there are efforts to reduce the monomer content (10) and to employ alternative activating agents that would be less toxic (11).

Its brittle nature after curing and low fatigue strength make PMMA vulnerable to fracture under high mechanical loading and production of wear debris in situations when other harder materials rub against it. The cellular response to PMMA particles can promote an inflammatory response (12,13) that can result in osteolysis. This process has been referred to as “cement disease” (14). This underscores the importance of reducing the circumstances that can result in the production of PMMA debris.

Silicone. Silicones (15) are polymers having a backbone comprising alternating silicon and oxygen atoms with organic side groups bonded to the silicon through covalent

bonding with the carbon atom. One form of silicone commonly used for the fabrication of implants is polydimethylsiloxane (PDMS). In PDMS, methyl (CH₃) side groups are covalently bonded to the silicon atom and it can be used in three forms: (a) a fluid comprising linear polymers of varying molecular weight (i.e., chain length); (b) a cross-linked network referred to as a gel; and (c) a solid elastomer comprising a highly cross-linked gel filled with small particles of silica. In considering the performance of silicone implants, the role of each form of PDMS in the device need be considered. Attributing specific biological responses to individual components of a silicone device is complicated by the many molecular forms of silicone that the implant comprises.

The PDMS elastomers contain a noncrystalline silica particles 7–22 nm in diameter that has been surface-treated to facilitate chemical bonding of the particle to the PDMS gel. Addition of the silica particle to a highly cross-linked PDMS gel is done to modify the mechanical properties of the elastomer. One of the challenges in investigating tissue responses that may have been elicited by the release of the silica particles is their small size that requires transmission electron microscopy (TEM) for analysis.

Polyethylene. Ultrahigh molecular weight polyethylene (UHMWPE) (16,17) has a very low frictional coefficient against metal and ceramics, and is therefore used as a bearing surface for joint replacement prostheses. Moreover, the wear resistance of UHMWPE is higher than other polymers investigated for this application. Low strength and creep, however, present potential problems.

The term polyethylene refers to plastics formed from polymerization of ethylene gas. The possibilities for structural variation on molecules formed by this simple repeating unit for different molecular weight, crystallinity, branching, cross-linking, and so on, are so numerous and dramatic with such a wide range of attainable properties that the term polyethylene truly refers to a subclass of materials. The earliest type of polyethylene was made by reacting ethylene at high (20,000–30,000 lb/in.²) pressure and temperatures of 200–400 °C with oxygen as catalyst. Such material is referred to as conventional or low density polyethylene. Much polyethylene is produced now by newer, low pressure techniques using aluminum–titanium (Ziegler) catalysts. This is called linear polyethylene due to the linearity of its molecules, in contrast to the branched molecules produced by high pressure processes. The linear polymers can be used to make high density polyethylene by means of the higher degree of crystallinity attained with the regularly shaped molecules. Typically, there is no great difference in molecular weight between the low density and high density varieties, (e.g., 100,000–500,000). However, if the low pressure process is used to make extremely long molecules, (i.e., UHMWPE), the result is different and quite remarkable. This material, with a molecular weight between 1 and 10 million, is less crystalline and less dense than high density polyethylene and has exceptional mechanical properties. The material is used in very demanding applications and is by far the most successful polymer used in total joint replacements. It far outperforms the various acrylics, fluorocarbons,

polyacetals, polyamides, and polyesters that were tried for such purposes. In recent years, cross-linking methods including chemical agents and ionizing radiation have been implemented in an attempt to further improve the wear performance of UHMWPE.

The principal biocompatibility issue with polyethylene relates to the inflammatory response provoked by particles of the polymer, as can be generated by the wear of total joint replacement prostheses (18,19).

Absorbable Polymers. Absorbable polymers have been used in the fabrication of surgical implants for decades in the form of absorbable sutures. More recently, this class of materials has been investigated for the application of resorbable devices including fracture fixation implants and scaffolds for tissue engineering. The principal issues associated with the implementation of absorbable polymers as implants include: mechanical properties (i.e., strength), degradation rate, and biological response to the degradation products.

Synthetic Absorbable Polymers. One of the classes of polymers used frequently for the fabrication of absorbable implants is the alpha-hydroxy acids including L-lactic acid, glycolic acid, and dioxanone. These molecules normally are used in their polymeric forms: poly L-lactic acid (PLLA), polyglycolic acid (PGA), and polydioxanone. Copolymers of lactic and glycolic acids are also frequently employed.

This particular class of polyester undergoes breakdown as a result of the hydrolytic scission of the ester bond. The access of water to this bond in PGA is much greater resulting in a more rapid degradation rate compared to that which occurs with PLLA, which has a bulkier CH_3 side group instead of the H atom in PGA. The copolymer of polylactic and polyglycolic acid can be designed to have an intermediate degradation rates. While the majority of the breakdown of these polymers is due to hydrolytic scission there is some lesser extent of nonspecific enzymatic action.

Several factors affect the rate of breakdown of these polymers: the relative amount of monomers comprising the copolymers, the degree of crystallinity, and the surface area. These polymers are normally broken down to natural body components excreted in the urine or exhaled. The process of degradation involves the gradual decrease in the average molecular weight of the polymer as hydrolysis proceeds. At some point, the molecular weight decreases to the extent that the polymer becomes soluble in the aqueous environment and there is a bolus release of the molecules. Depending on the mass of the implanted device, the concentration of the molecules may elicit an inflammatory response (20).

Natural Absorbable Polymers. Myriad devices are fabricated from collagen (21), the principal structural protein of the body. The collagen molecule comprises three tightly coiled helical polypeptide chains. *In vivo* the collagen molecule, tropocollagen, is assembled to form fibrils that in turn assume various orientations and configurations to form the architecture of various tissues. The wide array of properties of tissues comprising collagen, from dermis to

musculoskeletal tissues including articular cartilage, meniscus, and ligament, is due to differences in the chemistry, density, and orientation of the fibrils formed from the collagen molecule.

Collagen is soluble in specific solutions in which the chains can become disentangled to produce gelatin. It can be isolated from tissue and purified through the use of several agents: acids, alkalis, enzymes, and salt. Treatment in acid results in the elimination of acidic proteins and glycosaminoglycans that result in the dissociation of the collagen fibrils. A similar effect can be achieved using alkaline extraction with the removal of basic proteins. Proteolytic enzymes that cleave the telopeptides, that serve as natural cross-linking agents for collagen, allow for the dissolution of collagen molecules and aggregates in aqueous solutions. Salt extraction leads to the removal of newly synthesized collagen molecules and certain noncollagenous molecules thus facilitating the disaggregation of collagen fibrils.

That collagen is soluble in acidic medium facilitates its extraction from tissues and reprocessing into biomaterials. Several factors are critical determinants of the properties of reconstituted collagen biomaterials. The degree to which denaturation or degradation of the collagen structures isolated from tissue occurs will affect the mechanical properties. These properties will also be affected by the degree to which the material is subsequently cross-linked.

An important biological property related to the molecular structure of collagen is the collagen-induced blood platelet aggregation. The quaternary structure of collagen resulting from the periodic aggregation of the collagen molecules has been well documented. Methods for isolating and purifying collagen fibrils, that result in the preservation or destruction of this quaternary structure are employed to produce either hemostatic or thromboresistant biomaterials. Another factor relates to the removal of soluble components that might serve as antigens. The immunogenicity can be reduced, to clinically nonsequential levels, by chemically modifying the antigen molecules.

A wide variety of methods have been employed for the fabrication of collagen sutures, fleeces for hemostasis, and sponge-like materials for scaffolds for tissue engineering.

Ceramics

Ceramics are typically three-dimensional (3D) arrays of positively charged metal ions and negatively charged non-metal ions, often oxygen. The ionic bond localizes all the available electrons in the formation of a bond. Network organization ranges from highly organized, crystalline, 3D arrays to amorphous, random arrangements in glassy materials.

Ceramics, for reasons described above, may be the most chemically inert implant materials currently in use. However, their relatively low tensile strength, high modulus, and brittleness limit the applications in which they may be used. Current techniques allowing the formation of ceramic coatings on metallic substrates have revitalized interest in ceramics for hard tissue applications.

Aluminum Oxide. Aluminum oxide has been found of value for the articulating components of total joint arthroplasties because of its high wear resistance and its low coefficient of friction when prepared in congruent, polished geometries. The brittle nature of alumina remains a detriment.

Calcium Phosphates/Hydroxyapatite. Calcium-based ceramics, closely related to the naturally occurring hydroxyapatite in bone, have generated a large amount of interest in recent years. The ability to bond directly to bone as well as their osteoconductive capability promise to enhance biological fixation of implant devices. Hydroxyapatite is only slightly resorbable and is used in both dense and porous forms as a permanent implant. Tricalcium phosphate is bioabsorbable to varying degrees, depending on formulation and structure. There are currently a wide array of calcium phosphate materials undergoing investigation as bone graft substitute materials (see the Section on Calcium Phosphate Materials as Matrices for Bone Regeneration: Bone Graft Substitute Materials).

Composite Materials

Composite materials are combinations of two or more materials, and usually more than one material class (i.e., metals polymers, ceramics). They are used to achieve a combination of mechanical properties for specific applications. Composite technology, much of it developed for the aerospace industry, is beginning to make its way into biomedical materials. Carbon fiber reinforced polymers are being investigated as substitutes for metals. The advantage is that devices with comparable strength, but with significantly lower stiffness can be produced. Moreover, these types of composite devices are radiolucent.

BIOLOGICAL RESPONSE TO BIOMATERIALS

The biological processes comprising the tissue response are affected by implant-related factors including (22):

1. The "dead space" created by the presence of the implant.
2. Soluble agents released by the implant (e.g., metal ions or polymer fragments).
3. Insoluble particulate material released from the implant (e.g., wear debris).
4. Chemical interactions of biological molecules with the implant surface.
5. Alterations in the strain distribution in tissue caused by the mismatch in modulus of elasticity between the implant and surrounding tissue, and the movement of the implant relative to adjacent tissue as a result of the absence of mechanical continuity.

Study of the tissue response to implants requires methodology capable of measurements at the molecular, cellular, and tissue levels. Moreover, time is an important variable owing to the criticality of the temporal relationship between the molecular and cellular protagonists of the

biological reactions, and because implant-related factors act with different time constants on the biological responses. The dynamic nature of implant-tissue interactions requires that the final assessment of tissue compatibility be qualified by the time frame in which it has been evaluated.

The tissue response to an implant is the cumulative physiological effect of (1) modulation of the acute wound healing response to the surgical trauma of implantation and the presence of the implant, (2) the subsequent chronic inflammatory reaction associated with the presence of the device, and (3) remodeling of surrounding tissue as it adapts to the presence of the implant (23). Moreover, the healing and stress-induced adaptive remodeling responses of different tissues vary considerably. In this regard, the response of various tissues to the same implant can vary greatly.

In considering the biological response that might be elicited by an implant, the healing-remodeling characteristics of the four basic types of tissue: connective tissue, muscle, epithelia, and nerve, should be recalled. The characteristics of the parenchymal cells in each type of tissue can provide a basis for understanding the tissue response to an implant. The following characteristics of an implant site are determinants of the biological response:

1. Vascularity.
2. The nature of the parenchymal cell with respect to its capability for mitosis and migration, because these processes determine the regenerative capability of the tissue.
3. The presence of regulatory cells such as macrophages/histiocytes.
4. The effect of mechanical strain, associated with deformation of the extracellular matrix, on the behavior of the parenchymal cell.

Surgical wounds in avascular tissue (e.g., the cornea and inner third of the meniscus) will not heal because of the limited potential for the proliferation and migration of surrounding parenchymal cells and the absence of a fibrin clot in the wound site into which the cells can migrate. Gaps between an implant and surrounding avascular tissue can remain indefinitely. Implant sites in vascular tissues in which the parenchymal cell does not have the capability for mitosis heal by the formation of scar in the gap between the implant and surrounding tissue. Moreover, adjacent cells that have died as a result of the implant surgery will be replaced by fibroblasts and scar tissue.

Normal Local Tissue Response

Wound Healing. Implantation of a medical device initiates a sequence of cellular and biochemical processes that lead to "healing by second intention" (i.e., healing by the formation of granulation tissue within a defect; as opposed to the healing of an incision, i.e., healing by first intention). The first phase of healing in vascularized tissues is inflammation, which is followed by a reparative phase, the replacement of the dead or damaged cells by healthy cells. The pathway that the reparative process takes depends

on the regenerative capability of the cells comprising the injured tissue (i.e., the tissue or organ into which the implant has been placed). Cells can be distinguished as labile, stable, or permanent based on their capacity to regenerate. Labile cells continue to proliferate throughout life, replacing cells that are continually being destroyed. Epithelia and blood cells are examples of labile cells. Cells of splenic, lymphoid, and hematopoietic tissues are also labile cells. Stable cells retain the capacity for proliferation, although they do not normally replicate. These cells can undergo rapid division in response to a variety of stimuli and are capable of reconstitution of the tissue of origin. Stable cells include the parenchymal cells of all of the glandular organs of the body (e.g., liver, kidney, and pancreas), mesenchymal derivatives such as fibroblasts, smooth muscle cells, osteoblasts and chondrocytes, and vascular endothelial cells. Permanent cells are those which cannot reproduce themselves after birth. Examples are nerve cells.

Tissues comprised of labile and stable cells have the capability for regeneration after surgical trauma. The injured tissue is replaced by parenchymal cells of the same type, often leaving no residual trace of injury. However, tissues comprised of permanent cells are repaired by the production of fibrocollagenous scar. Despite the capability of many tissues to undergo regeneration, destruction of the tissue stroma, remaining after injury or constructed during the healing process, will lead to formation of scar. The biological response to materials thereby depends on the influence of the material on the inflammatory and reparative stages of wound healing. Does the material yield leachables or corrosion products that interfere with the resolution of inflammation initiated by the surgical trauma? Does the presence of the material interfere with the stroma required for the regeneration of tissue at the implant site? These are the types of questions that need to be addressed when assessing the "biocompatibility" of materials.

A number of systemic and local factors influence the inflammatory-reparative response. Systemic influences include age, nutrition, hematologic derangements, metabolic derangements, hormones, and steroids. While there is a prevailing "conventional wisdom" that the elderly heal more slowly than the young, there are few control data and animal experiments to support this notion. Nutrition can have a profound effect on the healing of wounds. Prolonged protein starvation can inhibit collagen formation, while high protein diets can enhance the rate of tensile strength gained during wound healing. Local influences that can affect wound healing include infection, inadequate blood supply, and the presence of a foreign body.

Fibrous Tissue Interface. The very presence of the implant provides a dead space in tissue that attracts macrophages to the implant-tissue interface (24). These cells are attracted to the prosthesis as they are to any dead space (e.g., bursa or joint space), presumably because of certain microenvironmental conditions (e.g., low O₂ and high lactate). In this regard it is not clear why macrophages are absent from the surface of osseointegrated implants (see below).

Macrophages along with fibroblasts of the scar comprise synovial tissue (25) that can be considered the chronic inflammatory response to implants (unless the device is apposed by osseous tissue, i.e., osseointegrated). This process is often termed "fibrous encapsulation" (26,27). The presence of regulatory cells such as macrophages at the implant-tissue interface can profoundly influence the host response to a device because these cells can release proinflammatory mediators if irritated by the movement of the device or substances released from the biomaterial (28). The inflammatory response of the synovial tissue around implants is comparable to the inflammation that can occur in the synovium lining any bursa (e.g., bursitis); hence, the response to implants has been termed "implant bursitis" (25).

Response to Implants in Bone: Osseointegration, Bone Ingrowth, Chemical Bonding of Bone to a Biomaterial.

Wound healing governs the makeup of the tissue that forms around implants. Because of its capability for regeneration bone should be expected to appose implants in osseous tissue, and form within the pore spaces of porous coatings. Is this bone bonded in any way to the implant? Bonding of a prosthesis to bone would enhance its stability, limiting the relative motion between the implant and bone. In addition, bonding might provide a more favorable distribution of stress to surrounding osseous tissue.

Bonding of bone to an implant can be achieved by mechanical or chemical means. Interdigitation of bone with PMMA bone cement or with irregularities in implant topography, and bone ingrowth into porous surfaces, can yield interfaces capable of supporting shear and tensile as well as compressive forces. These types of mechanical bonding have been extensively investigated and are reasonably well understood. Chemical bonding of bone to materials could result from molecular (e.g., protein) adsorption-bonding to surfaces with subsequent bone cell attachment. This phenomenon has undergone intensive investigation in recent years but is not yet as well understood as mechanical bonding.

The term "osseointegration" has been used to describe the presence of bone on the surface of an implant with no histologically (light microscopy) demonstrable intervening nonosseous (e.g., fibrous) tissue. All implants in bone should become osseointegrated unless the bone regeneration process is inhibited.

The bone ingrowth into a porous-surface coating on an implant leads to an interlocking bond that can serve to stabilize the device. In order for the porous material to accommodate the cellular and extracellular elements of bone, the average pore diameter should be above ~100 μm .

The bone ingrowth process proceeds in two stages. The surgical trauma of implantation initially leads to the regeneration of bone throughout the pores of the coating. Then mechanical stress-induced remodeling leads to resorption of bone from certain regions of the implant and continued formation and remodeling of bone in other regions.

Previous investigations have provided evidence of bone bonding to many different types of calcium phosphate

materials, calcium carbonate substances, and calcium-containing "bioactive" glasses. Chemical bonding was evidenced by the high strength of the implant-bone interface that could not be explained by a mechanical interlocking bond alone. In addition, TEM has shown that there is no identifiable border between these calcium-containing implants and adjacent bone.

Many recent studies have investigated the bonding of bone to one particular calcium phosphate mineral, hydroxyapatite, chosen because its relationship to the primary mineral constituent of bone; natural bone mineral is a calcium-deficient carbonate apatite. Experiments have been performed on both hydroxyapatite coated metallic implants and on particulate and block forms of the mineral employed as bone substitute materials. Histology of specimens from animals and retrieved from human subjects show that a layer of new bone $\sim 100\ \mu\text{m}$ in thickness covers most of the hydroxyapatite surface within a few weeks of implantation and remains indefinitely. This layer of bone is attached to the surrounding osseous tissue by trabecular bridges.

In studying the mechanism of bone bonding, researchers have found that within days of implantation, biological apatites precipitate (from body fluid) onto the surface of the calcium-containing implants. These biological apatites are comparable to the carbonate apatite that is bone mineral. Proteins probably adsorb to this biological mineral layer thereby facilitating bone cell attachment and the production of osteoid directly onto the implant. This osteoid subsequently undergoes mineralization as it does normally in osteogenesis, thus forming a continuum of mineral from the implant to the bone. In this light, the bone cell responds to the biological apatite layer that has formed on the implant and not directly to the implant itself. Recent studies have shown that this biological apatite layer forms on many different calcium phosphate substances, explaining why bone bonding behavior has been reported for many different types of calcium phosphate materials. Of course, the clinical value of this phenomenon will depend (1) for coatings, on how well these substances can be bonded to implants; and (2) for bone graft substitute materials, their strength, modulus of elasticity, and ability to be resorbed. However, the finding that bone can become chemically bonded to certain biomaterials is a significant advance in our understanding of the implant-bone interface.

Effects of Implant-Induced Alterations of the Mechanical Environment. The presence of the implant can alter the stress distribution in the extracellular matrix (ECM), and thereby reduce or increase the strains experienced by the constituent cells. Many studies have demonstrated immobilization-induced atrophy of certain tissues resulting from the decrease in mechanical strains. Loss of bone mass around stiff femoral stems and femoral condylar prostheses of total hip and knee replacement devices has been associated with the reduced strains due to "stress shielding". Hyperplasia and hypertrophy of tissue in which mechanical strains have increased due to the presence of an implant have also been evidenced.

Criteria for Assessing Acceptability of the Tissue Response

The *in vivo* assessment of tissue compatibility of biomaterials requires that certain criteria be implemented for determining the acceptability of the tissue response relative to the intended application of the material-device. The biomaterial-device should be considered biocompatible only in the context of the criteria used to assess the acceptability of the tissue response. In this regard, every study involving the *in vivo* assessment of tissue compatibility should provide a working definition of biocompatibility. Biomaterials-devices implanted into bone can become apposed by the regenerating osseous tissue, and thus be considered compatible with bone regeneration. However, altered bone remodeling around the device due to stress shielding, with a net loss of bone mass (i.e., osteopenia), could lead to the assessment that the material-device is not compatible with normal bone remodeling. In situations in which the implant is surrounded by fibrous tissue the macrophages on the surface of the material are the expected response to the dead space produced by the very presence of the implant. The synovial tissue thus produced might be considered an acceptable response relative to the chemical compatibility of the material. Utilization of the thickness of the scar capsule around implants alone as a measure of biocompatibility is problematic because it can be influenced by movement of the tissue at the site relative to the implant.

The cellular and molecular make-up of tissue and the interactions among these components are complex. Therefore, criteria for assessing certain features of the biocompatibility of biomaterials-devices should focus on specific aspects of the biological response. The tissue compatibility of materials should be assessed specifically in the context of the effects of the material-device on certain aspects of the response. Moreover, it is important to note that materials yielding acceptable tissue compatibility in one site of implantation might yield unfavorable results in another site.

Degeneration of the Biomaterial-Tissue Interface

As noted earlier it is the wound healing response that initially establishes the tissue characteristics of the implant-tissue interface. Several agents have the potential for initiating degenerative changes in the interface tissue. Others probably act as promoters to stimulate the production of proinflammatory mediators that stimulate tissue degradation, and potentiate the failure process. Of the many factors affecting the implant-tissue interface, motion of the prosthetic component and particulate debris are two of the most important. However, it is difficult to determine the causal relationships between these factors and implant failure from only studying the end-stage tissue. Other histopathological findings and laboratory studies indicate that metal ions and immune reactions might play roles in the degenerative processes leading to prosthesis loosening in certain patients. Systemic diseases and drugs employed for the treatment of the disorders could also serve as factors contributing to the breakdown of the implant-bone interface. Finally, there might be interindividual differences in genetically determined cellular responses that could explain why prostheses fail in

some patients in whom there is a low mechanical risk factor for failure.

Effects of Implant Movement. Movement of the implant relative to the surrounding tissue can interfere with the wound healing response by disrupting the granulation tissue. In the case of implants in bone this relative movement, if excessive, can destroy the stroma required for osseous regeneration, and a fibrous scar results. Another important effect of implant motion is the formation of a bursa within connective tissue in which shearing and tensile movement has led to disruption of tissue continuity and led to the formation of a void space or sack (lined by synovial-like cells). It is to be expected, then, that tissue around prosthetic components removed due to loosening might display features of synovial-like tissue. The presence of synovial cells (macrophage and fibroblast-like cells) is important because they could be activated by other agents, such as particulate debris, to produce proinflammatory molecules. The process of activation of this tissue might be similar to that which occurs in inflammatory joint synovium or bursitis.

An explanation of how prosthetic motion leads to the formation of the synovial-like tissue can be found in previous studies (29) that have shown that "synovial lining is simply an accretion of macrophages and fibroblasts stimulated by mechanical cavitation of connective tissue". These findings are based on experiments in which the mechanical disruption of connective tissue was produced by injection of air and/or fluid into the subcutaneous space of animals (30). The resulting sack was initially described as a "granuloma pouch". Later studies (29) demonstrated that the membrane lining the pouch displayed the characteristics of synovium, and referred to this tissue as "facsimile synovium".

Prosthetic motion can also contribute to wear of the prosthetic component abrading against the bone cement sheath or surrounding bone, thereby generating increased amounts of particulate debris that might contribute to activation of the macrophages and synovial-like cells at the implant-tissue interface.

Effects of Implant-Derived Particles. Particulate debris can be generated from the abrasion of the implant against surrounding tissue. Understandably, the potential for wear is greater with materials-devices rubbing against a hard surface such as bone and with the articulating components of joint replacement prostheses. This particulate debris can induce changes in the tissue around the implants. Adverse responses have been found to both metallic and polymeric particles. The biological reactions to particles are related to (1) particle size, (2) quantity, (3) chemistry, (4) topography, and (5) shape. While it is not clear what role each of these factors play in the biological response, particle size appears to be particularly important. Particles small enough to be phagocytosed ($<10\ \mu\text{m}$) elicit more of an adverse cellular response than larger particles.

Particulate metallic particles (viz., cobalt-chromium alloy particles) can induce rapid proliferation of macrophages and focal degeneration of synovial tissues (31).

Because previous animal investigations and histopathological studies of tissues retrieved from human subjects have suggested that titanium alloy is more "biocompatible" than cobalt-chromium alloys it has been assumed that titanium particulate debris would be less problematic than particles of cobalt-chromium alloy. Histology of pigmented tissue surrounding titanium implants has generally revealed considerably fewer macrophages and multinucleated foreign body giant cells than seen around cobalt-chromium alloy particles and polymeric particulate debris. However, titanium alloy particles generated by the abrasion of femoral stems against bone cement in human subjects can cause histiocytic and lymphoplasmacytic reactions to the metallic particles (32). Titanium particles have also been found to cause fibroblasts in culture to produce elevated levels of PGE_2 . These findings show that there may be adverse aspects of the biological response to titanium particles as well as to cobalt-chromium alloy particulate debris.

Many investigations evaluating the histological response to polyethylene and polymethylmethacrylate particles in animals and in tissue recovered from revision surgery have revealed the histiocytic response to these polymer particles. Moreover, it has been shown that this macrophage response can lead to bone resorption.

Synovial cells also respond to calcium-containing ceramic particles (33). Local leukocyte influx, proteinase, PGE_2 , and tumor necrosis factor (TNF) levels have been measured after injection of calcium containing ceramic materials into the "air pouch model" described above. The TNF was detected in significant amounts after injection of the ceramics. These substances also provoked elevated leukocyte counts and levels of proteinase and PGE_2 , showing that substances with surface chemistries that elicit a beneficial tissue response (e.g., bone bonding) when implanted in bulk form can cause destructive cellular reactions when present in particulate form.

Investigations indicate that most biomaterials, when present in particulate form in a size range small enough to be phagocytosed ($<10\ \mu\text{m}$), can elicit a biological response that could cause the bone resorption that initiates and promotes the loosening process. This degenerative process has been referred to as "small particle disease".

Metallic Ions. Animal and human investigations have revealed elevated levels of metal ions in subjects with certain types of implants (viz., total joint replacement prostheses). Our knowledge is still incomplete with respect to the mechanisms of metal ion release. Results are often variable with respect to the concentration of specific metal ions in certain tissues and fluids. The fact that metal in ionic form is often not distinguished from that present as particles serves to confound interpretation of results.

Rises in serum and urinary chromium levels in patients who have undergone conventional cemented cobalt-chromium alloy hip replacement have previously been reported (34). However, an attempt to determine the valency of chromium as either +3 (III) or +6 (VI) from the concentration of metal ion in blood clot was not successful. This experiment was based on the fact that erythrocytes display

a unidirectional uptake of Cr(VI) while effectively excluding Cr(III). The distinction of the valency of chromium is important because Cr(VI) is much more biologically active than Cr(III).

Unfortunately, our knowledge of the local and systemic biological and clinical sequelae of metal ion release has not significantly advanced over the past several years. Addition of cobalt ions in the form of cobalt fluoride solutions to the media of synovial cells can stimulate their production of neutral proteinases and collagenase (35). These findings may be relevant to findings of tissue degradation (e.g., osteolysis) around implants in that metal ions could activate synovial cells in the surrounding synovial tissue to produce agents that promote tissue degeneration.

Diseases and Drugs. There has been little work correlating the failure of implants with disease states and drugs employed to treat the disorders. Some observations indicate that antiinflammatory agents, as well as certain anticancer drugs, can reduce the amount of bone formation around devices in the early stages of wound healing after implantation. Little is known, however, about the role of these and other agents on tissue remodeling and degeneration at the biomaterial-tissue interface.

Immune Reactions

It is not infrequent that two patients matched for sex, age, weight, activity level, and other factors, that might be expected to affect the performance of the prosthesis (implanted with the same device by same surgeon), have very different outcomes. This suggests that immune reactions, or genetically determined responses, might play a role in the failure of prostheses in some patients.

Immune responses include antibody and cell-mediated reactions and activation of the complement system. Certain small molecules released from implants (e.g., metal ions), while not antigenic themselves, can bind to existing antibodies and then to larger antigenic molecules or carrier proteins and subsequently elicit antibody production by activation of B lymphocytes by the small molecule (the "hapten") and by activation of helper T lymphocytes by the carrier protein to which it is bound.

The cell types that might be expected to occur at sites of antibody and cell-mediated reactions are not often found in tissue retrieved with revised devices. These cells include lymphocytes and plasma cells. The finding of occasional lymphocytic infiltrates in peri-implant tissue does not provide enough information for the role of immune reactions to implant. Immune reactions to polymeric materials (viz., silicone) have also been suggested as the cause of certain systemic diseases. However, mechanisms for such a response, and its prevalence, remain in question. Much more additional work is necessary to determine the role of immune reactions in the response to implantable devices.

The complement system, comprising circulating proteins and cell-surface receptors, plays an important role in immune processes engaged in the host defense against infectious agents. The complement system consists of 20–30 proteins circulating in blood plasma. Most of these are

inactive until they are cleaved by the chemical action of an enzyme of the interaction with a biomaterial surface. Once activated, the proteins can initiate a cascade of reactions resulting in the mobilization of immune cells resulting in inflammatory processes. Previous studies have demonstrated that many biomaterials can activate (cleave) certain molecules (C_3 and C_5) in the complement system and thereby stimulate the alternative pathway of the immune response. It has been suggested that complement activation by biomaterials could play a role in adverse reactions to certain devices. However, additional studies are required.

One form of cell-mediated immune reaction associated with implants, that has been studied, is the delayed hypersensitivity response. "Metal allergy" has been incriminated as the cause of failure in certain patients (36). However, results obtained to date are not definitive. "The incidence of metal sensitivity in the normal population is high, with up to 15% of the population sensitive to nickel and perhaps up to 25% sensitive to at least one of the common sensitizers Ni, Co, and Cr. The incidence of metal sensitivity reactions requiring premature removal of an orthopedic device is probably small (less than the incidence of infection). Clearly, there are factors not yet understood that caused one patient, but not another, to react" (37).

A similar situation exists with respect to sensitivity reactions to polymeric materials including bone cement (PMMA). The monomer of PMMA is a strong skin sensitizer (38). However, failure of cemented devices has not yet been correlated with a hypersensitivity response in patients.

The fact that there is no clear etiology of the prosthesis loosening in some patients while in other individuals with multiple risk factors for failure the prosthesis functions well has suggested that there may be genetic determinants for loosening.

Carcinogenicity

Chromium and nickel are known carcinogens and cobalt is a suspected carcinogen. Therefore, it is understandable that some concern might be raised about the release of these metal ions into the human body from implants. Fortunately, there have been few reports of neoplasms around implanted devices (e.g., total joint replacement prostheses). While no causal relationship has been evidenced, there is a high enough index of suspicion to warrant serious investigation of this matter through epidemiological and other studies. The use of porous coated metallic devices (with large surface area) in younger patients (e.g., noncemented total joint replacement prostheses) has added to concern about the long-term clinical consequences of metal ion release because of the significant increase in exposure of patients to metal ions.

Prior publications have reviewed the relationship of metallic ion release to oncogenesis (1), and reports of neoplasms found around orthopedic implants have been reviewed (39). The difference in the tumor types, time to appearance, and type of prosthesis confounds attempts to conclude an association of the neoplasm to the implant materials and released moieties.

In an epidemiological investigation conducted in New Zealand (40), >1300 total joint replacement patients were followed to determine the incidence of remote site tumors. The incidences of tumors of the lymphatic and hemopoietic systems were found to be significantly greater than expected in the decade following arthroplasty. It is important to note that the incidences of cancer of the breast, colon, and rectum were significantly less than expected. The investigators acknowledged that while the association might be due, in part, to an effect of the prosthetic implants, other mechanisms, particularly drug therapy, require consideration. Somewhat similar results were obtained from another recent study (41) of the cancer incidence in 443 total hip replacement (McKee–Farrar) patients operated on between 1967 and 1973 (followed to the end of 1981). The risk of leukemias and lymphomas increased while the risk of breast cancer decreased. The authors concluded that the local occurrence of cancer associated with prostheses made of cobalt–chromium–molybdenum as reported in the literature as well as animal experiments indicate that “chrome–cobalt–alloy plays some role in cancerogenesis (sic)”.

In a recent publication (42), a nationwide cohort study performed in Sweden to evaluate cancer incidence among > 100,000 hip replacement patients found no overall cancer excess relative to the general population. The standardized incidence ratios (SIRs) were, however, elevated for prostate cancer and melanoma and reduced for stomach cancer risk. Long-term follow-up (> or = 15 years) revealed an excess of multiple myeloma. The study found no material increase in risk for bone or connective tissue cancer. The investigators noted that, while hip implant patients had similar rates of most types of cancer to those in the general population, excesses in certain types of cancers warranted further investigation, particularly because of the ever-increasing use of hip implants at younger ages.

BACTERIAL INFECTION

Biomaterial surfaces can provide favorable substrates for the colonization by bacteria. The adherence of bacteria to solid surfaces is facilitated by the their production of a “biofilm”. The biofilm is a complex structure comprising bacterial cells encapsulated in a polymeric matrix. The detailed composition of the matrix has yet to be fully determined. Little is still known about how certain biomaterials may favor the production and adherence of a biofilm. Studies are still seeking to understand how certain material characteristics might favor bacterial colonization.

Infection following material implantation may be defined as multiplication of pathogenic microorganisms in the tissue of the host after a material implantation, causing disease by local cellular injury, secretion of a toxin, or antigen–antibody reaction in the host. The pathogenic microorganisms could be bacteria, fungi or viruses; the most common pathogenic microorganisms are bacteria.

Implant-related infection is one of the most serious and difficult complications to treat, often requiring reoperation including the surgical removal of the implant, and it may result in osteomyelitis, amputation, or even death. About

25–50% of infected vascular prostheses for cardiac, abdominal, and extremity vessel replacement cases result in amputation or death (43–45). Infectious complications are the principal concerns in the use and development of implanted materials for several indications.

The Biological Response to Bacterial Infection

We have noted above that the surgical trauma associated with the implantation of medical device is an injury that elicits an inflammatory response. Bacteria are another form of injurious agent that similarly elicits inflammation. While there are similarities in the cellular reactions to these two forms of injury there are important differences. That cells of the immune system are involved in the inflammatory reaction to bacterial infection is cause for use of the term “immune response” to describe the biological process elicited by a bacterial infection.

The immune response (also called the “immune reaction”) is a defense function of the body that protects it against invading pathogens, foreign proteins, and malignancies. It consists of the “humoral immune response” and the “cell-mediated immune response”. In the humoral immune response, B lymphocytes produce antibodies that react with specific antigens brought by invading pathogens, foreign proteins, and malignancies. The antigen–antibody reactions activate the complement cascade, which causes the lysis of pathogens or cells bearing those antigens. The humoral response may begin immediately on invasion by an antigen in acute type or up to days later in chronic type. In the cell-mediated immune response, T lymphocytes mobilize tissue macrophages in the presence of foreign antigen, which causes the pathogens or cells bearing those antigens been taken by phagocyte.

An implant-related infection occurs when an adequate number of a sufficiently virulent organism overcomes the host’s immune response and establishes a focus of infection at the implant site. Implant-related infections remain a formidable challenge to the surgeon as well as material scientist. The high success rate obtained with antibiotic therapy in most bacterial diseases has not been obtained with implant-related infections for several known and as yet unidentified reasons. One important factor is that the sites on and around implants colonized by bacteria have little or no blood supply and thus do not allow blood-borne antimicrobial agents to reach the bacteria. The biofilm in which the bacteria grow may also shield the pathogens from the antimicrobial agents. Illness, malnutrition, and inadequacy of the immune system may be other factors that allow for the development implant-related infections.

Classification of Pathogens in Environment

Pathogens in the environment can be divided into three categories: primary pathogen, opportunistic pathogen, and nonpathogen. Primary pathogens are organisms that can cause infection in normal host when it has attached to the host’s tissue and has gained sufficient numbers. It is also called a professional pathogen. Only a very small proportion of microbial species may be considered to be primary or

professional pathogens, and even among these species only a relatively small number of clones have been shown to cause infection. Pathogenic organisms are highly adapted to the pathogenic state and have developed characteristics that enable them to be transmitted, to attach to surfaces, to invade tissue, to escape host defenses, to multiply, and thus to cause infection.

Opportunistic pathogens are those organisms that can only cause infection in impaired hosts. For opportunistic pathogens, the state is the main determinant of whether infection will be the outcome of their interaction with the host's local tissue. This group of organisms may lack effective means to overcome an unimpaired host's defense mechanisms. They have limited growth opportunities outside their restricted niche in an unimpaired individual. As a result, infection may be only a rare consequence of the host-microbe encounter.

Nonpathogens are harmless members of the normal flora in healthy individuals. They may, however, in some rare situations, act as virulent invaders in an individual with severe deficiencies in host defense mechanisms.

The Most Common Bacteria that Cause Implant-Related Infection and Routes of Transmitting Pathogens

Studies of infected implants that have been retrieved for analysis indicate that a few species seem to dominate implant-related infections. Coagulase negative staphylococci are most frequently involved in the implant-related infections. Aerobic Gram-negative bacteria and anaerobic bacteria, which are usually present in deep infections (46), can also cause implant-related infection. *Staphylococcus aureus* (*S. aureus*) and *Staphylococcus epidermidis* (*S. epidermidis*) have been most frequently isolated from infected implant material surfaces. However, *Escherichia coli* (*E. coli*), *Pseudomonas aeruginosa*, β -hemolytic streptococci, and enterococci have also been isolated (43,47). These bacteria more often act as a component of mixed infections.

The different physical and chemical properties of implant material surfaces appear to be responsible for favoring infection with certain bacteria. *Staphylococcus aureus* is mostly involved in infection of metallic implants, such as metallic artificial joints, whereas *S. epidermidis* is a primary cause of infection of polymeric biomaterial implants, such as vascular grafts, catheters, and shunts (47).

The most pathogenic species is *S. aureus* because the infection caused by *S. aureus* often results in a much higher rate of mortality, and it is rarely cleared without removal of the implant. The recent emergence of *S. aureus* that are more resistant to all approved antibiotics raises more serious concerns for the future (48).

Implant-related infections may be the result of bacterial contamination of the implant material prior to its implantation. Pathogenic microorganisms may obtain access into the body by, direct contact, airborne spreading, contaminated water transmission, and blood stream transmission. If microorganisms exit in the host's tissue or on the skin or mucous membrane away from the implant site and break through blood barrier (e.g., associated dental treatment)

they can gain access to the blood circulation. This can bring the microorganisms to the implant site (i.e., hematogenous infection).

Risk Factors for Implant-Related Infections

Implant-related infections occur when an adequate number of a sufficiently virulent organism overcomes the host's defense systems. During this process, many factors may be involved or even cooperate in establishing a focus of infection at the local implant area. The risk factors may involve the implant material, the process of implantation surgery, and the host.

Material-Related Factors. A large surface increases the possibility of microorganism attachment and thus can lay a role in implant-related infection. The avascular zone surrounding a device also favors infection as it contains tissue fluid and is often free of microorganism-monitoring agents because of the absence of blood circulation. A small initial number of microorganisms can grow to significant numbers and cause infection without interruption.

Sterile implant materials are commonly packaged in sterile paper, cloth, and plastic bags. However, all of these may be accidentally broken without notice and allow bacterial contamination of the implant.

Implantation-Related Factors. Implantation-related factors include the operating environment, skin and wound care, and surgical technique. In the operating room, airborne microorganisms (usually Gram-positive bacteria) are a source of wound contamination, originating with operating room personnel. Each person in the operating room sheds as many as 5000–55,000 particles/min. Conventional operating room air may contain 10–15 bacteria/ft³ (49).

The microorganisms present on the host's skin are another source of wound contamination. Although the skin and hair can be sterilized with disinfectant agents, it is almost impossible to sterilize the hair follicles and sebaceous glands because the disinfectants now used in surgery do not penetrate an oily environment. Many disinfectants that do penetrate the oily environment, such as hexachlorophene, are absorbed by the body and have potentially toxic side effects. For this reason, skin preparations now used in surgery have a limited effect on sebaceous glands and hair follicles where microorganisms normally reside and reproduce (49). Because the skin can never be disinfected completely, the number of residual microorganisms present on the skin after disinfection builds the possibility of infection.

Any factor or event that delays wound healing increases the risk of implant-related infection. Ischemic necrosis, seroma, hematoma, wound infection, and suture abscesses are common preceding events for implant-related infection. Surgical technique and operating time also contribute to infection rates.

Host-Related Factors. Systematic factors that can contribute to implant-related infections include: immunological status, nutrition, chronic disease, and infection at a remote site or bacteremia caused by other reasons. A

deficiency in the host's defense mechanisms predisposes the host to infection by specific groups of opportunistic pathogens (49). Deficiencies in the immune system may be acquired (such as acquired immune deficiency syndrome, AIDS) or may result from congenital abnormalities. Malnutrition and chronic disease decreases both the immune and inflammatory response to microorganism invasion. Although the contaminating microorganisms may be few in number, the altered host's defense mechanisms implies that even small bacterial counts have to be regarded as highly virulent species.

If there is infection at a remote site in the host, the microorganisms can be brought to the implant site by blood stream and cause implant-related infection. Under several other conditions which the blood barrier are broken, such as a dental treatment, microorganisms are transported by the blood stream to find their way to the implant site, causing hematogenous infections (50,51). Infection of total hip arthroplasties after dental treatment is not rare (52).

The Most Common Feature of Implant-Related Infection: Biofilm

At the implant site, the surface of the material is immersed in the tissue fluid of the host's local tissue. If microorganisms appear, they have a strong tendency to colonize surfaces to form a microecosystem in which various microbial strains and species grow in a complex community-like structure, which is called biofilm.

Biofilms are defined as bacterial populations reside and produce in matrix that adheres to a surface, interface, or each other. During most implant-related infections, microbial products may assist the development and persistence of the infection in association with adsorbed macromolecules from the biological environment in which the implant material is placed. In the presence of implant material, bacteria elaborate a fibrous exopolysaccharide material called the "glycocalyx". The glycocalyx modifies the local environment in favor of the pathogen by hiding and protecting the organism from surfactants, antibodies, phagocytes, and antimicrobial agents. This increases the population of microorganisms on the surface of implant materials *in vivo* (53,54). These protective biofilms may act as bases in predisposing to tissue invasion and also result in the persistence of infection. Biofilms are implant-associated and troublesome. They have been reported to be 500 times more resistant to antibiotics than planktonic cells (55).

Growth of the organisms is the main mechanism of multiplication in a biofilm and eventually leads to the formation of a thick film. The biofilm is formed in three phases. The first phase is the formation of "conditioning film". As soon as the implantation of material performs, the material surfaces adsorbed macromolecules from the surrounding fluid, forming a conditioning film. The macromolecules are a number of extracellular proteins that interact with host intracellular matrix and blood proteins. For example, joint materials adsorb macromolecules from synovial fluid, bone materials adsorb macromolecules from plasma, while dental materials adsorb macromolecules from salivary fluid. The conditioning film forms within seconds of exposure of the implant to a body fluid (56).

This conditioning film provides a suitable substrate for microorganism's adhesion.

The second phase is an initial, reversible adherence of microorganisms to the conditioning film. This adhesion depends on the physicochemical characteristics of the microbial cell surface, the material surface and the conditioning film. Microorganisms can reach the surface via various transport mechanisms, such as diffusion, convection or sedimentation (57). Implants can become contaminated before or during surgery, and more likely, by hematogenous seeding (58). Several factors are reported to contribute to this initial adherence, including surface hydrophobicity, proteinaceous adhesins, and capsular polysaccharides, such as fibrinogen, fibronectin, thrombospondin, von Willebrand factor, collagen, bone sialoprotein, and elastin (59). It seems that different bacteria is helped by different group of factors. *Staphylococcus aureus* appears to be enhanced by mostly fibronectin and plasma glycoprotein in adhering to polymethylmethacrylate *in vivo*, and this may contribute to the establishment of infection (60).

The third phase of biofilm development is microcolony formation and exopolymer production, which results in the firm anchoring of the biofilm and complex biofilm architecture. The adhered organisms multiply and form microcolonies and higher ordered structure glycocalyx. As soon as glycocalyx have been formed, the organisms gain some resistance. In favor of the protection, the microorganisms keep multiplying within this matrix. New layers of film are added and allowing the microorganisms room to multiply, forming thick biofilms (56). Biofilm protects the resident microorganisms against environmental attacks and antibiotics. However, the mechanism for resistance is not well understood.

As biofilms grow thicker and thicker, microorganisms on the periphery of the expanding biofilm may detach, which plays a large part in the pathogenesis of septic processes (61,62).

Latent Infections

As the biofilm protects microorganisms against environmental attacks and antibiotics, the microorganisms can survive in the biofilm for a long period of time when the host's defense system is strong or sufficient concentration of antibiotics is exit. There is no clinical symptom or sign of infection, but the microorganisms exit in the implant site. However, if the host's defense system becomes weakened or a sufficient concentration of antibiotics is no longer administered, the microorganisms may become more active, and cause a latent infection.

Latent infection also can be caused in other situations by a remote wound. The remote wound can give microorganisms access to the blood circulation. The blood stream can bring the microorganisms to the implant, causing a latent infection. Infection of total hip arthroplasty after dental treatment is not rare (52).

The Outcomes of Infection

Implant-related infection produces all the symptoms of infectious inflammation with a wide spectrum of severity.

The clinical presentation is determined largely by the virulence of the infecting pathogen, the extent of the area involved, the location of the infection and the nature of the infected host tissue. The infection may cause large changes to the host's internal environment as well as the implant material. As we mentioned in former section, *S. aureus* is a common pathogen in implant-related infection. In the mean while, it is particularly a very virulent pathogen in this setting and usually produces a fulminant infection.

The early stage of implant-related infection may be obvious or obscure. Signs and symptoms vary with the location and extent of tissue or organ involvement. Common characteristics of infection, such as fever, chills, nausea, vomiting, malaise, erythema, swelling, and tenderness may or may not be present. The classic triad is fever, swelling, and tenderness or pain. Tenderness or pain probably is the most common and earliest symptom. Swelling may be mild. Fever is not always a consistent finding.

During the mid-late stage of infection, the severity of the infection, its specific microorganism, and the particular tissue, site, and material involved all introduce morphologic variations in the basic patterns of acute and chronic infection. The implant-related infection can appear as serous inflammation, fibrinous inflammation, suppurative or purulent infection, abscesses, or more seriously lead septicemia, septic shock, or patient death.

Serous inflammation is marked by the outpouring of a thin fluid derived from the blood serum. Fibrinous inflammation is a fibrinous exudate develops when the vascular leaks are large enough. These two are the clinical appearance of mild infection. Fibrinous exudate may convert to scar tissue if the infection is controlled in this stage (63).

Suppurative or purulent infection is commonly seen in implant-related infection. It is characterized by the production of large amounts of pus or purulent exudate consisting of neutrophils, necrotic cells, and tissue fluid. Certain pyogenic (pus-producing) microorganisms (e.g., staphylococci) produce this localized suppuration.

Abscesses are focal localized collections of purulent inflammatory tissue caused by suppuration buried in a tissue. They are produced by pyogenic bacteria. Abscesses have a central region that appears as a cavity full of pus that consists of necrotic tissue, died white blood cells, bacteria, and material. There is usually a zone of neutrophils around this necrotic focus. Vascular dilation, parenchymal and fibroblastic proliferation occurs outside this region, indicating the beginning of repair. Sometimes, the abscess may become walled off by connective tissue that limits it from further spread (64).

Microorganisms on the periphery of the expanding biofilm may detach or separate. These microorganisms may present in blood and can be confirmed by blood culture, which is called bacteremia. If the bacteria are strong enough to survive in blood and produce toxin, it is called septicemia, which can be life-threatening.

Diagnosis of Implant-Related Infection

The specific diagnosis of implant-related infection is dependent, in large part, upon isolation of the pathogen by aspiration of secreted fluid or by culture of tissue obtained

at debridement. However, there are other assessments that can indicate an infection, such as blood count and different morphologic examinations.

Roentgenographic studies are helpful in implant-related infections. Plain roentgenograms show soft tissue swelling, joint space narrowing or widening, bone destruction and non-X-ray transparent implant materials. These roentgenograms can reveal (1) abnormal lucencies at the material–host tissue interface, (2) bone or periosteal reaction, (3) motion of components on stress views, or (4) changes in the position of implant materials. If initial roentgenograms are normal in the evaluation of a suspected implant-related infection, other imaging modalities that show soft tissue swelling and loss of normal fat planes about the involved site should be used.

Computed tomography (CT) scanning can help determine the extent of surrounding tissue involvement. Pus within the cavity can cause an increased density on the CT scan. Adjacent soft tissue abscesses also are easily seen. However, the use of CT scan is limited if the implanted material is made of metal.

Magnetic resonance imaging (MRI) can also be implemented for evaluating implant-related infections. The images can reflect the increase in water content resulting from edema in the implant or surrounding tissue due to infection. The MRI detects changes much earlier in the course of disease than roentgenograms, because it shows the condition of the surrounding soft tissue.

Fate of Material During Infection

The biofilm and bacterial modification of the microenvironment around implants may affect the biomaterial in several ways. Biodegradable materials, such as collagen, may degrade faster than expected due the elevated levels of enzymes and the changes in pH. Such implants may collapse before being replaced by host tissue and thus become a component of the local abscess. The low pH often found at sites of infection may also accelerate the corrosion of metallic materials. Implant-related infections indirectly affect implant materials by causing the destruction of surrounding tissue thus contributing to loosening of the implant.

Treatments of Implant-Related Infection

Successful treatment of an implant-related infection often depends on both extensive and meticulous surgical debridement and effective antimicrobial therapy. Debridement should be emphasized because infection often persists despite treatment with systemic antibiotic therapy in the absence of extensive and meticulous debridement of the implant-tissue interface.

It is of paramount importance to confirm the microorganism causing the infection. Distinguishing infection from pure inflammation is also very important because they have some similarities. The timing and selection of bacteria culture are critical. Many implant-related infections are deep seated, and adequate culture specimens are difficult to obtain. In spite of this, every effort should be made to obtain a culture specimen. The preferred specimen in implant-related infections is aspirated fluid. A deep

wound biopsy or a curetted specimen after cleaning the wound is acceptable.

Antibiotic therapy should begin as early as implant-related infection is diagnosed. Treatment with systemic antibiotic therapy can at least prevent the infection from transmission. In the meanwhile, local symptoms and signs of infection should be observed carefully. If there are signs show the infection is not under control, a debridement may be indicated.

Treatment of an implant-related infection at mid-late stage may require both systemic antimicrobial treatment and local surgical treatment. Antibiotic treatment alone sometimes may still be sufficient at this stage, however, it should be performed under careful observation and cannot last long. If there are signs that the infection is not under control, surgery is needed.

Surgery may go hand in hand with antibiotic treatment. The purpose of surgery is clearance of the necrotic tissue with the bacteria and augmentation of the host response. Debridement and irrigation removes necrotic and avascular tissue, bacteria, and harmful bacterial products. It is essential when pus is found on aspiration, signifying an abscess, or when roentgenographic changes indicating pus, necrotic material, and chronic inflammation. If an abscess has formed, removal of the implant is indicated.

Frequently, the only way to treat an infected large implant is to remove it in associate with antibiotic treatment.

If the infection is very severe, septic shock may exist and threaten the patient's life. At this situation, the most important work is antishock and save life. Supported by antishock and antibiotic treatment, removal of implant and open debridement, or even amputation must be performed.

How to Prevent Implant-Related Infection

Recognizing the unique characteristics and outcomes of implant-related infections, the best course is prevention. The close relationship and cooperation of implant designer, manufacturer, and surgeon are necessary for prevention of implant-related infection. The implant must be kept free of bacteria, while the surgeon should evaluate the risk of infection in each patient by considering both host- and surgeon-dependent factors. Simply stated, it is much easier to prevent an implant-related infection than to treat it.

Sterilization Methods. There are several methods for sterilizing implants prior to implantation. The first concern when choosing a sterilization method is the physical and chemical properties of the implant material itself as well as the packaging material required to maintain the implant sterile prior to delivery to the operative site. Autoclaving is the method of choice for the sterilization of metallic or heat-resistant implants. The advantages of autoclaving are efficacy, speed, process simplicity, and no toxic residues. The disadvantages are the relatively high temperature of the process (121 °C) may damage some non-heat resistant implant materials as well as the packaging materials. Thus, most nonmetallic implants and packaging materials cannot be sterilized by this method.

Ethylene oxide (EtO) gas sterilization is a low temperature sterilizing process. It is compatible with a wide range of implant and packaging materials. It is commonly used to sterilize a wide range of medical implants, including surgical sutures, absorbable and nonabsorbable meshes, absorbable bone repair devices, heart valves, and vascular grafts. The advantages of EtO are its efficacy, high penetration ability, and compatibility with a wide range of materials. The main disadvantage is EtO residuals in the sterilized materials.

Exposure to ⁶⁰Co gamma rays is another widespread sterilizing method. Gamma rays have a high penetrating ability. This method of sterilization is widely used for medical products, such as surgical sutures and drapes, syringes, metallic bone implants, knee and hip prostheses. The advantages of ⁶⁰Co gamma-ray sterilization are efficacy, speed, process simplicity, no toxic residues. The main disadvantages are the very high costs and incompatibility of some radiation sensitive materials such as the fluoropolymer and polytetrafluoroethylene (PTFE).

Medical implant may also be sterilized with machine-generated accelerated electrons called electron beam sterilization. It has a similar range of applications and material compatibility characteristics as the ⁶⁰Co process. However, the main disadvantages are short penetration distance. This limits its usage. A unique application for this method is the on-line sterilization of small, thin materials immediately following primary packaging.

Several new technologies are emerging that have potential utility for implant material sterilization, such as gaseous chlorine dioxide, low temperature gas plasma, gaseous ozone, vapor-phase hydrogen peroxide, and machine-generated X rays. Machine-generated X rays have the advantage of a nonisotopic source and penetrating power similar to gamma rays.

Prevention of Operative Contamination, Wound Sepsis Contiguous to the Implant, and Hematogenous Infection. The importance of irrigation during and at the end of surgery has been well documented. The principles of no dead space, no avascular tissue, evacuation of hematomas, and soft tissue coverage should be practiced strictly during implantation surgery. Good surgical technique and minimal operating times also contribute to lowering of infection rates. Prophylactic antibiotics are definitely indicated when implants are involved. New methods are on the way of developing. Direct local delivery of polyclonal human antibodies to abdominal implant sites reduced infection severity and mortality in an animal model of implant-related peritoneal infection (65).

Any bacteremia can induce an implant-related infection by the hematogenous route (51,66,67). Dentogingival infections and manipulations are known causes of streptococcal and anaerobic infections in prostheses (51). Pyogenic skin processes can cause staphylococcal and streptococcal infections of joint replacement. Genitourinary and gastrointestinal tract procedures or infections are associated with Gram-negative bacillary, enterococcal, and anaerobic infections of prostheses (66,68). Twenty-to-forty percent of prosthetic joint infections are caused by the hematogenous route (68).

To prevent hematogenous implant-related infection, any factor that might predispose to infection should be avoided before insertion of the implant material. For elective implant surgery, the patient should be evaluated for the presence of pyogenic dentogingival pathology, skin, and other even very small local infection. Perioperative antibiotic prophylaxis is also very important. It has been reported to reduce infections in total joint replacement surgery (69).

For patients with indwelling implant materials, it is of paramount importance to diagnose and treat infections in any location as early as possible. This reduces the risk of seeding bacteria to the implant materials hematogenously in large extent. Any situation likely to cause bacteremia, even a dental care should be avoided or seriously evaluated.

Antimicrobial Biomaterials

Two factors necessary for an implant-related infection are attachment of bacteria to the implant surface and multiplication of bacteria to a significant number. Antibacterial materials are designed to decrease the surface attachment of microorganism and/or inhibit the multiplying of microorganism.

A variety of antibiotics incorporating implant materials were designed to inhibit the microorganism against multiplying. Antibiotics for incorporation in materials should have a broad antibacterial spectrum, sufficient bactericidal activity, high specific antibacterial potency, low rate of primary resistant pathogens, minimal development of resistance during therapy, low protein binding, low sensitizing potential, marked water solubility, and stable (70). During these years, various antibiotics have been evaluated both *in vitro* and *in vivo*. The studies are most regarding their suitability for incorporation in materials.

Cefazolin loaded bone matrix gelatin (C-BMG) was made from putting cefazolin into BMG by vacuum adsorption and freeze-drying techniques (71). It was tested for repair of long segmental bone defects and preventing infection in animal experiment. The effective inhibition time to staphylococcus aureus of C-BMG was 22 days *in vitro*, while 14 days *in vivo*. The drug concentration in local tissues (bone and muscle) were higher than that of plasma, and the drug concentration in local tissues was higher in early stage, later it kept stable low drug release.

Rifampin-bonded gelatin-sealed polyester was tested in another animal experiment (72). Their results indicated that rifampin-bonded gelatin-sealed polyester grafts were significantly more resistant to bacteremic infection than were silver/collagen-coated polyester grafts.

For developing antibiotics delivery biodegradable materials, polylactide-polyglycolide copolymers were mixed with vancomycin (73). The mixture was compressed and sintered at 55°C to form beads of different sizes. The biodegradable material released high concentrations of antibiotic *in vitro* for the period of time needed to treat infection. The diameter of the sample inhibition zone ranged from 6.5 to 10 mm, which is equivalent to 12.5–100% of relative activity. By changing the processing parameters, the release rate of the beads was able to be controlled. This

provides advantages of meeting the specific requirement for prevention of implant-related infection.

Besides incorporating antibiotics in implant materials, antimicrobial materials have been made in different ways. Bovine serum albumin was used to coat material surfaces by using carbodiimide, a cross-linking agent (74). The inhibition rate of the albumin coating on bacterial adherence remained high throughout the experiment. This suggests the potential use of this cross-linked albumin coating to reduce bacterial adherence and thus the subsequent possibility of prosthetic or implant infection *in vivo*.

In the future, the use of implant materials will surely increase with growing demands for a higher quality of life. In 1997, operating expenses allocated to tissue engineering exceed \$450 million and fund the activities of nearly 2500 scientists and support personnel. Growth rate is 22.5% / annum (75). At the beginning of 2001, operating expenses allocated to tissue engineering exceed \$600 million and fund the activities of nearly 3300 scientists and support personnel. Spending by tissue engineering firms has been growing at a compound annual rate of 16% (76). However, implant-related infection remains a significant problem in this field. Research on the development of biomaterial surfaces with antimicrobial properties has increased to an annual expenditure of ~\$430 million (75).

INTRODUCTION

Biomedical electrodes are used in various forms in a wide range of biomedical applications, including:

1. The detection of bioelectric events such as the electrocardiogram (ECG).
2. The application of therapeutic impulses to the body [e.g., cardiac pacing and defibrillation and transcutaneous electrical nerve stimulation (TENS)].
3. The application of electrical potentials in order to facilitate the transdermal delivery of ionized molecules for local and systemic therapeutic effect (iontophoresis).
4. The alternating current (ac) impedance characterization of body tissues.

Good electrode design is not as simple and straightforward a matter as is often assumed, and all electrode designs are not equal in performance (1). One must, therefore, not simply choose an electrode with as conductive a metal plate as possible, which unfortunately, was and appears to still be the case in many designs. Probably due to this mistaken view, it would appear that the associated electronic systems are often first developed and the electrode design is left to the end, almost as an afterthought. If the clinician is to properly diagnose the patient's cardiac problem, for example, it is imperative that the measured biosignal is clear, undistorted, and artefact-free. Unfortunately, monitoring bioelectrodes, if they are not chosen correctly, give rise to significant problems that make biosignal analysis difficult, if not impossible. Similarly, stimulation electrodes must be well-chosen if they are to optimally supply the therapeutic waveforms without causing trauma to the patient.

Current or charge is carried by ions inside the patient's body and by electrons in the electronic device itself and in its leads. The "charge-transfer" mechanism between current/charge carriers takes place at the electrode-patient interface and is of major importance in the design of an optimal electrode. Both the electrode-electrolyte interface and the skin under the electrode (collectively known as the contact) give rise to potentials and impedances that can distort the measured biosignal or adversely affect the electrotherapeutic procedure.

Implanted electrodes are generally made from inert or noble materials that do not react with surrounding tissues. Unfortunately, as a consequence, they tend to give rise to large interface impedances and unstable potentials. Implanted biosignal monitoring electrodes, in particular, require stable potentials and low interface impedances to minimize biosignal distortion and artifact problems. External biosignal-monitoring electrodes can generally use

high electrical performance nonnoble materials such as silver–silver chloride without fear of biocompatibility problems (2). They do, however, have to address the additional and very significant problem of the skin with its sizeable impedance and unstable potential. Along with the desired biosignal, one amplifies the difference between the two contact potentials. If the contact potentials were identical (highly improbable), they would cancel each other out due to the use of a differential amplifier. If the potential mismatch were very large (several hundred mV), the amplifier would not be able to cope and would saturate. If the mismatch in contact potentials is small and stable, this mismatch will be amplified along with the biosignal, and the biosignal will appear shifted up or down on the oscilloscope screen or printout paper, which would generally not be a major problem as the additional voltage offset can be easily removed. What is a significant problem, however, is when the contact potentials fluctuate with time. Their mismatch, therefore, varies and the baseline of the biosignal is no longer constant, which leads to the problem termed baseline wander or baseline drift, which makes analysis of some of the key features of the biosignal difficult. Filtering out of the drift is often not an option, as the filtering often also removes key components of the desired biosignal.

Large mismatched contact impedances can cause signal attenuation, filtering, distortion, and interference in biosignal monitoring. If contact impedances are significant compared with the input impedance of the amplifier, they can give rise to signal attenuation as a result of the voltage divider effect. Attenuation of the signal is not a major problem, after all, the amplifier is going to be used to amplify the signal by a factor of around 1000 (in the case of an ECG). A significant problem develops, however, because the contact impedance varies with frequency. The frequency-dependence of the contact impedance is a consequence of the presence of parallel capacitances at the electrode-electrolyte interface or at the skin under the electrode. At very high frequencies, the contact impedances are very small and, therefore, no attenuation of the high frequency parts of the biosignal exists. At low frequencies, the contact impedances can be very large and, hence, significant attenuation of low frequency components of the biosignal can exist. The overall signal is not only attenuated, it is also distorted with its low frequency components selectively reduced. The measurement system in effect acts as a high pass filter and the signal is differentiated. In the case of the ECG, the P, S, and T waves are deformed, leading in particular to a modification of the S–T segment. The S–T segment is of vital importance to the electrocardiologist, hence the importance of avoiding such biosignal distortions.

50/60 Hz interference can be amplified along with any monitored biosignal due to the mismatch of the contact impedances. Displacement currents flow from power lines through the air to the monitor cables and then through the electrodes and the patient to ground. If the contact impedances are not identical, the displacement currents flowing through the two contact impedances connected to a differential amplifier will give rise to different voltages at the amplifier's inputs. This 50 Hz offset voltage will be amplified along with the desired biosignal and its amplitude

is proportional to an electrode–skin impedance mismatch (3).

Other applications, such as electrical impedance plethysmography and electrical impedance tomography (4), do not monitor intrinsic biosignals emanating from the body, but inject small currents or voltages into the body and record the resultant voltages or currents. The electrical properties of the body or a body segment can then be calculated. In many of these applications, the magnitude and mismatch of contact impedances can give rise to significant errors or artifacts (5). As relatively high frequencies are often involved in these techniques, even the series resistance of the gel pad (which is generally ignored) may become significant.

Although interface impedance and potential are generally less critical for implanted stimulation electrodes, many such electrodes (e.g., implanted pacing electrodes) are used to monitor biosignals as well as to deliver the required stimulation impulses. Even in the case of a purely stimulating electrode, a low interface impedance is required to minimize energy waste and to prolong the life of the power source. Various techniques are therefore used to effectively decrease the otherwise large interface impedances of the noble or inert materials used for their biocompatible properties. Electrode material and high electrical performance is generally less critical for external stimulation electrodes such as TENS and external defibrillation electrodes. Current density distribution is of major importance in these applications in order to avoid electrical hotspots and resultant burns to the skin. In some applications, such as TENS and external pacing, it is even sometimes advantageous to use a relatively resistive electrode material or gel, as this has been found to optimize current density distribution under the stimulation electrode.

As in the above applications, the avoidance of current density hotspots is one of several key factors in iontophoretic, transdermal delivery (6). An additional important constraint that is generally not relevant in other electrotherapies is the maintenance of the delicate electrochemical balance at the electrode/reservoir/skin interface. The electrode potential and impedance, as well as the composition of the drug reservoir, must generally remain within certain narrow ranges in order to avoid the deterioration of the electrode, the contamination of the drug reservoir, and the irritation of the patient's skin.

The electrical properties of the electrode contacts are, therefore, of great importance in most applications. Ideally, the contact with the patient should give rise to the following:

- Zero potential. Unfortunately, zero potential is not possible and a more realistic goal is to achieve a low, stable potential at each of the contacts.
- Zero Impedance. Unfortunately, zero impedance too is not possible and a more realistic goal is to achieve impedances at the two contacts that are low and as similar as possible.

The potentials and impedances of the electrode–electrolyte interface and the skin will therefore be studied in more depth in the following sections.

ELECTRICAL PROPERTIES OF ELECTRODE–SKIN INTERFACE

As briefly outlined above, the electrode–electrolyte interface and the skin under the electrode both give rise to potentials and impedances that can either distort any measured biosignal or give rise to problems during electrical stimulation.

The Electrode–Electrolyte Interface

The Electrode–Electrolyte Potential. When a metallic electrode comes in contact with an electrolyte (in body tissues or in an electrode gel), an ion–electron exchange occurs as a result of an electrochemical reaction. A tendency exists for metal atoms M to lose n electrons and pass into the electrolyte as metal ions, M^{+n} , causing the electrode to become negatively charged with respect to the electrolyte (Fig. 1). Reaction (1) is termed oxidation.

Similarly, under equilibrium conditions, some of the ions in solution M^{+n} take n electrons from the metal and deposit onto the electrode as metal atoms M . The electrode becomes positively charged with respect to the electrolyte. Reaction (2) is termed reduction.

The overall chemical reaction taking place at the interface is therefore

Under equilibrium conditions, the rate at which metal atoms lose electrons and pass into solution is exactly balanced by the rate at which metal ions in solution deposit onto the electrode as metal atoms. The current flowing in one direction, i_0 , is equal to and cancels out the current flowing in the opposite direction. The electrode is said to be

Figure 1. The electrode–electrolyte interface and reactions involved in generating its reversible or equilibrium potential.

behaving reversibly and the common value of currents, i_0 , is termed the exchange current (density). Although the net current flowing through the electrode interface is zero, a potential difference is found to exist between the electrode and the electrolyte and depends on the position of the equilibrium between the two processes (1) and (2). Generally, the metal is negative relative to the electrolyte. The potential difference depends on the relative activities (or concentrations) of the ions present and on the electrode metal (7). This potential has been termed the equilibrium, reversible, or half-cell (i.e., one interface only) potential in the literature.

When trying to measure the potential of a half-cell (i.e., one interface only), one is immediately faced with a problem, as one requires two electrodes to make a potential measurement, thus effectively creating an electrochemical cell with two electrode–electrolyte interfaces. One, therefore, measures not only the potential of the electrode–electrolyte interface under study, but also that of the second electrode used to complete the circuit. If one uses the same metal for the second electrode to that used in the first, the potentials will be identical (in theory at least) and will cancel each other out. The measured potential will be (theoretically) equal to zero. (In practice, however, slight differences in the composition of the metal used, the electrode surfaces, and in the gel will result in differences in the two half-cell potentials.) If, on the other hand, one uses a different metal for the second electrode, the measured potential of the cell will be due to the combination of the potentials of the two half-cells. It will be impossible to separate the potential of the half-cell under investigation.

In order to resolve this problem, early electrochemists decided to measure all electrode interface potentials with respect to a standardized electrode or reference electrode. The standard hydrogen electrode (SHE) was chosen to be the universal reference electrode and its half-cell potential was specified as zero. Other metal-to-ion interface potentials were then measured with reference to SHE and the entire measured offset voltage was attributed to electrode system being tested.

Hydrogen electrode consists of a platinized plate submerged to one-half its height HCl over which hydrogen gas at atm is bubbled. The half-cell potential of SHE depends on concentration of hydrogen ions in the solution, hence it is quite stable and reproducible. At the time that this decision was reached, the necessary glass blowing and silver soldering were common skills and the SHE was thus easy and inexpensive to make. Although, however, it is no longer convenient for modern routine measurements as a reference electrode (the flowing hydrogen gas is potentially explosive), electrode potentials are standardized with respect to the SHE (7).

The reversible, equilibrium, or half-cell potential of a given electrode–electrolyte interface depends on the activity (almost synonymous with concentration) of the ions taking part in the reactions (Table 1). This potential, E_{rev} , is given by the Nernst equation,

$$E_{rev} = E_0 + [RT/nF] \ln[\text{activity of oxidized form} / \text{activity of reduced form}] \quad (1)$$

Table 1. Reversible Potentials for Common Electrode Materials at 25 °C^a

Metal and Reaction	Potential E^V, V
$Al \rightarrow Al^{3+} + 3e^-$	-1.706
$Zn \rightarrow Zn^{2+} + 2e^-$	-0.763
$Cr \rightarrow Cr^{3+} + 3e^-$	-0.744
$Fe \rightarrow Fe^{2+} + 2e^-$	-0.409
$Cd \rightarrow Cd^{2+} + 2e^-$	-0.401
$Ni \rightarrow Ni^{2+} + 2e^-$	-0.230
$Pb \rightarrow Pb^{2+} + 2e^-$	-0.126
$H_2 \rightarrow 2H^+ + 2e^-$	0.000 by definition
$Ag + Cl^- \rightarrow AgCl + e^-$	+0.223
$2Hg + 2Cl^- \rightarrow Hg_2Cl_2 + 2e^-$	+0.268
$Cu \rightarrow Cu^{2+} + 2e^-$	+0.340
$Cu \rightarrow Cu^+ + e^-$	+0.522
$Ag \rightarrow Ag^+ + e^-$	+0.799
$Au \rightarrow Au^{2+} + 3e^-$	+1.420
$Au \rightarrow Au^+ + e^-$	+1.680

^aThe metal undergoing the reaction shown has the magnitude and polarity of standard half-cell potential, E_0 . Listed when the metal is referenced to the standard hydrogen electrode (3).

E_{rev} is the reversible, equilibrium, or half-cell potential
 E_0 is the standard half-cell potential (measured relative to the standard hydrogen electrode)

R the universal gas constant,

n the number of electrons involved in reaction,

T the absolute temperature (K).

Activity, $a = \gamma C$, where C is concentration and γ , the activity coefficient, is a measure of the interaction between ions. When solution is infinitely dilute, $\gamma = 1$ and activity is equal to concentration.

Note the two components of E_{rev} . One is constant, E_0 , whereas the other will vary due to slight variations in concentration, from one electrode to another. If two chemically identical electrodes make contact with the same electrolyte/body, the two interfaces should, in theory, develop identical half-cell potentials. When connected to a differential amplifier, the half-cell potentials of such electrodes would cancel each other out and the offset voltage would be zero. The electrode potentials would, therefore, make zero contribution to a biosignal they were being used to detect. Unfortunately, slight differences in electrode metal or gel result in the creation of offset voltages, which can greatly exceed the physiological variable to be measured. Generally, a more significant problem is that the electrode offset voltage can fluctuate with time, thus distorting the monitored biosignal (8).

The Electrode–Electrolyte Impedance. It has already been stated that in the electrode and the connecting lead, electrical charge is carried by electrons, whereas in the gel and in the human body, charge is carried by ions. A transition exists at the interface between the electrode and the electrolyte where charge is transferred from one kind of carrier to the other. In order for some of the ions in the electrode gel or in the body fluids to transfer their charge across the interface, many must first diffuse to

Figure 2. The electrode–electrolyte interface. A metal in an electrolyte forms a double layer of charge. (Redrawn from Ref. 7).

the electrode–electrolyte interface under the influence of electrostatic attraction. Here they stick (or adsorb, as it is termed in electrochemistry) to the electrode surface and form the outer Helmholtz plane (OHP) (7). If the electrode has a negative charge relative to the electrolyte, positive ions will be attracted to the interface region and adsorb onto the electrode surface. As a consequence, there is a layer of negative charge on the metal surface and a layer of equal but opposite charge on the electrolyte side of the interface, both separated by a small distance across the OHP (see Fig. 2). A double layer of charge therefore exists at the interface, and such a system behaves like a parallel-plate capacitor. Not altogether surprising, the interface's capacitance is often termed the double-layer capacitance, C_{dl} , and is connected in parallel to the charge-transfer resistance in our simple equivalent circuit model.

Just in case one believed that the electrode interface was that simple, one must point out, for example, that as well as the cations electrostatically attracted to the negatively charged electrode surface (coulombic adsorption) anions may exist that are adsorbed on the electrode surface and form the inner Helmholtz layer or plane (IHP). These anions have tended to lose their hydration sphere and, consequently, are in close contact with the electrode. As they are negative ions adsorbed onto a negative electrode surface, electrostatic forces cannot be responsible. Some force *specific* to the ion (rather than its electric charge) must be responsible, hence the use of the term specific

adsorption to describe this phenomenon. The van der Waals or chemical forces is thought to be responsible (7).

In order to understand some aspects of the double-layer capacitance, it is good to consider the basic equation for a parallel-plate capacitor. If two identical conductive plates, each of area $A \text{ cm}^2$, are separated by a distance $d \text{ cm}$, which is filled with a material of dielectric constant ϵ_0 , then the capacitance of this parallel-plate capacitor, C_{pp} , is given by:

$$C_{pp} = \epsilon_0 A / d \quad (2)$$

and the magnitude of the capacitive impedance, Z_{pp} , is given by

$$Z_{pp} = 1 / 2\pi f C_{pp} \quad (3)$$

where f is the frequency of the applied ac signal and π is a constant.

Some dc (or faradaic) current does, however, manage to leak across the double layer due to electrochemical reactions (1) and (2) taking place at the interface. These reactions experience a charge transfer resistance, R_{CT} , which can be thought of as shunting the nonfaradaic, double-layer capacitance and whose expression can be derived from the Butler–Volmer equation.

For small applied signal amplitudes (7),

$$R_{CT} = \frac{RT}{nF} \frac{1}{i_0} \quad (4)$$

A good electrode, from an electrical point of view, will have a very low value of R_{CT} . Charge will be transferred across the interface almost unimpeded and little voltage will be dropped across the interface. One should note that R_{CT} is inversely proportional to i_0 . i_0 is the exchange current [i.e., the current flowing across the interface (in both directions) under equilibrium conditions (no net current flow)]. Simplistically, if an interface can cope with large currents under equilibrium conditions, it will be able to cope well with currents under nonequilibrium conditions. A good electrode system will therefore be characterized by a large value of exchange current or a low value of R_{CT} .

The interface impedance should theoretically be well represented by an equivalent circuit model comprising the double-layer capacitance in parallel with the charge transfer resistance, R_{CT} . Both are in series with R_{TOTAL} , the relatively small resistance due to the sum of the lead and electrolyte resistances.

Complex Impedance Plot. If, for each frequency of ac signal used to measure the impedance, the real part of the measured impedance (Z' or R_S) is plotted on the x axis and the imaginary part (Z'' or X_S) on the y axis of a graph, one obtains a Nyquist or complex impedance plot. The impedance locus for the above simple equivalent circuit model (Fig. 3.) of the interface impedance is plotted on a complex impedance plot in Fig. 4. *Note:* Electrochemists plot $-X_S$ versus R_S and not X_S versus R_S as electrode (and tissue) impedances tend to be capacitive and thus negative. It is generally found easier to look at the plots with the Z'' axis inverted. Low frequency data are on the right side of the

Figure 3. Simple equivalent circuit model of the electrode–electrolyte interface. C_{dl} represents the double-layer capacitance, R_{CT} the charge transfer resistance, R_{TOTAL} the sum of the lead and electrolyte resistances, and E_{rev} represents the reversible or equilibrium potential.

plot and higher frequencies are on the left, which is generally the case for electrode interface data.

The impedance locus has the form of a semi-circle with high and low frequency intercepts with the real axis at 90° (due to the presence of C_{dl} in parallel with R_{CT}). At very low frequencies, the impedance is equal to $R_{TOTAL} + R_{CT}$, the diameter of the semicircle being equal to R_{CT} . At higher frequencies, the impedance is influenced by the value of the parallel capacitance C_{dl} . As the capacitive impedance decreases with increasing frequency, current therefore flows through it and the total impedance of the parallel combination decreases. The reactive component and the phase angle increases from zero, reaches a maximum value (which depends on the relative sizes of R_{TOTAL} and R_{CT}), and then decreases again toward zero (see Figs. 4 and 5). The frequency at which the reactive component reaches its maximum value (ω_0) is given by $\omega_0 = 1 / R_{CT} C_{dl}$ (Fig. 4).

At high frequencies, the impedance is determined by the series resistance R_{TOTAL} .

Bode Plot. Another popular method of presenting impedance data is the Bode plot. The impedance is plotted

Figure 4. Impedance plot for simple equivalent circuit model of the electrode–electrolyte interface. The impedance locus is semi-circular as a result of the parallel combination of C_{dl} (the double layer capacitance) and R_{CT} (the charge transfer resistance), both of which are in series with R_{TOTAL} , the sum of the lead and electrolyte resistances.

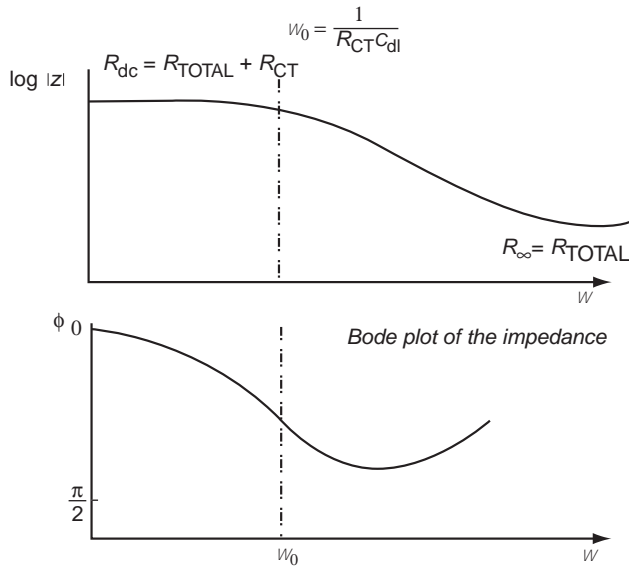

Figure 5. Bode plot for the simple ‘3-component’ equivalent circuit model. The magnitude of the impedance decreases from its low frequency value ($R_{\text{TOTAL}} + R_{\text{CT}}$) to R_{TOTAL} at very high frequencies. The phase angle of the overall interface impedance increases from 0° at low frequencies, reaches a maximum, which depends on the relative sizes of R_{TOTAL} and R_{CT} and then decreases again.

with log frequency on the x axis and both the absolute value of the impedance ($|Z| = [Z'^2 + Z''^2]^{1/2}$) and the phase-shift ($\phi = \tan^{-1}[Z''/Z']$) on the y axis. Unlike the complex impedance plot, the Bode plot explicitly shows frequency information.

The Bode plot for the electric circuit of Fig. 3 is shown in Fig. 5.

As in the complex impedance plot, the magnitude of the impedance is equal to $R_{\text{TOTAL}} + R_{\text{CT}}$ at very low frequencies (R_{dc}). The phase angle is zero at this point as the impedance is purely resistive. At very high frequencies, the magnitude of the impedance (R_{∞}) is equal to that of the series resistance R_{TOTAL} . At frequencies in between these two limits, the interface impedance is influenced by the value of the parallel capacitance C_{DL} . As the capacitive impedance decreases with increasing frequency, current therefore flows through it and the total impedance of the parallel combination decreases. The phase angle increases from zero, reaches a maximum value (generally less than 90° or $\pi/2$ rad), and then decreases again toward zero (see Fig. 5).

The above model can be used to explain most key aspects of the electrode–electrolyte interface. It must be pointed out, however, that the equivalent circuit is a gross approximation.

For example, diffusion of ions to the interface from the bulk of the electrolyte (gel or patient) takes place at a finite rate and thus gives rise to impedance to current flow, especially at low frequencies. The diffusion (often termed Warburg) impedance is generally located in series with the charge transfer resistance, both of these being in parallel with the double-layer capacitance. The diffusion impedance has been ignored in the above model as it tends

not to be observed for many biomedical electrode systems over the range of frequencies typically used.

A further simplification is the use of a simple capacitance in the above model. Such ideal capacitive behavior is rarely observed with solid metal electrodes. Instead, an empirical pseudo capacitance or constant phase angle impedance, Z_{CPA} , is often used that has a constant phase angle, much like a capacitor.

$$Z_{\text{CPA}} = K(i\omega)^{-\beta} \quad (5)$$

where K is a measure of the magnitude of Z_{CPA} and has units of $\Omega\text{s}^{-\beta}$, and β is constant such that $0 < \beta < 1$. The phase angle of this empirical circuit element ($\phi = \beta\pi/2$ radians or $90\beta^\circ$) generally lies between 45° and 90° (9). Typically, β has a value of 0.8 for many biomedical electrode systems.

Fricke (10) used the term polarization to describe the constant phase angle impedance and postulated that it was due to spontaneous depolarization of the electrode. Although he did not enlarge on the hypothesis, many authors have used Fricke’s terminology over the intervening years. The present author must concur with Cole and Curtis’ observation that “the use of the term polarization for describing the unexplained effects occurring at the metal–electrolyte interface is only an admission of our ignorance” (11).

The two most likely causes of the observed constant phase angle impedance are specific adsorption and surface roughness effects (12). With solid biomedical electrodes, the nonideal behavior is probably due to the surface roughness of the electrodes (13), which is supported by reports that roughing an electrode surface decreases the measured value of phase angle.

It is also naive to think that surface effects will only distort the nonfaradaic impedance and will have no effect on R_{CT} as assumed in the above model. It is more realistic that surface effects will affect the parallel combination of C_{dl} and R_{CT} giving rise to skewed (14,15) or distorted (16) arcs. The simple equivalent circuit used in this presentation is, however, a useful approximation that enables qualitative interpretation of much of the published data.

Polarization. Since the work of Fricke (10), the term polarization has been used to describe just about anything associated with the electrode–electrolyte interface—frequency-dependence, nonlinearity, noise, and so on. Polarization has been defined as “the departure of the electrode potential from the reversible value upon the passage of faradaic current” (7).

Under equilibrium conditions, the electrode potential E is equal to its reversible potential E_{rev} . When a dc or faradaic current, i_{dc} , is applied to the electrode interface, it must flow through the resistance R_{CT} , which is in parallel with C_{dl} . From Ohm’s law, the voltage dropped across this charge transfer resistance will be equal to i_{dc} multiplied by R_{CT} (Fig. 6). The electrode potential E is now given by:

$$E = E_{\text{rev}} + i_{\text{dc}}R_{\text{CT}} \quad (6)$$

The electrode, therefore, is no longer operating at its equilibrium or reversible value E_{rev} . This change in the

Figure 6. Polarization, the departure of the electrode potential from its reversible value upon the passage of faradaic current.

electrode interface's potential from its equilibrium value is termed polarization. The degree of polarization is measured by the additional voltage dropped across R_{CT} , (or overpotential, η , as it is termed in electrochemistry) where:

$$\eta = /E - E_{rev}/ \quad (7)$$

An ideal nonpolarizable electrode would have a value of R_{CT} equal to zero and, hence, would exist no resistance to faradaic current. The nonfaradaic impedance would effectively be shorted out and the total interface impedance would be zero. In this case, current would pass freely across the interface unimpeded. Measured biosignals, for example, would be unattenuated and undistorted. A perfect electrode system! The electrode potential would always remain constant at its reversible value.

A perfectly polarizable electrode would not permit the flow of any dc or faradaic current as the charge-transfer resistance in this case is infinite. Such an electrode is sometimes termed a blocking electrode. No faradaic charge would cross the interface, even for large overpotentials, and the electrode couples capacitively with the tissues/electrolyte in this extreme case (Fig. 7).

Real electrodes are, however, neither perfectly polarizable nor perfectly nonpolarizable. Any net current flow across an electrode–electrolyte interface will experience a finite faradaic impedance across which an overpotential will develop.

An electrode system that has a very low value of R_{CT} lets current traverse the interface almost unimpeded, wastes little energy at the interface, has a relatively small overpotential, and has a relatively nonpolarizable electrode system. Such electrode systems are highly sought after, especially when recording small biosignals from the body surface.

Electrodes made of noble metal come closest to behaving as perfectly polarizable electrodes. As these metals are inert, they tend not to react chemically with the surrounding electrolyte or tissue. Noble metals are, therefore, generally used in the construction of implant electrodes where chemical reaction with surrounding tissues must be avoided in order to minimize tissue toxicity problems. Little steady current can pass in such cases as the charge transfer resistance for these electrodes is therefore very large (Fig. 7). The small current that does pass represents the charging and discharging of the double-layer capaci-

Figure 7. The dc current–voltage plots for Ideal Nonpolarizable, General Polarizable, and Ideal Polarizable electrode interfaces.

tance. A problem, therefore, exists when designing implant electrodes. For a biocompatibility point of view, one requires a noble, hence polarizable, electrode system, whereas from an electrical performance point of view, one requires a nonpolarizable system. A compromise is achieved by using a polarizable electrode and roughening the surface of the electrode, thus decreasing the large interface impedance.

Transient Response and Tissue Damage. The response of the electrode system to sine waves of varying frequencies has been considered above (Complex Impedance and Bode plots) as this is a very useful tool in analyzing circuits or, in this case, electrode systems. Equally relevant is the response of an electrode system to voltage and current steps or pulses, as these will approximate therapeutic stimulation applications.

It must be borne in mind that the conversion from electrical to ionic current takes place at the electrode-tissue interface. Based on the simple equivalent circuit model, current can flow either through the parallel resistance or through the double-layer capacitance.

Current flowing through the parallel resistance involves faradaic charge transfer reactions. At the anode, the electrolysis of water and the oxidation of organic compounds can occur. The oxidation of the electrode itself can also occur, which results in the dissolution of metal. At the cathode, hydrogen ions are reduced to form hydrogen gas, which results in a change in pH near the electrode. The new chemical by products in all of these reactions may lead to tissue damage and, hence, faradaic charge transfer reactions must be avoided (17,18). Current must not, therefore, be allowed to flow through R_{CT} .

Figure 8. Voltage response to a pulse or step in current.

For current flowing through the double-layer capacitance, no charge actually crosses the electrode-tissue interface. Instead, ions in the tissue are attracted or repelled by charges on the electrode, resulting in transient pulses of ionic current. As no net current flows through the interface and electrochemical reactions are not involved, capacitive current is relatively safe. One must therefore seek, as far as possible, to couple capacitively with tissue when seeking to stimulate tissue without causing trauma.

If one applies a pulse of current of amplitude I_{dc} at time $t=0$, the voltage response of the electrode-interface equivalent circuit model and, it is believed, the electrode-patient system is as shown in Fig. 8.

$$V(t) = I_{dc}R_{TOTAL} + I_{dc}R_{CT}(1 - \exp[-t/R_{CT}C_{dl}]) \quad (8)$$

At $t=0$, the applied current flows unopposed through the capacitor and, hence, only sees the series resistance R_{TOTAL} . The initial voltage response is, therefore,

$$V_0 = I_{dc}R_{TOTAL} \quad (9)$$

The voltage response is then observed to gradually increase from V_0 . The initial increase in voltage with time is inversely proportional to the magnitude of the capacitance.

For long pulse durations, all of the current will flow through the resistances R_{CT} and R_{TOTAL} . The total resistance seen by the current is, therefore,

$$Z_{(t=\infty)} = R_{TOTAL} + R_{CT} \quad (10)$$

and the limit voltage V_{∞} is given by

$$V_{\infty} = I_{dc}(R_{TOTAL} + R_{CT}) \quad (11)$$

The voltage response will reach this limit value V_{∞} in a time period of approximately five time constants, T , where $T = C_{dl}R_{CT}$.

If a perfect step in voltage, V_{dc} , is applied to the electrode system or the three-component model, the

Figure 9. Current response to a pulse or step in voltage.

current response is as shown in Fig. 9 and given by the equation

$$I(t) = V_{dc} \left\{ \left(\frac{1}{R_{TOTAL} + R_{CT}} \right) \right\} + \left(\frac{R_{CL}/R_{TOTAL}}{R_{CT} + R_{TOTAL}} \right) \exp \left[-\frac{R_{CT} + R_{TOTAL}}{R_{CT}R_{TOTAL}C_{dl}} t \right] \quad (12)$$

At the beginning of the voltage step, the resultant current jumps to a relatively large value I_0 , where

$$I_0 = V_{dc}/R_{TOTAL} \quad (13)$$

As time passes, the resultant current decreases exponentially with an initial slope inversely proportional to the capacitance C_{dl} . Eventually, the current will reach a limiting value of I_{∞} , where

$$I_{\infty} = \frac{V_{dc}}{R_{TOTAL} + R_{CT}} \quad (14)$$

Tissue Damage. The rise in voltage response or the decrease in current response is often attributed in the literature to a mysterious phenomena called polarization. It is, in fact, nothing more than the transient response of a simple three-component circuit model.

When one applies pulses to an electrode-tissue interface (either for implanted or surface stimulation), the applied or resultant current initially flows into the patient via the double-layer capacitance. No reactions are associated with the capacitive flow of current and, hence, few undesirable effects exist when using short duration pulses (i.e. with a duration less than one time constant). As the pulse duration is increased, however, progressively more current flows through the parallel charge transfer resistance and the patient is more at risk due to the reaction byproducts, which is especially true if the pulse is applied for a length of time longer than five time constants giving the voltage or current response time to level off and reach its steady-state value of V_{∞} (or I_{∞}). At this point, most of the current is flowing through the charge-transfer resistance and charge is therefore injected into the tissues via a faradaic process. The byproducts of the electrochemical reactions involved in

the charge-transfer process will diffuse into the skin or tissue, causing chemical injury (19). As the leveling off of the voltage response is indicative of pure charge transfer control, this feature must be avoided at all costs by either avoiding long duration pulses or by using electrode systems with very long time constants, $T = C_{dl}R_{CT}$. In both cases, charge will be largely applied to the body via relatively safe capacitive processes.

It may not always be possible to use sufficiently short pulse durations to avoid tissue damage and still achieve therapeutic effect. It must also be noted that even when using short pulses where the current or voltage response has not leveled off, some current still flows through R_{CT} and a faradaic charge-transfer reaction takes place, with the associated, albeit reduced, problems (18). Over extended periods of stimulation, the byproducts will accumulate in the tissues. In the past, however, the applied waveforms found experimentally to minimize electrode and tissue damage are consistent with the basic goal of minimizing the flow of faradaic current across the electrode interface (20) and thus ensuring little, if any, net transfer of charge. Decreasing the duration, amplitude, and rate of current pulses have all been suggested as each ensures C_{dl} control of the transients and thus avoids, to some extent at least, the undesirable faradaic processes.

An alternative to using short pulse durations is to use electrode systems with long time constants [i.e., with a large value of R_{CT} (faradaic charge-transfer resistance) or C_{dl} (double-layer capacitance)]. As we have seen, noble metals react with difficulty with surrounding tissues and thus have large values of R_{CT} (19). For a given pulse duration, they tend to couple capacitively with tissue. The reactions on both anode and cathode are reversible, involving surface oxygen, and this reversibility explains the observed identical nature of anodic and cathodic waveforms (19). As a result, noble electrodes are widely used for physiological stimulation. Unfortunately, noble metals give rise to large interface impedances. From a biocompatibility point of view, one requires a noble (hence, large impedance) electrode system, whereas from an electrical performance point of view, one requires a low impedance system. A compromise is achieved by using such polarizable electrode materials and roughening the surface of the electrode, thus decreasing the large interface impedance. Roughening the electrode surface gives rise to a significant increase in the interface capacitance, thus increasing further the time constant ($T \uparrow = C_{dl} \uparrow R_{CT}$) and ensuring that the voltage or current response is even more dominated by the highly desirable capacitive processes while decreasing the interface impedance.

It would be a gross oversimplification to attempt to demystify biomedical electrode design by stating that all high performance biomedical electrodes simply have rough surfaces. However, a significant element of truth exists in the statement. For example, terms like activated, sintered, and porous have been used to describe implant electrodes for cardiac pacing and indicate that the electrode fabrication process results, deliberately or otherwise, in a rough-surfaced electrode. It could be argued that it is

often the surface finish rather than the electrode metal that gives rise to the favorable electrical properties reported, especially the low interface impedances.

Most electrical stimulation electrodes rely, to some extent, on faradaic mechanisms at the interface between the metal and the tissue. Even in the case of noble metal electrodes with short pulse durations, byproducts of the electrochemical reactions involved will accumulate over time in the tissues when a signal is applied in one direction (monophasic) and will eventually give rise to irritation. With surface stimulation, for example, early designs of electrodes incorporated thick pads of electrolyte-impregnated lint in order to distance the patient's skin from the electrode-electrolyte interface and the undesirable byproducts. Obviously, with implanted electrodes, that short term solution is not possible.

In particular, monophasic anodic pulses must be avoided as they will cause corrosion problems. Additionally, for most applications, cathodic stimulation has a lower threshold than anodic stimulation. Even in the case of monophasic cathodic pulses, however, current flows in only one direction and the chemical reactions at the interface are not reversed.

Biphasic waveforms are preferred in most electrotherapies as the byproducts of the forward reaction are thought to be recaptured by the reverse reaction (21). In using charge balanced waveforms, it is often believed that because no net charge transfer exists across the electrode-skin interface, no net flow of potentially harmful byproducts into the skin. Unfortunately, the electrochemical reaction that occurs to enable the flow of current during the first phase is not necessarily that involved in the second. Byproducts of the first reaction are therefore not always recaptured and may escape from the interface into the patient (22). However, it must be pointed out that the use of charge balanced biphasic waveforms does indeed greatly minimize the problem and, hence, its widespread use in a range of surface and implant applications. Additionally, surface biphasic stimulation is found to be more comfortable than monophasic.

Limit Voltages and Currents of Linearity. Although the non-linearity of the skin's electrical properties has been investigated under a range of conditions, the phenomenon is still far from well understood. "There appears to be, so far, no model available which accounts for both the linear and nonlinear behavior of the electrodes in the frequency and time domains" (23). It is an important feature of an electrode as 'it appears... that electrodes often introduce nonlinear characteristics that are erroneously ascribed to the biological system under study (24).

Schwan proposed empirical relationships for the limit current of linearity and the limit voltage of linearity.

Limit Current of Linearity. It has been observed that electrode-tissue interface impedance nonlinear behavior is first evidenced at low frequencies. As the applied current amplitude is increased, progressively higher frequency points are affected. Schwan proposed a limit current of

linearity i_L . He observed that the relationship between the angular velocity of a given impedance point and the current amplitude required to drive it into nonlinearity (deviate by more than 10% from its linear, small-signal value) was well expressed by the empirical relationship

$$i_L = B \omega^\beta \quad (15)$$

where B is a constant particular to the electrode system and β is the fractional power that appears in equation 5.

Schwan and others (25–28) have observed that this empirical relationship is valid for many electrode systems over wide frequency ranges.

The presence of β (a parameter describing the frequency dependence of the linear interface impedance) in a relationship describing the nonlinearity of the system was found most intriguing.

The solution to this mystery is quite simple when it is approached from the right direction. Generally, researchers have assumed that the observed nonlinear behavior is attributable to the high frequency Z_{CPA} impedance (Eq. 5), which they observe under linear, small-signal conditions and over the limited frequency ranges they use. However, in parallel with Z_{CPA} is the charge transfer resistance R_{CT} , which, in the linear range, has a very large value R_{CT}^0 , where

$$R_{CT(0)}^0 = \frac{RT}{nF} \frac{1}{i_0} \quad (16)$$

As a result, its contribution is either not observed or ignored.

The value of the charge-transfer resistance can be derived from the Butler–Volmer equation and is very nonlinear, decreasing rapidly with applied signal (ac or dc) amplitude. Compared with R_{CT} , Z_{CPA} is relatively linear. R_{CT} is therefore the source of the observed nonlinear behavior.

As the applied current amplitude is increased, the charge transfer resistance decreases rapidly, causing the diameter of the impedance locus to decrease. As the low frequency end of the arc is dominated by the charge transfer resistance, the effects of such nonlinearity will be first evidenced at these frequencies. Low frequency points are therefore the first to deviate significantly (by more than 10%) from their small-signal, linear values, as observed by Schwan and others. As the applied signal amplitude is further increased, the diameter of the impedance locus decreases further, and progressively higher frequencies are affected (29,30).

Simplistically, it can be shown that the following approximations can be made over limited ranges of frequency or applied signal amplitude:

- Approximate relationship between applied current and R_{CT}

$$i \propto 1/R_{CT} \quad (17)$$

- Approximate relationship between R_{CT} and the frequency at which nonlinearity occurs

$$R_{CT} \propto \omega^{-\beta} \quad (18)$$

Then, by cancelling R_{CT} , in the above two equations,

- Approximate relationship between applied current and the frequency at which nonlinearity occurs

$$i_L \propto \omega^\beta \quad (19)$$

as found by Schwan. The presence of β in the expression of an electrode system's nonlinear behavior is therefore simply due to the presence of a very nonlinear resistance in parallel with a relatively linear, frequency-dependent Z_{CPA} . A more accurate calculation based on the equivalent circuit model outlined above and the Butler–Volmer equation was published (29).

Limit Voltage of Linearity. Schwan and others (25,28) also postulated that the electrode–electrolyte interface impedance becomes nonlinear at a certain limit voltage, V_L , which they found to be independent of the frequency of the applied signal.

Using the Butler–Volmer equation and the equation for the impedance of the equivalent circuit model, the voltage limit of linearity can be calculated for a range of frequencies (31). It can be shown that the charge-transfer resistance decreases pseudo exponentially with applied voltage amplitude, initially causing low frequency impedance points on the locus to deviate from their small-signal values (32,33).

At very low frequencies, such that $\omega \rightarrow 0$, the voltage limit of linearity, V_L , approximates to the voltage at which the charge-transfer resistance decreases by 10% from its small-signal value, which occurs at $V_L = 40/n$ mV, where n is the number of electrons per molecule oxidized or reduced (31).

As the applied voltage is increased above this low frequency limiting value, the charge transfer resistance further decreases and affects progressively higher frequency points (i.e., become nonlinear). The derived log (f) versus V_L plot is found to be a straight line over a wide range of frequencies. V_L is observed to increase only very slightly with frequency, which would agree qualitatively with Onaral and Schwan's results (28), where V_L increased from 106 to only 129 mV over the frequency range of 10 mHz–100 Hz for platinum electrodes in saline, which would also explain why, in the past, V_L has been assumed constant and independent of the applied frequency.

Electrode Metals. As biocompatibility is of great importance in implants, implant electrode materials are generally confined to those that are essentially inert and do not react with the surrounding tissues. As cardiac pacing electrodes were among the first implanted and have had a long, generally successfully and well-researched history, most conclusions drawn on the suitability of materials for implant electrodes are based on pacing electrodes.

Implant electrodes are and have been generally made from noble metals such as gold, platinum, iridium, rhodium, and palladium. Platinum has been the most widely used as it has excellent corrosion resistance and produces relatively low polarization (34). Platinum, however, is mechanically relatively soft and for many applications is

alloyed with much harder iridium, producing platinum-iridium. Other noble metal alloys that have been used include gold-platinum-rhodium, platinum-rhodium, and gold-palladium-rhodium.

Passive metals, such as titanium, tantalum, zirconium, tungsten, and chromium, have been successfully implanted. Titanium has been widely used because it forms a nonconducting oxide layer at the surface. This coating prevents charge transfer at the electrode interface. Titanium, therefore, exhibits a high resistance to corrosion. Stainless steel is similar in that it acquires a protective oxide layer that renders it inert. Although stainless steels were used in early pacing electrodes, they do not appear to have the required corrosion resistance for long-term use. Stainless-steel pacing electrodes were discontinued after the 1960s because of unreliable corrosion resistance (34,35).

Some early pacing electrodes were made of Elgiloy (an alloy of Fe, Ni, CO, Cr, and MO from Elgin Watch Co.) However, Elgiloy has marginal corrosion resistance and produces a relatively high polarization overvoltage. It was discontinued in the 1980s. Carbon is an inert, nonmetallic element that has similar electrochemical characteristics to noble metals and continues to be used successfully as an implant electrode. Materials such as zinc, copper, mercury, nickel, lead, copper, silver, silver chloride, iron, and mild steel have been found toxic to body tissues and are normally not used.

Biocompatibility has been defined as the ability of a material to perform with an appropriate host response in a specific application (36). Strictly speaking, no such thing as a biocompatible material exists as an implant's biocompatibility will also depend on a range of variables including its shape and surface finish.

Stimulation threshold is a key parameter in implant stimulation electrode design. When activated vitreous carbon electrodes were first introduced in pacing electrodes, they were found to have relatively low chronic thresholds. These thresholds were thought to be the result of the superior biocompatibility of the carbon electrode. Other researchers similarly interpreted the low thresholds observed for their new exotic materials such as indium oxide, titanium nitride, and semimetal ceramics. Stokes (34), however, concluded that "material selection appears to have little or nothing to do with threshold evolution—as long as the material is biocompatible and reasonably corrosion resistant. Thus our experiments with biocompatible materials such as carbon, titanium, platinum, iridium oxide, and many more have all produced about the same results when tested as polished electrodes, all other factors held equal". Stokes went on to point out "while the bulk properties of an electrode material are important, it is the electrode-tissue interface that determines the electrode's performance. In fact, the surface microstructure of the electrode is critical" (34). It would appear that the microstructure of an electrode surface may affect cellular adhesion and activation, thus reducing the foreign body response. It is, therefore, the surface structure of many of the new materials (resulting from their fabrication process) that gives rise to the observed positive effect on threshold evolution over time, rather than the biocompatibility of the bulk material.

Another advantage of porous and microporous implant surfaces is their reduced interface impedance. Although interface impedance is generally less critical for implanted stimulation electrodes, many such electrodes (e.g., implanted pacing electrodes) are used to monitor bio-signals as well as to deliver the required stimulation impulses. Decreased interface impedance helps in this regard.

Implanted biosignal monitoring electrodes require stable potentials as well as low interface impedances to minimize biosignal recording problems. These metals have high positive standard electrode potentials (E^0 in Eq. 1) and are the lowest ones on the electromotive series. As noble metal electrodes do not tend to react chemically with the electrolyte, the Nernst equation is not defined and the measured potential is often influenced more by any traces of impurities on the surface than by the intrinsic properties of the metal itself. The electrode potential can drift randomly, especially immediately following implantation. It may fluctuate widely under apparently identical circumstances, which is an inherent disadvantage of noble materials.

External biosignal monitoring electrodes can generally use high electrical performance nonnoble materials such as silver-silver chloride without fear of biocompatibility problems (2). Silver-silver chloride has been found to be an excellent electrode sensor material as, when it is in contact with a chloride gel, it has the following characteristics:

1. A low, stable electrode potential.
2. A low level of intrinsic noise.
3. A small value of charge transfer resistance (i.e., it is relatively nonpolarizable).
4. A small interface impedance.

A silver-silver chloride electrode is generally made by the deposition of a layer of silver chloride onto a silver electrode. Silver chloride is a sparingly soluble salt and, thus, effectively provides the silver electrode with a saturated silver-chloride buffer, which facilitates exchanges of charge between the silver electrode and the sodium chloride environment of the gel and human body. The system behaves as a reversible chloride ion electrode, and the Nernst potential, in this case, depends on the activity (which is closely related to concentration) of the environment chloride ions and not on that of the silver ions. The potential of this electrode is, therefore, quite stable (as well as small) when the electrode is placed in an electrolyte containing Cl as the principal anion—as is the case in the human body and electrode gels (2).

Electrical noise (potential fluctuations) can occur spontaneously at the electrode interface without any physiological input. Ag/AgCl electrodes have been shown to be particularly stable and resistant to noise (37).

A silver-silver chloride electrode has a relatively large value of exchange current density (2) (Eq. 4) and, hence, a very low value of charge transfer resistance, R_{CT} . Charge is transferred across the interface with relative ease and little voltage is dropped across the interface. The electrode therefore operates close to its equilibrium or reversible

potential. Ag-AgCl electrodes are, therefore, relatively nonpolarizable.

When a smooth-surfaced electrode is chlorided, the AgCl deposit can give rise to a very rough surface and thus to relatively very low interface impedances (37,38). K , the magnitude of the interface pseudocapacitance (Eq. 5), is observed to decrease following the deposition of an AgCl layer (39). However, although AgCl facilitates the interfacial electrochemistry, it is very resistive having a resistivity of around 10^5 – $10^6 \Omega \cdot \text{cm}$ (2). As the layer thickness increases, the series resistance, R_{TOTAL} will therefore increase. This series resistance dominates the very high frequency interface impedance, and the latter will also increase with chloride deposit. Therefore, an optimal layer thickness exists, for a given frequency, that decreases the interface impedance and yet does not significantly increase the series resistance, R_{TOTAL} (29). The optimal silver chloride layer thickness consequently depends on the frequency range of interest (40).

Tin-stannous chloride, a material somewhat similar to silver–silver chloride, was used in some biosignal electrodes (41).

Electrode material and high electrical performance is generally less critical for external stimulation electrodes such as TENS and external pacing electrodes (current density distribution is the key concern). The majority of commercially available TENS electrodes are molded from an elastomer such as silicone rubber or a plastic such as ethylene vinyl acetate and loaded with electrically conductive carbon black. Mannheim and Lampe (42) pointed out that the only tangible disadvantage with having a large electrode interface impedance is that more power will be required from the stimulator to drive the stimulating current through the electrodes into the patient.

Graphite-loaded polyesters and similar materials are used in external pacing electrodes, for example. Some are constructed using tin as the metal layer. In early electrodes, the combination of tin and the chloride-based gel gave rise to pitting of the metal. Improvements made to the gels and the use of high purity tin have effectively removed this problem.

Although silver–silver chloride has been and still is used in some external electrostimulation electrodes, it should be used with care. Silver chloride is deposited electrolytically and can therefore be either removed by the passage of current or a thicker, high resistance layer deposited, depending on the polarity of the electrode, which can be a significant problem in iontophoretic transdermal drug delivery and may cause problems in multifunction pads, which include a silver–silver chloride layer to enable distortion-free monitoring of the ECG through electrodes designed to deliver the pacing or defibrillation impulses.

The Skin

Structure of the Skin. The skin is a multi layered organ that covers and protects the body. It is made up of three principal layers—the epidermis, the dermis, and the subcutaneous layer. (*Note:* In the literature, variations exist in the terminology used to denote these layers.)

The epidermis, the outermost layer, is around $100 \mu\text{m}$ thick, depending on body site. It is the strongest layer, providing a protective barrier against the outside hostile environment. Unlike any other organ of the body, the epidermis renews itself continually. It can be subdivided into several layers, with the basal layer forming the innermost layer and the stratum corneum the outermost layer. Cells in the basal layer constantly multiply and, as they are pushed up toward the skin's external surface, the cells undergo changes. Eventually, layers of compacted, flattened, nonnucleated, dehydrated cells (called corneocytes) form the stratum corneum. These dead cells are continuously being shed and are replaced from the underlying epidermal layers. The intercellular spaces between corneocytes are occupied by arrays of bilaminar membranes with the morphological features of polar lipids (43). This matrix appears to serve to bind the cells and the stratum corneum has been described in terms of corneocyte bricks surrounded by lipid mortar (44). On average, the stratum corneum comprises around 20 cell layers thick and has a thickness of around 10 – $15 \mu\text{m}$. Thickness will, however, vary with the number of cell layers making up the stratum corneum and the state of hydration. On some body areas, it can be several hundred micrometers thick. The epidermal layer is traversed by numerous skin appendages such as hair follicles, sebaceous glands, and sweat glands.

The underlying layers of the epidermis are, in contrast, a relatively aqueous environment. The transition from an essentially nonconductive, lipophilic membrane (the stratum corneum) to an aqueous tissue (viable epidermis and dermis) gives rise to the skin's barrier properties.

The dermis is the second layer of the skin and, with an approximate thickness of 2mm , is considerably thicker than the epidermis. It is formed from a dense network of connective tissue made of collagen fibers, giving the skin much of its elasticity and strength. Embedded in the dermis are blood vessels, hair follicles, sebaceous and sweat glands, and several types of sensory nerve endings.

The final layer of the skin (the subcutaneous layer) is found beneath the dermis layer. It contains structures of connective tissues and enables the skin on most parts of the body to move freely across the underlying bone structures. It is one of the body's areas for fat storage and acts as a cushion to protect delicate organs lying beneath the skin.

Skin Impedance

Electrical Properties of the Skin. As the stratum corneum is relatively nonconductive, it presents a high impedance to the transmission of electric currents. As a result, the impedance of the skin is the largest component of the overall interelectrode impedance (Fig. 10). Nonetheless, due to the stratum corneum's dielectric properties and its thinness, it permits capacitive coupling between a conductive metal electrode placed on the skin surface and the underlying conductive tissues. One can imagine the relatively nonconductive stratum corneum sandwiched between the conductive electrode and the conductive tissues underlying the stratum corneum forming a parallel-plate capacitor. The stratum corneum's electrical impedance is, therefore, often represented by a simple capacitor, C_{SP} . (The subscript SP refers to Skin and Parallel.)

Figure 10. Schematic representation of the skin and its equivalent circuit model.

Some ions do, however, manage to cross the stratum corneum via paracellular pathways and through the skin's appendages (hair follicles, sweat ducts, sebaceous glands, imperfections in the integrity of the skin). As skin appendages extend through the stratum corneum barrier they can act as shunts to the interior. The flow of ionic current can be represented electrically by a large resistance, R_{SP} , in parallel with C_{SP} .

The underlying layers of the epidermis are, in contrast, relatively conductive and can be collectively represented by a tissue resistance, R_{Tissue} .

A simple equivalent circuit model of the overall electrode-gel-skin system is therefore shown in Fig. 10 and includes the electrode lead resistance, R_{Lead} ; the electrode-gel interface impedance (the double-layer capacitance, C_{dl} , in parallel with the charge transfer resistance, R_{CT}); the gel resistance, R_{Gel} ; the skin impedance (the parallel combination of a capacitance, C_{SP} and a resistance, R_{SP}), and the underlying tissue resistance, R_{Tissue} .

It must be borne in mind that this equivalent circuit model is a simplification of the rather complex electrical properties of the skin. For example, it has been found experimentally (45,46) that the capacitance of the skin is better described by an empirical, constant phase angle impedance, Z_{CPA} , where

$$Z_{CPA(S)} = K_S(j\omega)^{-\alpha} \quad (20)$$

[which is similar to the empirical expression for the pseudo capacitance often used to represent the nonideal capacitive properties of the electrode interface's double-layer capacitance (Eq. 5)].

K has units of $\Omega \cdot s^{-\alpha}$. The parameter α is constant such that $0 \leq \alpha \leq 1$. The fractional power, α , of the capacitive impedance has been found to be related to the degree of hydration of the stratum corneum (47). If the epidermal layer behaved as a simple capacitance, α would equal unity. The actual value of α , normally around 0.8–0.9, is a measure of the deviation from this ideal behavior.

The use of C_{SP} will, however, be sufficient for this present review. The lead resistance, the gel resistance, the tissue resistance, and the electrode-gel interface impedance are all relatively small in comparison with the large skin impedance. Skin impedance, therefore, generally dominates and will be studied in more depth.

The Skin's Parallel Capacitance, C_{SP} . It was suggested above that the electrode-skin interface can be approximated by a capacitor with the stratum corneum forming the dielectric layer sandwiched between the electrode and the underlying tissues that form the conductive plates. It can be seen from Eq. 2 that the skin's capacitance will increase as the thickness of the stratum corneum decreases, its dielectric constant increases, or the area of the electrode increases.

The number of cell layers in the stratum corneum can range from 12 to 30 (48). Epidermal thickness can, therefore vary greatly for different body sites within the range of about 10 to well over $100 \mu\text{m}$ (49). The stratum corneum can be, for example, as thick as $400\text{--}600 \mu\text{m}$ in the palm and plantar areas and as little as $10\text{--}20 \mu\text{m}$ on the back, legs, and abdomen (50). The value of the capacitance of the skin is related to the thickness and composition of the stratum corneum and has a typical value in the range $0.02\text{--}0.06 \mu\text{F} \cdot \text{cm}^{-2}$ when measured using electrodes with "wet" electrolyte gels several minutes following electrode application (51,52). As the stratum corneum is typically at least 10 times as thick on the palms of the hands and soles of the feet as compared with other body areas, the skin capacitance at these points is considerably smaller than at other sites on the body. The stratum corneum on the face and scalp is not as thick as on other body parts and is characterized by large capacitance values.

Dark-skinned subjects have stratum corneum layers that are more dense and contain more layers of cells than fair-skinned subjects (48). Not surprisingly, they are characterized by skin capacitances that are much lower (skin impedances, Eq. 3, much higher) than those for fair-skinned subjects. One should therefore take care when assessing a new electrode system or associated device that they are tested on a range of subjects and skin sites. What may work well on a subject with low skin impedance in a warm and humid environment may be found later to fail on a high impedance subject, especially in a cold or dry environment.

The Skin's Parallel Resistance, R_{SP} . Although the stratum corneum does not easily allow foreign substances to traverse it, some current, carried by ions, manages to flow through it. The difficulty or resistance, this current experiences in passing through the skin is represented in the equivalent circuit (Fig. 10) by the parallel resistance, R_{SP} .

The skin's resistance is highly dependent on the presence and activity of sweat glands and on the presence of other appendageal pathways. An average human skin surface is believed to contain between 200 and 250 sweat ducts on every square centimeter (53). The density of sweat glands varies greatly over the body surface with a value of approximately 370 per cm^2 on the palms of the hands and the soles of the feet and a value of approximately 160 per cm^2 on the forearm (49). The diameter of the ducts can range from 5 to $20 \mu\text{m}$. It is, therefore, not surprising that R_{SP} is reported to vary greatly from patient to patient, from body site-to-body site, and with time. The measured values of R_{SP} are much smaller on areas with high densities of sweat glands, such as the palms of the hands (in spite of the thicker stratum corneum layer), especially when the

glands are active in response to thermal or psychophysiological stimuli.

An average human skin surface is reported to contain between 40 and 70 hair follicles per square centimeter (53). The presence of a high density of hair follicles (which act as low resistance shunts) gives rise to a very low value of skin parallel resistance, R_{SP} . However, this observation is counterbalanced by the difficulty in making firm mechanical and electrical contact to hirsute body sites or patients. In such cases, the skin impedance is very large at best. Generally, the electrodes fall off and, hence, require the shaving of the skin site prior to electrode application.

Observed intersite and interpatient variations in skin impedance tend to be due to large variations in R_{SP} . In the low frequency range, dominated by R_{SP} , regional differences in skin impedance were observed by Rothman (54), Lawler et al. (55), and Rosell et al. (56). Low frequency skin impedance was observed to decrease in the following order: thumb, forearm, abdomen and, smallest of all, forehead. Similarly, Almasi and Schmitt (57) observed the low frequency skin (10 Hz) impedance to decrease in the order of outer forearm, leg, inner forearm, back, chest, earlobes, and forehead. The forehead appears to have a very low skin impedance value (58), presumably as a result of the stratum corneum on the face and scalp being thinner than that on other body parts (48) and the presence of a high density of sweat glands. Almasi and Schmitt (57) plotted their average impedance values for the body sites on a complex impedance plot and found that most of the points lay along a "smooth common locus of monotonically increasing phase angle and impedance magnitude." This behavior was successfully interpreted by McAdams and Jossinet (32), who showed that such frequency loci were formed when the skin's parallel resistance varied greatly from site to site while the skin's capacitance remained relatively constant. Two body sites did not fit the locus and, hence, the physical explanation; these sites were the palm and fingertips. These body sites have much larger epidermal thicknesses and, hence, have skin capacitance values much smaller than other body sites.

One must be very careful when assessing different electrode designs or gels. Testing different electrodes on different patients is certain to give misleading results due to the intersubject variations, unless, of course, large numbers of subjects are used and statistically significant differences are observed.

R_{SP} varies greatly over time due to a number of parameters including room temperature and psychophysiological stimuli. The latter effect is exploited in so-called lie detectors. Schmitt and Almasi (59) reported that a considerable daily variation exists in a given subject, and seasonal changes have also been reported (60). Testing a range of electrodes on the same subject but on different days is, therefore, not optimal either, as day-to-day variations in skin impedance, especially fluctuations in R_{SP} , will nullify the validity of this approach. For example, Searle and Kirkup (61) found that the diurnal variations on a given subject for a given electrode was much larger than any difference between the range of electrode designs they tested in any one recording session. It should be further noted that the electrode test sites should be allowed to

recover for several days between experiments to enable the skin to recover. For example, peeling off an adhesive electrode will remove some of the underlying stratum corneum. Any electrode subsequently tested on the site will benefit from this prior skin stripping (see below).

Electrode designs must, therefore, be compared *in vivo* by testing them at the same time on the same subject. One must still bear in mind the significant differences in skin impedance that exist over the subject's body, as outlined above. Even testing the electrodes at the same time on a limb of a given subject remains problematic. The different skin sites involved, even if located close together, will give rise to significant differences in the measured electrode-skin impedances, which may be wrongly attributed to the electrode designs or gels under test. Searle and Kirkup (61), for example, showed that testing a range of dry electrode metals on the inner forearm gave rise to potentially very misleading results. Electrodes placed closer to the wrist gave rise to lower impedances due to the presence of a higher concentration of sweat glands.

Electrodes must therefore be repeatedly tested at the same time, under the same conditions, varying their relative positions in order to clearly establish their relative performances. McAdams et al. developed a four-channel impedance monitoring system to enable the simultaneous comparison of electrode designs/gels (62).

Skin Potential Motion Artifact. A potential difference E_S , given by the Nernst equation, exists across the epidermis as a result of ionic concentration differences. This potential varies from patient to patient, from site to site, and depends on gel composition (if used) and skin condition.

The skin surface is normally negative with respect to the inside of the body. Skin potential becomes more negative when sweat glands are active, and palmar and plantar surfaces, with their higher sweat gland concentrations, are the most negative. Increasing gel concentrations of NaCl or KCl also render the site more negative. The parameter E_S has a typical value of 15–30 mV (63).

The dependence of the skin potential on the thickness of the epidermal layer is important to many ECG recording applications. If the thickness of the layer is changed by stretching or pressing down on the skin, the skin potential can vary by 5–10 mV compared with, for example, the 1 or 2 mV ECG signal. As these fluctuations generally result from patient movement, they are termed motion artifact. Motion or skin-deformation artifact is a serious problem during exercise cardiac stress testing of patients on treadmills or exercise bicycles, during ambulatory monitoring, and while monitoring patients lying in bed (64,65) (Fig. 11).

Figure 11. Disturbance of biosignal due to patient movement. (Redrawn from Ref. 65.)

Abrading or puncturing the skin is often used in stress testing to remove or bypass the problem source. Although skin potential increases with gel concentration, artifact gradually decreases with time as the conductive electrode gel soaks into the skin and renders the stratum corneum more conductive. High concentration gels are often used for short-term diagnostic applications where the risk of skin irritation is outweighed by the need for clear traces.

In general, hydrogel-based electrodes (see below) should not be used for stress testing or in other monitoring applications that are likely to suffer motion artifact problems. Hydrogels tend not to hydrate the skin and, hence, do not actively attack the source of the problem. The same comment applies for dry (gel-less) electrodes.

In stress testing and ambulatory event monitoring, modified electrode locations are used to avoid muscular or flabby areas of the body and thus minimize skin-deformation (and EMG) artifact. Stress loops are formed in the connecting leads, which are taped to the patient and used to avoid direct pull on electrodes and the underlying skin. The use of foam-backed electrodes tends to absorb any pull on the electrode and minimizes artifact.

Electrode Gels and Their Effects. Dry electrodes are successfully used in some monitoring applications. Suitably designed gel-less electrodes have advantages when used in the home environment where the patient may not remember or have the time to apply gel electrodes prior to use (66).

For many home-based monitoring applications, electrodes are manufactured from noncorroding materials such as stainless steel, which can be repeatedly washed and reused. Unfortunately, such polarizable materials give rise to poor electrical performances. In order to ensure good, stable electrode potentials, silver-silver chloride electrodes should be used (see below).

Jossinet and McAdams (67) demonstrated that the impedance of a dry electrode decreases pseudoexponentially due to the gradual buildup of sweat under an occlusive, gel-less electrode and the resultant progressive hydration of the underlying skin. Searle and Kirkup (61) reported that the decrease in skin impedance of dry electrodes is polyexponential and requires two time constants, one very short (~ 45 s) and the other almost 10 times longer (~ 450 s), possibly indicating two different processes at work.

Given that the surface of the skin is irregular, a flat dry electrode will initially only make contact with a few 'peaks' on the skin surface. Therefore, a smaller effective contact area exists than one would otherwise expect. However, as sweat builds up under the occlusive, dry electrode, a better contact with the skin will result in a relatively rapid increase in the measured value of C_{SP} . Human sweat contains a small amount of sodium chloride [~ 0.1 – 0.4% NaCl (49)], and hence serves as a weak electrolyte. It is suggested by the author that this accounts for the shorter time constant. (The longer time constant is probably indicative of the progressive hydration on the underlying skin resulting in a gradual decrease in R_{SP} .) As will be outlined below, R_{SP} is observed to decrease with a time constant of around 10 min in the presence of an electrolyte gel, which

agrees quite well with the 7.5 min observed by Searle and Kirkup (61).

Before leaving gel-less electrodes, it should be pointed out that in certain applications that employ very high frequency signals, such as electrical impedance tomography (EIT), the use of a gel pad may not be needed as it will contribute a small but significant contact resistance to the desired measurement (5). In such instances, the use of a very thin spray of moisture onto the electrode surface prior to its firm application to the patient's skin may be all that is required. Profiled dry electrodes firmly pressed onto the skin may also be adequate for certain home-based biosignal applications. If skin impedance is a problem with standard button electrode designs, this can be addressed by increasing the electrode area in the noncritical axis. For example, long, narrow, dry electrodes are used for precordial ECG recording, which enable a large contact area while ensuring sufficient interelectrode distances on the chest (66).

Electrode gels serve (1) to ensure a good electrical contact between the electrode and the patient's skin, (2) to facilitate the transfer of charge at the electrode-electrolyte interface between the two kinds of charge carrier (electrons in the electrode and ions in the gel), and (3) to decrease the large impedance of the stratum corneum.

Two main types of electrode gel exist, viz. wet gels (often described as pastes, creams, or jellies) and hydrogels.

Wet gels are generally composed of water, a thickening agent, a bactericide/fungicide, an ionic salt, and a surfactant (68). The ionic salt is present to achieve the appropriate electrical conductivity of the gel, which will depend on the specific application. As the major portion of ions present in tissue fluids and sweat are sodium, potassium, and chloride (Cl^-), in order to ensure biocompatibility, the ionic salts most commonly used in electrode gels are NaCl (sodium chloride) and KCl (potassium chloride). High concentrations of these salts tend to be better tolerated by the body than other salts. The ions in the gel serve not only to ensure electrical conductivity of the gel but to decrease the skin impedance by diffusing into the skin due to the existing concentration gradient. A relatively high concentration of electrolyte will also decrease the value of the charge transfer resistance (thus rendering the electrode more nonpolarizable).

When a standard pregelled wet electrode is applied to the skin, the gel rapidly fills up the troughs on the electrode and skin surfaces, thus ensuring maximum effective contact area. The skin capacitance, C_{SP} , is therefore observed to initially increase rapidly in value following electrode application and then to remain relatively constant (32). [A similar effect was probably noticed by Searle and Kirkup (61) as a result of sweat accumulation under a dry occlusive electrode.] Although C_{SP} does not exhibit a strong time dependence, it does vary with the electrolyte composition and concentration (49), increasing with increasing concentration (69).

Following electrode application, the skin's parallel resistance, R_P , generally decreases with time in a pseudo exponential manner as the ions in the gel diffuse through the skin rendering it more conductive (32,70) (see Fig. 12).

Figure 12. Variation of skin resistance with time for a range of gel concentrations and skin preparation techniques (1).

It has been observed, however, that when a cold gel is applied to a skin site, the measured value of R_{SP} is observed to initially increase (32,56), which is attributed to the cold gel causing the sweat pores to contract. Once the gel and skin has warmed up, the value of R_{SP} is observed to decrease as the electrolyte ions diffuse through the epidermal layer.

The skin temperature effect should be borne in mind when assessing a range of electrode designs. If, for example, the patient/subject removes his/her shirt just before the tests, the electrodes tested at the start of the experiment will have an advantage (i.e., smaller skin impedance) over those tested later as the uncovered skin sites will gradually cool down with time following removal of the shirt. Meaningful *in vivo* assessment of electrodes is not straightforward, and wrong conclusions can very easily be made by the unaware or the unscrupulous.

The time constant for the skin's parallel resistance, R_{SP} , appears to be inversely proportional to the concentration of the gel. The decay has a time constant of around 10 min (1), thus indicating that it takes almost 1 h for the electrode-skin impedance to decrease to its lowest value. For example, 50/60 Hz interference, linked to mismatch of electrode-skin impedances, is often observed experimentally to decrease with time. One should, therefore, where possible, apply the electrodes to the patient first, for example, before setting up the rest of the measurement system, to enable the skin impedance to decrease as much as possible.

High salt concentrations give rise to a more rapid diffusion of ions into the skin and a more rapid decrease in the skin's parallel resistance, R_{SP} (1,32) (Fig. 13). Such aggressive gels tend to be used in short-term biosignal monitoring applications such as stress testing, where instant, high quality traces are required (71). Biological tissues cannot tolerate long-term exposure to salt concentrations, which depart significantly from physiological levels [$\sim 0.9\%$ NaCl for body fluids and around $0.1\text{--}0.4\%$ NaCl for human sweat (49)]. Aggressive gels (5% NaCl) should not be used, for example, for the long-term monitoring of bed-ridden patients or for the monitoring of neonates. In the latter case, the incompletely formed skin is very susceptible to

Figure 13. Variation of skin resistance with time for a hydrogel-based electrode. Fluctuations are due to variations in subjects state of relaxation/arousal (32).

skin irritation problems. In any monitoring application, aggressive gels should not be used in combination with skin abrasion (see below). It is especially to be avoided in longer term monitoring applications where the removal of the body's defensive barrier coupled with the long-term exposure to an aggressive gel will lead to severe discomfort to the patient.

The second kind of electrode gel commonly used in electrode systems are hydrogels. Hydrogel-based electrodes have recently become popular for numerous biomedical applications including resting ECG. Hydrogels are solid gels, which originally incorporated natural hydrocolloids (e.g., Karaya gum a polysaccharide obtained from a tree found in India) (68). The use of natural hydrocolloids give rise to variable performances and, in some cases, an unattractive color. Synthetic (e.g., polyvinyl pyrrolidone) hydrocolloids are now widely used.

The use of such solid gels entails numerous advantages when they are used in conjunction with screen-printing or similar technologies. The use of an adhesive hydrogel pad dispenses with the need of the standard gel-impregnated sponge, gel-retaining ring, and surrounding disk of adhesive foam that are used in wet-gel electrode designs. It is possible to construct thin, lightweight, highly flexible electrode arrays with accurately defined electrode/gel areas, shapes, and interelectrode distances (72,73).

Hydrogels also tend to cause less skin irritation compared with wet gels. A simplistic explanation of the advantageous/disadvantageous features of hydrogels is that hydrogel serves principally to ensure a good electrical contact between the skin and the electrode and that they do not significantly affect (compared with wet gels) the properties of the stratum corneum.

The impedance of the gel layer can be represented by a simple resistance in series with the impedances of the skin and the electrode plate-electrolyte interface. The magnitude of the gel resistance will depend on the composition and concentration of the gel and on the dimensions of the gel layer. Hydrogels are generally more resistive than wet gels. Typical resistivities for wet gels are of the order of $5\text{--}500 \Omega\cdot\text{cm}$ (the higher the salt concentration, the lower the

resistivity) compared with 800–8000 $\Omega\cdot\text{cm}$ for hydrogels (the higher resistivity hydrogels tend to be used in cardiac pacing electrodes). Wet ECG electrodes, for example, have a gel layer thickness of around 0.3 cm and typical areas of 3 cm^2 . The resistance of a wet gel layer is, therefore, generally in the range 0.5–50 Ω . Although hydrogels have higher resistivities, this disadvantage is generally compensated for by the use of larger gel areas, which need not necessarily entail the use of a larger overall electrode area as the adhesive hydrogel may not require the use of a large surrounding disk of adhesive foam. Another way to compensate for hydrogel's inherent disadvantage is to decrease the gel layer thickness, a variable generally ignored in electrode design even though it can have a significant effect on electrical performances. Many commercial hydrogels used in biosignal monitoring electrodes have layer thicknesses of around 1 mm (compared with around 3 mm for pregelled wet electrodes) and, coupled with larger areas of around 7 cm^2 , can lead to hydrogel pad resistances in the range 10–100 Ω (5).

It is suggested that further improvements can be made to the performances of hydrogel electrodes (and wet electrodes) by the use of even thinner gel layers. It must be borne in mind that gel-layer resistance is not solely determined by the dimensions and properties of the gel pad. When a large area gel pad is used in conjunction with a small area sensor, the dimensions of the smaller sensor will largely determine the magnitude of the gel-layer resistance, the overlapping section of gel pad carrying relatively little current, which is important in both biosignal monitoring and electrostimulation applications.

Hydrogels, being hydrophilic, are used for wound dressings in order to absorb exudate. They are, therefore, poor at hydrating the skin and will even absorb surface moisture. With hydrogel electrodes, R_{SP} is observed to fluctuate with sweat gland activity and the subject's state of mental arousal, decreasing during increased activity and gradually increasing again as the hydrogel absorbs the excess surface moisture (74,75). In contrast, C_{SP} remains relatively constant after a slight initial increase (32).

Hydrogels are therefore not only more resistive than wet gels, but they hydrate the skin less effectively and give rise to higher skin impedances (i.e., higher values of R_{SP} and lower values of C_{SP}). Typical values of R_{SP} for hydrogels can be as high as 15 $\text{M}\Omega\cdot\text{cm}^2$ compared with a high of 5 $\text{M}\Omega\cdot\text{cm}^2$ for wet gels (75). Once again, this disadvantage can be overcome, at least partially, by the use of larger hydrogel pad areas. An additional way of increasing the value of C_{SP} is the use of thinner hydrogel pads (32).

Skin Preparation Techniques. In the clinical environment, the skin site is often degreased using an alcohol wipe prior to electrode application, which probably removes some of the loose, outermost cells of the stratum corneum and the poorly conducting lipid substances from the surface of the skin (55). However, the use of alcohol wipes may initially increase the impedance of the skin by dehydrating the outer layers of the skin (76). Motion artifact also may increase initially following application of alcohol to the skin (64). When wet gel electrodes are applied to alcohol-wiped skin, the gel will eventually penetrate the degreased skin

more readily once the electrode has been on the skin for several minutes, leading to a more rapid decrease in skin impedance and possibly to a decrease in motion artifact, which may not be the case, however, in the case of hydrogel electrodes, which do not actively hydrate the skin. The use of an alcohol wipe accompanied by vigorous rubbing should result in low initial impedances due to the additional mild abrasion.

A related method of rapidly decreasing skin impedance is to prerub the skin site with a high concentration electrolyte, thus forcing the gel into the outer layers of the skin, resulting as in a significant decrease in R_{SP} (Fig. 12) and an increase in C_{SP} , especially when accompanied by vigorous rubbing. Arbo-prep cream is supplied for this purpose and it is claimed to reduce skin resistance by up to 90% (from 40 or 50 to 4 or 5 $\text{k}\Omega$, according to an advertisement). Some commercial gels such as Hewlett-Packard's Redox paste contain abrasives such as crushed quartz, which, when rubbed into the skin prior to electrode application, greatly reduce skin impedance. Such aggressive gels should only be used in short-term biosignal monitoring applications such as stress testing where high quality traces are required.

The outer layers of the stratum corneum can also be removed by rubbing the skin with abrasive pads especially designed for this purpose, which can give rise to a major decrease in R_{SP} (Fig. 12) and an increase in C_{SP} .

Unomedical, for example, markets a small disposable skin preparation abrasive pad that, when adhered to the finger tip, can be used to dramatically reduce skin impedance. A Skin Rasp, which resembles a strip of Velcro, is marketed by Medicotest for this purpose. The Quinton Quick-Prep Applicator, rotates the abrasive center of the Quick-Prep electrodes, causing a marked decrease in skin impedance. ECG electrodes are often supplied with abrasive pads built into the electrode release backing.

In skin stripping, the stratum corneum is progressively removed by repeatedly applying and removing adhesive tape to and from the skin (55,77). Skin stripping can greatly decrease skin impedance as a consequence of a dramatic decrease in the value of R_{SP} and an increase in C_{SP} . As the outermost layers of the stratum corneum are the most resistive, the most significant decrease in skin impedance is achieved with the first few strippings (77). Therefore, no need exists for the complete removal of the stratum corneum, which would obviously be clinically unacceptable due to the discomfort (pain, bleeding, or irritation) caused to the patient during and following the recording. The more the skin is abraded for a given gel composition, the sooner discomfort develops and the more severe the irritation. The level of irritation also varies with the salt concentration and the additives present in the gel.

As pointed out above, abrading or stripping the skin is often used in stress testing to decrease motion artifact (63) as well as the 50/60 Hz noise induced by any mismatch of the contact impedances. High concentration gels are also often used for such demanding applications, rapidly soaking the skin and, thus, effectively removing the source of the problem.

The use of both skin abrasion/stripping and an aggressive gel will, however, maximize the potential for severe

skin irritation problems. These approaches should not be used together. Even with the use of mild gels, it is probably unwise to abrade the skin for long-term monitoring applications. The increased length of exposure of the abraded skin to the gel will be conducive to skin irritation. Somewhat surprisingly, long-term monitoring electrodes are sometimes commercially supplied with integral abrasive pads, which is not only risky but probably unnecessary as the use of a suitable mild gel would eventually decrease the skin impedance without the need for skin abrasion.

ELECTRODE DESIGN

External Biosignal Monitoring Electrodes

Historical Background. In 1887, Augustus Waller, using Etienne Jules Marey's modification of the capillary electrometer, obtained surface ECGs (as opposed to recording directly from the exposed heart of an animal) of one of his patients, 'Jimmy'. The patient turned out to be his pet dog. Waller used two buckets of saline to measure the canine ECG, one for the front paws and one for the hind paws (78–80).

Waller eventually succeeded in recording the first human ECG in 1887 using the capillary electrometer (Fig. 14) (81). However, he initially concluded "I do not imagine that electrocardiography is likely to find any very extensive use in the hospital. It can at most be of rare and occasional use to afford a record of some rare anomaly of cardiac action" (82).

It was, therefore, left to a more visionary and tenacious Dutchman, Willem Einthoven, to establish the clinical relevance of this strange new trace and to develop and commercialize a clinically acceptable system based on the string galvanometer. Einthoven's achievement was truly awesome. However, it must be pointed out that he did build (very significantly, it is conceded) on the work of earlier pioneers. The electrode system used, for example, was

Figure 14. Human subject connected to capillary electrometer via large area bucket electrodes (81).

Figure 15. Early commercial ECG machine and electrodes (84).

Waller's bucket electrode, whereas the moving photographic plate recording technique was originated by Marey (83).

The input impedance of Einthoven's galvanometer was such that very low contact impedances were necessary, hence, the very large bucket electrodes (Fig. 15) (84). Obviously, the range of applications was somewhat limited.

Realistically, only one's limbs could be conveniently placed into the buckets. Hence, the use of limb leads exists in electrocardiography, even to the present day. It is, therefore, important to note several points. Present state-of-the-art is often based on historical quirks rather than on a profound scientific basis. The monitoring device and amplifier determined the electrode size, design, and location of the electrodes, which in turn determined the clinical application and the presentation of the physiological data.

Einthoven's device in its early form could not be used for the monitoring of bed-ridden patients or for ambulatory monitoring. These applications had to wait for improvements to be made to the amplifiers, which then enabled the use of smaller electrodes that could be more conveniently attached in other anatomical locations. However, the early monitoring locations and the form of the signals observed became accepted as standard and there is often considerable resistance to novel monitoring scenarios (e.g., smart clothing), which require or are based on different lead systems and present physiological data in a different format to that familiar to the clinician.

In the 1920s vacuum tubes were used to amplify the electrocardiogram instead of the mechanical amplification of the string galvanometer, which led to smaller, more rugged systems that were transportable (Fig. 16) (84). The input impedances of the new ECG monitors were larger, and the large metal buckets could be replaced by smaller metal-plate electrodes (still large compared with present-day electrodes) (83). These advances enabled bedside monitoring, and, by the 1930s, some ECG devices could be carried to the patient's home. Not unsurprisingly, the new plate electrodes were attached to the limbs, both for historical and practical reasons. The metals used were chosen for their availability and ease of machining (Fig. 17). They included German silver, nickel-silver,

Figure 16. Mobile ECG used to monitor bed-ridden patient in hospital ward circa 1920 (84).

and nickel-plated steel. The foil plates were used in conjunction with moistened pads of paper toweling, lint, cotton gauze, or sponge and were generally held in place with rubber straps. Around 1935, conductive gels were developed to replace the soaked pads. A wide range of gel ingredients were assessed, and it was noticed that the presence of an abrasive in the gel greatly reduced the skin impedance (5).

They also noted that slightly abrading the skin before applying the electrolyte helped achieve very low skin impedances.

A dry version of the plate electrode was reported by Lewes (85). The multipoint stainless-plate electrode resembled a large nutmeg grater that penetrated the skin when firmly strapped onto the limb or applied to the skin with a slight rotary movement, thus resulting in a very significant reduction in skin impedance.

Modern versions of the limb plate electrode still exist. Some have a convenient spring clip mechanism, which dispenses with the need for the rubber strap.

In the 1930s, clinicians, some using electrodes held on the chest by the patient himself or by another member of clinical staff, experimented with precordial leads and established their clinical value (86). In 1938, the American Heart Association and the Cardiac Society of Great Britain defined the standard positions and wiring of chest leads V1–V6 (87).

Research then focused on the development of electrodes that could be conveniently attached to the chest to enable convenient routine clinical measurements. Several designs

Figure 17. Metal plate limb electrode.

involved a rubber bulb, which was used to create suction sufficient to hold the metal electrode on the chest. One of the first suction electrodes was developed by Rudolph Burger in 1932 for the precordial leads (88). The suction electrode shown in Fig. 18a (85,89) is one developed by Ungerleider (89). Another more recent system incorporated the multipoint electrode of Lewes (85) into the suction head (Fig. 18b). The most popular suction electrode design, widely used around the world and still in use today, was developed by Welch (90) and often called the Welch or Suction cup/bulb electrode (Fig. 19) (3). It consists of a hollow, metallic, cylindrical electrode that makes contact with the skin at its base. A rubber suction bulb fits over the other end of the cylinder. The suction bulb was squeezed while the electrode was held against the skin. Upon releasing the bulb, the electrode is held in place. The suction electrode can be used anywhere on the chest and can even be used on hairy subjects. A single electrode can, if necessary, be used to take a measurement at a given location and then moved to another site.

Although the Welch cup electrode became widely used as a precordial electrode, it could only be realistically used for resting (supine) diagnostic ECG recording. The weight and bulk of the electrode generally rules out its use on upright, ambulatory, or clothed subjects. Since then, more suitable, lightweight, low profile suction electrodes have been developed that are pneumatically connected to remote vacuum pumps (37). Some arrays of suction electrodes are commercially available, for example, for use with exercise bicycles for cardiac stress testing (72).

A method had to be invented to attach small disks of suitable metal and their conductive gel coating to a patient's chest (in the case of ECG) or to other body parts in the case of other biosignal applications, such as EEG and EMG. Simply taping a metal disk to the skin site with a sandwiched gel layer was a method often used (91).

Figure 18. Early designs of suction precordial electrode (a) Ungerleider (89). (b) Lewes (85).

Figure 19. A metallic suction electrode is often used as a pre-cordial electrode on clinical electrocardiographs (3).

Conically formed metal disk electrodes were and often still are used for EEG recordings (Fig. 20). The base of the metal cone is attached to the patient's scalp using elastic bandages, wire mesh, or more recently, using a strong adhesive such as colloidon. Aperture exists in the apex of the cone to enable the introduction into the recessed electrode of electrolyte gel or to enable the abrasion of the underlying skin by means of a blunt hypodermic needle. The cone electrodes were often made of gold as it has high conductivity and inertness, desirable in reusable electrodes. More recently, Ag/AgCl has been used.

Early plate electrode designs were presumably very messy and gave rise to considerable artifact problems. The observed artifacts were attributed to disturbance of the double-layer region at the electrode/skin (or, more precisely, electrode/electrolyte) interface [termed the electrokinetic effect by Khan and Greatbatch (94)]. When the electrode moves with respect to the electrolyte, the distribution of the double layer of charge on electrode interface was thought to change and cause transient fluctuations in the half cell potential or give rise to a streaming potential.

Recessed or floating electrodes were introduced in an effort to protect the electrode-gel interface from such mechanical disturbance and resultant movement artifact.

Figure 20. Conically formed metal disk EEG electrodes.

Figure 21. Examples of a floating or recessed biosignal electrode. (a) Recessed electrode with top-hat structure. (b) Cross-sectional view of the electrode in (a)(3).

A metal disk was recessed in a plastic housing that was filled with electrolyte gel prior to application to the patient. The top hat-shaped container was adhered to the skin by means of an annulus of double-sided adhesive tape, (Fig. 21) (3). Later a gel-impregnated sponge was used to ensure good electrical contact between the electrode disk and the skin surface. The electrode disk was, therefore, not in direct contact with the skin, which was found to reduce motion artifact. At first, various metal plates were used as the electrode conductor, then a sintered Ag/AgCl disk with preattached wire ensured better performances for more demanding applications.

Modern Disposable Electrodes. The top hat housing was eventually replaced with a smaller retaining ring or plastic cup and the electrode was held in place by means of a surrounding disk of adhesive foam. The plastic cup holds the gel-impregnated sponge in place and stops the gel from spreading beyond the set boundary, either during storage or use on the patient. Low cost Ag/AgCl-plated plastic eyelets (part of a snap fastener) are used in these disposable electrodes and the leads are connected to the electrodes via the electrodes' snap fastener studs. The rigid retaining ring was, however, uncomfortable as it did not allow the electrode to conform optimally to body contours. It was eventually removed in many modern disposable electrodes and the recess is now often formed by a hole in the adhesive foam layer. The backing label serves to hold the snap and eyelet in place as well as to present the company's logo (Fig. 22). The resultant electrode structure is much more flexible and more comfortable to wear.

The use of a snap fastener-style connection in disposable electrodes has one significant drawback for certain applications. The male stud protruding from the back of the electrode and the female connector required on the connecting lead results in a relatively heavy, large-profile electrode/connector interface, which is less than optimal for applications such as neonatal and pediatric monitoring. The use of such electrodes in long-term monitoring of bed-ridden patients could lead to considerable discomfort and the heavy connection could also give rise to significant motion artifact problems. The integrated lead design seeks to overcome these disadvantages. A thin, highly flexible lead wire is bonded directly to the back of a specially designed Ag/AgCl-coated eyelet, which results in a very low profile, lightweight electrode-connector system much used in neonatal and pediatric monitoring and attractive for long-term monitoring applications (Fig. 23).

Figure 22. Modern wet gel disposable electrode. (Courtesy of Unomedical A/S.)

In an effort to decrease motion artifact, many electrode designs feature an offset center. The connector, often in the form of a snap fastener, is separated from the gelled sensor by a strip of metal or similar conductive layer. The connector is thus 1 or 2 cm away from the metal–gel–skin interface, and it is possible to connect the lead to the electrode or to pull on the connector without pulling directly on the gelled, skin site, thus causing artifact problems. This design appears well suited for stress testing applications although arguably less so for long-term monitoring of bed-ridden patients due to the bulky connector. The invention was patented by Manley (93) and the concept

Figure 24. An example of an off-set connector electrode. (Courtesy of Unomedical A/S.)

has been commercially exploited very successfully by Ambu A/S.

More recently, many other manufactures supply electrodes with offset connectors (Fig. 24). Leadlock have developed an electrode that incorporates a slit in the foam backing. Once the electrode has been applied to the patient and the lead connected to it, part of the foam backing is used tape down the lead, locking it in place and minimizing direct pull on the connector and underlying electrode/skin interface.

A wide range of backing materials now exists, and some are better suited for specific monitoring applications, types of patients, skin types, and so on. Given the great variety of materials, adhesives, and designs used, the following comments are generalizations.

Open-cell foam layers, made from a plastic such as polyethylene, are much used and have thicknesses typically in the range 1–2 mm. They have a 10–100 μm coating of a pressure-sensitive adhesive, generally a polymeric hydrophobic substance (68,94). Adhesive foams generally give rise to firm adhesion, are resistant to liquids, and tend to cushion lead pull, thus giving rise to less artifact. They are, therefore, generally well-suited to cardiac stress testing and similar applications. However, as they are occlusive and generally have a relatively aggressive adhesive, they can give rise to more skin irritation and they must be used with caution for neonatal and long-term monitoring.

Porous, breathable layers, such as nonwoven clothes or tapes, have the advantages of being soft, stretchable, and conformable with the skin. (*Note:* The term micropore, although sometimes used loosely to describe any breathable backing material, is strictly a 3M product.) Porous layers tend to cause less mechanically induced trauma to the skin, which can occur with more rigid materials and is due to shearing of underlying skin layers. As they are highly air permeable and use milder adhesives, porous tapes cause less skin irritation and are well suited for long-term monitoring. Larger backing areas tend to be required. The gelled center can, however, pull away from the skin as a result of the stretchable backing. Ambu A/S

use a central ring of adhesive around the gelled eyelet to minimize this problem.

As we have already seen, wet (as opposed to solid gels) vary in composition and concentration depending on the application. Aggressive gels with higher concentrations of electrolyte or including abrasive particles are used for short-term, demanding monitoring applications such as cardiac stress testing. Mild gels are used in pediatric and neonatal applications due to the increased vulnerability of the patient's skin. It should be noted that no matter how hypoallergenic a gel or an adhesive is claimed to be, some patients will experience some form of skin reaction to one of the components.

Solid Conductive Adhesive Electrodes. The growing monitoring market has led to the development of even lower-cost disposable electrodes. Solid conductive adhesive or hydrogel electrodes were first introduced by LecTec Corp around 1980 (95). Hydrogels are composed of a hydrocolloid, alcohol, a conductive salt, water, and a preservative. The hydrocolloid use can be either natural (e.g., Karaya gum) or synthetic (e.g., polyvinyl pyrrolidone) (68). Early hydrogel electrodes were based on the natural hydrocolloid, Karaya, which comes from the bark of a tree. The rather unaesthetic appearance of these early gels and the variations in their electrical and mechanical properties limited their widespread acceptance. The use of synthetic hydrocolloids, with their more attractive appearance and performances, has led to the recent revolution in electrode design.

Solid adhesive gels reduce the number of electrode parts required, dispensing with the need of a gel-impregnated sponge or a surrounding disk of adhesive tape, which gives rise to small-area, low profile electrodes suitable for neonatal monitoring, especially when coupled with integrated leads as discussed above (Fig. 23b).

Tab solid adhesive electrodes are now widely used for many biosignal monitoring (and stimulation) applications. Thin, highly flexible metallic/conductive foils or printed conductive ink layers are laminated with solid, adhesive hydrogels. A section of the foil or printed layer is left uncovered. Once the electrodes are cut out, the exposed conductive tab acts as a means of connection, the leads being connected via alligator clips (Fig. 25). Electrode design is therefore very simple and manufacturing costs are low. These flexible, low profile electrodes are best used for short-term, resting diagnostic monitoring. Tab electrodes are not suitable for ambulatory or long-term monitoring as the tab connection will cause the electrode to peel off quite easily when pulled from any angle other than directly downward. Also, hydrogels are hydrophilic and tend to absorb moisture, lose their adhesive properties over time, and fall off the patient if an additional adhesive backing is not used. Hydrogels, being solid, do not leave a messy residue on the skin requiring cleaning. Tab electrodes are also repositionable and are reuseable (on the same patient!) in certain home monitoring applications.

When used with an adhesive backing layer, the hydrophilic hydrogels tend to be relatively nondrying (a significant problem with pregelled wet electrodes) and their electrical properties may even improve as they absorb

Figure 25. Hydrogel-based tab electrode with connector. (Courtesy of Unomedical A/S.)

moisture. As they do not actively hydrate or otherwise affect the skin, they tend to be relatively nonirritating compared with wet gels.

Some disadvantages exist, however, associated with hydrogels. Hydrogels are more resistive than wet gels and, hence, the gel pad resistance will be higher, which can be compensated for by using larger hydrogel pad areas and thinner layer thicknesses as compared with those used with wet gels. Although the area of the solid adhesive gel in a tab electrode, for example, is considerably larger for this reason than that in a standard disposable wet gelled electrode, the absence of a surrounding adhesive layer results in the tab electrode having a smaller overall area.

Hydrogels, being hydrophilic, are poor at hydrating the skin and may even absorb surface moisture. They, therefore, give rise to larger skin impedances. This disadvantage can also be overcome, at least partially, by the use of larger hydrogel pad areas. Hydrogels are also more expensive than wet gels but generally lead to less expensive electrodes due to the simpler designs involved.

Hydrogels are more sensitive to motion artifact as they do not actively hydrate the skin. They are, therefore, not well-suited for stress testing.

The use of such solid gels entails numerous advantages when they are used in conjunction with screen printing technology (73,96), especially for body surface mapping and similar applications. It is possible to construct thin, lightweight, highly flexible electrode arrays with accurately defined electrode/gel areas, shapes, and interelectrode distances for a wide range of novel stimulation and biosignal recording applications. As the solid gel will not spread between electrodes, it is possible to position electrodes very close together without electrical shorting (Fig. 26).

Wearable Electrodes for Personalized Health. The recent and continuous trend toward home-based and ambulatory monitoring for personalized healthcare, although exciting and potentially leading to a revolution in healthcare provision, necessitates even more demanding performance

Figure 26. Cardiac mapping electrode harness.

criteria for the monitoring sensors (97,98). Many groups around the world are seeking to incorporate electrodes into clothing in order to monitor military personnel, firefighters and eventually the average citizen who wishes to monitor his or her health. Systems already exist on the market (e.g., Life Shirt) that resemble waistcoats into which one plugs-in standard ECG electrodes and other sensors. These sensors are removed and replaced periodically by the subject and, hence, require the knowledgeable involvement of the motivated wearer, presently military personnel, athletes, rescue workers, and so on.

For the more widespread use of wearable monitoring systems, especially by the average citizen, the system must be very easy and comfortable to use and require no preparation—literally as simple as putting on their shirt. Electrodes must, therefore, (1) require no prepping, (2) be located in the correct location once the smart garment is put on, (3) make good electrical contact with the skin, (4) not give rise to motion artifact problems, (5) not cause discomfort or skin irritation problems, and (6) be reusable and machine-washable. Although much work has been carried out in this novel area, it is not surprising given the above list of required performance criteria that the electrodes/sensors tend to form the bottleneck in the success of the overall monitoring systems. One must, therefore, not simply choose an electrode with as conductive a metal element as possible. Unfortunately, it would often appear that the associated electronic systems are first developed and the electrode design is left to the end, almost as an afterthought. The author would, therefore, suggest

that researchers start with the desired biosignal and establish the optimal body site(s) and electrode design for the given application before developing the rest of the monitoring system. This process may involve the use of novel lead or montage electrode positions in order to conveniently pick up artifact-free signals. Although this method will necessitate clinicians interpreting nontraditional waveforms, it will at least enable feasible monitoring and, as it involves novel body sites and electrode designs, it may well be patentable. After all, if it is not patented and commercialized, it will not benefit the patient.

One of the most promising smart garments is that developed under a European Fifth Framework programme called WEALTHY (Wearable Health Care System) (Fig. 27). WEALTHY is a wearable, fully integrated system, able to monitor a range of physiological parameters including electrocardiogram, respiration, posture, temperature, and a movement index. Fabric electrodes are made using conductive fibers woven into the stretchable yarn of the body-contour hugging garment and connections are integrated into the fabric structure (Fig. 27b). Various membranes are being assessed to ensure optimal electrode-skin contact and minimize skin irritation. The garment is comfortable and can be worn during everyday activities. It is washable and easy to put on.

External Electrostimulation Electrodes

Historical Background. The evolution of external stimulation electrode design shares some of the key landmarks as the development of biosignal monitoring electrode and, hence, this section will be somewhat shorter.

From the mid-1700s, when electrostatic generators were used to deliver arguably therapeutic impulses to various parts of the body, handheld (by the practitioner) electrodes had to be designed capable of delivering the impulses to the patient without shocking the practitioner who was holding them against the body part in question. The electrodes used tended to be simply long metal rods insulated with wooden handles (Fig. 28) (99). Although the electrodes were initially terminated in a simple metallic sphere, more exotic terminations were soon invented as these were observed to lead to different therapeutic effects on the body by means of the variations in the streams of the electric fluid. A modern parallel would be the use of different pencil electrodes (ball, loop, and needle) in electrosurgery for different effect.

Figure 27. (a) The WEALTHY physiological monitoring vest with integrated sensors. (b) An early version of the fabric electrodes.

Figure 28. Early electrostatic generator and handheld electrodes (99).

Around 1800 came the discovery of Galvanism (dc current) and Voltaic Piles (early batteries). Numerous examples exist of practitioners using their handheld probe for localized effect, and the second contact to the patient was made by means of a container of water into which the patient put a hand or foot (Fig. 29) (100).

Following the discoveries of self- and mutual induction (~1830), Guillaume Duchenne made great contributions to the clinical application of the new Faradic current. At that time, much interest existed in the localization of what became known as motor points. It was common to combine the prevailing interest in acupuncture and use needles to stimulate muscles and nerves under the skin, termed electropuncture (83). Duchenne was not happy with this approach and developed his own electrodes for localized electrization. His electrodes were in various shapes (disks spheroids, and cones) covered with leather

Figure 29. Container electrode. Used on the dead and the living (100).

Figure 30. Duchenne's moistened conical electrodes for localized electrization (101).

moistened with salt water prior to application (101). (Fig. 30).

During the 1900s, as with biosignal monitoring electrodes, electrostimulation electrodes involved the use of simple metal buckets or receptacles, filled with water or another electrolyte, into which the subject introduced their foot or hand, especially in early iontophoretic applications. Obviously, the range of applications was somewhat limited. Metal probes were still manually pressed against skin for short-term applications. The electrodes were either gelled before application or had moistened chamois coverings similar to those used by Duchenne. In the 1950s, early external pacing and defibrillator electrodes, termed paddles because of their shape, consisted of bare metal disks made of noncorrosive material and were simply pressed against the patient's chest (102) see Fig. 31.

Figure 31. Early pacing equipment and handheld electrodes (102).

Figure 32. Early pacing equipment and metal-plate electrodes (103).

Rigid metal plate electrodes were eventually held in place with rubber straps on the limbs and even the thorax (Fig. 32) (103). Some of these electrodes were and still are made with rigid stainless-steel plates (104). The foil plates were generally used in conjunction with moistened pads of paper toweling, lint, cotton gauze, or sponge. The pads were moistened by the therapist prior to electrode application with water or electrolyte. Such electrodes could be easily reused by simply washing and regelling the electrode. Being rigid, however, these plate electrodes did not always make optimal contact with the body surface and gave rise to current density hot spots. External cardiac pacing at this time, for example, was very painful (83).

Malleable metal foil electrodes were the next evolutionary step in electrode design. Malleable electrodes have been made using a range of metals including tinplate lead and aluminium foils (105). Such electrodes had the advantage of being able to conform, to some extent, with body contours, thus ensuring a better, more comfortable contact between the electrode and the patient than was the case with rigid plates. Wrinkles in malleable metal foil could, however, encourage preferential current flow through small areas of the gel and into the patient.

More convenient, disposable pregelled foil electrodes were then developed for a range of external electrostimulation applications. The metal foil was laminated onto an adhesive foam backing. A gel-impregnated sponge layer was located on top of the metal layer and the complete electrode is attached to the patient by means of the surrounding layer of adhesive backing foam.

Unfortunately, the wet gel in these disposable pregelled electrodes tended to pool to one side, depending on how they were stored, giving rise once again to current density hotspots. More recently, the gel-impregnated sponge layer has been replaced by a conductive adhesive gel layer, as it does not have the potential for pooling to one area during storage and it does not squeeze out under pressure (68) (Fig. 33).

Figure 33. Construction of a modern external pacing or defibrillation electrode (courtesy Unomedical A/S).

Current Density Considerations. The distribution of current density under an electrode is an important parameter when designing and using electrostimulation electrodes. In the simplest case, current density (the amount of current per unit of conduction area) is inversely proportional to the electrode/skin contact area. For a given current, the current density under a small-area electrode will be higher and more localized than that under a large-area electrode. Generally, an optimal electrode area exists for a given therapeutic application, based on a range of criteria including the anatomical position and size of the nerve/muscle/organ and the relative positions and sizes of the electrodes. Small electrodes are, therefore, well suited to target precisely known points such as motor points. If a small electrode is used in conjunction with a large-area electrode, the effect is more pronounced under the smaller of the two. In such monopolar stimulation, the small electrode is often used as the active electrode to target the therapeutic effect. The larger electrode is simply used to complete the electrical circuit and is termed the indifferent or dispersive electrode. The use of two equally sized electrodes is termed bipolar stimulation. In TENS, for example, bipolar stimulation is often used to stimulate large muscle groups sandwiched between the (large) electrodes. Too large an area of electrode, however, may cause the current to spread to neighboring tissues.

High current densities can cause tissue injury due to, among other things, heating effects. The passage of electricity through any conductor will cause the dissipation of heat within that conductor. The amount of heat generated in a tissue depends on spatial and temporal patterns of current density and tissue resistivity (49).

The total energy dissipated at an electrode–skin interface is given by the formula:

$$E = I^2 R t \tag{21}$$

where

- E is energy dissipated (J)
- I is root-mean-squared (rms) electrode current (A)
- t is the duration of current flow (s)
- R is the real part of the impedance at the electrode site (Ω).

The change in temperature at the skin, ΔT , site is proportional to the energy dissipated and, hence, ΔT is proportional to $I^2 R t$. When skin or muscle tissue is heated to about 45 °C for prolonged periods, thermal damage can result. For short durations (i.e., <5 s), a temperature rise approaching 70 °C would be needed to cause heat damage.

As the electrode–skin resistance, R , is not generally known for a given site, it is often found convenient to use a heating factor (HF), where

$$HF = I^2 t \quad (\text{A}^2 \cdot \text{s}) \tag{22}$$

Assuming uniform current density distribution under an electrode, it is possible to calculate the minimum area of electrode necessary to achieve therapeutic effect and avoid tissue trauma (42). In theory, the applied currents flowing through standard dispersive electrodes used for electro-surgery, for example, will generally not give rise to sufficiently high overall current densities to cause thermal damage. However, analysis shows that current density distribution is not uniform under a stimulation electrode and that localized hotspots can occur and cause considerable pain and trauma to the patient when applying apparently safe therapeutic impulses (49). At best, in cases such as TENS, the applied current may have to be limited to less

than therapeutic values due to the patients discomfort (68).

Many potential sources exist of accidentally high current densities. Wrinkles or breaks in the metal electrodes, gel squeezing out from under the electrode or drying out, electrodes partially peeling off the skin, poor electrode application, and so on can encourage preferential current flow through small areas of the gel and into the patient. However, current density hotspots can also occur due to poor electrode design, and a considerable amount of research has been and is being spent investigating this important problem.

In this presentation, stimulation electrodes have been divided into conductive electrodes and resistive electrodes in order to facilitate the review of the various design features.

With highly conductive metal electrodes, such as those used for external cardiac pacing, defibrillation, or electro-surgery, current density hotspots are observed to occur under the perimeter of the electrode, often evidenced in the past by annular-shaped burns to the patient (49,106).

Current density hotspot problems are now often studied using thermal imaging cameras. Thermograms of the patient's skin (or a substitute such as pig skin) are taken immediately following the application of a given series of pulses and the removal of the electrode under test (Fig. 34). Increases in skin temperature reflect the magnitude of the current density at a particular point (107).

Wiley and Webster (108) showed that current flow through a circular electrode placed on a semi-infinite medium could be solved analytically. They found that for an electrode of radius, a , and total current, I_0 , into the electrode, the current density into the body as a function of radial distance from the center, r , was given by:

$$J(r, 0) = \frac{J_0}{2[1 - (r/a)^2]^{1/2}} \quad (\text{A} \cdot \text{cm}^{-2}) \tag{23}$$

where $J_0 = I_0/\pi a^2$, (i.e., a hypothetical uniform current density).

Figure 34. (a) Schematic representation of the current density distribution under a conductive electrode plate. (b) Thermal image of the skin under an electrosurgical electrode following testing.

As a result of the approximations made in deriving this simple equation, the value of current density at the edge (when $r = a$) would theoretically approach infinity. More realistically, the current density at the perimeter can be around three times higher than that at the center of the electrode (109) (Fig. 34). The above equation shows that the middle portion of the electrode is relatively ineffective in carrying the current as half the total current flows through an outermost annulus 0.14 a wide or one-seventh of the radius.

Efforts in this area concentrate on encouraging more of the current to flow through the central portion of the electrode.

A main concern in the design of the conductive stimulation electrodes used for external cardiac pacing, defibrillation, or electrosurgery is the decrease in the high current densities observed at the edges.

In TENS, relatively resistive conductive rubber is often used and the opposite problem develops. When current is introduced into the conductive rubber (via a small metallic connector), it tends to flow into the skin immediately under the connector rather than laterally through the resistive electrode. Efforts in this area concentrate on encouraging the current to flow laterally through more of the electrode surface.

Modern Electrode Designs

Conductive Electrodes. Electrosurgery, external cardiac pacing, and defibrillation share a common problem: Electrodes tend to deliver or sink a substantial portion of the outgoing or incoming current through their peripheral area as opposed to providing a uniform current density along their surface. This problem is referred to in the literature as the fringe, edge, or perimeter effect.

Many suggestions have been made to reduce this edge effect observed with metal electrodes, including:

1. Increasing overall area of the electrode. Obviously, an increase in electrode area will lead to a decrease in current density (110,111). However, it is generally not practical to use very large electrodes as the applied electrical field must be sufficiently focused to stimulate the targeted tissues and them alone. Also, a strong commercial interest exists in decreasing the size of the electrodes to save money and to facilitate packaging and storage of the electrodes.
2. Avoiding sharp edges in the metal plate (110,111). It has long been observed that square or rectangular electrodes with angular edges concentrate the electrical field at their corners, giving rise to current density hotspots in these locations. Using round electrodes or rectangular ones with rounded edges have been found advantageous in this regard.
3. Making the gel pad slightly larger than the electrode to enable the electric field lines to spread out before reaching the skin (111) (Fig. 35). Using a gel pad much larger than the size of the metal plate has less effect than would be expected as the perimeter of such a large gel pad will carry little current and the additional gel is electrically redundant, which

Figure 35. Schematic representation of the current density distribution under an electrode plate coupled with a larger gel pad. Current is allowed to spread out beyond the boundaries of the metal plate, thus minimizing the edge effect.

arguably applies to some of the snap connection electrodes used in TENS that do not have an additional current dispersing element.

4. Increasing the overall resistance or thickness of the gel layer in order to give the current more time to spread out evenly through the gel (110,111). It is well-known that, in applications such as external cardiac pacing, the use of relatively resistive gels decreases the pain and burning to the patient's chest. Krasteva and Papazov (110) suggest that the use of a layer of intermediate resistivity, comparable with that of the underlying tissues, optimally improves the distribution. However, in other applications such as external defibrillation, a high resistance gel pad would lead to energy wastage and a decrease in the desired therapeutic effect. Taken to its logical conclusion, this approach results in the coating of the electrode metal plate surface with a dielectric film. Such capacitive electrodes have been shown to give rise to nearly uniform current densities (107).
5. Increasing the resistance or thickness of the gel at the edges. Kim et al. (112) proposed covering the electrode metal with resistive gel of increasing resistivity as one moved out from the center toward the periphery, according to a specific relation with respect to the electrode radius. Although an intriguing concept, the commercial manufacture of such an electrode system is not yet feasible.
6. Making the electrode conductive plate progressively more resistive toward the peripheral edge of the electrode. Wiley and Webster (108) suggested subdividing the electrode plate into concentric segments and connecting external resistors to the individual segments. The connected resistors had progressively higher resistances toward the periphery in order to equalize the currents in the separate segments. A simpler system that has been successfully commercialized was patented by Netherly and Carim (113). A resistive layer is deposited on the outer edge of the electrode conductive plate, thus forcing more current to flow through the central portion of the electrode (Fig. 36). Krasteva and Papazov (110) demonstrated theoretically that a high resistivity perimeter ring

Figure 36. 3M's electrocauter electrode. Note the green lossy dielectric material deposited around the peripheral edge of the electrode.

decreased the maximum periphery current by 12% without increasing the total interface resistance, hence the resistance to the defibrillation current.

Another related approach to this problem starts with a resistive graphite-based conductive layer and progressively builds up multilayered (at least two) coatings of more conductive silver/silver chloride toward the center of the electrode (114). The perimeter resistance is approximately 200 times that of the center, this is the technique exploited in Medtronic EDGE system electrodes for defibrillation, noninvasive pacing, and ECG monitoring (Fig. 37). It is claimed that the design distributes the current density evenly over the entire surface area of the electrode, rather than concentrating it at the edges.

7. Scalloping or otherwise shaping the edges of the metallic plate so that the length of the perimeter is

Figure 37. Medtronic's EDGE system electrode.

Figure 38. An electrostimulation electrode with cut-out metal plate in an effort to increase peripheral edge. The green sponge impregnated with gel has largely been removed to facilitate inspection of the underlying plate.

increased and, hence, the peripheral current density is decreased. Over the years, various designs have incorporated this concept. For example, it has been shown that using a figure-eight design rather than a rectangular metal plate reduced the maximum temperature (reflective of current density) by 30–50% (107). An alternative design is shown in Fig. 38. Caution is advised with this approach as the formation of fingers in the metal layer may serve only to concentrate the current at the tips of the fingers, and one could be effectively left with a reduced peripheral area.

8. Making holes in the central portion of the metal plate in order to provide internal peripheral edges to block the lateral flow of current. Some early claims were made that holes in the metal layer improved current density under the electrode. Presumably, it was believed that the holes blocked the current from flowing from the connector to the edge of the metal plate, forcing it to flow into the patient at the edges. It is the authors belief that such holes in the metal plate achieve little apart from further decreasing the area of the electrode and, if anything, increasing the current density at the edges. This impression appears to be confirmed by the work of Krasteva and Papazov (110), who investigated electrode structures with openings in the metal plate for skin breathing.

The author has suggested that the use of concave slits in the metal layer rather than circular holes may well have a favorable effect on current density distribution with the concave internal peripheral edges effectively blocking the lateral flow of current, forcing the trapped current to flow into the gel and, thus achieving a more uniform current density distribution over the surface of the conductive layer (115). Early work on the project with an industrial

partner appeared promising, but the work was never completed.

Resistive Electrodes. A TENS electrode system appears relatively simple and generally comprises a conductive plate, an ion-containing gel, a means of attachment to the skin, and a means of connection to the stimulators lead. Mannheimer and Lampe (42) pointed out, however, that of all the component parts of the overall TENS system, the electrode–skin interface has probably been the least understood and the most problematic. In addition to influencing the effectiveness of the treatment, poor electrode design can give rise to electrically, chemically, and mechanically induced skin irritation and trauma to the patient.

Initially, electrodes originally designed for ECG and other biosignal monitoring applications were used with TENS units, and some still are. Larger, more suitable electrode designs were eventually developed in order to reduce the current densities under the electrodes, to reduce skin irritation problems, and to increase stimulation comfort (116).

A large percentage of commercially available TENS electrodes are now molded from an elastomer (e.g., silicone rubber) or a plastic (e.g., ethylene vinyl acetate) and loaded with electrically conductive carbon black (Fig. 39) (3). Very few irritation or allergic reactions have been reported for conductive rubber electrodes as they do not generate the corrosion products often observed with metal electrodes (42). The great advantage of such electrodes is that they can be molded into almost any size or shape and a wide range of choice exists in the market. They can be made sufficiently thin to have high flexibility and, thus, are able to conform with body contours, making them suitable for a wide range of TENS applications.

Conductive rubber electrodes are often used in conjunction with an electrolyte gel and attached to the patient using elastic straps or custom-cut disks or patches of adhesive tape. Expanded polyester foam tends to give the most secure adhesion. However, as this backing is occlusive, the use of foam can give rise to skin irritation

Figure 39. Carbon-filled silicone rubber electrode (3).

problems. Breathable, cloth-like fabrics allow the transmission of air and moisture and generally cause less skin irritation problems. Cloth-like materials tend to stretch, however (an advantage when it accommodates skin stretching due to movement), which can lead to the electrode working loose and making poor contact with the skin, possibly resulting in current density hot spots.

Wet gels can squeeze out from under parts of the electrode and give rise to increased current densities in other areas. The use of hydrogel minimizes this problem source (68). Conductive, adhesive pads of solid hydrogel help ensure firm electrical contact between the electrode and the skin, reduce the incidence of current density hotspots, and often simplify the design of the electrode. As a large surrounding disk of adhesive tape is not required, the electrode size can be reduced to the active electrode area. These solid gel pads can be, depending on the application, replaced, refreshed, or simply reused in various semi- or totally-reusable electrode systems. In some applications, the gel pads can be removed and the conductive rubber electrode cleaned and regelled with a fresh gel pad for further use. In other cases, the electrode can be intermittently reused, on the same patient, by rehydrating the gel pad. Such reusable electrodes are ideal for home-based patient use.

One disadvantage with such conductive rubber electrodes is that they are relatively resistive. More power is required to drive the stimulating current through the resistive electrodes into the body and achieve the desired stimulation. Therefore, some reduction in battery life may occur which is generally not a significant problem, however.

A more serious problem involves current density distribution under the resistive electrode. When current is applied through the conductive rubber (via a small metallic connector), it tends to flow into the skin immediately under the connector rather than laterally through the resistive electrode, thus giving rise to a current density hotspot under the connector, which effectively, is the opposite problem to that encountered when using highly conductive electrodes.

Efforts to overcome this problem include incorporating conductive elements in the rubber to more evenly to help spread the current over the entire interface surface. Some electrodes have a thin metallic layer coated onto the back of the conductive rubber, which appear to give rise to the most uniform current density profiles (68).

The growing home-based market has led to the great variety of low cost disposable and reusable electrodes that are generally based on solid adhesive gels. Some electrodes are made using conductive cloth-like materials, thin metallic foils, aluminized carbon-filled mylar, or wire strands. Electrical connection is generally made to these electrodes via alligator clips, snap fasteners, or pin connectors. Many of these hydrogel-based electrodes can be trimmed to the desired size or shape by simply cutting with a pair of scissors. The current density profiles under these electrodes will very much depend on the relative resistivities of the metal and gel layers as well as on the actual design.

Snap fastener designs resembling standard ECG electrodes and are available with hydrogel pads or sponge

Figure 40. (a) Current density distribution under a conventional snap electrode. (b) Axelgaard's UltraStim snap electrode with current controlling grid. (c) Current density distribution under Axelgaard's UltraStim snap electrode. (Courtesy of Axelgaard Ltd.)

disks containing low chloride wet gels (to minimize skin irritation). These desists may require an additional current-dispersing element to ensure that the current spreads out beyond the immediate confines of the eyelet electrode (68). Axelgaard Ltd's UltraStim Snap Electrodes feature a highly conductive grid pattern printed on to a conductive flexible layer and coated with a moderately conductive adhesive gel layer. The conductivity of the conductive pattern is controlled through the use of various grid designs with preselected line widths and spacing as well as thickness and ink compositions (117). The pattern is thus used to control and optimize the spread of electric current over the surface of the electrode with an intentional current drop off toward the edge of the electrode (Fig. 40).

It is interesting to note that considering current density under conductive and resistive electrodes leads to a similar optimal design. To improve conductive electrodes, one places a resistive layer between it and the patient. To improve a resistive electrode, one puts a conducting layer either behind or in front of the resistive layer. Such sandwich electrode designs appear promising for a range of electrostimulation applications.

Garment Electrodes. A range of researchers in the TENS, FES, and body-toning areas of electrostimulation are endeavoring to incorporate electrodes in to body hugging garments to enable the convenient and accurate application of a (large) number of electrodes to the body part to be stimulated. The use of a large number of electrodes can enable, for example, several muscle groups to be stimulated together or sequentially in a coordinated manner to achieve a more natural movement of a limb. Garments are already on the market that resemble tight-fitting cycling shorts and have integrated wires and connectors for the attachment of standard TENS (or similar) snap electrodes prior to application. Other, more challenging designs include the integration of reusable electrodes into a stretchable garment.

Implant Electrodes

Implantable monitors/stimulators and their electrodes are used, or are being developed, for a wide range of applications, including cardiac pacing and defibrillation, cochlear implants; urinary control, phrenic nerve stimulation for

respiration control; functional electrical stimulation of limbs; vagal stimulation for control of epilepsy, spinal stimulation for chronic pain relief, deep-brain stimulation for Parkinsons disease or depression, bonehealing, and several visual neuroprostheses.

Implanted monitoring electrodes are used to more accurately pick up the desired signal while minimizing the contributions of extraneous signals. Implanted stimulation electrodes deliver the applied waveform more selectively to the targeted tissue, making the therapy more effective and, as the stimulation electrode is generally implanted away from cutaneous pain receptors and afferent nerve fibers, more comfortable for the patient. One significant drawback, however, is the greater potential for damage from improper electrode design, installation, and use.

The design of an implant electrode will depend greatly on the anatomical structure it is to be implanted against, into, or around. Electrodes can be or have been implanted in, on, or near a given muscle; in, on, or around a given nerve; in, on, or around a given bone; in, on, or around the spinal cord; and in or on the surface of the cerebellar cortex.

A review of all of these designs is beyond the scope of this chapter. The reader is referred to the appropriate chapters in this Encyclopedia.

To facilitate this overview of some of the key design possibilities, two main application areas will be concentrated on: muscular and neural electrodes. Muscular (especially cardiac) electrodes, using more traditional electrode fabrication, are presented in a separate section. Neural electrodes will be largely covered in the section on newer microelectrodes constructed using thin-film and similar techniques. These categories are very loose and a considerable degree of overlap obviously exists between applications and the various electrode fabrication techniques. Once again, the reader is referred to the appropriate chapters in this Encyclopedia for more detailed descriptions of electrodes and their fabrication for specific applications.

Cardiac electrodes are the most important example of muscular electrodes. As cardiac pacemakers and defibrillators have the longest and most successful track records as implantable devices, much of the science underpinning the newer (and future) implantable devices (muscular, neural, and other) has been developed by the cardiac implant pioneers. Key contributions were made in the areas of implant electrodes, biomaterials, and powersources, to

Figure 41. Kimer's electropuncture of the heart (103).

name but a few. The present review of electrodes is, therefore, largely based on cardiac electrodes. However, ideas can be gleaned from this area and, once suitably customized, applied to others with success. The advantageous aspects of biphasic impulses (discovered in the 1950s, arguably earlier) is a good example of something being rediscovered in a range of stimulation applications over the past few decades

Historical Background. Implant stimulation electrodes, or at least percutaneous stimulation electrodes, predate the earliest biosignal monitoring electrodes. In the early 1800s, there appeared a renewal of interest in acupuncture in Europe that had been introduced into Europe in the second half of the eighteenth century by Jesuit missionaries. In 1825, Sarlandière was the first to apply an electric (galvanic) current to thin metal needle electrodes (derived from acupuncture needles) thus creating electropuncture for the application of current to specific points on or in the body (98,118).

Electropuncture soon became the accepted method of stimulating muscles, nerves, or organs beneath the skin (83). Electropuncture of the heart was first attempted by Krimer in 1828 without recorded success (Fig. 41) (103). This technique was then abandoned for several decades. Meanwhile, W. Morton successfully introduced the use of ether as an anesthetic in 1846. Eventually, chloroform was found to be more suitable although cardiac arrest was a frequent complication of chloroform anesthesia in those early days. In 1871, Steiner overanesthetized horses, dogs, cats, and rabbits to produce cardiac arrest. He reported successfully applying an intermittent galvanic current to a percutaneous needle in the heart to evoke rhythmic contractions. Terms such as galvano and farado puncture soon started to appear in the literature (103).

In the early 1900s, cardio-stimulating drugs such as epinephrine were injected directly into the heart of sudden death victims by means of a large needle inserted through the chest wall to restore automatic activity. It was eventually established that one of the key factors in the occasional success of these intracardiac injection procedures was the actual puncture of the heart wall rather than the medication administered. Based on this observation, Hymen went on to build the first hand-cranked, spring-driven artificial pacemaker (119). He used transthoracic needle electrodes plunged into the atrium and even introduced the concept of using a bipolar needle arrangement as in having the two electrodes so close together that only a small pathway is concerned in the electric arc established by the heart muscle, an irritable point is produced (103).

In the 1950s, Lillehei, Weirich, and others pioneered the use of cardiac pacing for the management of heart block accidentally resulting from cardiac surgery and for other emergency cardiac treatment. Slender wire electrodes were implanted into the myocardium before closing the chest with the connecting leads thus exiting through the chest wall. Pacing impulses could then be delivered through these wires for a week or so until the heart healed. Once the heart had recovered, the electrodes were pulled out. Early versions of these electrodes consisted of silver-plated braided copper wires insulated with polyethylene or Teflon (103,120).

In 1958, Furman and Schwedel reported the first instance of transvenous pacing of the heart. They inserted a unipolar catheter electrode into the right ventricle of the patient through a superficial vein and paced the heart via the endocardial surface. The electrode used was a solid copper wire with a bare terminal tip (120). The electrode was withdrawn once the patient's heart resumed its own idioventricular rhythm. Although the cardiac pacing employed by Lillehei et al. and by Furman and Schwedel

Figure 42. (a) Chardack, Gage, and Greatbatch's wholly implantable pacemaker and the Hunter-Roth bipolar intramyocardial electrode (83) (b) Diagram of an early Hunter-Roth lead with two bipolar myocardial pin electrodes (35).

was much better tolerated than the external stimulation of Zoll, perielectrode infection was a major drawback as was the transport of the external pacemaker. The development of an implantable pacemaker, therefore, became the goal of several groups around the world.

In 1958, Senning and Elmqvist successfully implanted the first Pacemaker without leads emerging from the patient's chest to invite infection. The implanted unit was powered by cells that were recharged from outside the body using a line-connected, vacuum-tube radio-frequency generator. The electrodes/leads used were stainless-steel wires. The second version of the unit failed due to a lead fracture one week following implantation. It was then decided to abandon pacemaker therapy for this patient until better leads were developed (120).

At that time, many of the electrodes used were unipolar. The active electrode tended to consist of the bared tip of an insulated wire implanted in the myocardium whereas the indifferent electrode was a similar wire implanted subcutaneously in the chest wall. Unfortunately, the stimulation threshold was observed to rise following implantation during longer-term pacing. This increase in threshold was thought to be due to the development of scar tissue around the active electrode. Hunter and Roth developed a bipolar electrode system in 1959. This electrode consisted of two rigid, 0.5 cm long, stainless-steel pins attached to a silicone rubber patch. The cathode-anode pins were positioned in to myocardial stab wounds surgically created for the purpose and the pad was then sutured to the epicardial surface (35). The lead wire was a Teflon-coated, multistrand stainless-steel wire with an outer sleeve made from silicone rubber tubing (121).

In 1960, Chardack, Gage, and Greatbatch successfully produced a wholly-implantable battery-powered pacemaker (Fig. 42a). Initially, they used a pair of multistrand stainless steel wires in a Teflon sleeve with the bare ends sutured to the myocardium (35). Other metallic formulations were tried, such as solid wire, silver wire, stainless steel, orthodontic gold, and platinum and its alloys (122).

They eventually adopted the Hunter-Roth intramyocardial electrode (Fig. 42a and b). Considerable surgery was required as the pacemaker had to be implanted into the abdomen and the electrodes were sutured to the heart wall. The bipolar electrode did, however, dispense with the need of a dispersive chest electrode and the associated pain it caused (103). Stimulation thresholds tended to stabilize at much lower levels with this electrode (120), which enabled successful pacing for many months.

Breakage of lead wires, due to metal fatigue, was a major concern. One of the main problem areas occurred at the point where the two metal components were welded together (121). Corrosion also occurred at the small-area stainless-steel anode, causing cessation of pacing within a few months.

Chardack et al. (123) devised a replacement for the Hunter-Roth electrode based on a continuous helical coil of platinum-iridium (Fig. 43). The electrode was simply a few turns of the coiled lead wire, exposed and extended to enable fibrous tissue to grow between the spirals and firmly anchor the electrode in place. The use of a helical coil greatly increased flexibility and decreased the number of fatigue failures, as did the use of one continuous wire (without a join) for both lead and electrode. The use of the same metal for lead and electrode also had the advantage of preventing corrosion from galvanic action. Additionally, platinum-iridium is more corrosion resistant than the metals used in many electrodes prior to Chardack's electrode.

The sutureless screw-in lead was later introduced by Hunter in 1973 (35). The screw-in electrode was simply rotated into the myocardium and did not require a stab wound or sutures for insertion. The electrode was effectively the means of attachment. As this corkscrew electrode tended not to dislodge, it dominated pacing for a long time and is still used today for many epimyocardial implants (Fig. 44).

A thoracotomy was required to attach many of the above electrodes to the heart, which complicated surgical procedure and resulted in a 10% early mortality (122). The first so-called modern pacemaker, which combined an implanted generator and a transvenous lead, was developed simultaneously in 1962 by Parsonnet and Lagergren (124,125). The endocardial catheter electrodes could be

Figure 43. The "Chardack" electrode (a) (35) (b) Chardack et al. (123).

Figure 44. The corkscrew myocardial electrode (35).

installed under local anesthesia, and this approach virtually eliminated early mortality. As they did not require the opening of the chest cavity, the use of catheter leads opened the field of pacemaker implantation to non-surgeons in later decades.

To minimize the risk of venous perforation, the electrode leads were made flexible by winding bands of stainless steel around a core of textile fibers (120). The electrode was a small stainless-steel cylinder at the end of the catheter.

As time passed, the transvenous route progressively evolved over the myocardial approach, so much so that, at present, the transverse route is almost exclusively used for pacemaker implantation.

Cardiac pacing has been the earliest and most successful example of implanted electrodes and associated hardware. Many present and future developments in other implanted electrostimulation (and biosignal recording) areas are and will be based, to a large extent, on the pioneering work carried out in the pacing area.

Some Modern Electrode Designs. With the early transvenous leads, the stimulation threshold was observed to greatly increase if the electrode pulled away even slightly from the myocardium. A wide variety of active fixation devices was therefore invented. These devices included springs, deployable radiating needles, barbs, hooks, claws and screws designed to anchor the electrodes by actively penetrating the myocardium (35,126). The “Bisping” transvenous screw-in electrode is the most popular, as it allows

the screw helix to be extended from the tip once the lead has been successfully threaded through the vein and located against the desired part of the heart (Fig. 45). It can be used as a combined anchor and electrode. The screw can be retracted allowing for an easier extraction of the lead, when necessary. (Note: A similar design of electrode is used for detecting the fetal electrocardiogram during labor. The intracutaneous needles are screwed in to the fetus’ presenting scalp. Similar designs are also used in EEG monitoring.)

A wide variety of passive fixation devices were also invented. Various tines, flanges, and other soft, pliant projections were formed at the distal end of the lead, generally as an extension of the silicone or polyurethane lead insulation, and designed to passively and atraumatically wedge the electrode between endocardial structures such as trabeculae (Fig. 46). In some designs, the electrode has the form of a closed-loop helical coil that, when twisted clockwise, becomes lodged in the trabeculae (126).

Early electrodes had smooth metal surfaces. Techniques were then developed to roughen the surface in the hope of encouraging tissue in-growth, thus locking the electrode in place, minimizing mechanical irritation and excessive fibrous encapsulation, and ensuring low chronic stimulation thresholds. Studies found that porous electrodes did indeed achieve better fixation, thinner fibrous capsules, and stable thresholds.

A variety of porous electrode tips have been developed including totally porous structures such as CPIs meshed screen electrode and electrodes whose surfaces had been textured using a range of techniques (Fig. 47). Porous surfaces have been generated by coating metal surfaces with metallic granules, by sintering metal spheres to form a network of cavities, and by laser-drilling the surface of electrodes (126).

Not only does roughening improve electrode fixation and threshold stability, it has been found to have a very advantageous effect on interface impedance. From a stimulation point of view, one is keen to use a small-area electrode to increase current density at the small tip and

Figure 45. The “Bisping” transvenous screw-in lead with the helical screw electrode extended. [From S.S. Barold’s The Third Decade of Cardiac Pacing (35).]

Figure 46. Transvenous lead with silicone rubber tines (35).

thus decrease stimulation threshold. A small-area electrode also has a high pacing impedance that can decrease current drain on the generator and thus prolong implant life (35). However, one would also like to have a low sensing impedance in order to avoid excessive attenuation of the cardiac signal. Two ways that exit these conflicting criteria can be optimized, modifying the electrode surface or modifying its design.

Roughening the surface of a small-area electrode increases its effective area without changing its geometric or outer envelope surface area (35). Many electrode systems have been developed that incorporate this concept—electrodes with terms such as activated, porous, and sintered in their company's description. These electrodes have been found to be effective in lowering the electrode interface impedance under small-signal sensing conditions. [Note: the electrode–electrolyte interface is very nonlinear and, hence, smaller under stimulation.] Unfortunately, the reduction in interface impedance has been erroneously interpreted as rendering the electrode nonpolarizable. As stated previously, the word polarization appears to be used in a rather vague manner and has been used as the explanation of, among other things, the nonlinearity of the interface impedance as well as its frequency- and

time-dependence. The fact that the current or voltage response to a step in voltage or current is not a simple step has been attributed to polarization. The observed transient responses are merely due to the presence of the double layer capacitance (see Figs. 8, and 9). Roughening the surface of an electrode effectively increases the area of the interface and the value of C_{dl} , which in turn results in an increase in the response's time constant ($T = R_{CT}C_{dl}$). The observed response thus looks stretched out along the time axis. This flattened response has been mistaken for that of a purely resistive, nonpolarizable electrode. At any rate, roughening the surface of the electrode almost gives us the best of both worlds, a noble or inert electrode with a low interface impedance.

Another way of achieving a small stimulation surface area (high current density) while ensuring a large-sensing surface area (low interface impedance) is to modify the design of the electrode.

The porous electrode of Amundson involved a hemispherical platinum screen that enclosed a ball of compacted $20\ \mu\text{m}$ diameter platinum–iridium fibers (127). As electrolyte could penetrate this three-dimensional (3D) or multi-layered electrode, the design resulted in a major increase in

Figure 47. (a) Cross-section of a totally porous electrode (35). (b) Cross-section of a porous surface electrode (35). (c) Photo of totally porous electrode (126).

Figure 48. The differential current density (DCD) electrode (129).

effective surface area as well as promoting tissue in-growth and long-term stability of thresholds. Lagergren et al. (128) introduced the birdcage design, which also exploited some of these features (126).

One interesting example of a modified design by Parsonnet et al. involved the use of an electrolyte-filled hollow electrode, called a differential current density (DCD) electrode (129). The actual stimulating electrode is the mouth of the electrolyte filled pore, which can be small to provide high current density at the point of contact with tissue (Fig. 48). The inside of the hollow electrode chamber has a large metallic surface (a helical coil forming a cylinder) and thus gives rise to a low electrode-electrolyte interface impedance.

Figure 48 appears to be an electrode design that could readily be customized and used in a wide range of monitoring or stimulation applications. The electrode-electrolyte interface is effectively recessed and protected from any disturbance, a further advantage to those already listed above.

Several other designs exist that aim to achieve a similar effect by manipulating the current density distribution around an electrode tip. Electrodes with complex shapes have irregular patterns of current density with localized hotspots at points of greatest curvature (126). It is possible to exploit these areas of high current density for stimulation purposes while the larger overall surface area gives rise to a low interface impedance (130). A hollow, ring-tipped electrode (effectively similar to the DCD electrode) has a large current density at its annular mouth while having a large electrode-electrolyte interface area. Such electrodes are reported to have better stimulation thresholds and sensing characteristics than hemispherical designs and have proved popular. Several manufactures have combined this ring-tip design with increased surface porosity (126). Other related designs include a dish-shaped

Figure 49. The target tip electrode. Microporous, plantinized platinum electrode. The target appearance is due to shallow grooves separated by peaks. (Courtesy Medtronic, Inc.)

electrode for edge-focusing of current (with laser-drilled pores for interface impedance reduction) and a grooved hemispherical platinum electrode coated with platinum black particles (target-tip electrode, Fig. 49) (126,130).

Steroid-eluting electrodes were introduced in 1983 in an effort to minimize the growth of connective tissue. The first-generation electrode was made of titanium, with a platinum-coated porous titanium surface (Fig. 50). The electrodes incorporated a silicone core that was impregnated with a small quantity an anti-inflammatory corticosteroid (34). Upon implant, the steroid is gradually eluted into the interface between the lead electrode and the endocardium, reducing the inflammation and fibrosis that would normally occur. Steroid-eluting leads are characterized by a lower long-term capture threshold. Similar improvements in capture thresholds have been achieved (131,132).

Most cardiac electrodes now involve the combination of drugs and complex surface structures at the macro and micro scales.

For newer applications, such as Cochlear implant electrodes, an array of electrodes is involved. In some such multielectrode applications, one may be interested not only in the current density profiles under the surfaces of the individual electrodes, but in the interplay between the electrical fields produced by the electrodes in the array in the hope of achieving more effective stimulation or more effectively imitate physiological stimulation. For example, the Clarion hi-focus electrode system of Advanced Bionics Corp. incorporates 16 electrodes in a flexible array that are designed to deliver improved focused stimulation to the auditory nerve (133).

Microelectrodes. Over the past few years, exciting developments have taken place in areas of biomedical

Figure 50. (a) Steroid-eluting electrode. (b) Cross-sectional diagram of an early design of steroid-eluting electrode. Behind the electrode is the silicone rubber plug compounded with steroid. (Courtesy Medtronic, Inc.)

engineering that involve implantable devices for the recording or stimulation of the nervous system.

In the previous section, we saw the success in commercializing pacemakers. Other implant devices that have also reached the patient in clinical routine practice or research settings include Cochlear implants to restore hearing; deep-brain stimulators to alleviate symptoms of Parkinson's Disease and depression; vagal nerve stimulators to minimize the effects of epilepsy; as well as FES systems to restore or improve function in the upper extremity, lower extremity, bladder and bowel, and respiratory system (134,135). Other areas of research that are likely to come to fruition within the next few years include various visual prostheses to restore functional vision in the profoundly blind and the exploration of the brain-computer interface (134,136,137).

Much of the early research in these areas started around the 1960s (135). Where possible and appropriate, surface and percutaneous electrodes were first used to establish the feasibility of the given recording/therapy. Early implant electrodes involved fine metallic wires or small disks placed near, in, on, or around the targeted muscle or nerve. The fabrication of these electrodes was time-consuming and the electrode properties were not very reproducible given the variations in areas, surfaces, inter-electrode distances, and so on, which was particularly a problem when several electrodes were to be used in an array. As the demands on human implantable diagnostic/stimulation devices increases, an increased need for a larger number of smaller-area electrodes with well-defined and reproducible surfaces and dimensions generally occurs. Although, due to their high level of specificity, muscle-based electrodes will continue to be used, new electrode designs tend to concentrate more on direct nerve stimulation as this may provide more complete muscle recruitment and the same electrode may successfully recruit several muscles, thus reducing the number of electrode leads required (135). Electrodes are, therefore, needed that can interface electrically with the neural system at the micrometer scale (136).

For example, the goal for a high resolution retinal prosthesis is a 1000-electrode stimulating array in a 5×5 mm package (137). If this area of research is to be clinically successful and if the other areas are to continue to improve, microelectrodes must be (and are being) manufactured using the thin-film technologies associated with

the IC circuit industry. Microfabrication involves either material deposition or removal. Either rigid silicon wafers or flexible polyimide substrates act as platforms for the microelectrodes and associated circuitry. The deposited films (for connectors, leads, electrodes, or insulation) are produced by electroplating, evaporation, and sputtering. The layers can be photo-patterned and etched to sub-micrometer resolutions and finally encapsulated in biomaterials such as diamond-like carbon, bioceramic, or a biocompatible polymer. Processes such as photolithography, reactive ion etching (RIE), CMOS processing, MEMS processing, focused ion beam patterning, and AFM lithography can be used to achieve the desired microelectrode design.

The benefits of a microfabrication approach include a high degree of reproducibility in physical, chemical, and electrical characteristics. Microfabrication is a high yield, low cost process once the design and processing sequence have been developed. Additionally, precise control of the spatial distribution of electrode sites exists, which may be of interest when seeking to optimally stimulate or record from a target site. A high packing density of electrode sites for a given implant volume is also readily achievable using photolithographic techniques. The possibility exists of incorporating the interface circuitry directly on the micro-sensor platform thus reducing the need for complex interconnections.

The widespread availability of silicon micromanufacturing techniques has enabled the fabrication of a range of silicon-based wedge- or needle-shaped electrodes to allow penetration of the nervous tissue. 3D arrays of such structures have been developed for insertion into, for example, the cortex to detect local potentials (134).

1D arrays of electrodes are fabricated using lithographic patterning and deposition of thin-film metal leads and electrodes onto not only silicon, but also glass and even flexible polyimide substrates (136). Much of the work on silicon-based microprobe fabrication has been pioneered at the Center for Integrated Sensors and Circuits at the University of Michigan.

A 3D electrode array can be fabricated by assembling a range of 1D probes (such as those shown in Fig. 51). As each probe has multiple recording sites along its length, the complete volume of the tissue under study can be assessed, giving rise to very dense sampling. The Michigan Probe has evolved a large number of single-shaft, multishaft, and 3-D-stacked microelectrode arrays (136).

Figure 52. (a) Utah electrode array shown on a U.S. penny to convey size. (b) Modified Utah electrode array in which the length of the needles is uniformly graded (134).

Recent improvements in silicon microtechnology have made it possible to create not only planar microelectrodes but also penetrating brush electrode structures for *in vivo* measurements. In contrast to the University of Michigan's planar devices, the 2D and 3D cortical multimicroelectrode arrays developed at the University of Utah are fabricated out of a single solid block of silicon. Etching of the block results in a 10×10 array of needles, each 1.0–1.5 mm long, arranged on a 4.2×4.2 mm base. The metal and insulation layers are then applied, creating 35–75 μm long platinum recording tips (134,136,139) (Fig. 52a).

This design has the advantage of placing a relatively large number of recording sites in a compact volume of the cortex. However, with a single recording site on the end of each needle set at a fixed depth into the cortex, this version of the Utah array is classified as a 2D array as all the electrodes are in the same plane (140). The Utah probe can achieve high-density sampling by spacing many needles close together but does not have multiple sites along each shaft. When the length of the needles in such an array is graded (the array is said to be slanted, Fig. 52b) or the needles have some other distribution of lengths, these arrays are termed 3D as the electrode tips are no longer in the same plane. These designs are thought to give the better spatial selectivity (134,136).

Implanting such needle or brush electrode systems is obviously associated with damage of the tissue. Moreover, the stiffness of many systems may lead to damage of nervous tissue, especially if relative movement exists between the sharp needles and the delicate tissues. Breakage of the brittle needle is also a concern. Considerable efforts are therefore being directed at miniaturizing the width of the needles or at introducing more flexible materials.

For example, some versions of the Michigan Probe consist of four parallel, dagger-like probes connected to a micro-silicon ribbon cable. The ribbon cable is semiflexible

and allows the probes to move up and down with the cortex as it pulses (139).

In the development of subretinal stimulating arrays using current silicon micromanufacturing techniques, it has been pointed out that a planar, rigid implant is likely to mechanically damage the compliant, spherical retina (137). Concerns have also been expressed regarding the use of penetrating microelectrodes, the relative micro-motion between the array and the retina potentially provoking mechanical damage and a significant encapsulation response (134). The ideal retinal-stimulating electrode would therefore have the flexibility to match the curvature of the retina and the next generation of electrode arrays are likely to be constructed on flexible substrates.

Microelectrode arrays on flexible substrate have been demonstrated in a range of applications including the European project "Microcard", Si-Based Multifunctional Microsystem needle for Myocardial Ischemia Monitoring. Initially, work centered on silicon-based microprobes to monitor the electrical impedance of tissue, tissue temperature, pH, and local ionic concentrations of potassium, sodium, and calcium. These parameters were found to vary considerably when, for example, a heart undergoes an ischaemic phase, thus establishing the clinical value of the technique and device, (140).

In the course of the silicon probe development, it was foreseen that the brittle nature of silicon could make intact probe removal difficult. Additionally, the rigid needle could cause damage to the delicate tissues. The thrust of the project thus changed to the development of flexible, polymer-based probes.

Thin-film devices for the measurement of tissue impedance and ion concentrations were manufactured on flexible polyimide substrates (Fig. 53a) (141). Gold thin-film electrodes were deposited using an improved photolithography process for 1 μm resolution. Polyimide insulation

Figure 53. Microfabrication of sensors onto flexible substrates. 1D probe electrode array. [After Mastrototaro et al. (141).]

layers were spin-coated onto the PTFE surface after suitable conditioning, and they proved to be insulating and continuous.

Electrochemical characterization of the gold thin-film impedance electrodes showed them to possess high interface impedance. Pt and IrO oxide coatings were electrochemically applied to the gold thin-film surface and resulted in a drastic reduction in interface impedance for monitoring or stimulation applications (142).

Encircling neural electrodes may be of a cuff or spiral design. The term cuff electrodes applies to those devices that engulf the entire circumference of a nerve. First model, which rather stiff, carried only one or two electrodes and they were made using a platinum foil electrodes that were located on the inside of a cylinder of silicone rubber, which was wrapped around a nerve (Fig. 54b). (136). It is generally recommended that the diameter of the cuff be 50% larger than the nerve diameter to avoid nerve compression and necrosis due to swelling and fibrous tissue in-growth. Cuff electrodes do however have a long and successful track record in a range of FES applications (143).

The spiral electrode is a loose, open helix that is wound around the nerve (143). The open design can accommodate swelling and is very flexible. A version of this electrode is marketed by Cyberonics for use with their vagus nerve stimulator (Fig. 54b). New designs of nerve cuff electrodes seek to reshape the geometry of the nerve to more selectively stimulate or record from particular nerve fascicles. Efforts are also directed at controlling the electrical fields generated by the electrode arrays to better focus the stimulation (135).

Figure 54. (a) Neural cuff electrode. (b) Spiral electrode (Cyberonics).

As part of a European project NEUROS, NIBEC developed a flexible thin-film-based stimulation and sensing cuff electrode for FES-related application. IrO, Pt, and Au electrodes were deposited onto a polyimide substrate. In order to facilitate implantation and ensure good contact between nerves, fascicles and electrode surface was self-curling. Polyimide resin with a thermal expansion coefficient differing from that of the polyimide substrate was chosen so that the curing process gives rise to a residual stress and curl in the device. The diameter of the electrode cylinder could be made less than 1 mm.

Diamond-like carbon (DLC) encapsulation was deposited onto the device using a plasma-enhanced chemical vapor deposition (PECVD) process. Adhesion to the polyimide substrate was found to be satisfactory following the addition of a silane adhesion layer at the interface (144,145).

With the aid of microfabrication techniques, one can control the area and properties of the electrodes and greatly decrease them in size. However, as electrode area decreases, the interface impedances increase with resultant difficulties in making accurate measurement. The key to success in this case is in the choice of electrode design, material, and electrode surface topography.

A similar concept to Chardack's differential current density pacemaker electrode was suggested for use in thin-film electrodes. The metal electrode is housed within a hollow chamber (Fig. 55). The chamber is filled with electrolyte and has a small aperture to enable electrical contact with tissues (146). As the metal-electrolyte interface is relatively large, the interface impedance is relatively small. The interface is also protected from mechanical disturbance (similar to the floating electrode) and, hence, should suffer from less artifact. As the small aperture determines the area of contact with the tissue, the effective stimulation or recording area is very small.

Other 3D designs with etched meshes should be assessed for their potentially larger interfacial areas.

Once again, surface roughness is an important factor in decreasing interface impedance and possibly in helping anchor the electrode in position. Rough-surfaced electrodes must be used with caution, depending on the application, in case the surface causes damage to the surrounding tissues. Certain materials and the electrode fabrication processes involved may well result in favorable macro-, micro-, and nano- surface features. Presently, investigators are studying modifications to the electrode surface using such things as nanotubes. Nanotechnology offers much promise for

Figure 55. Thin-film differential current density electrode. [After Prohaska et al. (146).]

new sensor devices, particularly in the biomedical sector. Not only do individual nanotubes offer the possibility of using them as ultrafine needles for *in vivo* probing at the cellular level, but surfaces can be created with optimal distributions of clusters of nanotubes to maximize performance.

ELECTRODE STANDARDS

The Association for the Advancement of Medical Instrumentation (AAMI) produce a range of labeling, electrical, and other performance requirements for manufacturers and users to help ensure acceptable levels of product safety and efficacy. Some of the key electrode-related standards are briefly reviewed below.

Standards For Biosignal Monitoring Electrodes

Standards for Disposable ECG Electrodes. ANSI/AAMI EC 12 (2000)

Introduction. In an effort to minimize ECG recording problems associated with the performance of electrodes coupled to a standard ECG monitor or electrocardiograph, AAMI has proposed a series of simple bench tests designed to assess pregelled, disposable ECG electrodes.

Although originally conceived to assess disposable ECG electrodes, these standards are widely used to assess other biosignal monitoring electrodes, which is a consequence of the lack of other widely accepted standards for these monitoring applications and to the general applicability of the ECG standards to the other applications.

Although AAMI also lays down stipulations for electrode labeling, adhesion testing, and soon, only the electrical performance requirements are reviewed here.

AC Impedance. The average value of 10 Hz impedance for at least 12 electrode pairs connected gel-to-gel, at a level of impressed current not exceeding 100 μ A peak-to-peak, shall not exceed 2 k Ω . None of the individual pair impedances shall exceed 3 k Ω .

Low impedance electrodes are desirable to avoid signal attenuation and distortion and to minimize 50/60 Hz interference pickup. High electrode impedances can also give rise to serious burns when the ECG electrodes are used in the presence of electrosurgery or defibrillator discharges. (147).

The impedance of the skin's outer layer, the stratum corneum, is many times larger than that of the metal/electrolyte interface, and hence, the former is of key concern when endeavoring to ensure good electrode performance. The skin preparation technique, the extent of diaphoresis, and the ability of the electrode gel in penetrating and reducing the skin impedance are generally more important than the electrode-electrolyte interface impedance.

The Standards Committee decided that the electrode gel-to-gel impedances should be significantly less than the expected impedance of clean, dry skin to ensure a minimal contribution by the electrode itself to the overall impedance (147). In the UBTL tests carried out on behalf of the

Standards Committee, it was found that the mean 10 Hz impedance of a standard pair of ECG electrodes on unabraded skin was of the order of 100 k Ω . The AAMI committee chose 2000 k Ω as a reasonable limit for 10 Hz gel-to-gel impedance to ensure that the electrodes did not contribute significantly to the overall impedance nor to power dissipation in the presence of defibrillation overload and electro-surgery currents.

As the electrode-gel interface impedance is nonlinear and decreases with applied signal amplitude, the standard stipulates that the level of impressed current must not exceed 0.1 mA peak-to-peak when carrying out the test.

In the UBTL tests, it was found that the impedance as measured on abraded skin correlated well (99%) with the impedance measured with the electrodes connected gel-to-gel, whereas the impedance measured with electrodes applied to clean, dry skin correlates very poorly (47%) with the gel-to-gel measurements. Obviously, the bench test simply evaluates the ac impedance performance of the electrode-gel interface and will, therefore, not accurately predict or represent the clinical performance of an electrode on intact skin. For example, cases of electrodes that performed poorly as per the AAMI bench test exist, yet which proved very satisfactory *in vivo*. Conversely, some of the best electrodes according to the bench tests performed relatively badly *in vivo* (148).

DC Offset Voltage. After a 1 min stabilization period, a pair of electrodes connected gel-to-gel, shall not exhibit an offset voltage greater than 100 mV.

Ideally, the potentials of both electrodes used to monitor a biosignal should be identical and, thus, cancel each other out. Slight differences in the gels and metals used, however, result in an offset voltage. The potentials of the skin sites further complicate the recording, especially as these latter potentials (and their amplified difference) tend to be much larger. If the overall electrode-skin potential difference is larger than 300 mV, the amplifier may saturate and the biosignal will not be observed.

The UBTL report studied the correlation between gel-to-gel and electrode-skin offset voltages and found that gel-to-gel offsets were in the order of 2.5 times smaller than those recorded *in vivo* for the same electrodes on a patient's skin. As the maximum allowable *in vivo* dc offset should be less than 300 mV, the Committee decided that the limit for gel-to-gel dc offset should therefore be less than 300/2.5 mV (i.e., 100 mV).

Some reviewers of the standard argued that the limit should be reduced to 10 mV as this would help minimize motion artifact problems. The Committee rejected this suggestion, pointing out that no clear evidence exists that links high gel-to-gel offset voltages with motion artifact (largely caused by skin deformation).

Offset Instability and Internal Noise. After a 1 min. stabilization period, a pair of electrodes connected gel-to-gel, shall not generate a voltage greater than 150 μ V_{p-p} in the passband (first-order frequency response) of the 0.15–100 Hz for a period of 5 min following the stabilization period.

This standard is concerned with the problem of baseline wander, which introduces a low frequency component into the monitored biosignal making accurate diagnosis difficult. The American College of Cardiology's Task Force on the Quality of Electrocardiographic Records judged that drift rates less than $400 \mu\text{V} \cdot \text{s}^{-1}$, although not highly rated, were not considered unacceptable.

The UBTL report detailed several experimental limitations that prohibited their detailed study of *in vivo* dc offset drift. Consequently, no correlational analysis was carried out between dc offset drift measurements made with electrodes applied to human skin and those joined gel-to-gel. They, however, decided to use the factor of 2.5 they had observed between clinical and bench test result for dc offsets, given that the measurement techniques are fundamentally similar. A limit of $150 \mu\text{V} \cdot \text{s}^{-1}$ was therefore arrived at by dividing the $400 \mu\text{V} \cdot \text{s}^{-1}$ baseline drift rating by a factor of 2.5. As the test circuit used in the bench test differentiates the offset voltage, the offset instability requirement is specified in μV rather than $\mu\text{V} \cdot \text{s}^{-1}$.

The Committee was contacted and asked to decrease the limit from $150 \mu\text{V}$ to $40 \mu\text{V}$ p-p in order to be in line with the AAMI standard "Cardiac monitors, heart rate meters and alarms (EC13)". The working group agreed that this requirement could be made more stringent but refused to decrease the limit to $40 \mu\text{V}_{\text{p-p}}$. This requirement is under study and may well be altered.

This calculation involved in reaching the $150 \mu\text{V} \cdot \text{s}^{-1}$ limit implies that skin potential fluctuations are only 2.5 times larger than those of the electrode-gel interface, which is most unlikely, and problems developing from drifting electrolyte/skin potentials will depend on skin preparation, electrode design, and electrode gel rather than on the electrode-gel interface characteristics per se (64).

Defibrillation Overload Recovery. Five seconds after each of four capacitor discharges, the absolute value of polarization potential of a pair of electrodes connected gel-to-gel shall not exceed 100 mV. Also during the 30 s interval following each polarization potential measurement, the rate of change of the residual polarization potential shall be no greater than $\pm 1 \text{ mV} \cdot \text{s}^{-1}$.

It is important that a clinician, having defibrillated a patient, be able to see a meaningful ECG within 5–10 s in order to judge the efficacy of the delivered impulse and to decide if another is required. The offset voltage across the electrode-skin interfaces, which drastically increased as a result of the defibrillation impulse, must therefore return to below 300 mV within 5 s following the discharge. Once again, using the 2.5 factor between bench test and *in vivo* potentials, this requirement translates to a gel-to-gel bench test offset voltage under 100 mV within 5 s of applying an overload of 2 mC (representing the worst possible situation encountered *in vivo* where the defibrillator paddles are placed in immediate contact with the ECG electrodes). Electrodes made of stainless steel, for example, tend to acquire offset voltages of several hundred mV for minutes and, consequently, no ECG trace is observable on the monitor (68).

Following the initial 5 s the ECG must not only be visible on the monitor but must also be recognizable and clinically

useful. Hence, the stipulation that the offset voltage should not drift with time by more than $\pm 1 \text{ mV} \cdot \text{s}^{-1}$.

The UBTL results indicate good correlation exists between the results of this bench tests and animal tests, particularly at the higher recovery voltages encountered with non-Ag/AgCl electrodes.

Although only a very low percentage of ECG electrodes are, in fact, subjected to defibrillation impulses *in vivo*, the AAMI committee decided after some deliberation to insist that all ECG electrodes meet the proposed standard as it is impossible to guarantee that a given electrode would not be used in an emergency defibrillation situation.

Bias Current Tolerance. The observed dc voltage offset change across a pair of electrodes connected gel-to-gel shall not exceed 100 mV when the electrode pair is subjected to a continuous 200 nA dc current over the period recommended by the manufacturer for the clinical use of the electrodes. In no case shall this period be less than 8 h.

When a dc current passes through the metal-gel interface of an electrode, the electrode potential deviates from its equilibrium value and the electrode is said to be polarized. If the current is maintained indefinitely, the reactants become depleted causing the electrode potential to deviate further, possibly exceeding the limit allowable at the input of the ECG recording device.

Although most modern ECG recorders pass less than 10 nA of bias current through the electrodes, some older models can have bias currents as high as 1000 nA. A number of cardiac monitor manufacturers use dc bias currents to sense high electrode impedances to warn of disconnected leads or poorly affixed electrodes. The standard for cardiac monitors permits input bias currents of up to 200 nA. UBTL, therefore, adopted the 200 nA limit on the dc input bias current suggested for cardiac monitors for the tests. The ability of an electrode to cope with this value of bias current must therefore be demonstrated by not exceeding the AAMI dc offset requirement of 100 mV over the time period recommended by the manufacturer for the clinical use of the electrodes.

The 200 nA current level is generally well-tolerated by Ag/AgCl electrodes. Stainless-steel electrodes rapidly fail this test even at 10 nA with major increases in electrode potential.

Discussion. The AAMI standards bench tests are currently the only widely accepted electrode standard tests in use. The tests are simple and inexpensive to set up and have been widely embraced by manufacturers and users for production quality control purposes. One must bear in mind, however, that these tests evaluate only the electrode-gel interface and that they do not include the more important properties of the gel-skin interface. Assessment of the clinical performance of electrode impedance using the proposed bench tests is only relevant if the skin has been suitably abraded. Skin abrasion is not widely used by the clinical community and, hence, the relevance of at least some of the standard tests to the clinical situation is open to question.

Especially several decades ago, fulfillment of the AAMI requirements was commonly quoted as a guarantee

of the high *in vivo* electrical performance of an electrode. An electrode with, for example, a dc offset of 1 mV was widely believed by customers to be a much better electrode than one with an offset of 5 mV. This naivety appears to be on the wane, however, and manufacturers and customers are shifting toward low cost electrodes that score less highly in the AAMI tests but are good enough for a given application.

The author once supplied a leading company with dry metal-loaded polymer electrodes. The company connected the electrodes together and tested them as per the AAMI standards (for pregelled electrodes). Perfect electrical performances were measured given that what was effectively being assessed was metal-to-metal contact. Direct current offsets of 0 mV were obtain. Once the dry electrodes were applied to a patient's skin, a less than favorable result was obtained.

The attitude to adopt, therefore, when interpreting AAMI standard bench tests results for pregelled, disposable ECG electrodes is that electrodes that meet the AAMI standards have a tendency rather than a certainty to perform well *in vivo*. Electrodes that perform better as per the bench tests do not necessarily perform better *in vivo*. They are a useful set of tests nonetheless.

The ANSI/AAMI standard tests were conceived such that the test apparatus needed can be readily assembled by an electrode manufacturer. However, one can buy a convenient-to-use, custom-built electrode tester (as per AAMI standards) called the Xtratek electrode tester ET65A (Direct Design Corporation, Lenexa, Kansas.) (Fig. 56).

Electrocardiograph surface electrode testers also exist for the *in vivo* testing of the quality of (1) the design ECG electrodes, (2) the application of the electrodes, and (3) the skin preparation technique used.

The electrode tester generally measures the ac impedance and dc offset of the electrode-patient system. These measurements can be used, for example, in stress testing to decide if the skin sites have been sufficiently well prepared (i.e., contact impedances are low enough) to proceed with the clinical procedure. They can also be used to detect the presence of loose cables or bad contacts.

Figure 56. Early version of the Xtratek electrode tester ET65A. (Direct Design Corporation; Lenexa, Kansas.)

Standards for Stimulation Electrodes

Although not covered in this article, the following standards exist that stipulate minimum labeling, safety, and performance requirements for the given stimulators. The rationale for the standards is also presented.

- Transcutaneous electrical nerve stimulators ANSI/AAMI NS4.
- Implantable spinal cord stimulators ANSI/AAMI NS14.
- Implantable peripheral nerve stimulators ANSI/AAMI NS15.

Standards for Automatic External Defibrillators and Remote-Control Defibrillators. ANSI/AAMI DF 80 (2003)

AC Small Signal Impedance. The 10 Hz impedance for any of at least 12 electrode pairs connected gel-to-gel, at a level of impressed current not exceeding 100 μ A peak-to-peak, shall not exceed 3 k Ω . The impedance at 30 kHz shall be less than 5 Ω . The rationale for this requirement is based on the performance criteria in ANSI/AAMI EC 12 for disposable ECG electrodes. Interestingly, the permissible gel-to-gel 10 Hz impedance for large-area defibrillation pads is higher than that allowed for small-area ECG electrodes. The gel-to-gel impedance measured at 30 kHz will be largely that of the gel pads as the interface impedances at this frequency will be almost zero.

AC Large Signal Impedance. The impedance of an electrode pair connected gel-to-gel, in series with a 50 Ω load and measured at the maximum rated energy of the defibrillator shall not exceed 3 Ω . A value of 50 Ω is thought to represent the typical (rather low) *in vivo* transthoracic impedance between the electrodes. One wants the delivered energy to be dissipated in the patient's chest and not in the electrodes where the wasted energy may give rise to skin burns. The above requirement is therefore thought to provide a reasonable limit on the impedance contributed to the overall impedance by the electrode pair during defibrillation (<6%).

Combined Offset Instability and Internal Noise. A pair of electrodes connected gel-to-gel shall generate, after a 1 min stabilization period, a voltage no greater than 100 μ V peak-to-peak in the pass band of 0.5–40 Hz, for a period of 5 min following the stabilization period. The rationale for this requirement is based on the performance criteria in ANSI/AAMI EC 12 for Disposable ECG electrodes. The frequency range used is more limited in recognition that the cardiac monitor bandwidth is more appropriate in this application.

Defibrillation Recovery. The potential of a pair of gel-to-gel electrodes in series with a 50 Ω resistor and subjected to three shocks at 360 J or maximum energy at 1 min intervals shall not exceed 400 mV at 4 s and 300 mV at 60 s after the last shock delivery. The rationale for this requirement is largely based on the performance criteria in ANSI/AAMI EC 12 for Disposable ECG electrodes. An actual

defibrillation impulse is applied instead of that from a simulation circuit. The offset voltage across the simulated electrode-patient load must return to below 400 mV within 4 s following the discharge (slightly different values, 300 mV and 5 s, are used in ANSI/AAMI EC 12). As the patient's chest is represented by the 50 Ω resistor, no need exists for the 2.5 factor used in ANSI/AAMI EC 12 to correlate bench test and *in vivo* results.

DC Offset Voltage. A pair of electrodes connected gel-to-gel shall, after a 1 min stabilization period, exhibit an offset voltage no greater than 100 mV. The rationale for this requirement is based on the performance criteria in ANSI/AAMI EC 12 for disposable ECG electrodes.

Universal-Function Electrodes. With conventional defibrillators, it has been customary to use separate pregelled ECG electrodes for monitoring and defibrillator paddle electrodes for defibrillation. The monitoring electrodes are not capable of effectively delivering a defibrillation shock, and the paddle electrodes have only limited monitoring capability. For recent applications, particularly automatic external defibrillation, it is very desirable to use self-adhesive pregelled disposable combination electrodes that perform well in the dual monitoring and defibrillation functions. These electrodes may also be used for delivery of transcutaneous pacing. Hence, combination electrodes may become preferred for defibrillation, and it is appropriate in a standard for defibrillators to consider their use and to outline a few requirements for them.

If the electrodes are designed and intended for use in multiple modes (i.e., monitoring, defibrillation, and pacing) the electrode shall meet all (of the above) requirements after 60 min of pacing at the maximum current output and maximum pacing rate through a pair of gel-to-gel electrodes in series with a 50 Ω resistor.

No general performance standards exist for combination pacing/defibrillation/monitoring electrodes, the (above) requirements define the basic minimum controls necessary to ensure safe and reliable operation.

Standards for Electrosurgical Devices. ANSI/AAMI HF 18 (2001)

Introduction. Although AAMI lays down stipulations for the testing of a range of parameters, only the key electrical performance requirements for the dispersive electrodes are reviewed below.

Maximum Safe Temperature Rise. The maximum patient tissue temperature rise shall not exceed 6 °C when the dispersive electrode carries a current of 700 mA under the test conditions below, unless the device is labeled in accordance with 4.1.4.2 (i.e., for use on infants). For devices labeled for use on infants, the maximum patient tissue temperature rise shall not exceed 6 °C when the dispersive electrode carries a current of 500 mA under the test conditions stipulated in the standard. In monopolar electro-surgical procedures, the dispersive electrode must be able to reliably conduct the required surgical current without generating a significant rise in skin temperature. It is widely accepted that the maximum safe skin temperature

for short-term and long-term exposure is 45 °C, as normal resting skin temperature varies between 29° and 33 °C. Electrodes must not generate skin temperature increases approaching 12 °C. A 6 °C increase in temperature is therefore thought to represent an acceptable upper limit.

The temperature measurement method must have an overall accuracy of better than 0.5 °C and a spatial resolution of at least one sample per square centimeter of the electrode thermal pattern. The thermal pattern must include the area extending 1 cm beyond the geometry of the electrode under test. This degree of special resolution is stipulated as electrosurgical burns may be confined to very small areas and these must be detected. As current tends to flow to the edge of the electrode and spread out further in the skin, the test requires that the surround area of skin is also scanned.

The electrode under test is to carry a current from an electrosurgical generator of 700 mA_{rms} for 60 s, unless the device is labeled in accordance with 4.1.4.2, in which case the test current may be 500 mA. A current of 700 mA applied for 60 s yields a heating factor of 30 A² s. [Heating Factor = I^2t (A²s).] This value is far in excess of the maximum likely current and duration for a TUR (transurethral resection) procedure. A more realistic heating factor is less than 10 and, hence, the stipulated testing procedure is very conservative.

These tests must be conducted on human volunteers or on a suitably structured surrogate medium. When human volunteers are used, the tester must include a variety of body types in the sample group rather than concentrate on a single body type (thin, average, or thick layers of subcutaneous body fat). If surrogate media are used, the tester must demonstrate that the media are electrically and thermally similar to human volunteers. Human volunteer subjects are the reference standard. Current density distribution under an electrode depends on a wide range of factors, including the electrical properties of the skin and underlying tissues, hence, the need to test a given electrode on a wide range of individuals. The use of a surrogate material, even pig skin, which is commonly used, will not necessarily replicate with sufficient accuracy the clinical performance of the electrode. If a surrogate medium is used, the tester must demonstrate the equivalence of the test medium to human tissue. It is the Committee's view that no adequate surrogate medium has yet been suggested or used that has all of the properties of human tissue for the purpose of determining electrode performance.

Nessler et al. (149) point out that the above experiments are laborious, time-consuming, and expensive to perform. They have developed a new test device, swaroTEST, which includes a surrogate electronic skin, which, they claim, simulates the relevant electrical features of human skin and thus can replace the required volunteer experiments (Fig. 57). The device consists of a 3D resistor network representing the electric features of the skin and muscle tissue, and a temperature-sensing array (one transistor for each cm²) to measure the resultant temperature increase after a standardized current load (700 mA hf current during 60 s, proposed in the relevant AAMI HF-18 standard). The authors claim that a comparison of results obtained with their device and those with thermo camera images of

Figure 57. Swaro Test device with a measuring board electronic skin to simulate the electrical properties of human skin. It is hoped that this device will replace the human volunteer experiments required for ANSI.AAMI HF 18.

volunteer experiments correspond sufficiently well to justify the acceptance of their test device as a surrogate medium.

Electrode Contact Impedance. The electrode contact impedance must be low enough that the dispersive electrode represents the preferred current pathway, thus avoiding skin burns at alternative pathways. For conductive electrodes, the maximum electrode contact impedance shall not exceed 75Ω over the frequency range of 200 kHz–5 MHz when measured as described on a human subject. The frequency range of 200 kHz–5 MHz encompasses the frequency ranges of existing generators. As electrode-tissue impedance increases as applied current decreases, the committee decided on an impedance measuring current of 200 mA as it represents the lower limit of average currents reported for TUR procedures. Under these conditions, a maximum contact impedance value of 75Ω was judged an acceptable for the conductive electrodes.

For capacitive electrodes, the minimum capacitance shall be no less than 4 nF (0.004 μ F) when measured as described. In this case, electrode contact impedance is measured by placing the capacitively coupled dispersive electrode under test on a rigid metal plate larger than the electrode contact area. The test current and frequencies are the same as those specified for conductive electrodes. Their impedance characteristics are described in terms of capacitance as their impedances vary as the inverse of the frequency. The majority of capacitive electrodes that have been found to be clinically acceptable typically have a capacitance value of 4 nF, hence the minimum acceptable capacitance value specified by the Committee.

SUMMARY

With external biosignal monitoring electrodes, difficult challenges exist in the exciting new area of personalized

health. Such electrodes must form part of the patient's (or health-conscious citizen's) clothing and must continue to work, day after day, wash after wash, without gelling or preparation of any kind, without suffering from motion artifacts, and without causing skin irritation, which is no mean achievement.

An old monitoring problem still remains to be adequately conquered. A convenient and rapid method of applying many high performance electrodes to the head of a patient for EEG measurement awaits invention. The problem (and that of ECG ambulatory monitoring above) can be side-stepped to some extent by finding new electrode positions (montages or leads) that avoid the most problematic skin sites, hairy head in EEG and muscle and flabby areas in ECG.

For external stimulation, exciting new areas include public access defibrillation. The electrodes and their application to the victim must be almost literally fool-proof, given the seriousness of the possible consequences for all concerned. The electrodes must work after having been stored in the most inhospitable locations and possibly under extreme temperature fluctuations, for example, in the trunk of a car in the desert. In the more mainstream areas of cardiac pacing and defibrillation and electrosurgery, the optimal distribution of current density under the electrodes remains a goal still to be achieved. The solution to this problem offers the hope of decreased electrode areas and the design of truly multifunction pads.

The integration of electrodes into garments for FES and body toning is a relatively new area with considerable possibilities.

At present, implant electrodes and associated technologies already offer amazing potential for the deaf, lame, and even the blind. The development of multimicroelectrode arrays and waveforms that can help optimally shape the electrical fields to facilitate more effective and natural stimulation is a thrilling prospect. The interface properties of the microelectrodes will require further research so as to offset the potentially high interface impedances. Ideas already exploited in cardiac pacing, for example, may prove rewarding when adapted for these areas.

It is hard to overstate the potential of research being undertaken in the area of brain-machine interface. We live in exciting times.

INTRODUCTION

Biofeedback is a term that first arose in the 1960s for a methodology that uses instrumentation to record the physiological responses of organisms and then in real time give information about those physiological responses back to the organism. It is presumed that by getting such timely feedback about physiological responding, the organism will learn, through a trial and error basis, how to control the desired physiological response.

The most concise definition of biofeedback is probably that of Olton and Noonberg (1), who characterized it as, “any technique that increases the ability of a person to control voluntarily physiological activities by providing information about those activities” (p. 4). In practice, the process of clinical biofeedback training involves the use of a machine (usually a computer-based system in contemporary applications), which allows a therapist to monitor the patient’s bodily responses (most commonly surface muscle tension or surface skin temperature). Information concerning the patient’s physiological responses are then relayed back to the patient, generally either through an auditory modality (a tone that goes higher or lower depending on,

say, electrical activity of the target muscles increasing or decreasing) and/or a visual modality (now usually a computer screen where, e.g., surface skin temperature is sampled and then graphed on a second by second basis in real time). Through this physiological feedback, it is anticipated that the patient will learn how to control his/her bodily responses through mental means.

Biofeedback arose as an application of the learning theories of B.F. Skinner, Hull, Thorndike, Dollard and Miller, and John Watson. In particular, Neal Miller postulated that the established principles of learning that had so far been applied to overt behaviors could validly be applied to behaviors that were covert and presumed not under voluntary control.

Classical conditioning is also referred to as Pavlovian Conditioning after the seminal work of Russian scientists Pavlov and Sechenov in the early twentieth century. Classical conditioning is a laboratory learning paradigm by which a neutral stimulus (conditioned stimulus; CS) comes to elicit a new response (conditioned response; CR) by repeated pairing in close temporal proximity with another stimulus (unconditioned stimulus; UCS) that already elicits that response (unconditioned response; UCR). In subsequent presentations of the CS, the organism will then emit the UCR without pairing of the UCS. For example, the UCS might be food and the UCR is salivation, the CS, the ringing of a bell, is presented immediately prior in temporal pairing with the UCS, food. After repeated pairing of the ringing bell with food, the organism will come to salivate in response to the bell’s ringing. The behaviors conditioned in this paradigm are typically unlearned, such as most physiological responses utilized in biofeedback practice. However, the learning paradigm most often appealed to as the theoretical underpinning of the field of biofeedback is not classical conditioning. Rather, biofeedback is generally considered a form of operant conditioning. This learning theory postulates that the consequence of a response changes the likelihood that the organism will produce that response again. The essential assumption of operant conditioning is that behavior is lawful and follows the rules of cause and effect and probability.

A basic supposition of operant conditioning is, if you wish a behavior to continue, you reinforce or reward that behavior. If you wish a behavior to decrease, or to stop completely, you do not reinforce that behavior. Thus, within the theoretical framework of operant conditioning, the main way that you strengthen a behavior is to follow it in close temporal proximity with a reward. The definition of a reinforcer is any stimulus change that occurs after a response and tends to increase the likelihood that a response will be repeated. It is important that the reinforcer follow the desired behavior quickly such that the delay in the presentation of the reward is kept to an optimally short delay. As the delay in the reward increases, the effectiveness of the reinforcer is generally decreased. There are many examples of positive reinforcement in our everyday life—receiving a bonus for outstanding work, receiving an A in a course for intensive studying, scoring a touchdown in a football game and the crowd’s adulation.

In addition to positive reinforcement, there are three other possible consequences to behavior in operant

conditioning: (a) Negative reinforcement involves the removal of a consequence to a response that results in reduced likelihood that the behavior will be repeated in the future. (b) Positive punishment involves adding a consequence when a response is performed that serves to decrease the likelihood of the response occurring in the future. Examples are plentiful: child misbehaves, parent scolds child, child less likely to misbehave; drive over the speed limit, get ticket, less likely to speed; do poorly at work, get demoted, less likely to perform poorly on the job. Negative punishment involves the removal of a consequence to a behavior that serves to reduce the likelihood of that behavior occurring in the future. An example is a parent playing with their child who is clearly enjoying the playtime; the child starts to yell loudly, the parent stops playing with the child, parent less likely to engage in positive play with the child. In clinical biofeedback applications, these other types of reinforcement contingencies are rarely used, with biofeedback clinicians preferring to use positive rewards to influence behavior.

Perhaps the most important principle in operant conditioning that directly involves clinical biofeedback training is that of shaping. Shaping is the learning process by which the predefined target response is achieved through gradual and systematic reinforcement. The training begins with a simple, existing response and basic criteria for reinforcement, with gradually more stringent criteria applied for reinforcement in order to achieve more complex and reliable responses. After the initial behavior is reliably performed, reinforcement is given contingent on the performance of more complex or difficult responses. This pattern of increasingly stringent contingent reinforcement continues until the final target behavior is achieved. Shaping can be assisted by modeling the skill to be learned before shifting the reinforcement schedule. In clinical biofeedback, the target behavior in shaping is often tailored to the individual learning style and abilities of the patient. For example, a patient undergoing EMG biofeedback training may be initially reinforced for detecting gross changes in electrical activity in a particular muscle group. Following the initial success, the reinforcement is tapered and made contingent on the patient being able to detect ever more subtle changes in muscular tension in the target region. This may continue until the patient is unable to further demonstrate more refined skill in detecting muscle tension.

There are other principles within operant conditioning that also apply to biofeedback practice. One of these involves discrimination training, in which the organism demonstrates the ability to differentiate between at least two stimulus conditions by emitting a different response to each stimuli. In clinical biofeedback, the concept of discrimination applies to the patients' ability to distinguish relatively subtle differences in physiological states. Another important principle, indeed the mortar that lays the foundation of clinical biofeedback training, is the concept of generalization: If a response is conditioned to one stimulus, the organism may also respond to a similar stimulus (generalization), but not to a dissimilar stimulus (discrimination). Discrimination learning is a goal in the early stages of biofeedback training, while generalization is a longer range

goal. Clearly, the overarching aim of clinical biofeedback training is to take the learned process applied in the office setting and have that learning process come to apply to the everyday "real world" setting.

In addition to basic operant conditioning principles, there are general principles in basic psychophysiology that are important in clinical biofeedback training. The law of initial values states that the autonomic nervous system response to stimulation is a function of the prestimulus level (2). The higher the level of the response measure prior to a stressful stimulus being presented, the smaller the increase in response to the stressor, which is often referred to as a ceiling effect. Conversely, the higher the level of the measure prior to a relaxing stimulus being presented, the larger the decrease in response to the relaxing stimulus. When prestimulus response values are low prior to the presentation of a relaxing stimulus, this will lower the magnitude of the response and is often referred to as a floor effect. While the law has been shown to generally hold for measures of respiration and cardiovascular activity (such as heart rate and the vasomotor response), measures such as salivation and electrodermal response have not been found to be influenced by prestimulus values.

Homeostasis refers to the tendency of any organism to strive to maintain a state of equilibrium or rest. Homeostasis is believed to be maintained by a negative feedback loop, which is a theorized set of bodily mechanisms that provide information. This information directs the organism's physiological systems to decrease activity if levels of functioning are higher than normal, or to increase activity if levels are diminished relative to normal. Thus, all organisms strive to return to prestimulus levels of physiological arousal when presented with any stimulus.

Theories Underlying Clinical Biofeedback Training

There are two general theories underlying the use of biofeedback for most chronic benign medical disorders, such as anxiety, headache, musculoskeletal pain, and incontinence (3). The first is a direct psychophysiological theory, which attributes the etiology and/or maintenance of the disorder to specific physiological pathology. This biofeedback training modulates in a therapeutic direction. For example, it has traditionally been assumed that tension headache is caused by sustained contraction of skeletal muscles in the forehead, neck, and shoulder regions. Through the use of biofeedback, the patient learns to decrease muscle tension levels, leading to a decrease in headache activity. The second theory is predominantly psychological and postulates that there is a relationship between situational stress and the disorder in question. Through the use of biofeedback, the patient learns to regulate physiological responses such as muscle tension levels or sympathetic nervous system activity. This regulation leads to a decrease in overall stress levels, which brings about symptomatic relief. This amelioration of symptoms brought about by the learning of voluntary control of specific peripheral responses is postulated to be underpinned by central changes that occur along pain-relay and sympathetic pathways. For the case of headache treatment, this means that both muscle

relaxation and hand warming may indirectly dampen central brain mechanisms involved in the onset of headache. It is not necessary to view these theories as competing; they may be more appropriately viewed as complementary. Most clinicians subscribe to both theories, depending on the patient's presenting problem, clinical findings, and medical history.

Biofeedback Modalities and Instrumentation

Biofeedback instruments are first and foremost psychophysiological measuring instruments, to which has been added the capability to display the value of the measured parameter(s) in a form understandable to the subject. Feedback can be visual, auditory, or tactile.

The physiological measures generally employed in clinical biofeedback training are surface electromyographic activity (EMG) and skin surface temperature. Less often used physiological responses include measures of neuronal activity using electroencephalography (EEG), and measures of electrodermal response (skin resistance, skin conductance), cardiovascular activity (simple heart rate, heart rate variability, blood pressure, and vasomotor activity), and respiration (generally, respiration rate and depth).

Biofeedback instruments can be used to gain insight into a subject even if biofeedback therapy is not the goal. When assessment is the goal, care must be taken that the results are not contaminated by unintended biofeedback, such as the subject viewing the display. Subject spatial position with respect to windows, doors, and the professional must also be considered to avoid influencing the results. Environmental control of ambient temperature, humidity, and drafts is strongly recommended to minimize effects of these stressors on the subject.

Biofeedback instruments fall into three categories: research, clinical, and trainers. Research instruments are often configured from very flexible laboratory modules and their use is beyond the scope of this article. Many modern clinical instruments, however, are precise enough for basic or clinical research.

Clinical instruments are generally accurate, calibrated, and reliable. They are available as either stand-alone discrete units measuring a single parameter, or as computer-based multimodality systems. Some are comprehensive and accurate enough to be used for research. Trainers are single modality instruments intended to be purchased by or loaned/rented to the subject. They are less accurate and expensive than clinical instruments. Modern technology has made most trainers accurate and reliable despite their relatively low cost.

To protect both the subject and the professional, it is recommended that only FDA listed equipment be used. Even third-party software should meet this recommendation unless it is to be used only for educational purposes.

The biofeedback professional should have the proper academic credentials for the applications offered. Certification in use of the specific instrument modalities and applications is also recommended. The Biofeedback Certification Institute of America (BCIA), an affiliate of the Association for Applied Psychophysiology and Biofeedback

(AAPB), offers certification in many areas. The American Physical Therapy Association (APTA) offers certification in EMG treatment of urinary incontinence. It is further recommended that the biofeedback professional receive training for the specific instruments used as there are some differences among instruments of the same type.

Most modern instruments are manufactured using standards traceable to the National Bureau of Standards (NBS). Modern electronic technology permits instruments to remain calibrated throughout their life, with the exception of sensors, which must be replaced occasionally. Instrument performance while attached to a subject, even the same subject at different times, can vary widely from improperly placed sensors, electromagnetic interference (EMI) and the subjects' condition. Even the professional is not a psychophysiological constant. Therefore it is strongly recommended that the using professional invest in test instruments and fixtures for each modality to be used so they can independently establish that the instrument(s) are operating correctly. The test device could be as simple as a laboratory thermometer used in a stirred water bath to verify temperature or a precision resistor to verify electrodermal accuracy. Biopotentials (EMG, EEG, ECG) require an electrode meter, and electrical safety, a volt Ω -ampere meter. Some commercial ECG signal simulators also provide sine and square-wave outputs, useful for testing EMG, EEG, and ECG instruments.

Circuitry and software of commercial instruments varies as to amplifier bandwidth, filter cutoffs, signal rectifiers, and integrators, which make it difficult to measure accurately direct comparisons between instruments of the same type from different manufacturers. Comparing results from different instruments of the same model from one manufacturer depends on the technology used. Older instruments with discrete component filters vary more than modern instruments due to component tolerances. Modern computer-based instruments employing software filters are more similar.

Professionals making comparisons with other professionals should use relative values such as percent decrease in finger temperature. A rough rule of thumb follows: Instruments vary about $\pm 10\%$ across models and manufacturers, but subjects can vary as much as an order of magnitude in some measures. Lesson: Rely on known standard inputs to evaluate instrument performance.

Safety falls into three major areas: environmental, biological, and electrical. Environmental safety concerns trip hazards, sharp edges—corners, heaters, lamps and machinery in the subject—professional area. Biological safety concerns disinfecting re-useable sensors, subject chair, area, and so on. Disposable biopotential (EMG, EEG, ECG) electrodes are recommended. Until disposable EEG electrodes become available, they and all reusables should be cleaned and disinfected between uses. Electrical safety concerns both subject and professional. Battery powered instruments are intrinsically safe but if connected to an alternating current (ac), line operated device (i.e., computer, recorder, oscilloscope), through a nonisolated interface, they become a potential hazard.

Most computer-based instruments are isolated to stringent standards and provide complete electrical safety for

the connected subject. By isolating the computer system with a medical grade power transformer, the professional is also protected. Use the (recommended) ac current meter to verify isolation.

EMG Biofeedback Instrumentation

Biofeedback applications of EMG range from simple relaxation, using electrodes placed on the forehead, to complex neuromuscular retraining of stroke (cardiovascular accident, or CVA) victims utilizing four EMG channels on each of the affected and unaffected sides to retrain functional movements using both inhibition and reinforcement learning techniques.

The EMG signals for clinical biofeedback are the summation of muscle cell action potentials generated by the underlying muscles seen at the skin. They are acquired from surface electrodes applied over (or in the vicinity of) muscle(s) to be monitored. Signals from the electrodes are amplified and conditioned by high performance differential amplifiers. Signal characteristics of interest are in the range of 0.1–2000 μV amplitude, over a bandwidth of ~ 25 –500 Hz. The amplified signal is then processed to a form suitable for display to the subject.

EMG Electrodes. Muscle signals are acquired using two (active) electrodes located along the muscle fiber axis. A third electrode (common, often erroneously called ground) establishes the instrument common at the subject common potential. Well-placed surface electrodes provide an adequate EMG signal to enable subjects to learn control and change in the desired direction (i.e., relaxation, EMG lower; reeducation, EMG higher).

Needle or wire subcutaneous electrodes can collect a more comprehensive representation of the EMG (motor and nerve cellular action potentials), but their use is limited to Neurology or research, due to the complexity and invasive nature of the procedures.

A surface electrode is a complex electrochemical network. The manufacturing process reduces and stabilizes all internal parameters, leaving only the electrolyte–subject skin interface for the clinician to cope with. Fortunately, EMG amplifier technology has considerably reduced requirements for electrode preparation (for most applications) to a good skin cleaning using alcohol or a commercial prep solution. A surface electrode basically consists of a contact resistance (i.e., 10–100 k Ω), paralleled by a capacitance (i.e., 1 nF), in series with a half-cell potential (i.e., 300 mV “battery”).

The care required in electrode–lead–amplifier placement and mechanical stabilization depends on procedure dynamics and electrical environment considerations. For relatively static applications (i.e., relaxing in a chair), in a relatively benign electrical environment, much less preparation and virtually no stabilization are required. For dynamic (i.e., treadmill) applications in a hostile electrical environment (i.e., central urban), considerable care and expertise are required to obtain reliable signals. Proper electrode choice and stabilization means (i.e., taping) are required. Electrode mechanical stabilization is required in

dynamic applications to minimize disturbing the half-cell potentials that form at the electrolyte–skin interface.

Other considerations for electrode selection and placement include surface curvature, movement, and sweating.

Today, most EMG biofeedback clinicians use disposable electrodes in consideration of disease and litigation problems. One newer type of surface electrode (hydrogel) can be moved between (properly prepared) sites on one patient during one session, but using any type of electrodes between subjects is not recommended.

EMG Amplifiers. The EMG amplifiers have benefited considerably from integrated circuit technology and today achieve performance inconceivable two decades ago. Many products still connect to electrodes with a cable or leads, but some amplifiers are small enough to mount directly on the electrode structure. While the amplifier characteristics are exceptional, the performance of the EMG channel can be compromised by asymmetries in electrodes and connecting leads, resulting in unequal electrical induction, causing artifact to appear as a differential error signal. The following are considered to be minimal specifications for a modern EMG amplifier:

Low internal noise ($<0.5 \mu\text{V}$, p–p).

High input impedance ($Z_{in} > 100 \text{ M}\Omega$).

Flat bandwidth and sharp high and low frequency cut-offs ($>18 \text{ dB/octave}$).

High common mode rejection ratio ($\text{CMRR} > 10^7$).

Common mode input range ($\text{CMR} > \pm 200 \text{ mV}$).

Static electricity shock protection ($>2000 \text{ V}$).

Gain stability (all causes) $> \pm 1\%$.

Bandwidths (3 dB) in common use for clinical biofeedback are 25–500 Hz, primarily used for neuromuscular reeducation training, and 100–200 Hz used for relaxation training and where bandwidth must be limited because of EMI considerations. A hardware or software switch provides bandwidth selection. The narrow bandwidth loses some of the EMG frequency spectrum, but is adequate for many applications, having the advantages of lower in-band noise and less artifact susceptibility. Some manufacturers believe that a single bandwidth of ~ 30 –300 Hz captures most of the EMG signal and provides simplicity.

EMG Biofeedback Application Example. Consider the problem of acquiring a 1 μV signal from a muscle using two (active) surface electrodes and a reference (common) electrode. Characteristics of the reference electrode are not as critical as the actives because the high CMRR of the amplifier minimizes disturbances in its impedance and half-cell potential.

The two active signal acquiring electrodes are effectively back to back, in series with the (muscle) signal source impedance and generator. Impedance of the active electrodes is probably close, since they were applied in a like manner, and the very high input impedance of the amplifier makes differences negligible.

Active electrode half-cell potentials are a different matter. While they are similar, they are of such a great magnitude (i.e., 300 mV) compared to the signal (i.e., 1 μ V) that small abrupt changes in either half-cell potential will be coupled through the amplifier as a large artifact, which is the reason why it is so important to mechanically stabilize surface electrodes. Small disturbances of electrodes and leads outside of the frequency band of interest are not seen.

Leads connecting electrodes to the amplifier must also be stabilized to reduce artifact. They should be twisted and taped down for dynamic applications. Triode (equilateral triangle group) electrodes allow placing the miniaturized amplifier directly on the electrode(s), reducing lead length to zero. Amplifier and lead mass must also be considered in dynamic applications.

In some applications, such as treadmill and (internal) pelvic floor applications, some artifact must be tolerated and either average or quiescent levels used for training.

Following successful acquisition and amplification of the EMG signal it is usually rectified in a precision operational circuit or subroutine to produce the time-variant average that is needed for quantification and display. Older instruments provide integral average and modern instruments provide root-mean-square (rms) average that is loosely held as an analog of power by some authors. A related instrument response parameter is the time constant (TC) of integration that follows rectification.

Neuromuscular reeducation applications require a short (i.e., 50 ms) TC to sense the slightest voluntary (phasic) response and relaxation training as long as one second, to provide a more slowly changing display promoting relaxation, when tonic levels are of more interest.

Therapists having detailed knowledge of the frequency spectral characteristics of the specific muscle(s) being trained view (on an oscilloscope) the raw (filtered but not rectified ac) signal for assessment and training effectiveness. Raw EMG is seldom used as feedback due to its' visual complexity.

Stand-alone instruments use either analogue operational or microprocessor implemented filtering, rectification, averaging, and display. Most modern instruments are microcomputer based. The biofeedback instrument manufacturer provides signal acquisition and conditioning hardware to be interfaced, and software to be installed in a PC. Most recent biofeedback software has been for use on Windows operating system PCs.

Some stand-alone instruments have data storage, statistical reporting, and downloading capabilities. Microcomputer-based systems provide very sophisticated data reporting capabilities, with raw data exporting for advanced analysis. Some systems feature general purpose software for more advanced users and application specific software for less sophisticated users performing repetitive procedures, such as pelvic floor muscle strengthening and synchrony training for urinary incontinence.

Temperature Biofeedback Instrumentation

Temperature biofeedback is primarily used to improve poor peripheral blood flow caused by chronic sympathetic

arousal. Other medical conditions causing low peripheral blood flow must be ruled out prior to attempting biofeedback. Temperature is then taken as a partial integration of blood flow and thus of peripheral vasoconstriction caused by sympathetic arousal.

Training criteria are determined by the therapist for the particular subject, but digit temperature training goals range from 31.1 to 35 °C for most subjects.

There are several types of low cost "instruments" primarily used for group education. These include glass-alcohol thermometers, liquid-crystal (i.e., mood-dots and biotic bands), and digital thermometers. This section concerns itself with clinical grade instruments employing sensors, amplifiers, and displays.

Temperature Sensors. Small sensor(s) are affixed to finger(s) or toe(s) with porous surgical tape at nearly zero tension so as not to occlude blood flow, or provide a heat reservoir. The sensor(s) are in good thermal contact with, but electrically isolated from, the subject. Accuracy and linearity of modern commercial sensors are excellent, but it is essential to use sensors having a short thermal time-constant and minimal hysteresis so minute changes in temperature (i.e., blood flow) are immediately communicated to the subject.

Modern sensors are thermistors, compensated negative coefficient resistors that provide a linear negative change in resistance over the temperature range of 21–37.8 °C. A small direct current (dc) voltage is impressed across the thermistor resulting in increased current flow for increases in heat (due to increased blood flow) from the subject.

Temperature Amplifiers. Whether the temperature instrument is stand-alone or one modality of a multimodality system, the circuit consists of a compensated thermistor sensor, powered by a constant voltage, and a current-to-voltage amplifier that produces a temperature proportional voltage that is then displayed and/or digitized for further processing.

Amplifier characteristics depend on the thermistor resistance range, the excitation voltage, and the required output voltage. Bandwidths of 0–5 Hz provides adequate response and minimizes noise, improving resolution. Since signals are high level, a single-ended current amplifier can be used.

Absolute accuracy is important because both subjects and therapists tend to discuss readings in their respective groups for comparative purposes. Subjects particularly are very sensitive to numbers and an instrument differences could impede training progress.

Most instruments specify ± 0.56 °C absolute accuracy. It is often better than claimed and can be checked in a stirred waterbath against a standard lab mercury thermometer.

Resolution of most instruments is selectable for either 0.056 or 0.0056 °C resolution. Subjects tend to make large improvements in initial states of training and the coarser (0.056 °C) resolution is adequate. There is some question by these authors about whether the 0.0056 °C resolution has clinical utility.

Temperature Displays. A time-based line graph is the most common display, as it shows past history and current trend. Bar graphs, digital meters, and computer animation displays are also used. These should be selected by the therapist–subject team to be relevant to the subject's beliefs; and sometimes varied to keep motivation high.

Temperature Biofeedback Application. Sensor attachment is often the back of the finger or toe of interest using a breathable tape to prevent heat build-up. Tape tension should be just enough to affix the sensor without constricting blood flow. Lead length should be sufficient to allow the subject to achieve a comfortable position without lead tension.

Room temperature should be in the comfort range for the subject (i.e., 21.1–23.9°C) and without any breeze. Relative humidity should be between 30 and 50% to avoid humidity stress or evaporation cooling.

A location free of transient noises (i.e., office activity, elevator, emergency vehicles) will facilitate subject focus and relaxation.

EEG Biofeedback Instrumentation

The EEG biofeedback instrumentation is similar to EMG biofeedback instrumentation in acquiring the biopotential signal. The reader is encouraged to review the section on EMG biofeedback instrumentation for a background on the following section.

Whereas EMG instrumentation acquires surface muscle signals at the skin, EEG instruments acquire signals on the scalp generated by brain cellular activity below. The EMG activity in this region is considered artifact and care must be taken in EEG signal processing to minimize EMG contamination. When large EMG artifacts cannot be removed from the EEG signal, feedback must be blocked or held constant until the EMG artifact has passed.

The EEG signal is acquired on the scalp using surface electrodes, generally different from EMG electrodes, in either a differential (bipolar) or referential (monopolar) mode. High performance differential amplifiers increase and condition the signals. Signals of interest are in the range of 0.5–100 V (p–p), over the frequency range of 1–30 Hz. Newer clinical research extends the frequency range to 1–50 Hz.

Modern EEG biofeedback instruments perform digital filtering on the amplified and conditioned EEG signal to obtain the frequency band(s) or full spectrum of interest (i.e., fast fourier transform, FFT).

Viewing the full frequency spectrum EEG signal is of interest in assessing brain state(s) and is sometimes used as feedback, displayed as bilateral (left and right hemisphere) displays back to back about as vertical centerline.

More often the feedback display is less complicated, consisting of vertical bars or lights representing several spectral bands logically combined to reward increases in the band of interest (i.e., beta, 16–20 Hz) and decreases in the band to be reduced (i.e., theta, 4–9 Hz). The EMG activity is also monitored and acts to inhibit or freeze the feedback if present.

This logic is also used to drive a computer generated graphic animation sequence (i.e., games) and/or audio feedback comprising several types of files and songs (i.e., wav, midi). Auditory feedback is useful for closed eyes training and can also be used to provide simultaneous reward-inhibit band information when the visual presentation does not provide it, as in the case of animation sequence visual feedback.

EEG Electrodes. The EEG electrodes are placed on the scalp in a standardized grid called the 10–20 system. Coordinates are determined with respect to the midline, between the nasion and the inion, and a line between the right and left ears, in percent of the distance from the reference axis.

Bipolar recordings are made between (2) active scalp electrodes, with a neutral site serving as amplifier common (i.e., center forehead). An active pair of electrodes is used for each additional site to be monitored. Only one common is required unless the amplifiers have isolated commons, in which case they must be tied to the subject, usually at the same neutral site.

Monopolar recordings are made with a single scalp electrode (+) with respect to a chosen reference site (–). Amplifier common is placed at a third (neutral) site. For bilateral monopolar recording, the left channel has a scalp electrode (+) somewhere on the left side of mid-line with its reference (–) on the left ear. Amplifier common could be either the left mastoid bone or forehead.

The right channel placement somewhat mirrors the left with the active scalp electrode (+) on the right side of mid-line, the active reference (–) on the right ear, and the common on the right mastoid bone or forehead. The left and right active electrodes are placed according to training objectives, not necessarily symmetrical.

Multichannel systems are monopolar having a scalp electrode for each of the (20) sites in the 10–20 system, all having the same (forehead) reference and instrument common.

An Electro-Cap having 20 scalp and one reference–common electrode, sized to the subject, is worn. Electrode sites are prepared through holes in each electrode. A cable harness connects the cap to a junction-box for connecting amplifiers to desired sites, or directly to the instrument, for the 20 channel system. Since all sites are measured referentially (i.e., monopolar), differential comparison between any sites can then be accomplished in software or circuitry.

It is important that both active electrodes (i.e., +, –) have the same electrode material and electrolyte, since the initial stage of the amplifier is dc coupled, and a large difference in half-cell potentials could saturate (block) the amplifier. The (2) active electrodes must be prepared similarly even if one is a scalp (cup or disk) placement and the other an ear-clip.

Gold, silver–silver chloride, and tin are common active electrode materials. The common electrode can be a different type, usually a disposable silver–silver chloride EMG electrode.

Electrode sites are prepared by mild abrading and infusing a conductive “prep” gel to stabilize and improve conductance of the scalp. This is followed by application of

an thixo-tropic electrolyte (i.e., 10–20 paste). The cup or disk electrode is then pressed on the paste until it is firmly sealed. Viscous force holds the scalp electrode in place during recording. Hair is managed with tape or cottonballs, which also helps retain and stabilize the placement. Ear clip electrodes are spring retained.

Reusable cup scalp and ear clip electrodes are in common use despite potential health and litigation problems. Several disposable systems have been or are being developed, but are not in wide use at this writing.

Careful electrode preparation will result in an impedance of $<10\text{ k}\Omega$, usually measured using a 20 Hz ac impedance meter. The actual value required depends on the electrical environment of the treatment area. The EEG electrodes are generally unshielded, so electric induction is reduced with low impedance placements.

Electrode half-cell potentials must also be checked differentially with an electrode meter. Differences of more than $\pm 25\text{ mV}$ between the active electrodes usually indicates unstable placements or different materials used. If a different type of common electrode was used, a large half-cell potential difference between each active and the common is not problematical, as long as they are similar and stable.

EEG Amplifiers. Like EMG amplifiers, EEG amplifiers make good use of integrated circuit and surface-mount technologies to achieve performance never before seen. While amplifier characteristics are exceptional, the effective performance of the EEG channel can be compromised by asymmetries in electrodes, cables, and leads. The resulting imbalance between the plus (+) and minus (–) inputs to the differential amplifier can cause unequal electric induction producing an error that shows as increased noise or offset. Fortunately, most unwanted electric fields are outside the amplifier bandwidth. Still, good practice in electrode preparation, lead routing, and electrical environment control are necessary to avoid a setup that is electrostatically “hot”.

The following parameters are considered minimum for the modern EEG differential amplifier:

- Low internal voltage and current noise ($<1\ \mu\text{V}$, 100 pA, p–p)
- High input impedance ($Z_{in} >10^8$).
- Bandwidth (1–50 Hz).
- Frequency cutoffs ($>18\text{ dB/octave}$).
- High common mode rejection ratio ($>10^7$).
- Common mode input range (greater than $\pm 200\text{ mV}$).
- Static electricity shock protection ($>2000\text{ V}$).
- Gain stability (all causes) greater than $\pm 1\%$.

The amplified EEG signal is then digitally filtered to produce the desired bands of frequencies to be used for assessment, training, or mapping.

EEG Displays and Feedback. The modern EEG instrument utilizes a computer to perform the signal processing, auditory and visual display generation, data collection–reduction, and reporting necessary for effective assessment

and training. Today’s sophisticated programs require a fairly high performance computer to perform all these tasks in apparent real time. Most manufacturers design around readily available Windows based personal computers having the following minimum characteristics:

Processor:	Pentium 3
Speed:	600 MHz
Memory	256 MB
Storage	10 GB
Display resolution	800 × 600
Video memory	32 MB (4 × AGP)
Operating system	Windows ’98, or later
Auditory system	Sound Blaster Live
Speakers	Good quality with sub-woofer

Recent advances in clinical biofeedback have shown subjects can comprehend complex visual and multiparameter auditory feedback simultaneously. A higher performance computer with more working and video memory, and the very best auditory system is suggested for these applications.

A very useful feature of Windows’98 and later operating systems is the support of multiple display monitors. This makes it possible to stretch the display onto a second monitor. The therapist can construct displays having highly technical items on their monitor while the subject sees nontechnical items, such as animation.

A common use of the digitally filtered EEG signal is for treatment of Attention Deficit Disorder. Other applications using other bands of frequencies include hyperactivity and performance enhancement.

Full frequency spectrum displays are used to “quiet” a “noisy” brain under the guidance of a skilled therapist. Animation sequence displays accompanied by contingent auditory feedback provide effective training tools for the therapist.

Some 20 channel systems are capable of mapping the entire EEG frequency spectrum at every electrode location in the 10–20 coordinate system in (nearly) real time. The displays are updated in 50 ms providing a useful assessment mode.

EEG Biofeedback Application. The most important factor is the therapist’s training. The EEG assessment and biofeedback treatment has progressed considerably beyond that required to use the less complex modalities of temperature, electrodermal, and EMG. Fortunately, few schools are keeping up with advances. The International Society for Neuronal Regulation (ISNR) is a good source to inquiry. The Neurofeedback division of the Association for Applied Psychophysiology and Biofeedback (AAPB) and ISNR have together addressed several critical issues in EEG biofeedback methodology and clinical application.

As with most psychophysiological assessment and biofeedback applications environmental temperature (21.1–23.9 °C), humidity (30–50%), illumination (as required), auditory noise (transient free, white noise is usually acceptable), and therapist’s physical position with respect to the subject must be considered and controlled.

An electrically quiet environment is also desirable. Power lines, TV and radio antennas, and mobile communications are frequent sources of interference. Basement locations usually offer the electrically quietest locations and well-placed electrodes along with carefully routed leads provide the best immunity under the therapist's control.

Electrodermal Biofeedback Instrumentation

Electrodermal activity (EDA) is essentially a measure of palmar sweat gland activity of the fingers or hands. Bulk tissue impedance is largely ignored, being clinically less significant than the eccrine sweat gland activity, modulated by the sympathetic nervous system that modern instruments measure.

Electrodermal activity can be measured either as resistance, called skin resistance activity ($SRA = SRL + SRR$) or its reciprocal skin conductance activity ($SCA = SCL + SCR$). The SCA has the advantage of being a linear function of the number of sweat glands conducting, while SRA has a hyperbolic relationship to the number of sweat glands conducting.

Electrodermal activity includes both the tonic (average) level (SRL or SCL) and short-term (phasic) response (SRR or SCR). Training goals for SCA are to lower the tonic level, indicative of chronic sympathetic arousal and reduce the phasic changes percent, indicative of over reactivity, either spontaneously or in response to stimuli.

The magnitude of phasic changes tend to occur as a percentage of the tonic level. For conductance, a $1 \mu\text{S}$ SCR change from a tonic level of $5 \mu\text{S}$ SCL is approximately equivalent to a $2 \mu\text{S}$ SCR change from a $10 \mu\text{S}$ tonic SCL level (i.e., 20%).

Most modern instruments measure conductance although one manufacturer recently reverted to resistance so that the same programmable amplifier could be used to measure any variable resistance sensor (i.e., temperature). Since conductance and resistance are reciprocals, either can be displayed with the conversion made in circuitry or software.

Subject phasic responses are delayed by 1–3 s neurophysiologically. This latency limits the usefulness of EDA as an early in-training feedback modality. It is an excellent assessment modality where the subject receives no feedback.

The EDA is a passive electrical parameter and must be elicited by impressing a small voltage on (conductance), or passing a small current through (resistance) the two electrodes, usually placed on the fingers. Either method is referred to as "excitation".

The normal range of EDA for human subjects is

Conductance:	0.5–50 μS
Resistance:	2 M Ω –20 k Ω

Most untrained subjects range between 2 and 10 μS . A value of 50 μS would be indicative of a soaking wet hand.

Electrodermal Electrodes. Normal placement of electrodes is on the palmar surface of the index and middle fingers

of either hand, selection dictated by other modality sensors on a particular hand. Electrodes are held on the fingers by Velcro straps set for just enough tension to hold them on without causing blood "pulsing" or pounding in the fingers. Silver–silver chloride is the most common electrode material, but gold, stainless steel, and nickel-plated brass are also used.

Early instruments used monopolar (dc) excitation. At the values then used, electrode polarization and subsequent amplifier blocking tended to occur. Modern instruments use 10 μA current (resistance) or 200 mV (conductance) and reverse the excitation several times per second resulting in no net charge, thus avoiding electrode polarization. These values also limit current to 10 μA as required by the FDA.

Electrolyte between electrode and skin is not normally used clinically for EDA, but should be used, along with finger cleaning for clinical research or published studies.

Electrodermal Biofeedback Amplifier. Modern EDA amplifiers employ a switching technique to reverse electrode excitation several times per second to avoid electrode polarization. This requires a reversible voltage (conductance) or current (resistance) source, circuits easily implemented by operational amplifier techniques. Values are sampled after transient effects caused by the switching. The EDA is a relatively slowly changing modality and an effective amplifier bandwidth of 1–2 Hz is adequate.

The entire EDA (EDL + EDR) should be measured and later separated. Phasic changes (EDR) can be ac coupled to remove the EDL and amplified to produce the desired display sensitivity. This produces bipolar components to each phasic response (EDR), which can be difficult for subjects to understand.

Another method is to introduce an offset in the amplifier equal to the EDL resulting in only the phasic (EDR) component that can then be amplified separately. This method requires a relatively stable EDL or a circuit that samples the EDL and adjusts the offset continuously.

Electrodermal Feedback. Use of EDA as an assessment (without feedback) modality is highly recommended since it provides insight into the chronic sympathetic arousal level and reactivity of the subject.

Using EDA as a feedback modality in the beginning subject is discouraged as it is so nonspecifically reactive, subject relaxation and learning may be impeded. Advanced subjects, however, may find it challenging to control EDR while performing tasks.

For assessment, the time line graph of the entire EDA provides the most information on current and recent past history to the therapist.

The line graph, bar graph or contingent animation are all useful visual displays for the advanced subject.

Pitch-proportional (SCA) or pitch inversely proportional (SRA) auditory tones are useful for eyes-closed or task performance training. Care must be taken in choosing the pitch range to avoid alarming the subject with a "siren" effect.

Electrodermal Biofeedback Application. Silver–silver chloride electrodes are recommended. Low cost velcro-strap electrodes are affordable for each subject's course of training. Using these between subjects is not recommended from disease and therapist liability considerations. Disposable Ag/Ag CL EMG electrodes provide an alternative, but affixing them to digits is not as convenient.

Hand washing prior to the session is advisable for both uniformity and sanitation.

Use of electrolyte is not required for most clinical training, but should be used for clinical research or published studies. Saline gel or cream is suitable for most subjects. Non-saline gel is useful for allergic subjects. Hand washing following the session is good practice.

A small percentage (i.e., 7%) of subjects show little or no EDA. Always check the instrument with a known conductance–resistance standard (or the therapist) before concluding that the instrument is mal-functioning.

Since EDA is an elicited or exosomatic measure, care must be taken to place sensors from all used instrument modalities so that the current from EDA does not interfere with or impede other simultaneous measurements. Manufacture of multimodality biofeedback systems provide guidelines to minimize these situations. This is of particular concern if two EDA channels are used on the same subject.

As EDA is a relatively high level signal and excitation switching is slow, the modality is relatively impervious to electromagnetic interference.

Cardiopulmonary Biofeedback

Respiration (RSP) training has been shown to greatly improve the subjects' ability to relax and maintain self-regulation in the face of psychological and performance stressors. It tends to reduce performance anxiety and increases oxygen uptake and waste expulsion. It also increases peripheral circulation by reducing sympathetically activated vasoconstriction. Heart rate increase during inhalation is normal, implemented by the sympathetic nervous system. Para-sympathetic action slows heart rate during exhalation. Heart rate variability (HRV) training has also provided benefits in reducing rapid heart rate and tachycardia.

The HRV (measured as HR max - HR min) is frequently as high as 20 BPM in healthy 20 year-old adults, and decreases by age 50 often to ~10 BPM. Athletically active and physically well-conditioned individuals have higher variation in heart rate. Heart rate variability training aims at increasing the variability, and frequently increases it significantly higher than 20 BPM. Some authors have claimed that it goes as high as 50 BPM in peak training. Higher HRV is considered desirable in disease prevention and health promotion applications, and lower HRV correlates with cardiovascular morbidity and mortality. For example, lower HRV is a strong independent predictor of post-MI death (4).

By combining respiratory (RSP) and heart rate (HR) instrumentation, the interplay between respiration and heart rate, referred to as respiratory sinus arrhythmia (RSA), can be assessed and used as biofeedback to train

subjects to optimize their natural cardiopulmonary rhythms under the influence of stressors.

Norms for HRV training have been published (5). One of the persistent problems in the field is the failure of researchers and practitioners alike to adhere to standard nomenclature and normative values for training. The following HRV frequency ranges have been established as standard for cardiopulmonary training:

Cardiac Rhythms. High frequency: 0.15–0.4 Hz; low frequency: 0.04–0.15 Hz; very low frequency: 0.0033–0.04 Hz; and ultra low frequency: <0.0033 (beyond clinical biofeedback measurement technology) (5).

Recently, a more careful examination of HRV has shown the very slow rhythms to be of interest in assessing dysregulation, other than that caused by the ANS, to be discussed in a separate HRV section, below. The very low frequency (VLF) range is to some extent correlated with dysregulation. Rhythms in the low frequency range are to some extent correlated with optimal homeostasis. Higher HR oscillations are found in rhythms in this range.

The RSP rates vary from 2 to 30 bpm requiring channel bandwidths of 0–5 Hz to faithfully reproduce the RSP waveform. Trained subject's RSP rates at rest are individually optimum and range from 6 to 9 pm.

The HR rates vary from ~40–180 bPm. Trained subject's HRs rest at ranges between 60 and 80 BPM The HRV (RSA) of 8–16 BPM as a function of RSP is normal and desirable.

Some instruments are capable of RSA assessment and biofeedback only. Instruments designed for HRV generally can also perform RSA procedures.

Respiratory Sinus Arrhythmia Instruments. Instruments for RSA have one or two respiration channels and one heart rate channel. Two respiration channels are desirable to train the subject to breathe abdominally, not thoracically.

The RSA instruments are computer implemented. Time line graphs of abdominal and thoracic RSP along with a beat-by-beat line graph of HR comprise an excellent assessment and training display. The line or (better) filled line graph is the most common display as it shows recent past history as well as current performance. Digital meters showing RSP and HR rates can be added, but the display tends to be too complicated, particularly for beginning subjects.

Raw data is saved, so the session can be replayed as desired. Statistics can be generated, but care must be taken to consider the effect of artifact. Both RSP and PPG HR channels are susceptible to movement artifacts. Some instrument software permits editing the raw data to minimize artifact contamination of statistics.

Respiration Sensors and Amplifiers. Respiration sensors for biofeedback comprise a stretchable segment and a belt or chain that is wrapped around the circumference of the abdominal and the thoracic regions of the subject. A slight prestretch (set at the point of maximum exhalation) allows the sensor to operate over the full range of circumference change caused by breathing. Care must be taken that restrictive clothing does not impede breathing.

Circumference change caused by breathing is a relative measure affected by subject breathing, posture, type of sensor, even temperature depending on the type of sensor used. Three types of sensors are in common use.

1. Rubber Bellows (Air Filled): Following placement the system is sealed, and sensor internal pressure changes with stretch. A transducer (half or full bridge strain gage) measures pressure changes. A dc coupled bridge amplifier, with offset control, provides amplification and the ability to "position" the output at the desired level for display and/or quantification. Typical pressure variations are on the order of ± 15 mmHg (1.99 kPa) gage.
2. Tubular liquid-filled strain gage: An elastometric tube filled with a conductive thixo-tropic liquid. Changes in length and diameter of the tube, caused by breathing, varies the resistance of the gauge. Since the liquid is ionic, excitation (current or voltage) is reversed several times per second to prevent polarization. The amplifier comprises a reversible voltage or current source, gain, and offset capability to provide the desired output signal positively proportional to inhalation.
3. Magneto-position transducer: A magnetic armature is moved within an excited coil to produce a current proportional to movement. An elastomeric tubing provides a restorative force to track breathing movements. The amplifier converts the magnetically induced signal, provides gain and offset to provide a voltage positively proportional to inhalation.

Heart Rate Sensors and Amplifiers. Heart rate for clinical biofeedback is measured using either a finger photoplethysmograph (PPG) sensor or by acquiring the electrocardiogram (ECG) biopotential signal. The PPG sensor is easy to use, but its' output is subject to artifact from any disturbance of the placement. Acquiring the ECG requires placement of surface electrodes, but provides the virtually artifact-free signal that is required for reliable HRV analysis, and will be discussed in that section.

The PPG sensors employ an (invisible) infrared (IR) source of ~ 0.9 nm wavelength to illuminate the vascular bed of a finger (or toe). A photocell detects the backscatter caused by the opacity of blood at that wavelength. It is held in place with a Velcro strap or elastic band. The amplifier provides gain producing a pulse signal having information on HR, peripheral pulse amplitude (PPA), pulse volume (PPV) and rise and decay characteristics of the pulse.

Heart Rate Variability Instruments. Heart rate variability is useful for more than RSA training. Other factors, such as chemoreceptors, baroreceptors, the renin-angiotension system and various disease states affect HRV. Many of these variations occur at frequencies too slow to be perceived by or used as feedback for subjects.

Research has shown the frequency spectrum of HRV from 0.003 to 0.4 Hz to be useful in assessing dysregulation of various systems. When HRV spectral components are distributed throughout the range of 0.003–0.4 Hz, HRV is

said to be incoherent. In the coherent state, virtually all the energy occurs at one frequency in the range of 0.08–0.12 Hz and is individual specific.

The most comprehensive analysis of the slowest rhythms requires a 24 h data string of HR, such as is obtained in a Holter portable monitor of ECG, so various segments of Circadian rhythms can be analyzed. Data must be edited for artifact before spectral analysis by fast fourier transform (FFT) is performed. The comprehensive analysis can give insight into undiagnosed medical conditions.

In clinical psychophysiology, 5 min HRV data resolves frequencies from 0.003 to 0.4 Hz, adequate for observing ANS activity. Some instruments have added a 60 s HRV data gathering to provide 0.06–0.4 Hz spectral data, more easily obtained in the clinical situation, and adequate for determining coherence.

The ECG amplitude ranges between 0.3 and 2 mV for the QRS complex that is used to determine the interbeat interval from which the frequency spectrum is derived. The exact characteristics of the ECG signal are not as important in HRV applications as in clinical cardiology.

ECG Sensors and Amplifiers. The ECG is most reliably obtained by placement of chest electrodes using pregelled disposable Ag/AgCl sensors. For 24 h HRV studies, chest placement is mandatory.

In clinical psychophysiology, it is preferable not to remove clothing, so the wrist–wrist or wrist–ankle placement of sensors is preferred. Polarity of the ECG signal is important so the amplifier leads must be connected according to the manufacturer's instructions.

The EMG disposable sensors can be used to acquire the ECG in the clinic, but are not recommended for longer term studies as their adhesive surface area is considerably smaller than disposable ECG sensors, promoting half-cell disturbance artifact.

Typical ECG Amplifier Specifications:

Low internal noise ($< 2 \mu\text{V p-p}$).

High Input Impedance [$Z_{in} > 10 \text{ M}\Omega$].

Bandwidth (0.16–250 Hz).

Bandwidth cutoffs ($> 18 \text{ dB/octave}$).

Notch filter (60 Hz, in the United States).

Common mode rejection ratio [$\text{CMRR} > 10^7$].

Common mode input range ($\text{CMR} \pm 200 \text{ MV}$).

Static electricity shock protection ($> 2000 \text{ V}$).

Heart Rate Variability Instruments. The HRV instruments are computer implemented. They are also capable of performing RSA procedures using either ECG or PPG sensors to acquire HR.

Most HRV/RSA software is written for the Windows operating system. It is recommended that a fairly high performance computer be used to reduce HRV analysis computational time. A computer similar to that recommended for EEG is suitable.

Some instruments also support TMP and EDA in addition to the ECG, RSP, and PPG modalities.

One manufacturer offers a dual instrument interface making it possible for two computers to access one multimodality instrument, to perform simultaneous RSA/HRV, EEG, and other psychophysiological modality assessment and biofeedback procedures, with synchronized data collection. This instrument capability makes heart–mind interaction training and clinical research possible.

Heart Rate Variability Application. As with all biofeedback procedures establishing comfortable levels of temperature and humidity, with absence of transient auditory noise, is essential for focused, efficient, and reputable performance.

The Electromagnetic Interference (EMI) environment should meet the requirements of the most sensitive modality used (i.e., EEG).

Digitization of the ECG signal should be at least $256 \text{ s} \cdot \text{s}^{-1}$, with $512 \text{ s} \cdot \text{s}^{-1}$ recommended.

APPLIED CLINICAL EXAMPLES: TENSION AND MIGRAINE HEADACHE

We will now describe the typical EMG and hand surface temperature biofeedback procedures for tension and migraine headache, which we have used both clinically and in our research (3,6–8). As noted above, it is important to remember that when referring to EMG, the authors are alluding to surface electromyography, which uses noninvasive electrodes, is painless, and involves measuring the pattern of many motor action potentials; this is in contrast to EMG used as a diagnostic procedure in neurology, which uses invasive needle electrodes, measure the activity of a single motor unit, and is often quite painful.

The standard EMG biofeedback procedure for tension headache involves measuring the muscle tension in the frontalis muscle region by placing electrodes $\sim 2.5 \text{ cm}$ above each eyebrow and a ground electrode in the center of the forehead (9). The frontalis region has traditionally been assumed in clinical practice to be the best overall indicator of general muscular tension throughout the body. The standard thermal biofeedback training procedure involves attaching a sensitive temperature sensor, called a thermister, to a fingertip (usually the ventral surface of the index finger of the nondominant hand) with care taken not to create a tourniquet or inhibit circulation to this phalange.

EMG biofeedback is the modality most commonly used for tension headache, with the psychophysiological rationale being that muscle tension levels in the forehead, neck, and facial areas are directly causing or maintaining/exacerbating the headaches. It is also believed that individuals suffering from tension headache have high levels of stress and using EMG biofeedback as a general relaxation technique reduces their levels of stress, enabling tension headache sufferers to better cope with their headache activity.

Hand surface temperature biofeedback for migraine headache also has two possible mechanisms of action. The psychophysiological theory states that temperature biofeedback prevents the first of the two stages of migraine (vasoconstriction of the temporal artery and arterioles; the second stage is vasodilation, which causes the actual pain)

from occurring by decreasing sympathetic arousal and increasing vasodilation to the temporal artery and arterioles. An alternative mechanism of action is the use of temperature as a general relaxation technique.

The EMG or temperature signal is then electronically processed using transducers to provide the patient with information on changes in the electrical activity of the muscles or surface skin temperature on a moment by moment basis. Generally, the signals are sampled every one-tenth of a second and integrated over the entire second. Both are quite sensitive, with the EMG sensor generally detecting changes of magnitude as low as a hundredth of a microvolt. The temperature sensor typically detects changes as low as one-tenth of a degree Fahrenheit. Through this feedback, the patient undergoing EMG biofeedback training learns how to relax the musculature of the face and scalp, and also learns how to detect early symptoms of increased muscle tension. In temperature biofeedback, the patient is taught how to detect minute changes in peripheral skin temperature, with the training goal being to increase hand temperature rapidly upon detection of low hand temperature. For EMG biofeedback, the feedback signal is usually auditory, and may consist of a tone that varies in pitch, a series of clicks that vary in frequency, and so on. Given the choice, $>80\%$ of patients receiving thermal biofeedback choose the visual display. The feedback display can be the pen on a voltmeter, a numeric output of the actual surface skin temperature, or a changing graph on a video screen. The format of the visual feedback display does not seem to affect learning or treatment outcome (10).

Common Type of Feedback Schedules in Clinical Applications. One of the challenges faced by both the biofeedback clinician and patient is selecting what type of feedback is most appropriate to facilitate learning to achieve rapid therapeutic benefit. There has been little research in this area; however, there are abundant anecdotal reports among the biofeedback community. There are three types of feedback schedules in clinical practice. By far, the most widely used method for delivering feedback is an analog display, which provides continuous information to the patient. For example, a tone that varies in relative pitch and frequency depending on an increase or decrease in the response being measured. However, in many applications, this may provide too much information to the patient, leading to information processing overload, retarding the learning process. A second type of feedback schedule employed in clinical practice is a binary display, where the patient receives information that is discrete, depending on achievement of a predefined training threshold. In threshold training, the feedback is turned on or off depending on whether the patient falls above or below the threshold. Threshold training is a clinical application of an operant shaping procedure, where the patient is reinforced for achieving successively closer approximations to the training goal. The third type of feedback schedule is an aggregate display of the training progress. In this type of feedback, the patient is given summary information at the conclusion of the treatment session (e.g., data averaged over each min interval in a 20 min training session). In

clinical practice, the integrated display of aggregate feedback is the most commonly applied training schedule.

Training to Criterion. Training to criterion is a term used by clinicians that involves continuing biofeedback training until the patient achieves a specified criterion of a learning end state. For example, biofeedback training will persist until the tension headache patient has demonstrated reduced muscle tension levels in the frontalis region to a stable 1- μ V level. Although there is compelling logic behind this notion, there is little empirical data to support the practice of training to criterion. Exceptions to this are a report by Libo and Arnold (11) who found that every patient who achieved training criteria on both EMG and finger temperature also reported long-term improvement, and 73% of patients who did not improve failed to achieved training criterion in either modality. In another study, Blanchard et al. (12) presented data supporting the concept of training to criterion. They observed a discontinuity in outcome for migraine headache patients who achieve 35.6°C or higher at any point during temperature biofeedback training. Those who reached this level had a significantly higher likelihood of experiencing a clinically meaningful reduction in headache activity (at least 50%) than those who reached lower maximum levels. This apparent threshold was replicated in a subsequent study (13). More representative of the research is a recent study by Tsai et al. (14), where they found no evidence to support the concept of training to criterion in a study of hypertensives. Fifty-four stage I or stage II hypertensives were taught thermal, EMG, and respiratory sinus arrhythmia biofeedback. Most participants (76%) achieved the thermal criterion; only 33 and 41% achieved the EMG and respiratory sinus arrhythmia criterion, respectively. Achievement of the criterion level in any of the three modalities was not associated with a higher improvement rate. These results contradict the notion that training to criterion is associated with clinical improvement.

Electrode Placement. An important consideration to be made by the clinician utilizing EMG biofeedback is at what sites to place the electrodes. This decision depends in large part on which of the two general theories underlying the use of biofeedback the clinician adheres to. In most instances, electrode placements appear not to matter. However, for tension headache this may not be the case.

Although the vast majority of published reports on tension headache utilize the frontalis region electrode placement, there is some controversy about this practice. This is perhaps because the Task Force Report of the Biofeedback Society of America, in their influential position paper on tension headache (15), strongly implied that frontal placement was the "gold standard" for biofeedback with tension headache sufferers, making no mention of other site placements. In the standard placement, muscle activity is detected not only in the forehead, but probably also from the rest of the face, scalp, and neck, down to the clavicles (16).

Some writers (17,18) advocated attaching electrodes to other sites, such as the back of the neck or temporalis area, especially if the patient localizes his/her pain there. How-

ever, three of the four studies that compared biofeedback training from different sites between subjects found no advantage of one site over the other (19–21). Arena et al. (22) published the only systematic comparison of a trapezius (neck and shoulder region) versus frontal EMG biofeedback training regimen with tension headache sufferers. They found clinically significant (50% or greater) decreases in overall headache activity in 50% of subjects in the frontal biofeedback group versus 100% in the trapezius biofeedback group. The trapezius biofeedback group was more effective in obtaining significant clinical improvement than the frontal biofeedback group. Thus, there is some limited support for the use of an upper trapezius electrode placement with tension headache sufferers. More research needs to be done in this area.

Discrimination Training. A concept in clinical biofeedback applications that is quite often discussed, particularly among those practitioners of EMG biofeedback training, is that of discrimination training. In this procedure, patients are taught to discriminate high levels of muscle tension from moderate and low levels. Feedback is given contingent upon successful differentiation among these varying levels of muscle tension. For example, a patient is asked to produce maximal muscle tension in a particular region, and given feedback reflective of this high level of muscle activity, followed by instruction to halve this level and consequent feedback. Then, finally, they are asked to halve this again, that is produce one-quarter of the initial level of muscle activity, followed by appropriate feedback reflecting success at this level. To our knowledge, there is little reliable data demonstrating that individuals specifically taught a muscle discrimination training procedure have clinical outcomes superior to those taught a standard tension-reduction method.

Sensitivity–Gain. The gain or sensitivity of the feedback signal is important to facilitate the training process in clinical biofeedback. Too high a gain may interfere with learning by providing indiscriminate feedback for extraneous responding, leading to frustration on the part of the learner. In addition, in many response measures, too high a sensitivity leads to increased artifact. Conversely, setting the gain too low leads to lack of feedback for responses that may be clinically meaningful, thereby interfering with the learning process. In clinical practice, there are established ranges in various applications, depending on the response measure employed, individual differences in patient responsivity, and the nature of the disease state. Sensitivity may be adjusted as needed using a shaping procedure. Some response measures involve more frequent changes in gain settings than others. For example, gain is frequently adjusted in EMG biofeedback applications, because the goal often is detection of quite subtle muscular activity changes, but infrequently changed in hand surface temperature training, where gross changes in skin temperature are usually necessary for clinical improvement.

Session Length and Outline. Treatment sessions usually last 30–50 min; 15–40 min of each session is devoted to the actual feedback training. In our research (and in our

clinical work), we have typically used the following format for biofeedback training sessions:

1. Attachment of electrodes and initial adaptation: 10 min.
2. In-session baseline, during which patients are asked to sit quietly with their eyes closed: 5 min.
3. Self-control 1, during which patients are asked to attempt to decrease their forehead muscle tension levels in the absence of the feedback signal: 3 min.
4. Feedback training, with the feedback signal available: 20 min.
5. Self-control 2, during which patients are asked to continue to decrease their forehead muscle tension levels in the absence of the feedback signal: 3 min.

The two self-control conditions are included to determine whether generalization of the biofeedback response has occurred. Generalization involves preparing the patient to, or determining whether or not the patient can, carry the learning that may have occurred during the biofeedback session into the "real world". If the patient can decrease muscle tension without any feedback prior to the biofeedback condition (Self-control 1 condition), then the clinician can assume that between-session generalization has occurred. If the patient can decrease their muscle tension without any feedback following the biofeedback condition (Self-control 2 condition), then the clinician can assume that within-session generalization has occurred.

There are other methods clinicians use to train for generalization of the biofeedback response. For example, in an attempt to make the office biofeedback training simulate real world situations, many clinicians initially train patients on a recliner; then, once they have mastered the rudiments of biofeedback in this extremely comfortable chair, they progress to, respectively, a less comfortable office chair (with arms), an uncomfortable office chair (without arms), and, lastly, the standing position. Finally, giving the patient homework assignments to practice the biofeedback response in the real world is a routine way of preparing them for generalization.

BRIEF REVIEW OF CLINICAL OUTCOME LITERATURE FOR BIOFEEDBACK

Anxiety Disorders–Stress Reduction

Biofeedback as a general relaxation technique has been in existence since the late 1960s. Indeed, it is common practice to call any form of biofeedback "biofeedback assisted relaxation", stressing the stress-reduction quality of the procedure. Where diagnoses are given, it is usually generalized anxiety disorder, although mostly the research defines anxiety or stress by global self-report measures or a simple paper and pencil instrument such as the Spielberger State-Trait Anxiety Inventory (i.e., scoring in the ninetyieth percentile or above), rather than standard criteria such as the American Psychiatric Association's Diagnostic and Statistical Manual IV: revised (23). The primary

modalities used for anxiety and stress reduction are EMG, hand surface temperature, and EEG. Nearly all the research has demonstrated that biofeedback is superior to placebo and wait-list controls for the treatment of stress and anxiety. There is some data to suggest (24) that EEG biofeedback to increase alpha waves may be superior to forehead EMG biofeedback and EEG biofeedback to decrease alpha waves in terms of decreasing heart rate activity, but not in terms of decreasing self-reported anxiety levels, where there were no differences between the three groups. When biofeedback has been compared to relaxation therapy, there is no difference between the two treatments in terms of their clinical efficacy (25).

One typical study was that of Spence (26). He took 55 anxious subjects, and gave them either electrodermal response, hand surface temperature, or forehead EMG biofeedback based on a pretreatment psychophysiological assessment (subjects were given feedback corresponding to that physiological parameter that changed the most during stress). All groups reported significant reductions in their anxiety symptoms, and 15 months later 76% of subjects were still symptom-free for anxiety, regardless of the type of feedback they received.

Moore (27) reviewed the EEG biofeedback treatment of anxiety disorders and pointed out that there are many limitations in the research to date. Unfortunately, many of his concerns hold for the EMG and temperature biofeedback literature as well, such as comparisons to relevant placebos, examination of such factors as duration of treatment, type and severity of anxiety, and so on.

Tension and Vascular (Migraine And Combined Migraine–Tension) Headache

By a large margin, the greatest number of articles supporting the efficacy of biofeedback for any disorder in the clinical treatment literature pertains to its use with vascular and tension headache. For both types of headache, biofeedback has been shown to be superior to both pharmacological and psychological placebo, as well as wait list control, in numerous controlled outcome studies. Biofeedback for headache is usually compared to relaxation therapy or cognitive therapy (a form of psychotherapy focusing on changing an individual's pain-and stress-related self-statements and behaviors). Arena and Blanchard have recently reviewed the biofeedback treatment outcome literature on tension and vascular headache (3,7,8).

With tension headache, the biofeedback approach used is EMG (muscle tension) feedback from the forehead, neck, and/or shoulders. For relaxation therapy alone, successful tension headache treatment outcomes generally range from 40 to 55%, for EMG biofeedback alone, this value ranges from 50 to 60%, and for cognitive therapy, from 60 to 80%; when EMG biofeedback and relaxation are combined, the average number of treatment successes improves from ~50 to ~75%; when relaxation and cognitive therapy are combined, success increases from 40 to 65%. When compared to relaxation therapy, there is usually comparable efficacy.

For patients with pure migraine headache, hand surface temperature (or thermal) is the biofeedback modality of choice, and it leads to clinically significant improvement in

40–60% of patients. Cognitive therapy by itself gets ~50% success. A systematic course of relaxation training seems to help when added to thermal biofeedback (increasing success from ~40 to 55%), but cognitive therapy added to the thermal biofeedback and relaxation does not improve outcome on a group basis. Relaxation training alone achieves success in from 30 to 50% of patients, and adding thermal biofeedback boosts that success (from ~30 to 55%). There appears to be a trend in the literature for thermal biofeedback to be superior to relaxation therapy.

For patients with both kinds of primary benign headache disorders (migraine and tension type), the results with thermal biofeedback alone are a bit lower, averaging 30–45% success; relaxation training alone leads to 20–25% success. Thermal biofeedback consistently appears to be superior to relaxation therapy with combined headache. The best results come when thermal biofeedback and relaxation training are combined. With this combination treatment, results show 50–55% success rates (adding thermal biofeedback to relaxation raises success from 20 to 55%; adding relaxation therapy to thermal biofeedback increases success from 25 to 55%). Most experts strongly recommend a combination of the two treatments for these headache sufferers.

Lower Back Pain

Arena and Blanchard (7) recently reviewed the biofeedback literature for low back pain and concluded that biofeedback appears to hold promise as a clinically useful technique in the treatment of patients with back pain. While the evidence indicates that optimal clinical improvement is clearly obtained when biofeedback is used within the context of a comprehensive, multidisciplinary pain management program, the cumulative weight of the evidence suggest that EMG biofeedback is likely to be helpful, as a single therapy, in the treatment of musculoskeletal low back pain, obtaining success rates of from 35 to 68% improvement on follow-up.

However, there were many concerns about the literature. Only two studies have directly compared biofeedback to relaxation therapy, and both of these studies were significantly flawed so as to limit definitive conclusions. Direct comparisons of biofeedback to relaxation therapy are clearly needed. Longer (at least 1 year) and larger scale (at least 50/group) follow-up studies are required. Evaluations of treatments based on diagnosis (i.e., the cause of the pain) should be conducted. Comparisons of various biofeedback treatment procedures, such as paraspinal versus frontal electrode placement, or training while supine versus training while standing, are necessary. Finally, further evaluations of patient characteristics predictive of outcome, such as gender, race, chronicity, psychopathology, and psychophysiological reactivity, are needed.

Myofascial Pain Dysfunction

Myofascial pain dysfunction (MPD) syndrome, also known as temporomandibular joint (TMJ) syndrome, is considered a subtype of craniomandibular dysfunction that is caused by hyperactivity of the masticatory muscles. It is charac-

terized by diffuse pain in the muscles of mastication, mastication muscle tenderness, and joint sounds and limitations. Although disagreement exists as to the cause of the hyperactivity (e.g., occlusal problems vs. psychological stress), several researchers have examined the use of EMG biofeedback as a treatment, which can provide relief by teaching patients to relax the muscles of the jaw. Consistent with the logic of this approach, the most common electrode placement is on the masseter muscle, although frontal muscle placements have also been used. Excellent overviews of the treatment of MPD syndrome can be found (28,29).

Arena and Blanchard (7) recently reviewed the MPD biofeedback literature and noted that, although the majority of the studies had significant limitations, when taken as a whole they appeared to be quite impressive in support of the efficacy of EMG biofeedback for MPD syndrome. EMG biofeedback is at least as effective as traditional dental treatments such as occlusal splint therapy. Curiously, it was noted that no MPD syndrome study of biofeedback as a treatment in and of itself had been published since 1989. Given the extremely positive results, this observation is somewhat perplexing.

Deficiencies in the research on biofeedback treatment for MPD syndrome are similar to those discussed in the lower back pain section, above. Large scale outcome studies are needed, comparing (a) masseter versus frontal versus temporalis placement sites; (b) biofeedback versus relaxation; (c) biofeedback versus traditional dental strategies, and, (d) biofeedback in conjunction with other treatments versus traditional dental strategies. The latter approach has been used by Turk and co-workers (30–32), in a number of recent, methodologically elegant studies. In these studies various combinations of biofeedback, stress management training, and intraoral appliances were used, with results showing strong support for combined treatments. Finally, lack of long-term follow-ups, or for that matter, any follow-up at all, is a serious limitation that needs to be corrected.

Fibromyalgia

There have been a number of studies examining the efficacy of EMG biofeedback in the treatment of fibromyalgia (see Arena and Blanchard (5), for a review of the studies before 2000). The majority of the studies concluded that EMG biofeedback is useful in reducing fibromyalgic pain. Fibromyalgia is a type of nonarticular, noninflammatory rheumatism that is characterized by diffuse pain, sleep disturbance, tenderness, and functional impairment. Three studies have been published since 2000. Mueller et al. (33) gave 38 fibromyalgia patients EEG biofeedback, noted statistically significant decreases in pain, mental clarity, mood, and sleep. Van Santen et al. (34) compared physical fitness training to EMG biofeedback and usual treatment on 143 female patients with fibromyalgia. They found no difference between the three groups on any measure. Recently, Drexler et al. (35) broke 24 female fibromyalgia patients down into those with abnormal psychological test (MMPI) results and those with normal psychological test profiles. Psychologically abnormal

individuals were helped more by the biofeedback training than were psychologically normal individuals. Given the relatively promising results [all five of the pre-2000 studies (36–40) obtained positive results], it appears that large scale, controlled EMG biofeedback studies looking at factors such as psychological profiles and gender would now be appropriate.

Biofeedback for Gastrointestinal Disorders: Constipation Pain, Irritable Bowel Syndrome, Urinary, and Fecal Incontinence

The biofeedback literature on treatment of constipation pain, especially in children, is both impressive and growing. In adults, Jorge et al. (41) recently reviewed the literature and noted that, overall, mean percentage of success is 68.5% for studies that examine constipation attributable to paradoxical puborectalis syndrome. Mason et al. (42) examined 31 consecutive patients who received biofeedback training for idiopathic constipation. Twenty-two of the patients felt subjectively symptomatically improved. They noted that the symptomatic improvement produced by biofeedback in constipated patients was associated with improved psychological state and quality of life factors.

In the constipation pain literature regarding children, three studies particularly stand out. Benninga et al. (43) gave 29 children who suffered from constipation and encopresis an average of five sessions of EMG biofeedback of the external anal sphincter. At 6 weeks, 55% were symptom free. Another group of investigators (44) placed 13 children who suffered from constipation into a standard medical care group, while another group of 13 children were placed in a EMG biofeedback (of the external anal sphincter—from 1 to 6 sessions) plus standard medical care group. At 16 month follow-up, all children were significantly improved, with the biofeedback plus standard medical care group significantly more improved than the standard medical care only group.

One large scale study, however, does not support the efficacy of EMG biofeedback for constipation pain. In a procedure similar to Cox et al. (44), van der Plas et al. (45) placed 94 children who suffered from constipation into a standard medical care group, while another group of 98 children were placed in a five-session EMG biofeedback (of the external anal sphincter) plus standard medical care group. At 18 month follow-up, over one-half of the children in both groups were significantly improved, with no significant difference between the two groups. In spite of this large scale study suggesting no advantage to the inclusion of EMG biofeedback to conventional medical care, we believe that there is sufficient evidence to conclude that EMG biofeedback is a useful technique in treating the pain of both adult and childhood constipation, especially when the patient has proven refractory to standard medical care.

Biofeedback for irritable bowel syndrome has been in existence since 1972, but nearly all of the studies are small and uncontrolled. The type of feedback is generally thermal biofeedback, however, two groups have used novel feedback approaches with some success. Leahy et al. (46) have developed an electrodermal response biofeedback device

that uses a computer biofeedback game based on animated gut imagery. This significantly reduced symptoms in 50% of 40 irritable bowel syndrome patients. Radnitz and Blanchard (47), using an electronic stethoscope placed on subjects' abdomens, gave bowel sound biofeedback to five individuals with irritable bowel syndrome. Three of the five patients had reductions in their chronic diarrhea by over 50% (54, 94, and 100%). Results were maintained at 1- and 2-year follow-up (48). Large scale controlled outcome studies comparing biofeedback to pharmacological and dietary interventions for irritable bowel syndrome symptoms need to be conducted.

Biofeedback For Cancer Chemotherapy Effects

Biofeedback has been used to decrease the negative side effects of cancer chemotherapy, especially the anticipatory nausea. While biofeedback assisted relaxation does seem to help these patients, biofeedback by itself (i.e., not using a relaxation emphasis), while reducing physiological arousal, does not reduce the anticipatory nausea. This is an area where relaxation therapy seems to have a clear advantage over biofeedback. For example, Burish and Jenkins (49) randomly assigned 81 cancer chemotherapy patients to one of six groups in a 3 (EMG biofeedback/skin temperature biofeedback/no biofeedback) × 2 (relaxation/no relaxation) factorial design. They concluded, "The findings suggest that relaxation training can be effective in reducing the adverse consequences of chemotherapy and that the positive effects found for biofeedback in prior research were due to the relaxation training that was given with the biofeedback, not the biofeedback alone" (p. 17).

Biofeedback for Cardiovascular Reactivity: Hypertension, Raynaud's Disease, and Cardiac Arrhythmia

Biofeedback has been used as a treatment for essential hypertension since the late 1960s. The type of feedback used is either direct blood pressure feedback or temperature biofeedback. There appears to be no difference in terms of clinical outcomes between the two biofeedback modalities. In a recent influential meta-analysis of 22 randomized controlled outcome studies, Nakao et al. (50) found that biofeedback resulted in averaged blood pressure decreases of 7.3/5.8 mmHg (0.97/0.77 kPa) compared to clinical visits or nonintervention controls. It resulted in averaged blood pressure decreases of 4.9/3.5 mmHg (0.65/0.46 kPa) compared to sham or nonspecific behavioral interventions. Statistical analysis indicated that, after controlling for the effects of initial blood pressures, biofeedback decreased blood pressure more than nonintervention controls, but not more than sham or nonspecific behavioral interventions. Further analyses revealed that when the treatments were broken down into two types, biofeedback assisted relaxation, as opposed to simple biofeedback that did not offer other relaxation procedures, was superior to sham or nonspecific behavioral intervention. Nakao et al. (50) concluded that, "Further studies will be needed to determine whether biofeedback itself has an antihypertensive effect beyond the general relaxation response" (p. 37).

It has long been believed that temperature biofeedback is more efficacious than medication in the treatment of Raynaud's disease (51,52). Raynaud's disease is a disease of the peripheral circulatory system that is caused by insufficient blood supply to the hands and feet. It can result in cyanosis, numbness, pain, and, in extreme cases, gangrene and subsequent amputation of the affected finger or toe. The vasospastic attacks are triggered by cold and, to a lesser extent, anxiety and stress. Recent data, however, has failed to transparently support the belief that temperature biofeedback is a more effective treatment than medication for Raynaud's disease.

The Raynaud's treatment study (53) was a large, multicenter randomized controlled trial comparing sustained relief nifedipine, pill placebo, temperature biofeedback, and EMG biofeedback (a behavioral control) on 313 individuals diagnosed with primary Raynaud's disease. Results indicated that while nifedipine was significantly different from medication placebo in reducing vasospastic attacks, temperature biofeedback was not significantly different from psychological placebo (EMG biofeedback) in reducing vasospastic attacks. Comparison of nifedipine and temperature biofeedback indicated a nonsignificant ($p=0.08$) trend for the nifedipine to result in greater reductions in vasospastic attacks. However, 15% of the nifedipine group had to discontinue the treatment due to adverse reactions to the medication. The interpretation of the biofeedback results of the Raynaud's treatment study, however, have been criticized by the behavioral investigators of the project (54). They note that a substantial proportion of subjects in the temperature group (65%) did not achieve learning, compared to only 33% in a normal comparison group who achieved successful learning by the end of the 10 biofeedback sessions in the protocol.

EEG Biofeedback (Neurofeedback)

Ramirez et al. (55) exhaustively reviewed the scientific literature on EEG biofeedback treatment of Attention Deficit Disorder (ADD). These authors conclude that, as in many other areas of clinical biofeedback practice, the positive evidence from anecdotal sources and case reports is plentiful, but a dearth of rigorous studies does not allow firm inferences to be drawn about the therapeutic efficacy of enhanced alpha wave activity and hemispheric lateralized biofeedback training. The EEG biofeedback training with a combined training goal of modifying the pattern of theta and beta wave activity has shown promising implications for management of ADD in adults. Studies using the theta/beta training paradigm have reported significant improvement in academic, intellectual, and adaptive behavioral functioning following EEG treatment. Other studies using sensorimotor rhythm training (recording from the "Rolandic" cortex) have produced behavioral and cognitive improvements in ADD patients. Unfortunately, these studies like those in other therapeutic areas of biofeedback are plagued with methodological problems including small sample sizes, absent or inadequate placebo controls, no randomization to treatment conditions, and insufficient follow-up of patient status. However, some authors of recent nonrandomized studies contend that EEG biofeed-

back shows promising evidence of therapeutic efficacy on the core symptoms of childhood ADHD in comparison to or in combination with standard stimulant medication therapy, family counseling, and an individualized educational intervention (56).

Another clinical problem in which EEG biofeedback was tested in the early 1970s was for control of frequent and disabling seizures. These studies have been reviewed by Lubar (57). The most common types of EEG recording and feedback training successfully studied in human subjects are EEG alpha rhythm (8–13 Hz) recorded from the occipital region of the brain, theta activity (4–7 Hz), and beta activity (>14 Hz). With the introduction over the recent decades of effective and relatively safe antiepileptic drugs, interest in systematic research and clinical application of EEG biofeedback as a nonmedication method of seizure control has waned. However, intractable seizures are still encountered in routine clinical practice despite all pharmacotherapeutic efforts. Implantable stimulatory devices and surgical interventions are reserved for highly selected patients and carry significant risks. For those patients with uncontrolled seizure disorder who have been unresponsive to standard anticonvulsant medication regimens and/or are not candidates for surgical treatment, Lubar has advocated that they be considered for a trial of sensorimotor rhythm EEG biofeedback training for the most common types of psychomotor seizures (57). Note that the equipment is expensive and the training procedures are complex and time consuming, and thus practitioners familiar with EEG biofeedback treatment of epilepsy may be difficult to find.

Quantitative EEG recording and specialized biofeedback training protocols have been developed and tested in the treatment of addictive disorders such as alcoholism. Peniston et al. (58) studied a protocol for enhancing EEG alpha and theta wave activity, and improving "synchrony" among the brain wave rhythms along the power spectrum. Peniston et al. (58) propose that alcoholics have a predisposition to "brain wave desynchrony" and deficient alpha activity and show a vulnerability to alcohol's capacity to produce reinforcing (pleasant and relaxing) levels of slow brain wave activity. These investigators have evaluated the treatment in a series of studies suggesting that their neurotherapy protocol reduces subjective craving among severe alcohol abusers, improves psychological functioning on personality measures, increases alpha and theta activity levels, increases beta-endorphin levels, and increases time to relapse. However, a large, independent randomized controlled trial of Neurotherapy did not show the incremental benefit to relapse prevention of adding electronic neurotherapy to a traditional residential treatment program for severe, chronic alcoholics (59). Although widely practiced, the clinical utility and theoretical rationale of EEG biofeedback in treating alcohol abusers remains controversial among the scientific biofeedback community. While promising data exists to suggest the potential role of EEG biofeedback in substance abuse treatment, further research is needed to illuminate the conceptual basis of such treatment and the reliability of clinical improvements for alcoholism and other addictive disorders.

There are very limited data from controlled studies on the use of EEG biofeedback for control of symptoms associated with Tourette syndrome, a behavioral impulse control disorder characterized by a constellation of motor and vocal tics (involuntary behaviors). A few scattered case reports describe positive results using a course of EEG sensorimotor rhythm biofeedback training to treat complex motor tics and associated attention deficit symptoms (60). There may be overlap in this treatment approach with the observation that epilepsy cases with motor involvement show some remediation following sensorimotor EEG biofeedback training. There is speculation and anecdotal reports to suggest that anxiety, depression, and attentional symptoms associated with complex tics in Tourette's may be the most responsive targets for psychophysiological treatment. Because of the multiple symptom clusters of Tourette's, and the likelihood that different treatment protocols are needed to address the range of affected behaviors, focusing treatment on the whole condition is difficult, and often a prioritization of the most severe problems must occur to serve as the focus of clinical attention. Most patients are managed on a medication regimen by their physicians and EEG biofeedback is seen a useful adjunct in selected cases that have not responded adequately to pharmacologic management alone or where medication usage is to be reduced for some reason.

Cardiovascular Reactivity

Heart rate variability (HRV) biofeedback is being studied as a psychophysiological means of managing heart problems such as cardiac arrhythmia. Earlier isolated attempts at biofeedback interventions with cardiovascular ailments using simpler unitary heart rate (beats/min) or blood pressure (mmHg) measures have not been remarkably successful on modifying disease states. Heart rate variability is derived from the standard deviation of the beat-to-beat time interval (in ms) recorded in the laboratory with an ECG machine or with a Holter monitor using 24 h ambulatory monitoring methods. Heart rate variability has been proposed as a more robust metric of overall cardiac health in that it provides an indirect marker of the heart's ability to respond to normal regulatory impulses that affect its rhythm. With higher levels of HRV, it is proposed that there is a better balance between the combined sympathetic and parasympathetic inputs to the heart. Generally, greater HRV is associated with relaxed states and slow or regular breathing pattern. The HRV biofeedback training is claimed to offer a more precise method for helping clients to moderate the heightened sympathetic activity that is associated with elevated stress, anxiety, and dysphoric mood. Relatively greater levels of heart rate variability have been associated with better heart health. Biofeedback of breathing rate and depth is also used to increase respiratory sinus arrhythmia, which may be connected to therapeutic increases in HRV. A few small-scale studies have been conducted that show the clinical potential of HRV biofeedback in cardiovascular diseases (61); however, the results are inconsistent, and methodological problems abound with the

existing studies. As yet, there is little evidence from larger scale randomized controlled trials conducted at independent laboratories demonstrating the therapeutic efficacy of HRV biofeedback in specific cardiovascular disease states such as cardiac arrhythmia.

Incontinence: Urinary and Fecal

EMG biofeedback training of the bladder-urinary sphincter and pelvic floor musculature has been found to be an efficacious intervention for urge urinary incontinence, especially among female geriatric populations, and is usually related to destrusor muscle contraction instability or reduced bladder volume (62). Some form of Kegel exercises are often used to train the muscles of the pelvic floor that are in continuity with the external urethral sphincter. Biofeedback with behavior modification training of the anorectal-anal sphincter musculature along the pelvic floor has been reported to be successful in treatment of fecal incontinence of various etiologies (63). Small, insertable EMG sensors are usually used in current treatment protocols for urinary incontinence in female patients and for fecal incontinence. A second EMG channel with abdominal placement is often recommended to better isolate contraction of the pelvic muscles from activity of accessory muscle of the legs, buttocks, and abdomen during the training exercises. Some degree of voluntary contractibility of sphincter muscles and rectal sensitivity are necessary for successful biofeedback treatment. While biofeedback training for urinary incontinence has a longer history of usage, and thus a larger empirical base (64), there is considerable evidence to suggest the efficacy of EMG biofeedback in a majority of adult patients with fecal incontinence (65). Unfortunately, there was a great deal of variability in biofeedback instrumentation used among these studies, treatment protocols followed, and outcome measures with uncertain validity.

Stroke and Mild Traumatic Brain Injury

There is very limited research in the area of EEG biofeedback in treatment and rehabilitation of the neurological impairments resulting from stroke or closed head injury. There are a number of anecdotal reports and small case series that suggest a place for quantitative EEG analysis in the functional assessment of neurological symptoms secondary to stroke and head injury. A highly individualized QEEG protocol used in these studies is sometimes called EEG entrainment feedback recording from the surface of brain regions suspected to be pathologically involved in the functional impairments (66,67). Neuro-muscular reeducation is a general term used to describe assessment and treatment methods that may include EMG biofeedback and are applied to helping neurologically impaired patients (such as poststroke patients) with regaining gross motor functions necessary for carrying out activities of daily living and ambulation. In a meta-analysis of controlled trials using EMG biofeedback for neuromuscular reeducation in hemiplegic stroke patients, the authors concluded that EMG biofeedback resulted

in significant functional gains (68). While these results are promising, the specific effects of EMG biofeedback in stroke rehabilitation remain unclear as some of the studies reviewed included other interventions such as physical therapy or gait training as part of the rehabilitation program.

Sexual Dysfunction

Surface EMG biofeedback of targeted abnormalities in pelvic floor musculature are implicated in the pathogenesis of vulvovaginal pain (vulvodynia) syndromes such as dyspareunia resulting from vulvar vestibulitis. These have been successfully used in the stabilization of pelvic floor muscles leading to 83% reduction of pain symptoms, improved sexual function, and psychological adjustment at 6-month follow-up (69). As in other EMG biofeedback protocols for assessment and modification of abnormal pelvic floor musculature, an individualized assessment is performed to identify the patient's specific neuromuscular abnormality, with subsequent biofeedback training designed to modify the muscle tension and contractile weakness of the target muscles. However, gynecological surgery (vestibulectomy), on average, appears to produce superior outcomes (70).

FUTURE DIRECTIONS OF BIOFEEDBACK THERAPY

There are five areas that biofeedback research and clinical work are heading or should focus on. They are (1) expanding upon and refining current research; (2) applications of biofeedback and psychophysiological assessment to the "real world" environment (i.e., ambulatory monitoring); (3) applications of biofeedback training to new populations; (4) applications of biofeedback to applications of biofeedback to the primary care setting; (5) alternative methods of treatment delivery.

1. **Expanding Upon and Refining Current Research.** Although biofeedback is considered a mature treatment, there are surprisingly many basic areas that need to be explored further. Such basic questions as (a) whether massed versus distributed practice produces greater physiological learning, (b) whether the presence or absence of the therapist in the room retards or enhances the acquisition of the biofeedback response, (c) the usefulness of coaching, (d) is there any value in training to criterion, (e) whether group biofeedback enhances or retards psychophysiological learning or clinical affects clinical outcome, have not been satisfactorily answered. Moreover, with the notable exception of headache, nearly every area is missing large scale treatment outcome studies (i.e., 25 or greater subjects per condition), in which biofeedback treatment is compared to placebo, another psychological treatment, conventional medical treatment, and so on. Many studies fail to describe the instrumentation and biofeedback procedures sufficiently to allow replication of the research. Often diagnostic criteria are not given, or diagnoses

are commingled (e.g., conduct disorder children with attention deficit disorder children, or generalized anxiety disorder with simple phobias). Such failures to answer basic research questions or to conduct research in a scientifically acceptable manner are troubling and need to be corrected.

2. **Applications of Biofeedback and Psychophysiological Assessment To the "Real World" Environment** (i.e., ambulatory monitoring). Biofeedback clinicians have attempted to use their psychophysiological monitoring equipment to assist in setting treatment goals and to further explore the relationship between the mechanism of action believed to be involved in the underlying pathology of the disorder in question. For example, many clinicians use ambulatory blood pressure monitors to determine when their hypertensive patients are most reactive (work, driving, etc.) and tailor exercises to be maximized around those situations of elevated blood pressures. Use of such ambulatory equipment for other responses such as EMG, hand temperature, and respiration would be quite useful and such studies need to be performed.

There have been only a few studies examining the relationship between ambulatory monitoring in the naturalistic environment and the presumed pathological response underlying the disease, with the exception of bruxism and temporomandibular joint dysfunction, where measurement in the natural environment by telemetry, portable tape recording, and digital EMG integration have been reported (71). Unfortunately, with those exceptions, when such studies have been conducted, they have arrived at negative findings, quite possibly due to the difficulty in reducing the data and inability to control all the relevant variables (sleep is a relatively controlled environment). For example, Hatch et al. (72) had 12 tension headache subjects and nine nonheadache controls wear a computer-controlled EMG activity recorder in their natural environment for 48–96 consecutive hours. The EMG activity of the posterior neck or frontal muscles was recorded 24 h/day. During waking hours, subjects rated their perceived levels of stress, pain, and negative affect at 30-min intervals. The EMG activity of headache and control subjects did not differ significantly, and EMG activity did not covary with stress, pain, or negative affect. Cross-correlations among EMG activity, pain, and stress revealed little evidence of leading, contemporaneous, or lagging relationships. Interrupted time series analysis showed no consistent muscle hyperactivity during a headache attack compared to a headache-free baseline period.

Arena and co-workers designed a portable activity monitor for simultaneously recording and quantifying surface EMG signals and body movements in the natural environment (73). Two independent channels record EMG activity from symmetric muscle groups to determine contraction patterns. The EMG signals are amplified, filtered, integrated for 1 s, and converted to a digital value. Full scale was

jumper selected to accommodate a wide range of muscle activity. Electrode resistance >20 k Ω generates an alarm to signal poor contact or lead-off condition. The EMG voltages less than a preset threshold are not integrated.

The movement sensors are electrolytic potentiometers whose output are proportional to angular position and linear acceleration. The outputs are differentiated and summed to obtain angular acceleration with minimal response to linear movement. The peak value and 1 s integral are converted to digital values.

Subjective evaluation of pain and activity may be annotated by a 16-button keypad. An hourly auditory alarm reminds the user to enter subjective evaluations.

Data is saved in static random-access memory in binary coded 3-byte words. Power is supplied by a 9 V alkaline battery and converted to ± 5 V by switching regulators. At the end of 18 h of recording, all power is turned off except for standby power to memory. A low-battery condition will also switch power to the standby mode. Data retained in the standby mode is valid for at least 7 days.

Arena et al. demonstrated that the device is highly reliable in 26 healthy controls (74). They then had 18 tension-type headache subjects and 26 control subjects wear the device attached to the bilateral upper trapezius muscles for 5 consecutive days for up to 18 h a day (75). During waking hours, subjects rated their perceived levels of stress, pain, and physical activity at 60-min intervals. Similar to Hatch, the EMG activity of headache and control subjects did not differ significantly, and EMG activity did not covary with stress, pain, or physical activity levels. Examination of cross-correlations among EMG activity, pain, physical activity, and stress revealed little evidence of an isomorphic, precursor or consequence relationship. There were no consistent differences between a headache and nonheadache state on muscle activity levels.

Arena et al. (75) concluded that there were so many variables entering into the natural environment, that use of such devices required a sophistication not available to the average clinician or researcher, and that treating headache patients nomothetically as an aggregate, rather than idiographically, as individuals, may also present difficulties. For example, some individuals may lie down as soon as a headache begins, while others may continue with their daily routine. Other individuals may have consequence, precursor, or isomorphic relationships between their head pain, except the changes occur on an every 5 min basis rather than a 1 h basis. With still others, to identify a relationship 5 consecutive days is not enough. Given the fact that the technology has increased exponentially to allow much more sophisticated data reduction and statistical analysis, we feel that the time is now ripe for a renaissance in such an area of research, which has been dormant for nearly a decade.

3. Applications of Biofeedback Training to Other Populations. As biofeedback is considered to be an estab-

lished field, investigators have begun to take the treatments and expand it to other, similar clinical problems. For example, in the field of headache, biofeedback has been shown to be effective with the elderly, children, and pregnant women (6). Areas that need to be explored further to determine whether biofeedback treatment effects can be generalized are headaches in depressed individuals, headaches in individuals following cerebral aneurysm, headaches due to eyestrain, posttraumatic headache, and headache in multiple sclerosis patients. Similarly, the anxiety disorders literature needs to be expanded to include children, the elderly, anxiety due to a medical condition, and so on.

4. Application in Primary Care Medical Settings. Because of the growing recognition of the high prevalence of psychosomatic and psychophysiological disorders that present in primary care settings, the increased availability and implementation of psychophysiological assessment and biofeedback interventions in these healthcare settings appears to be timely (76). Many behavioral medicine interventions including biofeedback may be more efficiently and effectively delivered in these primary practice settings as the focus of these interventions is often toward the goals of preventing or slowing disease progression rather than treating severe or complicated problems that are well established. This approach is in contrast to conventional practice where patients with complicated medical problems or cooccurring psychological symptoms are referred out to specialty behavioral medicine clinics or other specialists (e.g., physical therapists) for psychophysiological treatment. As many chronic health problems are progressive in nature, by the time referral is made, the patient's condition is likely to have worsened to the point where behavioral intervention including biofeedback training may have far less impact than had it been instituted earlier in the disease course.

However, for biofeedback to be successfully integrated into the busy primary care office practice setting, certain modifications will have to be made in the context of assessment protocol and treatment delivery. First, behavioral assessment will have to be brief, but informative and practical, yielding results that are helpful to the primary care team in managing the patient's medical problems. The assessment results will have to be readily incorporated into the medical record of the patient rather than assigned privileged status, as mental health records frequently are, and therefore accessible to few if any providers for reference in primary care delivery. Second, the psychophysiology assessment and biofeedback treatment program will have to be carefully standardized and mid-level providers such as nurses, physician assistants, psychology technicians, or other mental health therapists trained in the competent and efficient delivery of these services. A doctoral level psychologist on staff or

consulting from another facility should be available to supervise these services to monitor quality and assess outcomes. Third, the rapid advancement of biofeedback equipment in terms of measurement accuracy, increased reliability with precision electronics, lowered cost, much improved portability through miniaturization, and enhanced patient convenience with alternative sensor technology has enabled the possibility of almost entirely home-based, self-administered treatment. Instruction and support can be provided by nursing staff, consultant psychologist, or other health professional through less frequent office visits and telephone consultation as needed. Arena and Blanchard have recently outlined in greater detail steps one should take to apply behavioral medicine techniques such as biofeedback to the treatment of headaches in the primary care setting (3).

5. Alternative Methods of Treatment Delivery. The availability of relatively low cost, high precision biofeedback training devices lends itself to the possibility of a limited-therapist-contact, largely home-based treatment regimen. Blanchard and co-workers published three separate studies (77–79) evaluating a treatment regimen of three sessions (>2 months) combining thermal biofeedback and progressive relaxation training. In all three instances, very positive results were found for this attenuated form of treatment. Similar results were reported by Tobin et al. (80).

We believe that some limited therapist contact is often necessary, so that patients understand the rationale for the treatment and that problems (trying too hard, thermistor misplacement, etc.) can be caught and corrected early. We also believe that detailed manuals to guide the home training, and telephone consultation to troubleshoot problems, are crucial in this approach. Given the national push for improving the efficiency of treatments, this approach has much to recommend it. We should also note that this home-based approach was not as successful as office-based treatment of essential hypertension with thermal biofeedback (81).

This limited therapist contact does not have to be face-to-face with the therapist, however. It can be conducted via the Internet or using a videoconferencing telemedicine application. Devineni and Blanchard (under review 82) conducted a randomized controlled study of an Internet-delivered behavioral regimen composed of progressive relaxation, limited biofeedback with autogenic training, and stress management in comparison to a symptom monitoring waitlist control. Thirty-nine percent of treated individuals showed clinically significant improvement on self-report measures of headache symptoms at post-treatment. At 2-month follow-up, 47% of participants maintained improvement. There was a 35% within-group reduction of medication usage among the treated subjects. The Internet program was noticeably more time cost-efficient than traditional clinical

treatment. Treatment and follow-up dropout rates, 38.1 and 64.8%, respectively, were typical of behavioral self-help studies.

Arena et al. (83) recently reported a small ($n = 4$) uncontrolled study investigating the feasibility of an Internet and/or telemedicine delivery modality for relaxation therapy and thermal biofeedback for vascular headache. Each subject was over the age of 50 and had suffered from headaches for >20 years. Subjects came into the clinic for treatment but never saw the therapist in person. Instead, all treatment was conducted through the use of computer terminals and monitors. The only difference between this treatment and office-based treatment was the physical presence of the therapist. Results indicated one of the subjects was a treatment success (>50% headache improvement, and two others had between 25 and 50% improvements. Thus, it seems that further exploration into the potential of telemedicine and internet delivery of psychophysiological interventions is warranted.

In summary, an attempt has been made to review the basic theories underlying the application of biofeedback training to the amelioration of a broad range of general medical and psychiatric disorders. Also covered are the main types of biofeedback systems, technical specifications of instrumentation, and engineering design considerations for major functional components of biofeedback apparatus. A sampling of the many clinical problem areas in which psychophysiological assessment technology and biofeedback instrumentation have been utilized with varying degrees of success is discussed. This coverage of instrumentation is not exhaustive. Given the rich basic science underpinnings of biofeedback and the wide appeal among both health professionals and the general public, this coverage was by necessity selective and opportunistic. Throughout this article are found references to key resources of primary literature and authoritative reviews of the biofeedback field. This technological area is one of the most promising of both professional psychology practice and consumer oriented general healthcare. The field of biofeedback is far from matured, with medical application of basic research finding beginning only ~30 years ago. The field is probably in its second generation with a more rigorous examination of its scientific underpinnings, casting aside unproven or implausible theories related to disease process and treatment efficacy, and development of a sound empirical basis for its assessment methods and interventions. We are witnessing the continued rapid advancement of microcomputer technology and digital electronics coupled with the accumulation of knowledge of the basic mechanisms involved in human health and disease. There is a great potential for an evolution of biofeedback from its early origins with focus on nonpathological states and development of body awareness, human potential, and wellness to a more refined and sophisticated understanding and application of techniques toward the maintenance of health and prevention of disease states that is seamlessly integrated into the individual's lifestyle.

BIOHEAT TRANSFER

JONATHAN W. VALVANO
The University of Texas
Austin, Texas

INTRODUCTION

Bioheat transfer is the study of the transport of thermal energy in living systems. Because biochemical processes are temperature dependent, heat transfer plays a major role in living systems. Also, because the mass transport of blood through tissue causes a consequent thermal energy transfer, bioheat transfer methods are applicable for diagnostic and therapeutic applications involving either mass or heat transfer. This article presents the characteristics of

Figure 1. Countercurrent blood vessels have arterial blood flowing in the opposite direction as venous blood.

bioheat transfer that distinguish it from nonliving systems, including the effects of blood perfusion on temperature distribution, coupling with biochemical processes, therapeutic and injury processes, and thermoregulation.

The study of bioheat transfer involves phenomena that are not found in systems that are not alive. For example, blood perfusion is considered a three-dimensional (3D) process as fluid traverses in a volumetric manner through tissues and organs via a complex network of branching vessels. Heat transfer is affected by vessel geometry, local blood flow rates, and thermal capacity of the blood (1). One factor that makes modeling blood perfusion difficult is the complex network of pairs of arteries and veins with countercurrent flow (2), as shown in Fig. 1. Arterial and venous blood temperatures may be different, and it is possible that neither is equal to the local tissue temperature. These temperatures may vary as a function of many transient physiological and physical parameters. The regulation of temperature and blood flow is quite nonlinear and has presented a major challenge to understand and model. Nevertheless, these critical processes must be accounted for in the design of many types of systems that interface with humans and animals.

Many scientists view life from either the macroscopic (systems) or the microscopic (cellular) level, but in reality one must be aware that life processes exist continuously throughout the spectrum. In order to better understand life processes at the molecular level, a significant research effort is underway associated with molecular biology. Because temperature and blood flow are critical factors, bioengineers are collaborating with molecular biologists to understand and manipulate the molecular and biochemical processes that constitute the basis of life. Research has found that the rates of nearly all physiological functions are altered 6–10%/°C (3). Similarly, heat can be added or removed during therapeutic or diagnostic procedures to produce or measure a targeted effect, based on the fact that a change in local temperature will have a large effect on rates of biochemical process rates. Thus, the measurement and control of temperature in living tissues is of great value in both the assessment of normal physiological function and the treatment of pathological states.

The study of the effects of temperature alterations on biochemical rate processes has been divided into three broad categories: hyperthermia (increased temperature), hypothermia (decreased temperature), and cryobiology

(subfreezing temperature). An extensive review of these domains has been published (4), to which the reader is referred for further details and bibliography.

Effects of Blood Perfusion on Heat Transfer

Blood perfusion through the vascular network and the local temperature distribution are interdependent. Many environmental (e.g., heat stress and hypothermia), pathophysiological (e.g., inflammation and cancer), therapeutic (e.g., heating-cooling pads) situations create a significant temperature difference between the blood and the tissue through which it flows. The temperature difference causes convective heat transport to occur, altering the temperatures of both the blood and the tissue. Perfusion-based heat transfer interaction is critical to a number of physiological processes, such as thermoregulation and inflammation.

The convective heat transfer depends on the rate of perfusion and the vascular anatomy, which vary widely among the different tissues, organs of the body, and pathology. Diller et al. published an extensive compilation of perfusion data for many tissues and organs and for many species (5). Charney reviewed the literature on mathematical modeling of the influence of blood perfusion on bioheat transfer phenomena (6).

The rate of perfusion of blood through different tissues and organs varies over the time course of a normal day's activities, depending on factors, such as physical activity, physiological stimulus, and environmental conditions. Further, many disease processes are characterized by alterations in blood perfusion, and some therapeutic interventions result in either an increase or decrease in blood flow in a target tissue. For these reasons, it is very useful in a clinical context to know what the absolute level of blood perfusion is within a given tissue. Many thermal techniques have been developed that directly measure heat flux to predict blood perfusion by exploiting the coupling between vascular perfusion and local tissue temperature using inverse mathematical solutions.

In 1948, Pennes (7) published the seminal work describing the mathematical coupling between the mass transfer of blood perfusion and the thermal heat transfer. His work consisted of a series of experiments to measure temperature distribution as a function of radial position in the forearms of nine human subjects. A butt-junction thermocouple was passed completely through the arm via a needle inserted as a temporary track, with the two leads exiting on opposite sides of the arm. The subjects were unanesthetized so as to avoid the effects of anesthesia on blood perfusion. Following a period of normalization, the thermocouple was scanned transversely across the mediolateral axis to measure the temperature as a function of radial position within the interior of the arm. The environment in the experimental suite was kept thermally neutral during experiments. Pennes' data showed a temperature difference of 3–4° between the skin and the interior of the arm, which he attributed to the effects of metabolic heat generation and heat transfer with arterial blood perfused through the microvasculature.

Pennes proposed a model to describe the effects of metabolism and blood perfusion on the energy balance

within tissue. These two effects were incorporated into the standard thermal diffusion equation, which is written in its simplified form as

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot k \nabla T + \rho_{bl} c_{bl} w (T_a - T) + Q_{met} \quad (1)$$

Metabolic heat generation, Q_{met} , is assumed to be homogeneously distributed throughout the tissue of interest as rate of energy deposition per unit volume. It is assumed that the blood perfusion effect is homogeneous and isotropic, and that thermal equilibration occurs in the microcirculatory capillary bed. In this scenario, blood enters capillaries at the temperature of arterial blood, T_a , where heat exchange occurs to bring the temperature to that of the surrounding tissue, T . There is assumed to be no energy transfer either before or after the blood passes through the capillaries, so that the temperature at which it enters the venous circulation is that of the local tissue. The total energy exchange between blood and tissue is directly proportional to the density, ρ_{bl} , specific heat, c_{bl} , and perfusion rate, w , of blood through the tissue. The basic principle that couples mass transfer to heat transfer is the change in sensible energy caused by the moving blood. The units of perfusion in equation 1 are volume of blood per volume of tissue per time (s^{-1}). This thermal transport model is analogous to the process of mass transport between blood and tissue, which is confined primarily to the capillary bed.

A major advantage of the Pennes model is that the added term to account for perfusion heat transfer is linear in temperature, which facilitates the solution of Eq. 1. Since the publication of this work, the Pennes model has been adapted by many researchers for the analysis of a variety of bioheat transfer phenomena. These applications vary in physiological complexity from a simple homogeneous volume of tissue to thermal regulation of the entire human body (8,9). As more scientists have evaluated the Pennes model for application in specific physiological systems, it has become increasingly clear that many of the assumptions to the model are not valid. For example, it is now well established that the significant heat transfer due to blood flow occurs in the terminal arterioles (vessels 60–300 μm in diameter) (10–17). Thermal equilibration is essentially complete for vessels $< 60 \mu\text{m}$ (precapillaries and capillaries). Therefore, no significant heat transfer occurs in the capillary bed; the exchange of heat occurs in the larger components of the vascular tree. The vascular morphology varies considerably among the various organs of the body, which contributes to the need for specific models for the thermal effects of blood flow (as compared to the Pennes model that incorporates no information concerning vascular geometry). It would appear as a consequence of these physiological realities that the validity of the Pennes model is questionable.

Many investigators have developed alternative models for the exchange of heat between blood and tissue. These models have accounted for the effects of vessel size, counter-current heat exchange, as well as a combination of partial counter-current exchange and bleed-off perfusion. All of these models provided a larger degree of rigor in the analysis, but at the compromise of greater complexity and

reduced generality. These studies also led to an increased appreciation of the necessity for a more explicit understanding of the local vascular morphology as it governs bioheat transfer, which has given rise to experimental studies to measure and characterize the 3D architecture of the vasculature in tissues and organs of interest (18). The quantitative analysis of the effects of blood perfusion on the internal temperature distribution in living tissue remains a topic of active research after one-half of a century of study (19).

THERAPEUTIC APPLICATIONS OF BIOHEAT TRANSFER

The elevation of tissue temperature into the 40–42°C range provides some relief from pain (analgesia). In addition, wound healing can be enhanced by this modest increase in temperature. Increased temperature does not cause healing by itself, but rather it creates the improved conditions for the natural processes to heal wounds.

Hot or cold packs can be used to create therapeutic heating for injuries near the skin surface. Heating packs are effective for injuries such as sprains, muscle strains, and postoperative swelling. Elevated temperatures cause an increase in blood perfusion, supplying nutrients to the injured tissue. During the first 12–24 h after injury, cold packs will reduce perfusion, thereby reducing vascular pressure and tissue swelling. Afterward, hot packs (up to 45°C) are applied to increase perfusion and promote healing (20).

When the injury is deeper, the therapy requires a volumetric heater, such as radio frequency (rf) electromagnetic heating, microwave frequency electromagnetic heating, and ultrasonic heating. The Industrial-Medical-Scientific (ISM) frequencies are 6.78, 13.56, 27.12, and 40.68 MHz. The ISM frequencies typically used in medical applications of microwaves are 915 MHz and 2.45 GHz. Medical ultrasonic devices operate in the 500 kHz to 10 MHz range. There are three engineering parameters to consider when designing a therapeutic device. The first parameter is the amount of local volumetric heat generation, the second parameter is the shape of the heating field, and the third parameter is the depth of penetration. Higher frequencies have shorter wavelengths, causing higher absorption and less penetration. The electrical properties of the tissue, which depend on structure and composition, strongly affect the effectiveness of volumetric heating using rf and microwave EM fields. Similarly, acoustic properties of the tissue are important in ultrasonic systems. Often the design of an effective therapeutic device hinges on proper control of the boundary conditions where energy is transferred across the transducer–tissue interface.

There is a systemic effect of local heating, controlled by the hypothalamus, involving both neuronal and hormonal signals. Local heating of organs or peripheral muscles can also cause a spinal cord mediated response. A local release of bradykinins can affect the vascular tone of the terminal arterioles (see Fig. 1), which in turn affect the vascular resistance to blood flow. In general, an increase in local temperature causes an increase in local blood flow,

whereas a decrease in local temperature creates a decrease in local blood flow, but the behavior is highly complex.

Smooth muscles surrounding the 40–200 μm diameter arterioles play a dominant role in controlling local blood flow. Normal capillary pressure is ~3.3 kPa (25 Torr). When local tissues are heated, these arterioles dilate causing an increase in capillary pressure and capillary blood flow. Edema occurs when this pressure widens gaps in the capillary wall causing excess fluid to leak from the vascular to intravascular space. High capillary flow promotes healing by removing wastes, delivering nutrients, and supplying oxygen. Leukocytes (white blood cells) control the healing process by first breaking down, then removing damaged and dead tissue.

The volumetric heating created by electromagnetic fields is governed by the electrical conductivity, σ ($S \cdot m^{-1}$), the imaginary part of the electrical permittivity, ϵ'' ($F \cdot m^{-1}$), and the magnitude of the local electric field, $|E|$ ($V \cdot m^{-1}$):

$$q''' = (\sigma + \omega\epsilon'')|E|^2 \quad (2)$$

where ω is the angular frequency of the field in $rad \cdot s^{-1}$. Direct heating from the magnetic fields in medical applications is usually neglected. Magnetic fields can be used to heat tissue, but because of Faraday's law of induction, the time-varying magnetic field will induce an electric field, and it is this electric field that heats the tissue. A comprehensive review of electromagnetic heating can be found in Roussy and Pearce (21). Tables of electrical and acoustic properties can be found in Diller (5).

THERMOREGULATION

Thermoregulation is an elaborate control system, used by mammals, to maintain internal body temperatures near a physiological set point under a large spectrum of environmental conditions and metabolic rate activities. Even though there have been many years of research, much remains unknown about the human thermoregulatory system. Therefore, active investigation continues. Heat transfer due to conduction, convective heat transfer via the blood flow, local generation of thermal energy, and thermal boundary conditions comprise the major components of thermoregulation. Once these individual mechanisms are understood, they can be combined to create mathematical models to simulate and predict thermoregulatory behavior. The mathematical models are used to design systems to interact thermally with the human body (such as a space suit) without compromising the health and safety of the subject.

The prevailing theory is that the main objective of a human thermoregulation system is to maintain the body core temperature at a constant value consistent with that required for normal physiological functions, regardless of the environmental conditions. An alternative theory, suggested by Chappuis et al. (22) and Webb (23), is that the goal of the human regulation system is to maintain the body's energy balance. In this theory, tissue temperatures are a result, rather than a cause, of the regulation process.

Nunneley (24,25) showed that temperature and internal energy storage of the human body vary with time of day, metabolic activity, and individuality of the human. To maintain body core temperature, the thermoregulatory system incorporates a number of energy production and dissipation mechanisms, many of them controlled by feedback from other body parameters. Examples of such feedback control are that for sweating, shivering, and varying blood flow.

Ganong (26) showed that the main control center for feedback mechanisms is located in the hypothalamus of the brain, where reflex responses operate to maintain the body temperature within its narrow range. The signals that activate the hypothalamic temperature regulating centers come largely from two sources: the temperature-sensitive cells in the anterior hypothalamus and cutaneous temperature receptors. The cells in the anterior hypothalamus sense the temperature of the body core or, specifically, the temperature of the arterial blood that passes through the head.

The theory of energy regulation is based on the demonstration of the existence of temperature sensors at several levels in the skin enabling the sensing of heat flow within and from the body. Evidence has also shown neurological sensing of thermal gradients, of which changes relate to the thermal regulating responses. Therefore, the hypothesis behind the theory of energy content regulation based on Webb's experimental observations is "Heat (energy) regulation achieves heat (energy) balance over a wide range of heat (energy) loads. Heat flow to or from the body is sensed, and physiological responses defend the body heat (energy) content. Heat (energy) content varies over a range that is related to heat (energy) load. Changes in body heat (energy) content drive deep body temperatures" (23). Energy regulation involves constantly changing metabolic energy production and the adjustment of heat losses to maintain a system in equilibrium. This mechanism is opposed to temperature regulation where adjustments are required to maintain body temperature.

The thermal energy balance over time within the human body combines the heat added by internal production minus the heat lost by various heat-transfer processes.

$$\Delta E = M - (W + Q_{\text{conv}} + Q_{\text{cond}} + Q_{\text{rad}} + Q_{\text{evap}} + Q_{\text{resp}}) \quad (3)$$

where ΔE is the rate of energy storage in the body (W), M is the metabolic energy production (W), W is the external work (W), Q_{conv} is the surface heat loss by convection (W), Q_{cond} is the surface heat loss by conduction (W), Q_{rad} is the surface heat loss by radiation (W), Q_{evap} is the surface heat loss by evaporation (W), and Q_{resp} is the respiratory heat loss (W).

The human body produces energy, exchanges heat with the environment, and loses heat by evaporation of body fluids. Thermal energy is produced by metabolism, a biochemical process occurring in cells has adenosine triphosphate (ATP) is combined with oxygen to produce the various life functions. Fulcher (27) defined the basal metabolic rate as "the minimal metabolism measured at a temperature of thermal neutrality in a resting homeotherm with normal body temperature several hours after

a meal and not immediately after hypothermia". Energy is also produced at an increased rate due to muscle activity, including physical exercise and shivering, and by food intake. Therefore, the total energy production in the body is determined by the energy needed for basic body processes plus any external work. Since the body operates with <100% efficiency only a fraction of the metabolic rate is applied to work. The remainder shows up as heat. The mechanical efficiency associated with metabolic energy utilization is zero for most activities except when the person is performing external mechanical work, such as in walking upstairs, lifting something to a higher level, or cycling on an exercise machine. When external work is dissipated into heat in the human body, the mechanical efficiency is negative. An example of negative mechanical efficiency is walking downstairs.

Convection, radiation, conduction, and evaporation of sweat at the skin surface allow heat to be dissipated from the body. There is also heat transfer, especially when the environmental air temperature is extremely high or low, through the respiratory tract and lungs. Storage of energy takes place whenever there is an imbalance of production and dissipation mechanisms. In many instances, such as astronauts in space suits or military personnel in chemical defense garments, energy storage is forced due to the lack of appropriate heat exchange with the environment.

The human thermoregulatory system is quite complicated and behaves mathematically in a highly nonlinear manner. It contains multiple sensors, multiple feedback loops, and multiple outputs. The control mechanisms to release excess energy include the production of sweat, and vasodilatation of the blood vessels in the skin. Conversely, to conserve energy there can be shivering of the muscles, and vasoconstriction of blood vessels, which engage in the transportation of heat to the surface of the body.

Heat transfer within the body is due to the internal conductance that governs the flow of heat from the core, through the tissue, to the surface. This component of heat transfer is governed by peripheral blood flow, the core-skin temperature gradient, and the conductivity of the body tissue. Blood flow provides the majority of the peripheral conductance where there is convection between blood and tissue and countercurrent heat exchange between the arteries and the veins. Blood flow is controlled according to metabolic needs of the body as well as the need to maintain the appropriate core temperature. When the core becomes too hot, the blood vessels in the skin dilate to allow increased blood flow to the surface of the skin. Then, the environment cools the blood and the cooler blood returns to the core. Increased blood flow to the skin surface increases extravascular pressure enabling greater sweat production, again adding to the cooling process. In contrast, when the core becomes too cold, blood flow to the skin is constricted to conserve the body's internal energy.

Sweating is centrally controlled by the hypothalamus. When the body senses an increase temperature the hypothalamus increases nerve impulses to the sweat glands. Shivering, on the other hand, is an involuntary response of the skeletal muscles when passive body cooling exceeds metabolic energy production.

This section briefly introduced the concepts of thermoregulation. For a quantitative analysis of this topic, see Wissler (8,9).

THERMAL INJURY

Thermal injury is defined as irreversible changes to living tissue caused by temperature. Injury can occur when the tissue temperature exceeds the range between which normal life processes exist. Both high and low temperature can cause irreversible changes to biomolecules, resulting in injury. Common examples are burns and frostbite. Recently, it has been discovered that under some kinds of moderate thermal stress that is subthreshold to injury, cells produce molecules that render temporary protection against levels of many types of stress (thermal, mechanical, chemical, etc.) that would normally cause injury. These protective molecules are called heat shock proteins, and they are the subject of widespread investigation to identify the kinetics of their expression and function. It is an effort to develop applications in which they may be induced either before or even after a traumatic event.

The most commonly encountered type of thermal injury is the burn. Accidental burns are encountered most frequently in domestic and industrial settings as well as many other venues of activity. Most burns result from the propagation of heat inward into tissues as a result of contact at the surface (skin) with a hot solid, liquid, or vapor. One exception is electrical burns in which the tissue temperature is elevated owing to I^2R dissipation of electric energy when a voltage is applied. In this case, the primary source of heating is internal since the impedance of muscle is higher than of skin and fat.

It is generally assumed that thermal burns can be modeled as a simple Arrhenius rate process such that

$$\Omega(t) = \int_0^t A e^{\Delta E/RT(\tau)} d\tau \quad (4)$$

where Ω is a dimensionless damage parameter (e.g., $\Omega = 1$ means first degree burn), A is a frequency factor (s^{-1}), ΔE is the activation energy in $J \cdot mol^{-1}$, R is the universal gas constant ($8.314 J \cdot mol^{-1} \cdot K^{-1}$), and T is the tissue temperature (K). The constants A and ΔE are tissue parameters, and $T(\tau)$ is the time history of the tissue temperature (28).

This model was first posed for predicting the severity of a burn as a function of the temperature and time of exposure at the skin surface by Moritz and Henriques (29) shortly after World War II. They also performed experiments to determine threshold conditions for eliciting first and second degree burns in humans and applied this data to determine values for the scaling constant and activation energy in their Arrhenius model. Their experiments were conducted at temperatures between 44 and 70°C and exposure times between 1 and 25,000 s. The model parameter values are $A = 3.1 \times 10^{98} s^{-1}$ and $\Delta E = 6.28 \times 10^5 kJ \cdot mol^{-1}$. Over the ensuing 50 years many subsequent investigators have studied this process with mathematical models and experimental investigations (30–40). Although a considerable body of literature has been accrued, there is by no means a consensus on how to

accurately predict the occurrence of thermal injury over the wide range of conditions that cause burns.

SUBZERO EFFECTS

One application of subzero temperatures is the long-term preservation of biologic tissue. Therapeutic devices based on subzero temperatures can be used to destroy cancerous cells or remove necrotic tissue. The rate of biochemical processes is governed by local temperature. Lowering the temperature has the effect of reducing reaction rates, and at sufficiently low temperatures, a state of suspended animation can be achieved. Because of the water component of physiological fluids, temperatures low enough to affect suspended animation normally result in freezing. The freezing of native biomaterials is nearly always lethal to the affected tissue upon thawing. The formation of ice has two damaging effects. The first effect is mechanical as intracellular ice crystals physically damage cell structures. The second and more lethal effect is osmotic. The local concentration of ions, such as Na^+ , K^+ , and Cl^- , are critical for sustaining life, and a high concentration of these ions is produced as liquid water freezes into ice. The effected injury can be used to benefit in cryosurgery for the purpose of destroying a target tissue, such as cancer. Alternatively, the tissue can be modified prior to freezing by the introduction of a chemical cryoprotective agent (CPA) to afford protection from freeze–thaw injury. The CPA either protects against the injurious effects of ice formation or blocks the formation of ice so that a glassy state results, which is called vitrification. Organ transplantation, blood banks, and animal husbandry are three applications that require the successful long-term cryopreservation of biologic tissue. The response of living biomaterials to freezing and thawing is intimately tied to the thermal history during processing, especially at subzero temperatures. Thus, bioheat transfer analysis has played a key role in the design and development of effective cryopreservation techniques. Polge was first to report the successful use of glycerol to freeze fowl sperm >55 years ago (41). Successes were reported in succession for other types of tissues having rather simple cell structures, such as erythrocytes, gametes and various cells obtained from primary cultures (42–44). Most of these cryopreservation techniques were derived via largely empirical methods, and starting in the 1970s it came to be realized that the cryopreservation of more complex systems, such as multicellular tissues and whole organs require a more rigorous scientific understanding of the mechanisms of the governing biophysical processes and cellular response to freezing and thawing. Since that time engineers have made significant contributions to the developing science of cryobiology, not the least of which has been to identify some of the key biophysical problems to be solved (45,46).

MEASUREMENT OF THERMAL CONDUCTIVITY AND THERMAL DIFFUSIVITY

While the other sections in this article presented brief overviews of the various disciplines within the field of

Figure 2. A glass-coated thermistor is placed into or on the surface of the tissue of interest.

bioheat transfer, this section will present in detail a specific measurement technique. In particular, this section presents an instrument used to measure thermal properties in tissue. The section begins with definitions of thermal properties, overviews of the technique, then develops the heat-transfer equations that form the basis of the instrument. Finally, calibration methods and error analyses are presented.

Definitions of Thermal Properties

Thermal conductivity (k) is the ability of a material to transport heat in the steady state. In one dimension, the total heat (Q) transported across a flat surface of area A and thickness Δx is related to the temperature gradient across the surface (ΔT) and the thermal conductivity of the material.

$$Q = -kA \frac{\Delta T}{\Delta x} \tag{5}$$

Thermal diffusivity (α) is the ability of a material to conduct heat in the transient state. Thermal properties of

conductivity and diffusivity are related. The quotient of conductivity divided by diffusivity equals density times specific heat.

$$\frac{k}{\alpha} = \rho c \tag{6}$$

Diffusivity is often defined in the partial differential equation used to describe transient heat transfer. Assuming homogeneous thermal properties, the Fourier conduction equation in one dimension is

$$\frac{\partial^2 T}{\partial x^2} = \frac{1}{\alpha} \frac{\partial T}{\partial t} \tag{7}$$

Measurement Technique

The technique involves inserting a thermistor into the tissue of interest or placing it on the tissue surface, as shown in Fig. 2. Thermometrics P60DA102M and Fenwal 121-102EAJ-Q01 are glass probe thermistors that make excellent transducers (shown on the left of Fig. 2). The diameter of these thermistors is ~ 0.15 cm. The glass-coated spherical probes provide a large bead size and a rugged, stable transducer. The Thermometrics BR55KA102M and Fenwal 112-102EAJ-B01 bead thermistors also provide excellent results (shown on the right of Fig. 2).

If the tissue is living, the properties measured are called effective thermal conductivity, k_{eff} , and effective thermal diffusivity, α_{eff} . Effective thermal properties include the contribution to heat transfer due to intrinsic conduction added to the contribution caused by the transport of blood through the tissue.

In the constant temperature heating technique (47–52), the instrument first measures the baseline tissue temperature, T_s . Then, an electronic feedback circuit applies a variable voltage, $V_o(t)$, in order to maintain the average thermistor temperature at a predefined constant, T_h . The electrical circuit used to implement the constant temperature heating technique is shown in Fig. 3. Three high quality, gold-plated, electromagnetic relays are used to switch the thermistor (R_s) between “heat” and “sense” mode. Figure 3 shows the position of the three relays in “heat” mode. Initially, the instrument places the circuit in “sense” mode with the three relays in

Figure 3. Instrumentation used for the constant temperature heating technique.

the opposite position as shown in Fig. 3. A precision +5.00 V reference (PMI REF02) supplies voltage to the four-resistor bridge, formed by the two 50 k Ω , R_{set} , and R_s resistors. The voltage difference $V_2 - V_1$ is fed to a differential amplifier, passed through a low pass filter, then fed to a 12-bit ADC.

Fundamental Equations

Resistance calibration is performed to determine the relationship between the ADC sample and the unknown R_s . Next, temperature calibration is performed by placing the thermistor adjacent to an accurate temperature monitor and placing the combination in a temperature-controlled waterbath. The thermistor resistance varies nonlinearly with its temperature. For small temperature ranges equation 8 can be used for temperature calibration.

$$R_s = R_0 e^{\beta/(T_s+273.15)} \quad (8)$$

where T_s is the temperature in degrees Celsius, and R_s is the thermistor resistance in ohms.

In heat mode, the integrator-inverter circuit varies the voltage across the thermistor until the thermistor resistance, R_s , matches the fixed resistor, R_{set} . It takes just a few milliseconds for the electrical control circuit to stabilize. Once stable, R_s is equal to R_{set} , meaning the volume average thermistor temperature is equal to a constant. The instrument uses a calibration temperature versus resistance curve to determine the heated temperature T_h from the fixed resistor R_{set} . The power applied to the thermistor, P , is calculated from $(V_0)^2/R_{set}$. The applied thermistor power includes a steady state and a transient term:

$$P(t) = A + Bt^{-1/2} \quad (9)$$

In order to measure thermal conductivity, thermal diffusivity, and tissue perfusion the relationship between applied thermistor power, P , and resulting thermistor temperature rise, $\Delta T(t) = T_h - T_s$, must be known. In the constant temperature method, ΔT is constant. The thermistor bead is treated as a sphere of radius a embedded in a homogeneous medium. Since all media are considered to have constant parameters with respect to time and space, the initial temperature will be uniform when no power is supplied to the probe.

$$T_b = T_m = T_s = T_a + \frac{Q_{met}}{w\rho_{bl}c_{bl}} \quad \text{at } t = 0 \quad (10)$$

Let V be the temperature rise above baseline, $V = T - T_s$. Both the thermistor bead temperature rise (V_b) and the tissue temperature rise (V_m) are initially zero.

$$V_b = V_m = 0 \quad \text{at } t = 0 \quad (11)$$

To solve this coupled thermistor-tissue system, equation 7 is written in spherical coordinates and the applied power is deposited into the thermistor, while the perfusion heat sink is added to the tissue, equation 1. Assuming the venous blood temperature equilibrates with the tissue

temperature and that the metabolic heat is uniform in time and space, the Pennes' bioheat transfer equation in spherical coordinates is given by

$$\rho_b c_b \frac{\partial V_b}{\partial t} = k_b \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial V_b}{\partial r} \right) + \frac{A + Bt^{-1/2}}{4/3\pi\alpha^3} \quad r < a \quad (12)$$

$$\rho_m c_m \frac{\partial V_m}{\partial t} = k_m \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial V_m}{\partial r} \right) - w\rho_{bl}c_{bl}V_m \quad r > a \quad (13)$$

where w is the tissue perfusion (s^{-1}). Perfect thermal contact is assumed between the finite-sized spherical thermistor and the infinite homogeneous perfused tissue. At the interface between the bead and the tissue, continuity of thermal flux and temperature leads to the following boundary conditions:

$$V_b = V_m \quad \text{at } r = a \quad (14)$$

$$k_b \frac{\partial V_b}{\partial r} = k_m \frac{\partial V_m}{\partial r} \quad \text{at } r = a \quad (15)$$

The other boundary conditions are necessary at positions $r \rightarrow 0$ and $r \rightarrow \text{infinity}$. Since no heat is gained or lost at the center of the thermistor:

$$k_b \frac{\partial V_b}{\partial r} = 0 \quad \text{as } r \rightarrow 0 \quad (16)$$

Because the thermistor power is finite and the tissue is infinite, the tissue temperature rise at infinity goes to zero:

$$V_m \rightarrow 0 \quad \text{as } r \rightarrow \text{infinity} \quad (17)$$

It is this last initial condition that allows the Laplace transform to be used to solve the coupled partial differential equations. The Laplace transform converts the partial differential equations into ordinary differential equations that are independent of time t . The steady-state solution allows for the determination of thermal conductivity and perfusion (49).

$$V_b(r) = \frac{A}{4\pi a k_b} \left(\frac{k_b}{k_m(1 + \sqrt{z})} + \frac{1}{2} \left[1 - \left(\frac{r}{a} \right)^2 \right] \right) \quad (18)$$

$$V_m(r) = \frac{A}{4\pi r k_m} \left(\frac{e^{(1-r/a)\sqrt{z}}}{1 + \sqrt{z}} \right) \quad (19)$$

where z is a dimensionless Pennes' model perfusion term ($w\rho_{bl}c_{bl}a^2/k_m$). The measured thermistor response, ΔT , is assumed be the simple volume average of the thermistor temperature:

$$\Delta T = \frac{\int_0^a V_b(r) 4\pi r^2 dr}{4/3\pi\alpha^3} \quad (20)$$

Inserting equation 18 into Eq. 20 yields the relationship used to measure thermal conductivity assuming no perfusion (49).

$$k_m = \frac{1}{\frac{4\pi a \Delta T}{A} - \frac{0.2}{k_b}} \quad (21)$$

A similar equation allows the measurement of thermal diffusivity from the transient response, again assuming no

perfusion (49).

$$\alpha_m = \left(\frac{a}{\sqrt{\pi} \frac{B}{A} (1 + 0.2 \frac{k_m}{k_b})} \right)^2 \quad (22)$$

Calibration Equations

The first calibration determines relationship between the ADC sample and the thermistor resistance when in sense mode. For this calibration, precision resistors are connected in place of the thermistor, and the computer-based instrument is used to sample the ADC in sense mode. A simple linear equation works well for converting ADC samples to measured resistance. In this procedure, the device acts like a standard ohmmeter.

The second calibration determines the relationship between thermistor temperature and its resistance. The instrument measures resistance, and a precision thermometer determines true temperature. Equation 23 yields an accurate fit over a wide range of temperature:

$$T = \frac{1}{H_0 + H_1 \ln(R) + H_3 [\ln(R)]^3} - 273.15 \quad (23)$$

where T is in degrees Celsius. Temperature resistance data are fit to Eq. 23 using nonlinear regression to determine the calibration coefficients H_0 , H_1 , and H_3 .

The applied power, $P(t)$, is measured during a 30 s transient while in heat mode. Nonlinear regression is used to calculate the steady-state and transient terms in equation 9. Figure 4 shows some typical responses. The steady-state response (time equals infinity) is a measure of the thermal conductivity. The transient response (slope) indicated the thermal diffusivity.

The third calibration maps measured power to thermal properties while operating in heat mode. Rather than using the actual probe radius (a) and probe thermal conductivity (k_b), as shown in Eqs. 21 and 22, the following empirical

equations are used to calculate thermal properties.

$$k_m = \frac{1}{(c_1 \Delta T/A) + c_2} \quad (24)$$

$$\alpha_m = \left(\frac{c_3}{B/A(1 + k_m/c_4)} \right)^2 \quad (25)$$

The coefficients c_1 , c_2 , c_3 , and c_4 are determined by operating the probe in two materials of known thermal properties. Typically, agar-gelled water and glycerol are used as thermal standards. This empirical calibration is performed at the same temperatures at which the thermal property measurements will be performed.

Error Analysis

It is assumed that the baseline tissue temperature, T_0 , is constant during the 30 s transient. Patel has shown that if the temperature drift, dT_0/dt , is $>0.002^\circ\text{C} \cdot \text{s}^{-1}$, then significant errors will occur (52). The electronic feedback circuit forces T_h to a constant. Thus, if T_0 is constant then ΔT does not vary during the 30 s transient.

The time of heating can vary from 10 to 60 s. Shorter heating times are better for small tissue samples and for situations where there is baseline tissue temperature drift. Another advantage of shorter heating times is the reduction in the total time required to make one measurement. Longer heating times increase the measurement volume and reduce the effect of imperfect thermistor-tissue coupling. Typically, shorter heating times are used *in vivo* because it allows more measurements to be taken over the same time period. On the other hand, longer heating times are used *in vitro* because accuracy is more important than measurement speed.

Thermal probes must be constructed in order to measure thermal properties. The two important factors for the thermal probe are thermal contact and transducer sensitivity. The shape of the probe should be chosen in order to minimize trauma during insertion. Any boundary layer between the thermistor and the tissue of interest will cause a significant measurement error. The second factor is transducer sensitivity that is the slope of the thermistor voltage versus tissue thermal conductivity. Equation 21 shows for a fixed ΔT k_m and k_b the thermistor power (A) increases linearly with probe size (a). Therefore larger probes are more sensitive to thermal conductivity. For large tissue samples, multiple thermistors can be wired in parallel, so they act electrically and thermally as one large device. There are two advantages to using multiple thermistors. The effective radius, $a = c_1/4\pi$, is increased from ~ 0.08 cm for a typical single P60DA102M probe to ~ 0.5 cm for a configuration of three P60DA102M thermistors. The second advantage is that the three thermistors are close enough to each other that the tissue between the probes will be heated by all three thermistors. This cooperative heating tends to increase the effective measurement volume and reduce the probe/tissue contact error. Good mechanical-thermal contact is critical. The probes are calibrated after they are constructed, so that the thermistor geometry is incorporated into the coefficients

Figure 4. Typical $P/\Delta T$ versus $t^{-1/2}$ data for the constant temperature heating technique. The agar-gelled water and glycerol curves are used for empirical calibration.

c_1 , c_2 , c_3 , and c_4 . The same waterbath, and probe configuration should be used during the calibration and during the tissue measurements.

Calibration is a critical factor when using an empirical technique. For temperatures $<0^\circ\text{C}$, ice and ethylene glycol are used as thermal standards. For temperatures between 0 and 15°C , agar-gelled water and ethylene glycol can be used as thermal standards. For temperatures between 15 and 75°C , agar-gelled water and glycerol were used. To prevent convection, 1 g of agar/100 mL of water should be added. A mixture of water and glycerol can be used to estimate the accuracy of the technique. The mass fraction, m , can be used to determine the true thermal properties of the mixture (53,54). The ability to determine measurement accuracy is critical for the acceptance of new technology. These two equations provide for the capability to create reference materials of known thermal properties, which can be used to experimentally determine measurement accuracy.

$$k_m = m k_g + (1 - m)k_w + 1.4 m(m - 1)(k_w - k_g - 2) - 0.014 m(m - 1)(T - 20^\circ\text{C}) \quad (26)$$

$$\alpha_m = m \alpha_g + (1 - m)\alpha_w \quad (27)$$

where T is in degrees Celsius. Self-heat thermistors have also been successfully used to measure the convective heat transfer coefficient on the endocardial surface of the heart (55,56).

ADDITIONAL STUDIES

In this article, the general concepts of bioheat transfer were introduced, and a detailed design and analysis of an instrument that measures thermal properties was presented. Although out of print, the 1985 book *Heat Transfer in Medicine and Biology*, is a wonderful collection of detailed works that address a wide spectrum of topics in bioheat transfer. The book *Optical-Thermal Response of Laser Irradiated Tissue* covers the issues involved in high temperature effect such as tissue damage and thermal ablation. Valvano's chapter titled Temperature Measurements, in *Advances In Heat Transfer: Bioengineering Heat Transfer*, covers many practical issues involved in measuring temperature in the biomedical setting. An in depth treatment of bioheat transfer topics can be found in the 2005 edition of *CRC Handbook of Heat Transfer*. This reference has excellent treatments of thermoregulation and low temperature effects.

INTRODUCTION

Historical Context

Electrical impedance measurements have been applied to the study of biologic systems for nearly 200 years. Indeed, the history of continuously flowing electricity began with Luigi Galvani's famous experiments on bioelectricity at the University of Bologna (1,2). It was not until the 1870s however, that Hermann Müller in Königsberg/Zürich discovered the capacitive properties of tissue and the anisotropy of muscle conductance based on alternating current measurements. In 1864, James C. Maxwell contrived his now famous equations by specifically calculating the resistance of a homogeneous suspension of uniform spheres as a function of their volume concentration (1). In 1928, Kenneth S. Cole expanded on Maxwell's model by determining

the impedance of a suspension of capacitively coated spheres over a range of frequencies.

Several additional and important developments occurred before the start of World War II. Rudolph Hoebbers studied the conductivity of blood and found it to be dependent on the stimulation frequency. Simultaneously, the electrical properties of proteins and amino acids were discovered and extensively studied by Oncley, Fricke, and Wyman (3). These contributions lead to further developments in the science of biophysics and electrophysiology.

Bioimpedance research accelerated after World War II. In 1950, Nyboer et al. launched an investigation into thoracic electrical bioimpedance (TEB) as an alternative to invasive methods of measuring cardiac function and published a novel method termed "Impedance Plethysmography" (4,5). However, Kubicek and Patterson were credited with the development of the original TEB system in conjunction with the National Aeronautics and Space Administration in the mid-1960s (6). This device was designed to monitor stroke volume (SV) and cardiac output (CO) noninvasively during space flight. In addition, Djordjevic and Sadove coined the term "electrohemodynamics" in 1981 to describe a science that relates the theories of fluid mechanics and elasticity to the continuous impedance signal and to the time variations of arterial blood pressure (7). Jan Baan et al. introduced the impedance or conductance catheter technique to measure real time chamber volume in the mid-1980s (8). This technique revolutionized the study of cardiovascular mechanics in both the laboratory and clinical settings by making the study of ventricular-pressure volume relationships practical.

More recently, bioimpedance applications have continued to expand, especially in the area of implantable devices. Modern pacemakers and defibrillators routinely use bioimpedance measurements to verify pacing lead performance and position, monitor minute ventilation and thoracic fluid content, and optimize programmable device features such as pacing rate and AV delay in a closed-loop fashion (9–11).

The terms bioimpedance or tissue impedance describe both the resistive and reactive components of tissue at the applied stimulus frequency. The capacitive reactive components of the measured tissue impedance change at higher frequencies due to the relative conductive properties of tissue fluids and cellular membranes. Bioimpedance methods can be categorized into two areas: impedance plethysmography and impedance cardiography. Impedance plethysmography, by definition, refers to the measurement of a volume change in a heterogeneous tissue segment using electrical impedance in which the changing impedance waveform (ΔZ) is used to determine cardiac, respiration, and peripheral volume change as a function of time. In contrast, impedance cardiography is a subdivision of impedance plethysmography that focuses on the measurement of cardiac stroke volume and widely uses the first derivative (dZ/dt) of the changing impedance waveform (ΔZ) to monitor fiducial time element points such as cardiac valve opening and closing. Both methods primarily use a single low frequency stimulus current (<100 kHz) where most of the elements in the current paths are primarily

resistive. Techniques such as impedance plethysmography and impedance cardiography primarily depend on resistive rather than reactive components of the blood impedance. Thus, applications using low frequency stimulus current to primarily measure the resistive component of bioimpedance will be categorized in this article as resistive applications of bioimpedance.

The second general category of bioimpedance measurement involves estimation of fluid volume distributions such as intracellular and extracellular volume, percent body fat vs. percent muscle mass, and cell and tissue viability. This area primarily employs a multifrequency stimulus current bandwidth (>1000 Hz) where most of the elements in the current path contain significant resistive and reactive components. Thus, applications using high frequency stimulus current to measure the resistive and reactive components of bioimpedance will be categorized as reactive applications of bioimpedance.

Bioimpedance Theory

When constant electric current is applied between two electrodes through a biological medium and the corresponding voltage is measured between the two source poles, the resultant impedance or bioimpedance is determined by Ohm's law. The recorded voltage is the sum of the potential difference contributions due to the electrical conductivity properties of the tissue medium. The exchange of electrons from source to sink occurs from electrons of the metal electrode (such as platinum or silver-silver chloride) to ions of the tissue medium. The electrode is the site of charge carrier exchange between electrons and ions and thus serves as a transducer of electrical energy. Impedance measurements most commonly use a two-electrode (bipolar) or four-electrode (tetrapolar) arrangement (Fig. 1). In the bipolar arrangement, the electrodes serve as both the current source (anode and cathode, respectively) and as the measurement electrodes. In the tetrapolar arrangement, one electrode serves as current source anode, one as the current source cathode, and the remaining two electrodes serve as the respective measurement electrodes. A disadvantage of the bipolar electrode system is electrode polarization due to a frequency-dependent polarization impedance. Therefore,

Figure 1. Bipolar (left) and tetrapolar (right) electrode configurations. With a constant current stimulation source, the change in measured voltage (ΔV) is proportional to the change in calculated impedance (ΔZ). Tetrapolar systems require additional electrodes but avoid electrode polarization effects.

the measured voltage in a bipolar impedance system reflects the combined impedance of both the tissue segment and the electrode tissue interface. When the voltage is measured with an isolated high input impedance electrode system, such as with the tetrapolar lead configuration, minimal current flows in the isolated sensing electrodes, thus problems with electrode polarization can be effectively reduced (12).

Endogenic ionic current movement between and within cellular structures encompasses the electrical properties of tissues and the term bioelectricity. In tissue and the living cell, an inseparable alliance exists between electricity and chemistry (1). The perception of current through human tissue is dependent on frequency, current density, effective electrode area, and current duration. The maximum sensitivity of the nervous system is approximately in the range of 10 to 1000 Hz for sine waves. At frequencies greater than 1 kHz, the sensitivity is strongly reduced.

Measured bioimpedance is a function of the real and reactive components of the tissue medium at the applied frequency of the stimulus current. Tissue characteristics at low frequencies are almost independent of cellular membrane reactance and internal intracellular resistivity. Thus, most of the applied current is conducted via the extracellular fluid. The cellular membrane behavior at intermediate or high frequencies is primarily a characteristic of membrane reactance and internal resistivity. The membranes are an impure reactance and, therefore, show a dielectric loss and a phase angle, which is independent of frequency (13). At higher frequencies, the cell's membrane reactance and resistance become negligible and the applied current is conducted through both the intracellular and extracellular fluid.

RESISTIVE APPLICATIONS OF BIOIMPEDANCE

Transthoracic Bioimpedance

The Cylindrical Model. Many applications of bioimpedance measurement focus on primarily resistive changes. These techniques are all based on the cylindrical model (Fig. 2) represented by a tissue volume with uniform cross-sectional area (A), length (L), and resistivity (ρ) (14).

$$R = \rho \frac{L}{A} \quad (1)$$

The resistance of the vessel segment is directly proportional to the resistivity of the conductive medium and length of the vessel segment and inversely proportional to the cross-sectional area of the vessel segment (Eq. 1). As shown in Fig. 2, as the cross-sectional area of the vessel segment increases from A_1 to A_3 , the measured resistance decreases. Resistivity (ρ) is a tissue property that varies substantially between tissues. Typical tissue resistivities are shown in Table 1 (15).

Equation 1 can be modified to determine the volume of the tissue by multiplying both sides of the equation by L , substituting impedance (Z) for resistance, and solving for

Figure 2. Cylindrical model of a vessel segment. A_1 – A_3 represent cross-sectional area changes of the tissue of the interest (e.g., blood). Tissue length (L) is often determined by measurement electrode spacing. Blood resistivity (ρ) also determines the resistance (R) of the tissue volume. Resistance measured is directly proportional to the measured voltage and indirectly proportional to the constant alternating current (i) applied to the vessel segment.

volume (V) as a function of time (Eq. 2):

$$V(t) = \rho \frac{L^2}{Z(t)} \quad (2)$$

The cylindrical model is based on several important assumptions: The electrical field, and hence current density, is homogeneous within the tissue of interest, the current is completely confined to the tissue of interest, and the values shown in Table 1 do not account for tissue anisotropy. Most biological tissues have lower resistivity in the longitudinal direction of cell or fiber orientation (12,16–18). For example, the ratio of resistivity in the transverse to parallel direction can be > 3 in cardiac tissue (18). These assumptions may not be valid for some applications of bioimpedance such as the conductance catheter technique for chamber volume estimation (see below). Therefore, the

Table 1. Various Tissue Resistivities in ohms-meter ($\Omega \cdot \text{m}$) (15)

Tissue	ρ ($\Omega \cdot \text{m}$)
Blood (Hematocrit = 45)	1.6
Plasma	0.7
Heart Muscle (Longitudinal)	2.5
Heart Muscle (Transverse)	5.6
Skeletal Muscle (Longitudinal)	1.9
Skeletal Muscle (Transverse)	13.2
Lung	21.7
Fat	25

Figure 3. Parallel-column model of the thoracic cavity. This two-column model (C_{TC} and C_{BV}) represents a thoracic cavity segment of length (L), cross-sectional areas of the great blood vessels (A_{BV}), and thoracic cavity segment (A_{TC}), and resistivities of the thoracic cavity segment tissues (ρ_{TC}) and blood volume (ρ_{BV}).

cylindrical model must be adjusted for particular applications.

The Parallel-Column Model. The parallel-column model, first described by Nyboer (5) (Fig. 3) is closely related to the cylindrical model, but accounts for current leakage into surrounding tissues. The model consists of a smaller cylindrical conductor (C_{BV}) of length L representing the large blood vessels of the thoracic cavity (i.e., aortic and pulmonary arteries) embedded in a larger cylindrical conductor (C_{TC}) of the same length (L) representing the tissues of the thoracic cavity. C_{BV} consists of blood with specific resistivity (ρ_{BV}) and time-varying cross-sectional area (A_{BV}). C_{TC} is assumed to be heterogeneous (i.e., bone, fat, muscle) with specific resistivity (ρ_{TC}) and constant cross-sectional area (A_{TC}). Thus, the cylindrical model of the time-varying volume can be modified:

$$V_T(t) = \rho_{BV} \frac{L^2}{Z_{BV}(t)} + \rho_{TC} \frac{L^2}{Z_{TC}} \quad (3)$$

where $V_T(t)$ represents the total volume change. As the distribution of the measured resistance and the net resistivity of the parallel tissues are unknown, calculation of absolute volume can be problematic. However, the constant volume term drops out when the change in volume is calculated from Eq. 3:

$$\Delta V_{BV}(t) \cong \rho_{BV} \left(\frac{L^2}{Z_0^2} \right) \cdot \Delta Z(t) \quad (4)$$

where Z_0 is the basal impedance measured and $\Delta Z(t)$ is the pulsatile thoracic impedance change. Thus, Eq. 4 links the parallel cylindrical model to TEB estimates of stroke volume (ΔV_{BV}).

Noninvasive Measurement of Cardiac Output. Transthoracic electrical bioimpedance (TEB) was first intro-

Figure 4. Transthoracic band electrode placement for stroke volume estimates. The two outer-band electrodes supply the stimulus current (I); the two inner electrodes measure the corresponding voltage (V). Impedance is calculated from the ratio of V/I (15).

duced by Patterson et al. in 1964 (19). As shown in Fig. 4 (13), this system employs two pairs of band electrodes positioned at the superior and inferior ends of the thorax in the cervical and substernal regions, respectively. The outer electrode pair drives a constant current (I) and the inner electrode pair is used to measure the corresponding voltage (V), which is a function of the varying impedance changes during respiration and the cardiac cycle.

Noninvasive measurements of stroke volume can be determined with the configuration in Fig. 4 by applying Eq. 5.

$$SV = \left[\rho_{BV} \left(\frac{L^2}{Z_0^2} \right) \cdot \Delta Z(t) \right] \cdot LV_{ET} \quad (5)$$

Cardiac output may then be determined by multiplying stroke volume (SV) by heart rate (HR). $\Delta Z(t)$ is the measured time-varying impedance signal, and Z_0 represents the nonpulsatile basal impedance.

Sramek et al. (20) modified Patterson et al.'s (19) parallel cylinder model into a truncated cone in order to improve stroke volume predictions (Eq. 6). The physical volume of the truncated cone was determined to be one-third the volume of the larger thoracic cylinder model.

$$SV = \left(\frac{L^3}{4.2} \right) \cdot LV_{ET} \cdot \left(\frac{(dZ/dt)_{\max}}{Z_0} \right) \quad (6)$$

Sramek et al. (20) also found that in a large normal adult population, the measured linear distance (L) is equal to 17% of body height (cm). Cardiac output is directly proportional to body weight (21). As ideal body weight is a linear function of overall height (22), the proportionality of height (H) to cardiac output can be represented in the first term of Eq. 6 by $(0.17H)^3/4.2$.

Figure 5. Impedance cardiography waveforms. Three waveforms depict the electrocardiogram (ECG), transthoracic impedance change as a function of time (ΔZ), and first-time derivative of the impedance change dZ/dt . Impedance waveforms are intentionally inverted to show a positive deflection during cardiac contraction. Fiducial points on the dZ/dt waveform are represented by the opening of the aortic and pulmonic valves (B), closure of the aortic (X) and pulmonic (Y) valves, mitral valve opening (O), ventricular pre-ejection period (PEP), and left ventricular ejection time (LVET). Q represents the end of atrial contraction (46).

Other empirical modifications to the original model have also been proposed in order to improve CO and SV estimates (20,22–28). In addition, various modifications to the external lead configuration have also been proposed to improve SV estimates, including the application of transoesophageal electrodes (29,30).

Several commercial bioimpedance systems are available for clinical noninvasive estimation of cardiac output and other hemodynamic parameters. The advantages of such systems include noninvasive application, relatively low cost, and lack of noninvasive alternatives. However, these techniques have gained somewhat limited clinical acceptance due to suspect reliability over a wide range of clinical conditions.

A myriad of validation studies of TEB estimates of cardiac output have been published with equivocal results (6,7,19,24,28,31–40). For example, Engoren et al. (35) recently compared cardiac output as determined by bioimpedance, thermodilution, and the Fick method and showed that the three methods were not interchangeable in a heterogeneous population of critically ill patients. Their data showed that measurements of cardiac output by thermodilution were significantly greater than by bioimpedance. However, the bioimpedance estimates varied less than the thermodilution estimates for each subject. In contrast, a meta-analysis of impedance cardiography validation trials by Raaijmakers et al. (38) showed an overall correlation between cardiac output measurements using transthoracic electrical bioimpedance cardiography and a reference method of 0.82 (95% CI: 0.80–0.84). The performance of impedance measurement of cardiac output was similar in various groups of patients with different diseases with the exception of cardiac patients, in which group the correlation was decreased. Additional investigations by Kim et al. (41) and Wang et al. (42) used a detailed 3D finite element model of the human thorax to determine the origin of the transthoracic bioimpedance signal. Contrary to the theory that lead to the parallel column model formulae, these investigators determined that the measured impedance signal was determined by multiple tissues and

other factors that make reliable estimates of cardiac output over a wide variety of physiological conditions difficult. Nevertheless, commercially available impedance plethysmographs provide estimates of cardiac output that may be useful for assessing relative changes in cardiac function during acute interventions, such as optimization of implantable pacemaker programmable options such as AV delay (11).

Cardiac Cycle Event Detection. TEB also focuses on measurements of the change in impedance (ΔZ) and the impedance first time derivative (dZ/dt) measured simultaneously with the electrocardiogram (ECG). Figure 5 depicts a typical waveform of the aforementioned parameters. Note that the impedance change (ΔZ) and the impedance first time derivative (dZ/dt) are inverted by convention (43). The value of dZ/dt is measured from zero to the most negative point on the waveform. The ejection time (LV_{ET}) is an important parameter in determining stroke volume (Eqs. 5 and 6). This systolic time interval allows an estimation of cardiac contractility. The Heather Index (HI) is another proposed index of contractility from systolic time intervals determined by the dZ/dt waveform (33,44) (Eq. 7):

$$HI = \frac{dZ/dt_{\max}}{QZ_1}$$

where dZ/dt_{\max} (point C) is the maximum deflection of the initial waveform derived from the ΔZ waveform and QZ_1 is the time from the beginning of the Q wave to peak dZ/dt_{\max} (Fig. 5). In this figure, point Q represents the time between the end of the ECG p-wave (atrial contraction) and the beginning of the QRS wave (ventricular depolarization) (45). Point B depicts the opening of the aortic and pulmonic valves. After the ventricles depolarize and eject the blood volume into the aortic and pulmonary arteries, points X and Y represent the end systolic component of the cardiac cycle as closure of the aortic and pulmonic valves, respectively.

Passive mitral valve opening and passive ventricular filling begins at point O. Although the timing of the various

fiducial notches of the dZ/dt waveform is well known, controversy remains with the origins of the main deflections and are not well understood (15).

Signal Noise. In TEB measurements, several filtering techniques have been proposed to attenuate undesired noise sources depending on which component of the impedance waveform is desired (i.e., respiratory, cardiac, or mean impedance) (47). Most of the signal processing techniques for impedance waves use ensemble averaging for the elimination of motion artifacts (48). A recent signal processing technique described by Wang et al. (48) uses the time-frequency distribution to identify fiducial points on the dZ/dt signal for the computation of left ventricular ejection time and dZ/dt_{\max} . As shown in Fig. 5, many of the fiducial points on the dZ/dt waveform are clearly identifiable, but may be somewhat more difficult to observe under severe interference conditions.

Filtering techniques have also been proposed to eliminate noise caused by respiration such as narrow band-pass filtering around the cardiogenic frequency. However, such filtering techniques often eliminate the high frequency components of the cardiac signal and introduce phase distortion (49). To help alleviate this problem, various techniques to identify breathing artifacts with forward and backward filtering have been employed (50,51). Despite these techniques, motion artifact remains with unknown frequency spectra that may overlap the desired impedance frequency spectra during data acquisition. Adaptive filters represent another approach and may eliminate the motion artifact by tracking the dynamic variations and reduce noise uncorrelated to the desired impedance signal (49). Raza et al. (51) developed a method to filter respiration and low frequency movement artifacts from the cardiogenic electrical impedance signal. Based on this technique, the best range for the cutoff frequency appears to be from 30–50% of the heart rate under supine, sitting, and moderate exercise conditions (51).

Applications of Transthoracic Bioimpedance. Hypertension. TEB has emerged as a noninvasive tool to assess hemodynamic parameters, especially within the frame-

work of hypertension monitoring (24–28,52–54). Measurement of the various hemodynamic components such as stroke volume, ejection time, systemic vascular resistance, aortic blood velocity, thoracic fluid content, and contractility (i.e., Heather Index) using impedance cardiography in patients with hypertension allows more complete characterization of the condition, a greater ability to identify those at highest risk, and allows more effectively targeted drug management (25,53). Several studies have used TEB to evaluate hemodynamic parameters and demonstrated that TEB-guided therapy improves blood pressure control (53,55,56). For example, in a three month clinical study by Taler et al. (55) 104 hypertensive patients were randomized to either TEB-guided therapy or standard therapy. The results showed improved blood pressure control in the TEB-guided group. The investigators concluded that measurement of hemodynamic parameters with TEB methods was more effective than clinical judgment alone in guiding selection of antihypertensive therapies in patients resistant to empiric therapy (53).

Pacemaker Programming. TEB estimates of cardiac index technique has been investigated as a noninvasive method to optimize AV delay intervals in pacemaker patients in an open-loop fashion (57,58). Ovsyshcher et al. (58) measured stroke volume changes at various programmed AV delays via impedance cardiography in dual-chamber pacemaker patients. The optimal and worst programmed AV delays were identified as the settings that produced the highest and lowest cardiac index, respectively. As shown in Fig. 6 (58), the highest cardiac index values resulted with mean AV delays <200 ms and the lowest cardiac index values resulted with mean AV delays >200 ms.

More recently, a study by Tse et al. (59) evaluated AV delay interval optimization during permanent left ventricular pacing using transthoracic impedance cardiography in conjunction with Doppler echocardiography over a range of AV intervals. This study revealed no significant difference between the optimal mean AV delay interval determined by transthoracic impedance cardiography and that determined by Doppler echocardiography. However, as shown in Fig. 7, the mean cardiac output at different AV

Figure 6. Highest and lowest cardiac indices at varied AV delays and pacing rates. Highest cardiac index values (closed circles) resulted with mean AV delays <200 ms and the lowest cardiac index values (open circles) resulted with mean AV delays >200 ms (58).

Figure 7. Cardiac output measured by impedance cardiography and Doppler echocardiography at various AV delay intervals (59).

delay intervals was significantly higher when measured by transthoracic impedance cardiography than when measured by Doppler echocardiography.

Electrical Impedance Tomography. Electrical impedance tomography (EIT) is a technique to reconstruct low resolution cross-sectional images of the body based on differential tissue resistivity (60). The image is created using an array of 16–32 electrodes, usually positioned around the thorax (Fig. 8). Impedance is computed from all electrodes as the drive electrodes rotate sequentially about the tissue surface. The “image” is then reconstructed using standard tomographic techniques. The advantages of EIT include low cost and the potential for ambulatory applications. The disadvantages include the low resolution of the image, the contribution of “out-of-plane” tissues to the “in-plane” image, and the limited clinical applications.

Recent improvements in hardware and software systems that increase the accuracy and speed of regional lung volume change have maintained interest in this technology (60–62). Besides pulmonary monitoring, other potential applications of EIT include neurophysiology, stroke detection, breast cancer detection, gastric emptying, and cryosurgery (63–66).

Lead Field Theory. An analysis of sensitivity is crucial to interpretation and application of EIT images as well as other bioimpedance applications. The sensitivity distribution of an impedance measurement provides the relation

Figure 9. High resolution computer simulated model of the thorax. Regions of both positive and negative sensitivity contribute to the total impedance measured. Negative impedance sensitivity regions, (1.54 Ω) and positive impedance sensitivity regions (red, 2.92 Ω) both contribute to the measure total impedance of 1.38 Ω. RL = contribution of right lung to measured impedance. LR = contribution of left lung to measured impedance (62).

between the measured impedance resulting from the conductivity distribution of the measured region. It describes the relative contribution of each region to the measured impedance signal. The contribution of any region to the measurement is not always intuitively obvious and the magnitude of the sensitivity may be less than zero (Fig. 9). Therefore, the relative contribution of various tissues to the reconstructed “image” can be difficult to interpret.

The applicability of lead field theory in impedance measurements has been shown theoretically by Geselowitz (67). According to that theory, appropriate selection of the electrode configuration enables increased measurement sensitivity and selectivity to particular regions (68). Also, the measured impedance change (ΔZ) can be evaluated from the change in conductivity within a volume conductor $\Delta\sigma$ and the sensitivity distribution S by (67):

$$\Delta Z = \int_v \frac{1}{(\Delta)\sigma} \bullet S_{dv} \tag{8}$$

Figure 8. Left: Cartoon representation of a system to generate an electrical impedance tomographic image: 16 electrodes around the chest inject currents and record the resultant voltage in a sequential manner. Right: Electrical impedance tomographic image of the thoracic cavity. Heart and lung tissue are distinguishable (60).

Figure 10. Simulated measurement sensitivities of tissues. Values are indicated for each tissue type in addition to three tissue groups consisting of pulmonary circulation, systemic circulation, and all the blood masses and heart muscle (68).

The measurement sensitivity S is obtained by first determining the current fields generated by a unit current applied to the current injection electrodes and the voltage measurement electrodes. These two lead fields form the combined sensitivity field of the impedance measurement associated with the electrode configuration by:

$$S = J_{LE} \bullet J_{LI} \quad (9)$$

where:

S = the scalar field giving the sensitivity to conductivity changes at each location,

J_{LI} = the lead field produced by current excitation electrodes,

J_{LE} = the lead field produced by voltage measurement leads.

Therefore, sensitivity at each location depends on the angle and magnitude of the two fields and can be positive, negative, or null. The relative magnitude of the sensitivity field in a tissue segment provides a measure of how conductivity variation in that tissue segment will affect the detected ΔZ (69).

Lead field theory suggests that the relative contribution of a tissue to the measured impedance depends on the properties of the tissue, the symmetric arrangement of the tissues, and the geometry of the applied current and voltage electrodes. The precise relative contribution of various tissues to measure impedance is therefore difficult to predict (Fig. 10) (68).

Intrathoracic Bioimpedance

Minute Ventilation. As described earlier, respiratory rate can be estimated with TEB. However, intrathoracic impedance sensing has also been applied to measure respiratory rate and minute ventilation in implantable devices such as pacemakers and implantable cardiac defibrillators (ICDs). Intrathoracic impedance vector configurations typically consist of a tripolar arrangement with

bipolar pacing or ICD leads placed in the right ventricle (RV) and the device “can” (metal case or housing) placed subcutaneously in the left or right pectoral region. A variety of anode/cathode electrode arrangements are possible with current source electrodes such as the proximal electrode (RV-ring) to can or the distal electrode (RV-tip) to can and voltage sense electrodes between RV-coil to can. Typically, a low energy pulse of low current amplitude (1 mA with pulse duration of 15 μ s) is delivered every 50 milliseconds (10). Figure 11 depicts a typical lead arrangement used for intrathoracic impedance measurements.

The electric fields generated with this electrode configuration must be arranged to intersect in parallel in order to provide the greatest sensitivity. The sensitivity of an electrode is proportional to the current density of the applied stimulus. Moreover, the sensitivity is highest close to the current-injecting electrodes and lowest toward the center of the tissue medium within the lead field vector,

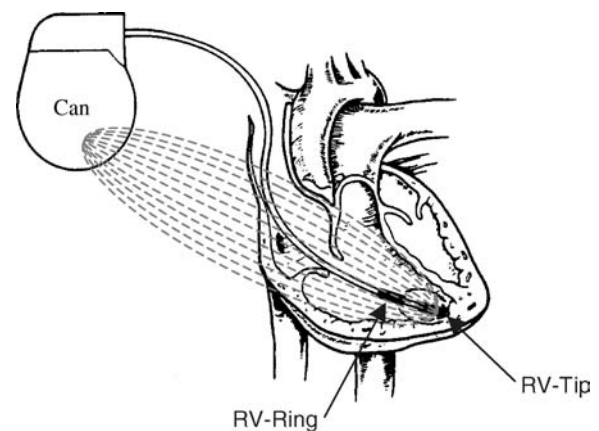

Figure 11. Lead configuration for intracardiac impedance measurements. Stimulus current injected from RV-tip to can. Voltage is measured from RV-Ring to can. The large size of the can reduces electrode polarization effects of the tripolar lead configuration.

Figure 12. Respiratory variation in impedance waveform. Electrocardiogram (ECG) shown with ΔZ waveform. ΔZ waveform is comprised of higher frequency cardiac components superimposed on the lower frequency respiratory variation component (46).

because the applied field current density is lowest in this region.

Experimental evidence indicates that the frequency and amplitude of the respiratory component of the bioimpedance signal are related to changes in both the respiratory rate and the tidal volume and, hence, the minute ventilation (MV). MV sensing in rate-adaptive pacing systems has also been shown to closely correlate with carbon dioxide production (VCO_2) (10). This relationship has been applied in some commercially available pacemakers with automatic rate-adaptive pacing features (9,10).

As shown in Fig. 12 (46), the amplitude of impedance changes during respiration are significantly larger than the higher frequency cardiac components. By magnitude, the change in the cardiac component of the impedance waveform is in the range of 0.1–0.2 Ω , which correlates to approximately 0.3–0.5% of the thoracic impedance (ΔZ) (46). Moreover, each component has a different frequency, typically 1.0–3.0 Hz for cardiac activity and 0.1–1.0 Hz for respiratory activity (9). This differentiation allows extraction of each signal by specific filtering techniques.

In general, the minute-ventilation sensor is characterized by a highly proportional relationship to metabolic demand over a wide variety of exercise types (10). However, optimal performance of impedance-based MV sensors to control pacing rate during exercise often requires careful patient-specific programming.

Fluid Status. Fluid congestion in the pulmonary circulation due to volume overload results in preferential transport of fluid primarily into the extracellular fluid space and not into the intracellular compartments. Clinical symptoms to assess fluid overload include hypertension, increased weight, pulmonary or peripheral edema, dyspnea, and left ventricular dysfunction. Recently, implantable device-based bioimpedance measurements have been applied to detect thoracic fluid accumulation in patients with congestive heart failure (CHF) and to

provide early warning of decompensation caused by factors such as volume overload and pulmonary congestion (32,70,71). This application is the result of a substantial body of new and historical experimental evidence (32,70–73).

Externally measured transthoracic impedance techniques have been shown to reflect alterations in intrathoracic fluid and pulmonary edema in acute animal and human studies (72). The electrical conductivity and the value for transthoracic impedance are determined at any point in time by relative amounts of air and fluid within the thoracic cavity (73). Additional studies have suggested that transthoracic impedance techniques provide an index of the fluid volume in the thorax (32,71). Wang et al. (70) employed a pacing-induced heart failure model to demonstrate that measurement of chronic impedance using an implantable device effectively revealed changes in left ventricular end-diastolic pressure in dogs with pacing-induced cardiomyopathy (Fig. 13) (70). Several factors were identified that may influence intrathoracic impedance with an implantable system, including (1) fluid accumulation in the lungs due to pulmonary vascular congestion, pulmonary interstitial congestion, and pulmonary edema; (2) as heart failure worsens, heart chamber dilation and venous congestion occur and pleural effusion may develop; and (3) after implant, the tissues near the pacemaker pocket swell and surgical trauma can cause fluid buildup (70).

Yu et al. (74) also showed that sudden changes in thoracic impedance predicted eminent hospitalization in 33 patients with severe congestive heart failure (NYHA Class III–IV). During a mean follow-up of 20.7 ± 8.4 months, 10 patients had a total of 25 hospitalizations for worsening heart failure. Measured impedance gradually decreased before admission by an average of $12.3 \pm 5.3\%$ ($p < 0.001$) over a mean duration of 18.3 ± 10.1 days. The decline in impedance also preceded the symptom onset by a mean lead time of 15.3 ± 10.6 days ($p < 0.001$). During hospitalization, impedance was inversely correlated with

Figure 13. Impedance vs. LVEDP during pacing-induced heart failure. Intrathoracic impedance via an implantable device-lead configuration and LVEDP are inversely correlated in a canine model of pacing-induced cardiomyopathy. A general trend for impedance to decrease as heart failure developed is shown. Once pacing induced heart failure was terminated, LVEDP and impedance returned to basal levels (70).

pulmonary wedge pressure (PWP) and volume status with $r = -0.61$ ($p < 0.001$) and $r = -0.70$ ($p < 0.001$), respectively. Automated detection of impedance decreases was 76.9% sensitive in detecting hospitalization for fluid overload with 1.5 false-positive (threshold crossing without hospitalization) detections per patient-year of followup. Thus, intrathoracic impedance from the implanted device correlated well with PWP and fluid status, and may predict eminent hospitalization with a high sensitivity and low false-alarm rate in patients with severe heart failure (Fig. 14) (74). Some commercially available implantable devices for the treatment of CHF or ventricular tachyarrhythmias now continually monitor intrathoracic impedance and display fluid status trends. This information is then provided to the clinician via direct-device interrogation or by remote telemetry.

Volume Conductance Catheter. The conductance catheter technique, first described by Baan et al. (8), enables continuous measurements of chamber volume, particularly left ventricular (LV) volume. This method has been used extensively to assess global systolic and diastolic ventricular function (75). In many respects, the conductance catheter revolutionized the study of cardiovascular mechanics in both the laboratory and clinical settings by making the study of ventricular pressure-volume relationships practical. The technique led to a renaissance of cardiac physiology over the past 25 years (76) by increasing the understanding of the effect of pharmacologic agents, disease states, pacing therapies, and other interventions on cardiovascular function. Conductance catheter systems are available for clinical and laboratory monitoring applications, including a miniature system capable of measuring LV volume and pressure in mice (77).

The conductance methodology is based on the parallel cylinder model (Fig. 3). However, the cylindrical model assumes that the volume of interest has a uniform cross-sectional area across its length. Therefore, the ventricular volume is subdivided into multiple segments determined by equipotential surfaces bounded by multiple sensing electrodes along the axis of the conductance catheter (Fig. 15).

Figure 14. Fluid status monitoring with an implanted device. A: Operation of algorithm for detecting decreases in impedance over time. Differences between measured impedance (bottom; \circ) and reference impedance (solid line) are accumulated over time to produce fluid index (top). Threshold values are applied to fluid index to detect sustained decreases in impedance, which may be indicative of acutely worsening thoracic congestion. B: Example of impedance reduction before heart failure hospitalization (arrow) for fluid overload and impedance increase during intensive diuresis during hospitalization. Label indicates reference baseline (initial reference impedance value when daily impedance value consistently falls below reference impedance line before hospital admission). Magnitude and duration of impedance reduction are also shown. Days in hospital are shaded (74).

Figure 15. Conductance catheter modeled in the left ventricle (LV). Stimulus current is injected from the proximal and distal catheter electrodes. Voltage is measured between the remaining adjacent electrode pairs. Total conductance is calculated by the summation of all segmental conductances measured in the individual segments.

The two most distal electrodes are used to generate an electric field, typically 0.4 mA p-p, at 20 kHz. The remaining electrodes are used in pairs to measure the conductance of several segments ($n = \text{number of segments}$), which represent the instantaneous volumes of the corresponding segment. The conductance is then converted to volume by modifying Eq. 2:

$$V(t) = \rho L^2 \sum_{i=1}^n G_i(t) \quad (10)$$

where G is the time-varying conductance of segment i . However, the conductance technique also violates two other key assumptions of the cylindrical model. First, the electrical field generated by the drive current electrodes is not homogenous and, second, the electric field is not confined to the chamber of interest (i.e., the LV). Thus, the multiple segment cylindrical model has been modified in order to allow conductance catheter estimates of volume to agree with gold standard estimates such as echocardiography (Eq. 11):

$$V(t) = \left(\frac{\rho L^2 \Sigma G(t)}{\alpha} \right) - V_P \quad (11)$$

where correction factor α accounts for nonhomogeneity of the electric field and the correction factor V_P accounts for the current leakage into the surrounding tissues. The terms α and V_P are related and may vary somewhat during the cardiac cycle (16,78). Various methods have been applied to determine the values of α and V_P , including the method of hypertonic saline injection.

Recently, the concept of dual-frequency excitation has been applied to estimate V_P for conductance volume measurements in mice (79). This method takes advantage of the relative reactive components of impedance between blood and tissue (80). Despite some theoretical limitations regarding the basic assumptions of field heterogeneity and current leakage, the conductance catheter technique has also been applied to the study of biomechanics in other chambers besides the left ventricle, including the right ventricle (81), right and left atria (82), and aorta (83,84).

Other Pacing Applications. Intracardiac impedance, or transvalvular impedance (TVI), can be used in the assessment of cardiac hemodynamics. This method involves determining the impedance between pacemaker leads in the right atrium and ventricle using a typical dual-chamber pacing configuration. The TVI waveform can be categorized into atrial, valvular, and ventricular components (Fig. 16) (85). Information derived from the atrial component may be useful to identify the loss of electrical capture in the atrium, or the impairment in atrial hemodynamic function associated with supraventricular tachyarrhythmias. The valvular and ventricular components may provide information on the presence, timing, and strength of ventricular mechanical activity (86).

In a study performed by Gasparini et al. (85), the representative TVI tracings (Fig. 16) were recorded from atrial ring to ventricular tip. TVI was measured by application of 64 Hz subthreshold current pulses of 125 μs duration and the amplitude ranging from 15 to 45 μA . The TVI

Figure 16. TVI during spontaneous A-V sequential activity. Fiducial points on the TVI waveform used to optimize A-V delay. t_1 corresponds to the end of atrial systole; t_2 corresponds to the end of ventricular ejection (85).

signal was recorded without high-pass filtering to determine the absolute minimum and maximum impedance in each cardiac cycle, which were assumed to reflect the end-diastolic volume and the end-systolic volume, respectively. TVI may represent a useful approach to determine hemodynamic parameters such as stroke volume, ejection fraction, pre-ejection interval, and atrio-ventricular delay. One significant advantage with this technique is that the source and sense leads are of those typically used in pacing systems and offer the advantage of a high signal-to-noise ratio (86). Moreover, the use of this technique has the potential to differentiate atrial from ventricular function that would be paramount if this technique is used for atrio-ventricular delay optimization (87).

Hematocrit Measurement. Measurement of the resistivity of whole blood has been investigated by a number of researchers, particularly in the area of transthoracic impedance techniques (88–91). A number of investigators have found blood resistivity to be an exponential function of hematocrit (Fig. 17) (15,89–95). These studies have demonstrated a strong correlation between the electrical resistivity of blood at frequencies between 20 to 50 kHz, as the red blood cell is the major resistive component in blood, compared with the relatively conductive plasma. Pop et al. (93) employed a four ring catheter electrode system with narrow electrodes spacing (2 mm center-to-center) to estimate hematocrit in the right atrium of anesthetized pigs. As shown in Fig. 17, good correlation existed between the hematocrit of blood and its electrical resistivity ($r^2 = 0.95–0.99$). Moreover, this study also showed a strong correlation between whole blood viscosity and electrical resistivity.

This interesting observation implies that intracardiac impedance has potential to monitor thrombosis risk in patients with hyperviscosity.

Blood Flow Conductivity Based on Erythrocyte Orientation. The electrical properties of blood are of practical interest in medicine because blood has the highest conductivity of all living tissues (89,96,97). Blood is a heterogeneous suspension of erythrocytes that have a higher resistivity than the suspending fluid (plasma). The resistivity of blood is a function of the resistivities of plasma,

the (fractional) packed-cell volume or hematocrit, and the orientation of the erythrocytes, due to their biconcave shape (98). The orientation of the erythrocytes can be influenced by the viscous forces in flowing blood, resulting in a shear rate-dependent resistivity. In stationary blood, the erythrocytes assume a random distribution while in flowing blood, the plane of the erythrocytes becomes oriented parallel to the axis of flow (99). Thus, minimum resistance occurs when the erythrocytes are oriented in an axial direction, parallel to the stream line. Conversely, maximum resistance occurs when the erythrocytes are oriented in a transverse direction to the stream line (100). The electrical properties of pulsatile blood flow are important when applying transthoracic bioimpedance to estimate cardiac output. In an experiment performed by Katsuyuki et al. (101), erythrocyte orientation, deformation, and axial accumulation caused differences in resistance between flowing and resting blood. Frequency characteristics of blood resistance under pulsatile flow showed that at low pulse rates, the resistance change was minimal, whereas at higher pulse rates, the resistance change increased because the orientation of the erythrocytes cannot follow the rapid changes of pulsatile blood flow. These results suggest that one mechanism of the varying resistance of blood in the aorta during pulsatile blood flow occurs because the orientation of the erythrocyte changes due to shear as a function of heart rate. Therefore, hemodynamic parameters such as cardiac output measured by impedance plethysmography must take into account the anisotropic electrical properties of oriented erythrocytes in blood. Moreover, the resulting resistance of flowing blood depends on the direction of the electrical field applied for impedance measurement and may be affected by the orientation of the erythrocytes during pulsatile flow (101).

REACTIVE APPLICATIONS OF BIOIMPEDANCE

Tissue Impedance

The reactive component of tissue impedance does not contribute significantly to measured impedance when the driving frequency range is less than 1 kHz (8,15). However,

Figure 17. Left figure depicts the correlation between hematocrit of blood and electrical resistivity in five subjects. Right figure depicts a similar correlation between hematocrit of blood and electrical resistivity based on equations by Maxwell–Fricke (upper curve) and Geddes and Sadler (lower curve) (15,93).

Figure 18. Relationship in phase angle and amplitude for tissue electrical properties. This example shows a capacitive tissue segment since the current waveform (I) leads the voltage waveform (V) by phase angle (θ) (103).

at higher driving current frequencies, the reactive component may contribute more substantially. As different tissues have different reactance, different frequencies may be selected for impedance measurement in order to discriminate various tissues (15,102).

Tissue impedance is characterized by four components: the in-phase component of voltage (V) with respect to the current intensity (I), the tissue resistance (R), and the phase angle (θ). The phase angle represents the time delay between the voltage and current intensity waves due to the capacitance of cell membranes (Fig. 18) (103).

Figure 19 shows cellular tissue structure representing alternating current distribution between a bipolar electrode pair at high and low frequencies. The change in polarity that occurs with AC current causes the cell membrane to charge and discharge at the rate of the applied frequency, and the impedance decreases as a function of increased frequency, because the amount of conducting volume increases through intracellular space. At higher frequencies, the rate of cell membrane charge and discharge becomes such that the effect of the cellular membrane on measured impedance becomes insignificant and the current flows through the intracellular and extracellular space (104).

Capacitance causes the voltage to lag behind the current (Fig. 18), creating a phase shift that is quantified as the angular transformation (θ) of the ratio of reactance to resistance (105). Note that the uniform orientation of cells in a tissue (Fig. 19) can result in anisotropy of electrical properties. That is, impedance will be lower in the longitudinal versus transverse direction of the tissue segment cellular structure (12,18).

The parallel-column model (Fig. 3) must be modified to describe higher frequency applications of bioimpedance in which the capacitive properties of the cell membranes become important. The Cole–Cole plot (Fig. 20) is a useful characterization of the three element RC model that describes the behavior of tissue impedance as a function of frequency (f), impedance (Z), resistance (R), reactance (X_C), and phase angle (ϕ) (103). The real components (R_1 and R_2) can be plotted versus the negative imaginary component of the capacitor (C) with reactance (X_C) in the complex series impedance ($R + jX_C$), with the frequency as a parameter where $j = (\sqrt{-1})$ (15). As the frequency is

Figure 19. Low and high frequency current distribution in a cellular structure. The low frequency stimulus current flows through the highly conductive extracellular space, whereas the high frequency stimulus current flows through both the extracellular and intracellular space once the reactance of the capacitive cellular membrane is reduced.

Figure 20. Cole–Cole plot and equivalent tissue impedance circuit. Resistance (abscissa) and reactance (ordinate) plotted as a function of frequency. A three-element electrical equivalent tissue impedance model is shown. At low frequency (f_L), the equivalent circuit is resistive and $R_0 = R_1 + R_2$. As the frequency increases, the phase angle (ϕ) increases until the resistance and reactance are equal at the characteristic frequency of the tissue (f_C). As the frequency increases beyond the characteristic frequency, the reactive element C is reduced to a low impedance and the tissue displays purely resistive properties where $R_\infty = R_1$. The depressed locus at angle α is presumed to represent electrode polarization.

changed between R_0 and R_∞ , the impedance will change continually along a curve in the R - X plane. At very low frequencies (f_L), the capacitive component of the system is effectively an open circuit so the reactance is equal to zero and the measured impedance (Z) is purely resistive (R_0). As the frequency increases, reactance (X_C) increases in proportion to resistance causing the phase angle (ϕ) to increase until a maximum angle is reached at the critical (characteristic) frequency (f_C). As shown in Fig. 20, phase angle is positively associated with resistance and negatively associated with reactance (106). Beyond the critical frequency, the reactance begins to decrease in proportion to resistance with increasing frequency and, at very high frequencies (f_H), the capacitive component is essentially short-circuited so the measured impedance is purely resistive at R_∞ (105).

If impedance of a tissue is measure over a broad spectrum, then the resultant impedance Cole–Cole plot can be fit to the three element model or other similar lumped-parameter models. Changes in the model elements can reflect changes in tissue properties due to pathological conditions such as ischemia (see below). In many biologic systems, the center of loci of the plot lies below the real axis and is represented by the angle α , a fixed number between 0 and 1 (2). This behavior can only be modeled by adding an inductive element to the electrical parameter model shown in Fig. 20. However, the physiological interpretation of the inductance is uncertain. Fricke et al. hypothesized that a possible source of this observed inductance might be electrode polarization (107). These investigations demonstrated behavior similar to constant depression angle of electrode polarization. They demonstrated that a frequency-dependent resistance and reactance could mathematically assume a constant depression angle (2). However, the physiologic explanation for $\alpha > zero$ remains

controversial. An additional theory related to the origin of the depressed loci is the distribution of time constants in a heterogeneous tissue segment. This distribution could result from variability in cell size or variability in properties of the individual cells (2).

Ischemia Detection. Tissue degradation due to ischemia can alter both the real and reactive components of bioimpedance (40). The dielectric polarization of matter (e.g., myocardial tissue) is given by the dimensionless parameter ϵ' , which is called dielectric permittivity. ϵ' describes the capacitance increase of a capacitor filled with matter:

$$\epsilon' = \frac{C}{C_0} \tag{12}$$

where:

C = a capacitor with matter (i.e., cellular structure),
 C_0 = vacuum capacitor.

As the dielectric polarization processes are frequency-dependent, they show relaxation phenomena with increasing frequency (108). The relaxation process is defined by the complex dielectric permittivity ϵ , thus:

$$\epsilon(\omega) = \epsilon'(\omega) - i\epsilon''(\omega) \tag{13}$$

where:

ϵ' = dielectric permittivity,
 ϵ'' = dielectric loss factor,
 $\omega = 2\pi f$,
 f = frequency of stimulus current,
 i = imaginary unit ($\sqrt{-1}$).

The method of dielectric spectroscopy has been proposed to investigate heart tissue during global ischemia, because the dielectric polarization of matter can be measured by the application of weak electric fields. An electrical circuit model to describe myocardial ischemia, initially developed by Gersing (109) and modified by Schaefer et al. (108), is depicted in Fig. 21. This model can be considered as a variation of the simplified three element physiologic model as shown in Fig. 20. The resistance R_{ext} describes the properties of the extracellular electrolyte, and the resistance R_{int} describes the intracellular cytosol. This model assumes that the transcellular current has to pass the membrane with capacitance C_m and the resistance R_m , through the cytosol, and from cell to cell through the interstitial membranes described by C_{is} or, alternatively, through gap junctions with resistance R_g (108,109). Application of this model enables quantification of the variation of intracellular coupling via gap junctions due to myocardial ischemia (108–111).

The measurement of alterations in impedance spectra with ischemia is often referred to as impedance spectroscopy. Myocardial electrical impedance (MEI), a specific application of impedance spectroscopy, has been shown to

Figure 21. Electronic equivalent model of heart tissue. Electrical elements consist of the intracellular (R_{int}) and extracellular resistance (R_{ext}), cellular membrane capacitance (C_m) and resistance (R_m), cell-to-cell interstitial membrane capacitance (C_{is}), and gap junction resistance (R_g).

identify localized and global myocardial tissue in various disease states in *in vitro* and *in vivo* experimental models (112).

Recently, MEI has been used in conjunction with electrocardiogram (ECG) ST-segment deviations to assess the magnitude of the ischemic region of the myocardium (103,112–116).

Injury currents, secondary to myocardial ischemia result in ST-segment displacements in the ECG of patients with myocardial ischemia (117). Injury currents deriving from resting depolarization in ischemic myocardial cells are associated with slow conduction through the myocardium. The mechanisms by which these injury currents correlate with the impedance spectroscopy alterations in the ischemic myocardial tissue are well described (103,108,109,112–117). Figure 22 depicts a segment of

Figure 22. Ischemic regions of myocardial tissue and corresponding ST-segment. Subendocardial ischemia (top) with depressed ST-segment. Transmural ischemia (bottom) with elevated ST-segment (117).

the myocardium with subendocardial and transmural ischemic tissue. Blood flow through the heart is interrupted during ischemia, and the tissue undergoes progressive changes leading to irreversible loss of its viability (108). Transmural ischemia causes ST-segment elevation and subendocardial ischemia causes ST-segment depression (117). The electrocardiographic differences between transmural and subendocardial ischemia are clinically important. Supply ischemia, as occurs following total interruption of flow through a coronary artery supplying a large area of the left ventricle, typically causes ST-segment elevation (63). In contrast, demand ischemia, as occurs during a stress test, begins in the subendocardial regions of the left ventricle and causes ST-segment depression (117).

The mechanism by which MEI changes with ischemia is not certain, but may well be associated with ultrastructural changes or cellular biochemical changes that occur in the myocardial tissue similar to those viewed by ST-segment deviations (113). The increase in MEI may result from reductions in the conductive fluid volume in the affected region of the myocardium (113). Gap junctions play a critical role in the propagation of electrical impulse in the heart, and its conductivity has been shown to be reduced and eventually abolished during ischemia and rapidly restored during reperfusion (103). Thus, gap junction closure is a reasonable hypothesis to explain observed impedance changes with ischemia. The intraintracardiac variation of intracellular and extracellular coupling is one possible explanation for the observed impedance changes of the dielectric frequency spectrum (108).

As MEI correlates with myocardial tissue viability (118,119), the measure has several important potential monitoring applications. Intraoperatively, MEI could be used to detect ischemia in aortic or myocardial tissue during cardiopulmonary bypass surgery as an early indication of damage. Following cardiopulmonary bypass, MEI could be used to assess reperfusion afforded by the new grafts. MEI could also aid in drug titration after cardiac surgery as well as to chronically monitor tissue perfusion with implantable devices such as pacemakers or cardioverter-defibrillators, or with patients whom have received a heart transplant (12,113,120).

In a study performed by Howie et al. (113), acute ischemia was induced in anesthetized dogs via left anterior descending (LAD) coronary artery occlusion for randomly assigned periods of 15, 30, 45, 60, or 120 min. MEI was simultaneously recorded using ventricular pacing leads sutured into the exposed heart tissue. As shown in Fig. 23, MEI increased immediately after LAD coronary artery occlusion and returned to baseline following reperfusion. A statistically significant increase occurred from baseline impedance when compared at 64, 68, 72, 76, and 80 min (113). This intracardiac technique used by Howie et al. suggested other possible applications for MEI with implantable devices and intracardiac pacing/monitoring leads. However, further development in the direction of optimal electrode placement to isolate the targeted tissue region and obtain the highest quality data for diagnosis of tissue alteration is warranted (12).

Figure 23. Change in myocardial impedance during LAD coronary artery occlusion (113).

Dialysis. Whole-body bioimpedance spectroscopy has been proposed by several investigators for measuring extracellular (ECW) and intracellular (ICW) water volumes in dialysis patients in order to assess nutritional status and to monitor hydration (121–125). An adequate assessment of body water compartments is crucial in dialysis patients because overhydration and underhydration are often difficult to detect and may result in severe morbidity in this population (126). Despite the continuous progress in the delivery of renal replacement therapy, mortality in patients on maintenance dialysis remains higher than in the general population (127).

During acute volume overload, most of the extra fluid collects in the ECW not the ICW. At very low frequencies, current only penetrates the ECW because the cell membrane acts as a capacitor and the impedance becomes equal to the ECW resistance (see Fig. 19). At very high frequencies, the injected current penetrates both the ECW and the ICW, and the impedance represents the total body water (TBW) resistance (125). Several investigators (128–131) have used single- and multiple-frequency impedance to monitor fluid shifts during hemodialysis. However, when attempting to determine precise fluid volumes from the measured impedance, difficulties occur due to the complex geometry of the human body and electrical inhomogeneity of nonconducting elements such as bone and fat (125). Signal processing methods to account for these aforementioned difficulties are described in the literature (104,124,125,132).

Whole-body bioelectrical impedance measurements typically apply single (e.g., 50 kHz) (133) or multifrequency (e.g., 5 to 1000 kHz) alternating currents applied via cutaneous electrodes placed on the hands and feet with more proximal electrodes uses for voltage measurements (126). The precise method for calculation of body fluid volumes depends on whether the single-frequency or multiple-frequency method is applied. The single-frequency method often uses an empirically derived regression formula to assess TBW, whereas the multiple-frequency method predicts the volume of TBW and ECW from a general mixture theory, assuming specific resistance values for ECW and

ICW (104,126,134). Moreover, the contribution of body weight, which is strongly related to ECW and TBW, is greater in the regression approach compared with the mixture approach (126).

Although reliable measurements of fluid content in dialysis patients have been reported (121–131), uncertainty remains regarding the agreement of whole-body bioimpedance in dialysis patients with tracer dilution techniques, which are considered the gold standard methods (126). One explanation for the lack of satisfactory agreement between techniques is that whole-body bioimpedance techniques consider the body as a multiple conductive cylinder model (e.g., arms, legs, trunk) connected in series (Fig. 24). With conductors connected in series, conductors with the smallest cross-sectional area (e.g., extremities) will determine most of the resistance, whereas the component with the largest cross-sectional area (e.g., trunk) will have minimal contribution to the resistance

Figure 24. Whole-body impedance measurement technique. Total Conductance (C_T) = Left Arm Conductance ($1/R_{LA}$) + Thoracic Cavity Conductance ($1/R_{TC}$) + Right Leg Conductance ($1/R_{RL}$).

although it contains a significant amount of body water (126). However, assessment of the sum of segmental bioelectrical impedance analysis measurements, which take into account resistance of the extremities and the trunk independently, have been shown to detect changes in trunk water more accurately (135). A seminal study performed by Patterson et al. (136) used multiple linear regression analysis combining data measured independently from the arms, legs, and trunk correlated with weight change on patients undergoing hemodialysis, gave a correlation coefficient of 0.87, whereas the correlation coefficient from measurements between just the wrist and ankle was 0.64.

Pulmonary Edema Detection. Patients developing pulmonary edema initially accumulate fluid in the interstitial spaces of the lung. As the condition progresses, fluid ultimately accumulates in the alveoli. To accurately measure pulmonary fluid status, the different bioelectric properties of blood, lung tissue, and extravascular fluid must be considered, and an impedance parameter not influenced by the patient's geometry should be used (137). Thus, using a dual-frequency measurement of thoracic impedance, an impedance ratio can be calculated that represents the ratio between intracellular and extracellular water. This ratio, therefore, changes as a result of the fluid shift caused by edema formation. As the low frequency current only passes through the extracellular resistance, the measured low frequency impedance (Z_{LF}) over a specified thoracic length equals the total extracellular resistance. As the frequency is increased, current is divided over the intracellular and extracellular compartments. Therefore, the measured high frequency impedance (Z_{HF}) over a specified thoracic length equals the parallel equivalent of intracellular and extracellular impedance. Thus, a dual-frequency impedance ratio that represents the intracellular/extracellular impedance fraction can be defined by Z_{HF}/Z_{LF} . As pulmonary fluid accumulates in the extracellular space, the impedance ratio increases (137).

INTRODUCTION

The past two decades have witnessed revolutionary changes in biomedical research and biotechnology and an explosive growth of biomedical data. High throughput technologies developed in automated DNA sequencing, functional genomics, proteomics, and metabolomics enable production of such high volume and complex data that the data analysis becomes a big challenge. Consequently, a promising new field, bioinformatics has emerged and is growing rapidly. Combining biological studies with computer science, mathematics, and statistics, bioinformatics develops methods, solutions, and software to discover patterns, generate models, and gain insight knowledge of complex biological systems.

Figure 1. Central dogma of molecular biology.

Before bioinformatics is discussed further, a brief review of the basic concepts in molecular biology, which are the foundations for bioinformatics studies, is provided. The genetic information is coded in DNA sequences. The physical form of a gene is a fragment of DNA. A genome is the complete set of DNA sequences that encode all the genetic information for an organism, which is often organized into one or more chromosomes. The genetic information is decoded through complex molecular machinery inside a cell composed of two major parts, transcription and translation, to produce functional protein and RNA products. These molecular genetic processes can be summarized precisely by the central dogma shown in Fig. 1. The proteins and active RNA molecules combined with other large and small biochemical molecules, organic compounds, and inorganic compounds form the complex dynamic network systems that maintain the living status of a cell. Proteins form complex 3D structures that carry out functions. The 3D structure of a protein is determined by the primary protein sequence and the local environment. The protein sequence is decoded from the DNA sequence of a gene through the genetic codes as shown in Table 1. These codes have been shown to be universal among all living forms on earth.

The high throughput data can be generated at many different levels in the biological system. The genomics data are generated from the genome sequencing that deciphers the complete DNA sequences of all the genetic information in an organism. We can measure the mRNA levels using microarray technology to monitor the gene expression of all the genes in a genome known as transcriptome. Proteome is the complete set of proteins in a cell at a certain stage, which can be measured by high throughput 2D gel electrophoresis and mass spectrometry. We also can monitor all the metabolic compounds in a cell known as metabolome in a high throughput fashion. Many new terms ending with “ome” can be viewed as the complete set of entities in a cell. For example, the “interactome” refers to the complete set of protein-protein interactions in a cell.

Bioinformatics is needed at all levels of high throughput systematic studies to facilitate the data analysis, mining, management, and visualization. But more importantly, the major task is to integrate data from different levels and prior biological knowledge to achieve system-level understanding of biological phenomena. As bioinformatics touches on many areas of biological studies, it is impossible to cover every aspect in a short chapter. In this chapter, the authors will provide a general overview of the field and focus on several key areas, including sequence analysis, phylogenetic analysis, protein structure, genome analysis, microarray analysis, and network analysis.

Sequence analysis often refers to sequence alignment and pattern searching in DNA and protein sequences. This area can be considered classic bioinformatics, which can be dated back to 1960s, long before the word bioinformatics appeared. It deals with the problems such as how to make an optimal alignment between two sequences and how to

Table 1. The Genetic Code

First Position	Second Position				Third Position
	T	C	A	G	
T	TTT Phe [F]	TCT Ser [S]	TAT Tyr [Y]	TGT Cys [C]	T
	TTC Phe [F]	TCC Ser [S]	TAC Tyr [Y]	TGC Cys [C]	C

Figure 2. Possible alignments of two sequences.

search sequence databases quickly with an unknown sequence. Phylogenetic analysis is closely related to sequence alignment. The idea is to use DNA or protein sequence comparison to infer evolution history. The first step in this analysis is to perform multiple sequence alignment. Then, a phylogenetic tree is built based on the multiple alignments. The protein structure analysis involves the prediction of protein secondary and tertiary structures from the primary sequences. So far, the analyses focus on individual sequences or a handful of sequences. The next three areas are involved in system-wide analysis. Genome analysis mainly deals with the sequencing of a complete or partial genome. The problems include genome assembly, gene structure prediction, gene function annotation, and so on. Many techniques of sequence analysis are used in genome analysis, but many new methods were developed for the unique problems. Microarray technologies provide an opportunity for biologists to study the gene expression at a system level. The problems faced in the analysis are completely different from sequence analysis. Many statistical and data mining techniques are applied in the field. Network analysis is another system level study of the biological system. Biological networks can be divided into three categories: metabolic network, protein-protein interaction network, and genetic network. The questions in this area include network modeling, network inference from high throughput data, such as microarray, and network properties study. In the following several sections, the authors will provide a more in-depth discussion of each area.

SEQUENCE ALIGNMENT

Pair-Wise Sequence Alignment

Sequence alignment can be described by the following problem. Given two strings of text, X and Y (which may be DNA or amino acid sequences), find the optimal way of

inserting dashes into the two sequences so as to maximize a given scoring function between them. The scoring function depends on both the length of the regions of consecutive dashes and the pairs of characters that are in the same position when gaps have been inserted. The following example from Abbas and Holmes (1) illustrates the idea of sequence alignment for two strings of text. Consider the two sequences, COUNTING and NTIG, shown in Fig. 2a. Figures 2b, 2c, and 2d show possible alignments obtained by inserting gaps (dashes) at different positions in one of the sequences. Figure 2d shows the alignment with the highest number of matching elements. The optimal alignment between two sequences depends on the scoring function that is used. As shall be shown, an optimal sequence alignment for a given scoring function may not be.

Now that what is meant by an optimal sequence alignment has been discussed, the motivation for doing so must be explained. Sequence alignment algorithms can detect mutations in the genome that lead to genetic disease and also provide a similarity score, which can be used to determine the probability that the sequences are evolutionarily related. Knowledge of evolutionary relation between a newly identified protein sequence and a family of protein sequences in a database may provide the first clues about its 3D structure and chemical function. Furthermore, by aligning families of proteins that have the same function (and may have very different sequences), a common subsequence of amino acids can be observed that is key to its particular function. These subsequences are termed protein motifs. Sequence alignment is also a first step in constructing phylogenetic trees that relate biological families of species.

A dynamic programming approach to sequence alignment was proposed by Needleman and Wunsch (2). The idea behind the dynamic programming approach can be explained using the two sequences, CCGAT and CA-AT, of Fig. 3a. If this alignment is broken into two parts (Fig. 3b),

Figure 3. Overview of the dynamic programming approach.

two alignments exist: the left is the alignment of the two sequences CCGA and CA-A, and the right is the alignment of the last elements T-T. If the scoring system is additive, then the score of the alignment of Fig. 3b is the sum of the scores of the four base-alignment on the left plus the score of the alignment of the pair T-T on the right. If the alignment in Fig. 3a is optimal, then the four-base alignment in the left-hand side of Fig. 3b must also be optimal. If this were not the case (e.g., if a better alignment would be obtained by aligning A with G), then the optimal alignment of Fig. 3c would lead to a higher score than the alignment shown in Fig. 3a. The optimal alignment ending at any stage is therefore equal to the total (cumulative) score of the optimal alignment at the previous stage plus the score assigned to the aligned elements at that current stage.

The optimal alignment of two sequences ends with either the last two symbols aligned, the last symbol of one sequence aligned to a gap, or the last symbol of the other sequence aligned to a gap. In the author's analysis, x_i refers to the i th symbol in sequence 1 and y_j refers to the j th symbol in sequence 2 before any alignment has been made. The authors will use the symbol $S(i,j)$ to refer to the cumulative score of the alignment up until symbols x_i and y_j , and the symbol $s(x_i,y_j)$ to refer to the score assigned to matching elements x_i and y_j . The authors will use d to refer to the cost associated with introducing a gap.

1. If the current stage of the alignment matches two symbols, x_i and y_j , then the score, $S(i,j)$, is equal to the previous score, $S(i-1,j-1)$, plus the score assigned to aligning the two symbols, $s(x_i,y_j)$.
2. If the current match is between symbol x_i in sequence 1 and a gap in sequence 2, then the new score is equal to the score up until symbol x_{i-1} and the same symbol y_j , $S(i-1,j)$, plus the penalty associated with introducing a gap, $-d$
3. If the current match is between symbol y_j in sequence 2 and a gap in sequence 1, then the new score is equal to the previous score up until symbol y_{j-1} and the same symbol x_i , $S(i,j-1)$, plus the gap penalty $-d$

The optimal cumulative score at symbols x_i and y_j is:

$$S(i,j) = \max \begin{cases} S(i-1,j-1) + s(x_i,y_j) \\ S(i-1,j) - d \\ S(i,j-1) - d \end{cases}$$

The previous equation determines the new elements at each stage in the alignment by successive iterations from the previous stages. The maximum at any stage may not be unique. The optimal sequence alignment (s) is the one that provides the highest score, which is usually performed using a matrix representation, where the cells in the matrix are assigned an optimal score, and the optimal alignment is determined by a process called trace back (3,4).

The optimal alignment between two sequences depends on the scoring function that is used, which brings the need for a score that is biologically significant and relevant to the phenomenon being analyzed. Substitution matrices present one method of achieving this alignment using a "log-odds" scoring system. One of the first substitution matrices used to score amino acid sequences was developed by Dayhoff et al. (5). Other matrices such as the BLOSUM50 matrix (6) were also developed and use databases of more distantly related proteins.

The Needleman-Wunsch (N-W) algorithm and its variation (3) provide the best *global* alignment for two given sequences. Smith and Waterman (7) presented another dynamic programming algorithm that deals with finding the best *local* alignment for smaller subsequences of two given sequences rather than the best global alignment of the two sequences. The local alignment algorithm identifies a pair of subsegments, one from each of the given sequences, such that no other pair of subsegments exist with greater similarity.

Heuristic Alignment Methods

Heuristic search methods for sequence alignment have gained popularity and extensive use in practice because of the complexity and large number of calculations in the dynamic programming approach. Heuristic approaches search for local alignments of subsegments and use these alignments as "seeds" in which to extend out to longer sequences. The most widely used heuristic search method available today is BLAST (Basic Local Alignment Search Tool) by Altschul et al. (8). BLAST alignments define a measure of similarity called MSP (Maximal Segment Pair) as the highest scoring pair of identical length subsegments from two sequences. The lengths of the subsegments are chosen to maximize the MSP score.

Multiple Sequence Alignments

Multiple sequence alignments are alignments of more than two sequences. The inclusion of additional sequences can improve the accuracy of the alignment, find protein motifs, identify related protein sequences in a database, and predict protein secondary structure. Multiple sequence alignments are also the first step in constructing phylogenetic trees.

The most common approach for multiple alignments is progressive alignment, which involves choosing two sequences and performing a pairwise alignment of the first to the second. The third sequence is then aligned to the first and the process is repeated until all the sequences are aligned. The score of the multiple alignment is the sum of scores of the pairwise alignments. Pairwise dynamic programming can be generalized to perform multiple alignments using the progressive alignment approach; however, it is computationally impractical even when only a few sequences are involved (9). The sensitivity of progressive alignment was improved for divergent protein sequences using CLUSTAL-W (10) (available at <http://clustalw.genome.ad.jp/>).

Many other approaches to sequence alignment have been proposed in the literature. For example, a Bayesian

approach was suggested for adaptive sequence alignments (11,12). The data that is now available from the human genome project has suggested the need for aligning whole genome sequences where large-scale changes can be studied as opposed to single-gene insertions, deletions, and nucleotide substitutions. MuMMer (12) follows this direction and performs alignments and comparisons of very large sequences.

PHYLOGENETIC TREES

Biologists have long built trees to classify species based on morphological data. The main objectives of phylogenetic tree studies are (1) to reconstruct the genealogical ties between organisms and (2) to estimate the time of divergence between organisms since they last shared a common ancestor. With the explosion of genetic data in the last few years, tree building has become more popular, where molecular-based phylogenetic studies have been used in many applications, such as the study of gene evolution, population subdivisions, analysis of mating systems, paternity testing, environmental surveillance, and the origins of diseases that have transferred species.

From a mathematical point of view, a phylogenetic tree is a rooted binary tree with labeled leaves. A tree is binary if each vertex has either one or three neighbors. A tree is rooted if a node, R , has been selected and termed the root. A root represents an ancestral sequence from which all other nodes descend. Two important aspects of a phylogenetic tree are its topology and branch length. The topology refers to the branching pattern of the tree, and the branch length is used to represent the time between the splitting events (mutations). Figure 4a shows a rooted binary tree with six leaves. Figure 4b shows all possible distinct rooted topologies for a tree with three leaves.

The data that is used to construct trees is usually in the form of contemporary sequences and is located at the leaves. For this reason, trees are represented with all their leaves “on the ground level” rather than at different levels.

The tree-building analysis consists of two main steps. The first step, estimation, uses the data matrix to produce a tree, \tilde{T} , that estimates the unknown tree, T . The second step provides a confidence statement about the estimator \tilde{T} , which is often performed by bootstrapping methods.

Tree-building techniques can generally be classified into one of four types: distance-based methods, parsimony methods, maximum likelihood methods, and Bayesian methods. For a detailed discussion of each of these methods, see Li (13).

Figure 4. (a) Rooted tree with six leaves. (b) All possible topologies for three leaves.

Tree-building methods can be compared using several criteria such as accuracy (which method gives the true tree, T , when we know the answer?), consistency (when the number of characters increases to infinity, do the trees provided by the estimator converge to the true tree?), efficiency (how quickly does a method converge to the correct solution as the data size increases?), and robustness (is the method stable when the data does not fulfill the necessary assumptions?). To clarify some of these issues, read Holmes (14), where a geometric analysis of the problem is provided and these issues are further discussed.

The second part of the tree-building analysis is concerned with how close we believe the estimated tree is to the true tree. This analysis builds on a probability distribution on the space of all trees. The difficult part of this problem is that, exponentially, many possible trees exist. A nonparametric approach using a multinomial probability model on the whole set of trees would not be feasible as the number of trees is $(2N-3)!!$. The Bayesian approach defines parametric priors on the space of trees, and then computes the posterior distribution on the same subset of the set of all trees. This analysis enables confidence statements in a Bayesian sense (15).

PROTEIN FOLDING, SIMULATION, AND STRUCTURE PREDICTION

The main motivation for this study is that the structure of a protein greatly influences its function. Knowledge of protein structure and function can help determine the chemical structure of drugs needed to reverse the symptoms that develop due to its malfunction.

The structure of a molecule consists of atoms connected together by bonds. The bonds in a molecular structure contribute to its overall potential energy. The authors shall neglect all quantum mechanical effects in the following discussion and consider only the elements that contribute largely to the potential energy of a structure [as suggested by Levitt and Lifson (16)].

- 1. Pair Bonds:** A bond that exists between atoms physically connected by a bond and separated by a distance b . It is like a spring action where energy is stored above and below an equilibrium distance, b_0 . The energy associated with this bond is $U(b) = \frac{1}{2}K_b(b - b_0)^2$, where b_0 can be determined from X rays and K_b can be determined from spectroscopy.
- 2. Bond Angles:** This bond exists when an angular deviation from an equilibrium angle, θ_0 , occurs between three atoms. The bond angle energy associated with the triplet is $U(\theta) = \frac{1}{2}K_\theta(\theta - \theta_0)^2$.
- 3. Torsion Angles:** This bond exists when a torsion angle, ϕ , exists between the first and fourth atoms on the axis of the second and third atoms. The energy associated with this bond is $U(\phi) = K_\phi(1 - \cos(n\phi + \delta))$, where θ is an initial torsion angle.
- 4. Nonbonded pairs:** Bonds also exist between atoms that are not physically connected in the structure. These bonds include:

- a. Van der Waal forces, which exist between nonbonded pairs and contribute to energy, $U(r) = \epsilon[(\frac{r_0}{r})^{12} - 2(\frac{r_0}{r})^6]$, r_0 is an equilibrium distance and ϵ a constant.
- b. Electrostatic interactions, which contribute to an energy of $U(r) = \alpha \frac{q_i q_j}{r}$; and
- c. Hydrogen bonds, which result from van Der Waals forces and the geometry of the system, and contribute to the potential energy of the structure.

The total potential energy function of a given structure can thus be determined by the knowledge of the precise position of each atom. The three main techniques that are used for protein structure prediction are homology (comparative modeling), fold recognition and threading, and *ab initio* folding.

Homology or Comparative Modeling. Comparative modeling techniques predict the structure of a given protein sequence based on its alignment to one or more protein sequences of known structure in a protein database. The approach uses sequence alignment techniques to establish a correspondence between the known structure “template” and the unknown structure. Protein structures are archived for public use in an Internet-accessible database known as the Protein Data Bank (<http://www.rcsb.org/pdb/>) (17).

Fold Recognition and Threading. When the two sequences exhibit less similarity, the process of recognizing which folding template to use is more difficult. The first step, in this case, is to choose a structure from a library of templates in the protein databank, called fold recognition. The second step “threads” the given protein sequence into the chosen template. Several computer software programs are available for protein structure prediction using the fold recognition and threading technique such as PROSPECT (18).

Ab Initio (New Fold) Prediction. If no similarities exist with any of the sequences in the database, the *ab initio* prediction method is used. This method is one of the earliest structure prediction methods, and uses energy interaction principles to predict the protein structure (16,19,20). Some of these methods include optimization where the objective is to find a minimum energy structure (a local minimum in the energy landscape has zero forces acting on the atoms and is therefore an equilibrium state).

Monte Carlo sampling is one of the most common techniques for simulating molecular motion. The algorithm starts by choosing an initial structure, A , with potential energy, $U(A)$. A new structure, B , is then randomly generated. If the energy of the new structure is less than that of the old structure, the new structure is accepted. If the energy of the new structure is higher than the old structure, then we generate a random number, $RAND$, from a uniform distribution $U(0,1)$. The new structure is accepted if $e^{-\frac{\Delta E}{KT}} > RAND$, where $\Delta E = E_B - E_A$ is the difference in energy levels, K is Boltzman’s constant, and T is the temperature in kelvins. Otherwise, the new structure

is rejected. Another random structure is then generated (either from the new accepted structure or from the old structure if the first one was rejected) and the process is repeated until some termination condition is satisfied (e.g., the maximal number of steps has been achieved).

Another type of analysis uses molecular dynamics uses equations of motion to trace the position of each atom during folding of the protein (21). A single structure is used as a starting point for these calculations. The force acting on each atom is the negative of the gradient of the potential energy at that position. Accelerations, a_i , are related through masses, m_i , to forces, F_i , via Newton’s second law ($F_i = m_i a_i$). At each time step, new positions and velocities of each of the atoms are determined by solving equations of motion using the old positions, old velocities, and old accelerations. Beeman (22) showed that new atomic positions and velocities could be determined by the following equations of motion

$$x(t + \Delta t) = x(t) + v(t)\Delta t + [4a(t) - a(t + \Delta t)] \frac{(\Delta t)^2}{6}$$

$$v(t + \Delta t) = v(t) + [2a(t + \Delta t) + 5a(t) - a(t - \Delta t)] \frac{\Delta t}{6}$$

where $x(t)$ = position of the atom at time t , $v(t)$ = velocity of the atom at time t , $a(t)$ = acceleration at time t , and Δt = time step in the order of 10^{-15} s for the simulation to be accurate.

In 1994, the first large-scale experiment to assess protein structure prediction methods was conducted. This experiment is known as CASP (Critical Assessment of techniques for protein Structure Prediction). The results of this experiment were published in a special issue of *Proteins* in 1995. Further experiments were developed to evaluate the fully automatic web servers for fold recognition. These experiments are known as CAFASP (Critical Assessment of Fully Automated Structure Prediction). For a discussion on the limitations, challenges, and likely future developments on the evaluation of the field of protein folding and structure prediction, the reader is referred to Bourne (23).

GENOME ANALYSIS

Analysis of completely sequenced genomes has been one of the major driving forces for the development of the bioinformatics field. The major challenges in this area include genome assembly, gene prediction, function annotation, promoter region prediction, identification of single nucleotide polymorphism (SNP), and comparative genomics of conserved regions. For a genome project, one must ask several fundamental questions: How can we put the whole genome together from many small pieces of sequences? where are the genes located on a chromosome? and what are other features we can extract from the completed genomes?

Genome Assembly

The first problem is pertaining to the genome mapping and sequence assembly. During the sequencing process, large DNA molecules with millions of base pairs, such as a

human chromosome, are broken into smaller fragments (~100 kb) and cloned into vector such as bacterial artificial chromosome (BAC). These BAC clones can be tiled together by physical mapping techniques. Individual BACs can be further broken down into smaller random fragments of 1–2 kb. These fragments are sequenced and assembled based on overlapping fragments. With more fragments sequenced, enough overlaps will exist to cover most of the sequence. This method is often referred as “shotgun sequencing”. Computer tools were developed to assemble the small random fragments into large contigs based on the overlapping ends among the fragments using similar algorithms as the ones used in the basic sequence alignment. The widely used ones include PHRAP/Consed (24,25) and CAP3 (26). Most of the prokaryotic genomes can be sequenced directly by the shotgun sequencing strategy with special techniques for gap closure. For large genomes, such as the human genome, two strategies exist. One is to assemble large contigs first and then tile together the contigs based on the physical map to form the complete chromosome (27). Another strategy is called Whole Genome Shotgun Sequencing (WGS) strategy, which assemble the genome directly from the shotgun sequencing data in combination with mapping information (28). WGS is a faster strategy to finish a large genome, but the challenge of WGS is how to deal with the large number of repetitive sequences in a genome. Nevertheless, WGS has been successfully used in completing the *Drosophila* and human genomes (29,30).

Genome Annotation

The second problem is related to deciphering the information coded in a genome, which is often called genome annotation. The process includes the prediction of gene structures and other features on a chromosome and the function annotation of the genes. Two basic types of genes exist in a genome: RNA genes and protein encoding genes. RNA genes produce active RNA molecules such as ribosomal RNA, tRNA, and small RNA. The majority of genes in a genome are protein encoding genes. Therefore, the big challenge is how to find the protein encoding region in a genome. The simplest way to search for a protein encoding region is to search for open reading frames (ORF), which is a contiguous set of codons between two stop codons. Six possible reading frames for a given DNA sequence exist, three of which start at the first, second, and third base. The other three reading frames are at the complementary strand. The longest ORFs between the start codon and the stop codon in the same reading frame provide good, but not sufficient, evidence of a protein encoding region. Gene prediction is generally easier and more accurate in prokaryotic than eukaryotic organisms due to the intron/exon structure in eukaryote genes. Computational methods of gene prediction based on the Hidden Markov Model (HMM) have been quite successful, especially in prokaryote genome. These methods involve training a gene model to recognize genes in a particular organism. As a result of the variations in codon usage, a model must be trained for each new genome. In a prokaryote genome, genes are packed densely with relatively short intergenic sequences.

The model reads through a sequence with unknown gene composition and find the regions flanked by start and stop codons. The codon composition of a gene is different from that of an intergenic region and can be used as a discriminator for gene prediction. Several software tools, such as GeneMark (31) and Glimmer (32) are widely used HMM methods in prokaryotic genome annotation. Similar ideas are also applied to eukaryote gene prediction. As a result of the intron/exon structure, the model is much more complex with more attention on the boundary of intron and exon. Programs such as GeneScan (33) and GenomeScan (34) are HMM methods for eukaryote gene prediction. Neural network-based methods have also been applied in eukaryote gene prediction, such as Grial (35). Additional information for gene prediction can be found using expressed sequence tags (ESTs), which are the sequences from cDNA libraries. As cDNA is derived from mRNA, a match to an EST is a good indication that the genomic region encodes a gene. Functional annotation of the predicted genes is another major task in genome annotation. This process can be also viewed as gene classification with different functional classification systems such as protein families, metabolic pathways, and gene ontology. The simplest way is to infer annotation from the sequence similarity to a known gene (e.g., BLAST search against a well-annotated protein database such as SWISS-PROT). A better way can be a search against protein family databases [e.g., Pfam (36)], which are built based on profile HMMs. The widely used HMM alignment tools include HMMER (37) and SAM (38). All automated annotation methods can produce mistakes. More accurate and precise annotation requires manual checking and a combination of information from different sources.

Besides the gene structures, other features such as promoters can be better analyzed with a finished genome. In prokaryotic organisms, genes involved in the same pathway are often organized in an operon structure. Finding operons in a finished genome provides information on the gene regulation. For eukaryotic organisms, the completed genomes provide upstream sequences for promoter search and prediction. Promoter prediction and detection has been a very challenging bioinformatics problem. The promoter regions are the binding sites for transcription factors (TF). Promoter prediction is to discover the sequence patterns that are specific for TF binding. Different motif finding algorithms have been applied including scoring matrix method (39), Gibbs sampling (40), and Multiple EM for Motif Elicitation (MEME) (41). The results are not quite satisfactory. Recent studies using comparative genomics methods on the problem have produced some promising results and demonstrated that the promoters are conserved among closely related species (42). In addition, microarray studies can provide additional information for promoter discoveries (see the section on microarray analysis).

Comparative Genomics

With more and more genomes being completely sequenced, comparative analysis becomes increasingly valuable and provides more insights of genome organization and

evolution. One comparative analysis is based on the orthologous genes, called clusters of orthologous groups (COG) (43). Two genes from two different organisms are considered orthologous genes if they are believed to come from a common ancestor gene. Another term, paralogous genes, refers to genes in one organism and are related to each other by gene duplication events. In COG, proteins from all completed genomes are compared. All matching proteins in all the organisms are identified and grouped into orthologous groups by speciation and gene duplication events. Related orthologous groups are then clustered to form a COG that includes both orthologs and paralogs. These clusters correspond to classes of functions. Another type of comparative analysis is based on the alignment of the genomes and studies the gene orders and chromosomal rearrangements. A set of orthologous genes that show the same gene order along the chromosomes in two closely related species is called a synteny group. The corresponding region of the chromosomes is called synteny blocks (44). In closely related species, such as mammalian species, the gene orders are highly conserved. The gene orders are changed by chromosomal rearrangements during evolution including the inversion, translocation, fusion, and fission. By comparing completely sequenced genomes, for example, human and mouse genomes, we can reveal the rearrangement events. One challenging problem is to reconstruct the ancestral genome from the multiple genome comparisons and estimate the number and types of the rearrangements (45).

MICROARRAY ANALYSIS

Microarray technologies allow biologists to monitor genome-wide patterns of gene expression in a high throughput fashion. Gene expression refers to the process of transcription. Gene expression for a particular gene can be measured as the fluctuation of the amount of messenger RNA produced from the transcription process of that gene in different conditions or samples.

DNA microarrays are typically composed of thousands of DNA sequences, called probes, fixed to a glass or silicon substrate. The DNA sequences can be long (500–1500 bp) cDNA sequences or shorter (25–70 mer) oligonucleotide sequences. The probes can be deposited with a pin or piezoelectric spray on a glass slide, known as spotted array technology. Oligonucleotide sequences can also be synthesized *in situ* on a silicon chip by photolithographic technology (i.e., Affymetrix GeneChip). Relative quantitative detection of gene expression can be carried out between two samples on one array (spotted array) or by single samples comparing multiple arrays (Affymetrix GeneChip). In spotted array experiments, samples from two sources are labeled with different fluorescent molecules (Cy3 and Cy5) and hybridized together on the same array. The relative fluorescence between each dye on each spot is then recorded and a composite image may be produced. The relative intensities of each channel represent the relative abundance of the RNA or DNA product in each of the two samples. In Affymetrix GeneChip experiments, each sample is labeled with the same dye and hybridized to different

Figure 5. An image from a spotted array after laser scanning. Each spot on the image represents a gene and the intensity of a spot reflects the gene expression.

arrays. The absolute fluorescent values of each spot may then be scaled and compared with the same spot across arrays. Figure 5 gives an example of a composite image from one spotted array.

Microarray analyses usually include several steps including: image analysis and data extraction, data quantification and normalization, identification of differentially expressed genes, and knowledge discovery by data mining techniques such as clustering and classification. Image analysis and data extraction is fully automated and mainly carried out using a commercial software package or a freeware depending on the technology platforms. For example, Affymetrix developed a standard data processing procedure and software for its GeneChips (for detailed information, see <http://www.affymetrix.com>); GenePix is widely used image analysis software for spotted arrays. For the rest of the steps, the detailed procedures may vary depending on the experiment design and goals. We will discuss some of the procedures below.

Statistical Analysis

The purpose of normalization is to adjust for systematic variations, primarily for labeling and hybridization efficiency, so that the true biological variations can be discovered as defined by the microarray experiment (46,47). For example, as shown in the self-hybridization scatter plot (Fig. 6) for a two-dye spotted array, variations (dye bias) between dyes is obvious and related to spot intensities. To correct the dye bias, one can apply the following model:

$$\log_2(R/G) \rightarrow \log_2(R/G) - c(A)$$

where R and G are the intensities of the dyes; A is the signal strength ($\log_2(R \cdot G)/2$); M is the logarithm ratio ($\log_2(R/G)$); $c(A)$ is the locally weighted polynomial regression (LOWESS) fit to the MA plot (48,49).

After correction of systematic variations, we want to determine which genes are significantly changed during the experiment and to assign appropriately adjusted p values to the genes. For each gene, we wish to test the null hypothesis that the gene is not differentially expressed. The P value is the probability of finding a result

Figure 6. Self-hybridization scatter plot. The y axis is the intensity from one dye; the x axis is the intensity from the other dye. Each spot is a gene.

by chance. If P value is less than a cut-off (e.g., 0.05), one would reject the null hypothesis and state that the gene is differentially expressed (50). Analysis of variance (ANOVA) is usually used to model the factors for a particular experiment. For example,

$$\log(m_{ijk}) = \mu + A_i + D_j + V_k + \varepsilon_{ijk}$$

where m_{ijk} is the ratio of intensities from the two dye-labeled samples for a gene; μ is the mean of ratios from all replicates; A is the effect of different arrays; D is the dye effects; and V is the treatment effects (51). Through F test, it will be determined if the gene exhibits differential expression between any V_k . For a typical microarray, thousands of genes exist. We need to perform thousands of tests in an experiment at the same time, which introduce the statistical problem of multiple testing and adjustment of p value. False discovery rate (FDR) (52) has been commonly adopted for this purpose.

For Affymetrix GeneChips analysis, even though the basic steps are the same as spotted microarrays, because of the difference in technology, different statistical methods were developed. Besides the statistical methods provided by Affymetrix, several popular methods are packaged into software such as dChip (53) and RMA (54) in Bioconductor (<http://www.bioconductor.org>). With rapid accumulation of microarray data, one challenging problem is how to compare microarray data across different technology platforms. Some recent studies on data agreements have provided some guidance (55–57).

Clustering and Classification

Once a list of significant genes is obtained from the statistical test, different data mining techniques would be applied to find interesting patterns. At this step, the microarray dataset is organized as a matrix. Each column represents a condition; each row represents a gene. An entry is the expression level of the gene under the corresponding condition. If a set of genes exhibit the similar fluctuation

Figure 7. Hierarchical clustering of microarray data. Rows are genes. Columns are RNA samples at different time points. Values are the signals (expression levels) that are represented by the color spectrum. Green represents down-regulation whereas red represents up-regulation. The color bars beside the dendrogram show the clusters of genes that exhibit similar expression profiles (patterns). The bars are labeled with letters and description of possible biological processes involving the genes in the clusters. [Reprinted from Eisen et al. (58).]

under all of the conditions, it may indicate that these genes are co-regulated. One way to discover the co-regulated genes is to cluster genes with similar fluctuation patterns using various clustering algorithm. Hierarchical clustering was the first clustering method applied to the problem (58). The result of hierarchical clustering forms a 2D dendrogram as shown in Fig. 7. The measurement used in the clustering process can be either a similarity, such as Pearson's correlation coefficient, or a distance, such as Euclidian distance.

Many different clustering methods have been applied later on, such as k means (59), self-organizing map (60), and support vector machine (61). Another type of microarray study involves classification techniques. For example, we can use the gene expression profile to classify cancer types. Golub et al. (62) first reported using classification techniques to classify two different types of leukemia as shown in Fig. 8. Many commercial software packages (e.g., GeneSpring and Spotfire) offer the use of these algorithms for microarray analyses.

COMPUTATIONAL MODELING AND ANALYSIS OF BIOLOGICAL NETWORKS

The biological system is a complex system involving hundreds of thousands of elements. The interaction among the elements forms an extremely complex network. With the development of high throughput technologies in functional genomics, proteomics, and metabolomics, one can start looking into the system-level mechanisms governing the interactions and properties of biological networks. Network modeling has been used extensively

Figure 8. An example of microarray classification. Genes distinguishing acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL). The 50 genes most highly correlated with the ALL-AML class distinction are shown. Each row corresponds to a gene, with the columns corresponding to expression levels in different samples. Expression levels for each gene are normalized across the samples such that the mean is 0 and the SD is 1. The scale indicates SDs above or below the mean. The top panel shows genes highly expressed in ALL, the bottom panel shows genes more highly expressed in AML. [Reprinted from Golub et al. (62).]

in social and economical fields for many years (63). Many methods can be applied to biological network studies.

The cellular system involves complex interactions between proteins, DNA, RNA, and smaller molecules and can be categorized in three broad subsystem, metabolic network or pathway, protein network, and genetic or gene regulatory network. *Metabolic network* represents the enzymatic processes within the cell, which provide energy and building blocks for cells. It is formed by the combination of a substrate with an enzyme in a biosynthesis or degradation reaction. Considerable information about metabolic reactions has been accumulated through many years and organized into large databases, such as KEGG (64), EcoCyc (65), and WIT (66). *Protein network* refers to the signaling networks where the basic reaction is between two proteins. Protein-protein interactions can be determined systematically using techniques such as yeast two-hybrid system (67) or derived from the text mining of literatures (68). *Genetic network or regulatory network* refers to the functional inference of direct causal gene interactions (69). One can conceptualize gene expression as a genetic feedback network. The network can be inferred from the gene expression data generated from microarray

or proteomics studies in combination with computation modeling.

Metabolic network is typically represented as a graph with the vertex being all the compounds (substrates) and the edges being reactions linking the substrates. With such representation, one can study the general properties of the metabolic network. It has been shown that metabolic network exhibits typical property of small world or scale-free network (70,71). The distribution of compound connectivity follows a power law as shown in Fig. 9. Nodes serving as hubs exist in the network. Such property makes the network quite robust to random deletion of nodes, but vulnerable to selected deletion of nodes. For example, deletion of hub nodes will cause the network collapse very quickly. A recent study also shows that the metabolic network can be organized in modules based on the connectivity. The connectivity is high within modules, but low between modules (72).

Flux analysis is another important aspect in metabolic network study. Building on the stoichiometric network analysis, which only uses the well-characterized network topology, the concept of elementary flux modes was introduced (73,74). An elementary mode is a minimal set of enzymes that could operate at steady state, with the

Figure 9. a. In the scale-free network, most nodes have only a few links, but a few nodes, called hubs (filled circle), have a very large number of links. b. The network connectivity can be characterized by the probability, $P(k)$, that a node has k links. $P(k)$ for a scale-free network has no well-defined peak, and for large k , it decays as a power-law, $P(k) \approx k^{-\gamma}$, appearing as a straight line with slope $-\gamma$ on a log-log plot. [Reprinted from Jeong et al. (70).]

enzymes weighted by the relative flux they need to carry out the mode to function. The total number of elementary modes for given conditions has been used as a quantitative measure of network flexibility and as an estimate of fault-tolerance (75,76).

A system approach to model regulatory networks is essential to understand their dynamics. Recently, several high-level models have been proposed for the regulatory network including Boolean models, continuous systems of coupled differential equations, and probabilistic models. *Boolean networks* assume that a protein or a gene can be in one of two states, active or inactive, represented by 1 or 0. This binary state varies in time and depends on the state of the other genes and proteins in the network through a discrete equation:

$$X_i(t + 1) = F_i[X_1(t), \dots, X_N(t)] \quad (4)$$

Thus, the function F_i is a Boolean function for the update of the i th element as a function of the state of the network at time t (69). Figure 10 gives a simple example.

Gene expression patterns contain much of the state information of the genetic network and can be measured experimentally. We are facing the challenge of inferring or reverse engineering the internal structure of this genetic network from measurements of its output. Genes with similar temporal expression patterns may share common genetic control processes and may, therefore, be related functionally. Clustering gene expression patterns according to a similarity or distance measure is the first step toward constructing a wiring diagram for a genetic network (78).

Differential equations can be an alternative model to the Boolean network and applied when the state variables X are continuous and satisfy a system of differential equations of the form

$$\frac{dX_i}{dt} = F_i[X_1(t), \dots, X_N(t), I(t)]$$

where the vector $I(t)$ represents some external input into the system. The variable X_i can be interpreted as representing concentrations of proteins or mRNAs. Such a model has been used to model biochemical reactions in the metabolic pathways and gene regulation (69).

Bayesian networks are provided by the theory of graphical models in statistics. The basic idea is to approximate a complex multidimensional probability distribution using a product of simpler local probability distributions. Generally, a Bayesian network model is based on a directed acyclic graph (DAG) with N nodes. In genetic network, the nodes may represent genes or proteins and the random variables X_i levels of activity. The parameters of the model are the local conditional distributions of each random variable given the random variables associated with the

Figure 10. Target Boolean network for reverse engineering. (a) The network wiring and (b) logical rules determine (c) the dynamic output. The challenge lies in inferring (a) and (b) from (c). [Reprinted from Liang et al. (77).]

parent nodes

$$P(X_1, \dots, X_N) = \prod_i P(X_i | X_j : j \in N^-(i)) \quad (4)$$

where $N^-(i)$ denotes all the parents of vertex i . Given a dataset D representing expression levels derived using DNA microarray experiments; it is possible to use learning techniques with heuristic approximation methods to infer the network architecture and parameters. As data from microarray experiments are still limited and insufficient to completely determine a single model, people have developed heuristics for learning classes of models rather than single models, for instance, for a set of co-regulated genes (69). Bayesian networks have recently been shown to combine heterogeneous datasets, for instance, microarray data with functional annotation and mutation data to produce an expert system (79).

In this chapter, some major development in the field of bioinformatics were reviewed and some basic concepts in the field were introduced covering six areas: sequence analysis, phylogenetic analysis, protein structure analysis, genome analysis, microarray analysis, and network analysis. Due to the limited space, some topics have been left out. One such topic is text mining, which uses Natural Language Processing (NLP) techniques to extract information from the vast amount of literature in biological research. Text mining has become an integral part in bioinformatics. With the continuing development and maturing of new technologies in many system-level studies, the way that biological research is conducted is undergoing revolutionary change. Systems biology is becoming a major theme and driving force. The challenges for bioinformatics in the post-genomics era lie on the integration of data and knowledge from heterogeneous sources and system-level modeling and simulation providing molecular mechanism for physiological phenomena.

INTRODUCTION

The science of *biomagnetism* refers to the measurement of magnetic fields produced by living organisms. These tiny magnetic fields are produced by naturally occurring electric currents resulting from muscle contraction, or signal transmission in the nervous system, or by the magnetization of biological tissue. The first observation of biomagnetic activity in humans was the recording of the magnetic field produced by the electrical activity of the heart, or *magnetocardiogram*, by Baule and McFee in 1963 (1). In 1968, David Cohen (2) at the Massachusetts Institute of Technology reported the first measurement of the alpha rhythm of the human brain, demonstrating that it was possible to measure magnetic fields of biological origin that are only several hundred femtotesla in magnitude (1 femtotesla = 10^{-15} T)—more than 1 million times smaller than the earth's magnetic field ($\sim 5 \times 10^{-5}$ T). These early measurements were achieved using crude instruments consisting of inductance coils of 1–2 million windings in magnetically shielded enclosures and using extensive signal averaging. Instruments with increased sensitivity and performance based on the *superconducting quantum interference device*, or SQUID became available shortly after these pioneering measurements. The SQUID is a highly sensitive magnetic flux detector based on the

properties of electrical currents flowing in superconducting circuits, as predicted by Nobel laureate Brian Josephson in 1962 (3). The SQUID was soon adapted for use in biomagnetic measurements (4) and by the early 1970s, measurements of the spontaneous activity of the human heart (5) and brain (6) had been achieved without the need for signal averaging using superconducting sensing coils coupled to SQUIDs immersed in cryogenic vessels containing liquid helium. Thereafter, the field of biomagnetism continued to expand with the further development of SQUID based instrumentation during the 1970s and 1980s. The introduction in 1992 of multichannel biomagnetometers capable of simultaneous measurement of neuromagnetic activity from the entire the human brain (7,8) has resulted in widespread interest in the field of *magnetoencephalography* or *MEG* as a new method of studying human brain function.

Biomagnetic measurements are considered to have a number of advantages over more traditional electrophysiological measurements of heart and brain activity, such as the electrocardiogram or electroencephalogram. One significant advantage is that propagation of magnetic fields through the body is less distorted by the varying conductivities of the overlying tissues in comparison to electrical potentials measured from the surface of the scalp or torso, and can therefore provide a more precise localization of the underlying generators of these signals. In applications such as MEG and magnetocardiography (MCG), these measurements are completely passive and can be made repeatedly without posing any risk or harm to the patient. Also, biomagnetic signals are a more direct measure of the underlying currents in comparison to surface electrical recordings that measure volume conducted activity that must be subtracted from a reference potential at another location complicating the interpretation of the signal. In addition, magnetic measurements from multiple sites can be less time consuming since there is no need to affix electrodes to the surface of the body. As a result, biomagnetic measurements provide an accurate and non-invasive method for locating sources of electrical activity in the human body. The development of multichannel MEG systems has dramatically increased the usefulness of this technology in clinical assessment and treatment of various brain disorders. This has resulted in the recognition of routine clinical procedures by health agencies in the United States for the use of MEG to map sensory areas of the brain or localize the origins of seizure activity prior to surgery. Clinical applications of MCG have also been developed although to a lesser extent than MEG. This includes the assessment of coronary artery disease and other disorders affecting the propagation of electrical signals in the human heart. Another biomagnetic technique, known as *biosusceptometry*, involves measuring magnetized materials in the human body by measuring their moment as they are moved within a strong magnetic field. These measures can provide useful information regarding the concentration of ferromagnetic or strongly paramagnetic materials in various organs of the body, such as iron particles in the lung or iron-containing proteins in the liver. In addition, novel biomagnetometer systems are now available for the assessment of fetal brain and heart

function in utero, and may provide a new clinical tool for the assessment of fetal health. Currently, there are >100 multichannel MEG systems worldwide and advanced magnetometer systems specialized for the measurement of magnetic signals from the heart, liver, lung, peripheral nervous system, as well as the fetal heart and fetal brain are currently being commercially developed. Although biomagnetism is still regarded as a relatively new field of science, new applications of biomagnetic measurements in basic research and clinical medicine are rapidly being developed, and may provide novel methods for the assessment and treatment of a variety of biological disorders. The following section reviews the current state of biomagnetic instrumentation and signal processing and its application to the measurement of human biological function.

BIOMAGNETIC INSTRUMENTATION

SQUID Sensors and Electronics

The SQUID sensor is the heart of a biomagnetometer system and provides high sensitivity detection of very small magnetic signals. The most popular types of SQUIDs are direct current (dc) and radio frequency (rf) SQUIDs, deriving their names from the method of their biasing. The modern commercial biomagnetometer instrumentation uses dc SQUIDs implemented in low temperature superconducting materials (usually Nb). In recent years, there has been significant progress in the development of high Tc SQUIDs, both dc and rf. These devices are usually constructed from $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ceramics. However, due to their poorer low frequency performance and difficulties with reproducible large volume manufacturing they are not yet suitable for large-scale applications. An excellent review of SQUID operation can be found in (9).

The rf SQUID was popular in the early days of superconducting magnetometry because they required only one Josephson junction. However, in majority of low Tc commercial applications, the rf SQUIDs have been displaced by dc SQUIDs due to their greater sensitivity, although in recent years, interest in rf SQUIDs has been renewed in connection with high Tc superconductivity. The operation of SQUIDs is illustrated in Fig. 1a. The dc SQUID can be modeled as a superconducting ring interrupted by two resistively shunted Josephson junctions as in Fig. 1a (11). The Josephson junctions are superconducting quantum mechanical devices that allow passage of currents with zero voltage, and when voltage is applied to them, they exhibit oscillations with a frequency to voltage constant of $\sim 484 \text{ MHz} \cdot \mu\text{V}$. The resistive shunting causes the Josephson junctions to work in a nonhysteretic mode, which is necessary for low noise operation (9). An example of a thin-film dc SQUID, consisting of a square washer and Josephson junctions near the outside edge is shown in Fig. 1b (12,13). The usual symbol used to represent a dc SQUID is shown in Fig. 1c.

The SQUID ring (or washer) must be coupled to the external world and to the electronics that operates it (see Fig. 2a). When the dc SQUID is current biased, its I - V characteristics is similar to that of a nonhysteretic Josephson junction and the critical current I_0 is modulated

Figure 1. Thin-film dc SQUID. (a) Schematic diagram indicating inductances of the SQUID ring and shunting resistors to produce nonhysteretic Josephson junctions. (Reproduced with permission from Ref. 10).

by magnetic flux externally applied to the SQUID ring. The modulation amplitude is roughly equal to Φ_0/L (9), where Φ_0 is the flux quantum with magnitude $\sim 2.07 \times 10^{-15}$ Wb and L is inductance of the SQUID ring. The critical current is maximum for applied flux $\Phi = n\Phi_0$ and minimum for $\Phi = (n + 1/2)\Phi_0$. For monotonically increasing flux the average SQUID voltage oscillates as in Fig. 2d with period equal to $1 \Phi_0$. The SQUID transfer function is periodic (Fig. 2d) and to linearize it, the SQUID is operated in a feedback loop as a null detector of magnetic flux (14). Most SQUID applications use analogue feedback loop whereby a modulating flux with $\pm 1/4 \Phi_0$ amplitude is applied to the SQUID sensor through the feedback circuitry (Fig. 2a,b).

The modulation, feedback signal, and the flux transformer output are superposed in the SQUID, amplified, and demodulated in a lock-in detector fashion. The demodulated output is integrated, amplified, and fed back as a flux to the SQUID sensor to maintain its total input close to zero. The modulation flux superposed on the dc SQUID transfer function is shown in Fig. 2d and the modulation frequencies are typically several hundreds of kilohertz.

For satisfactory MEG operation, the SQUID system must exhibit large dynamic range, excellent interchannel matching, good linearity, and satisfactory slew rates. The analogue feedback loop is not always adequate and the dynamic range can be extended by implementing digital integrator as shown in Fig. 2c, and by utilizing the flux periodicity of the SQUID transfer function (15). The dynamic range extension works in the following manner: The loop is locked at a certain point on the SQUID transfer function and remains locked for the applied flux in the range of $\pm 1 \Phi_0$, Fig. 2d. When this range is exceeded, the loop lock is released and the locking point is shifted by $1 \Phi_0$ along the transfer function. The flux transitions along the transfer function are counted and are merged with the signal from the digital integrator to yield 32 bit dynamic range. This "flux slipping" concept can also be implemented using four-phase modulation (16), where the feedback loop jumps by $\Phi_0/2$ and can also provide compensation for the variation of SQUID inductance with the flux changes.

Flux Transformers

The purpose of flux transformers is to couple the SQUID sensors to the measured signals and to increase the overall magnetic field sensitivity. The flux transformers are superconducting and consist of one or more pickup coil(s) that are exposed to the measured fields. The pickup coil(s) are connected by twisted leads to a coupling coil that inductively couples the measured flux to the SQUID ring (as

(Reproduced with permission from Ref. 10).

shown in Fig. 2a). Because the flux transformers are superconducting, their gain is noiseless and their response is independent of frequency. The flux transformer pickup coil can have diverse configurations as shown in Fig. 3. A single loop of wire acts as a magnetometer and is sensitive to the magnetic field component perpendicular to its area, Fig. 3a and b. Two magnetometer loops can be combined with opposite orientation and connected by the same wire to the SQUID sensor. The loops are separated by a distance b and such a device is called a first-order gradiometer Fig. 3c–e, and the distance b is referred to as gradiometer baseline. The magnetic fields detected at the two coils are subtracted and the gradiometer acts as a spatial differential detector (this differential action is comparable to differential detection of electric signals (e.g., in electroencephalography, EEG). Fields induced by distant sources will be almost completely canceled by a gradiometer because both its coils will detect similar signals. On the other hand, near sources will produce markedly different fields at the two gradiometer coils and will be detected. Thus the gradiometers diminish the effect of the environmental noise that is typically generated by distant sources while remaining sensitive to near sources (e.g., neural sources). Similarly, first-order gradiometers can be combined with opposing polarity to form second-order gradiometers (Fig. 3f,g) and second-order gradiometers can be combined to form third-order gradiometers, (Fig. 3h). The flux transformers in Fig. 3 are called hardware flux transformers, because they are directly constructed in hardware by interconnecting various coils.

The main types of flux transformers used in commercial practice as the primary sensors are magnetometers (Fig. 3a), radial gradiometers (Fig. 3c), and planar gradiometers (Fig. 3d). These different sensor types will measure different spatial pattern of magnetic flux when placed over a current dipole as shown in Fig. 4. The radial magnetometer produces a field map with one maximum and one minimum, symmetrically located over the dipole with zero field measured directly above the dipole (Fig. 4a). The radial gradiometer in Fig. 4b produces similar field pattern as the magnetometer, except that the pattern is spatially tighter since it subtracts two field patterns measured at different distances from the dipole. The planar gradiometer field patterns are quite different from that of the

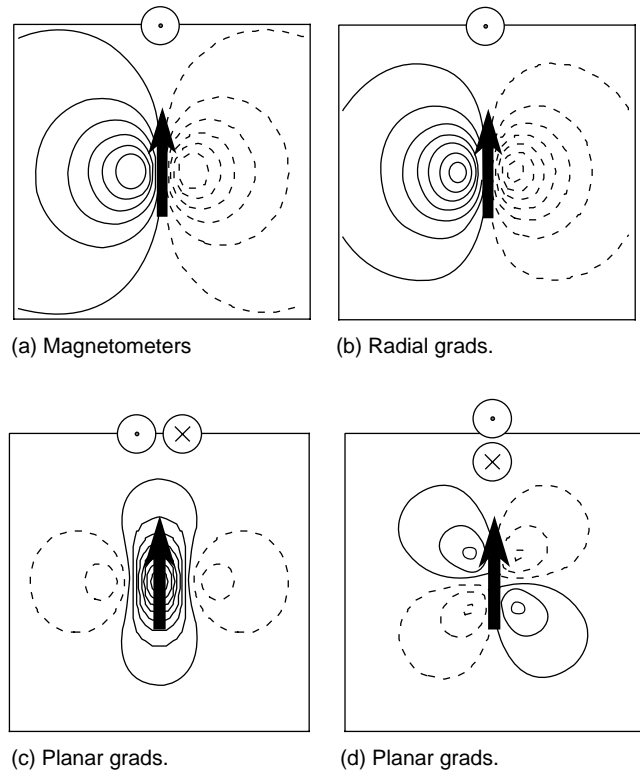

Figure 4. Response to a point dipole of several flux transformer types. A tangential dipole is positioned 2 cm deep in a semi infinite conducting space bounded by $x_3 = 0$ plane and its field is scanned by a flux transformer with its sensing coil positioned at $x_3 = 0$. Dipole position is indicated by a black arrow. Dimensions of each map are 14×14 cm. Schematic top view of the flux transformers is shown in the upper part of each figure. Solid and dashed lines indicate different field polarities. (a) Radial magnetometer; (b) radial gradiometer with 4 cm baseline; (c) planar gradiometer with 1.5 cm baseline aligned for maximum response; (d) planar gradiometer with 1.5 cm baseline aligned for minimum response. (Reproduced with permission from Ref. 10).

radial devices. If the two coils of the planar gradiometer are aligned perpendicular to the dipole, as in Fig. 4c, the planar gradiometer exhibits a peak directly above the dipole; if the two coils were aligned parallel to the dipole, the planar gradiometer exhibits a weak, clover-leaf pattern. When two orthogonal planar gradiometers are positioned at the same location, their two independent components can determine orientation of the current dipole located directly under the gradiometers (17).

In the absence of noise, there are no practical differences between these types of flux transformers. However, in the presence of noise, the signal-to-noise ratios (SNR) can differ greatly, resulting in significant performance differences between devices. For MEG applications, the magnitude of both the detected brain signal and environmental noise increases with increasing gradiometer baseline (distance between coils). Since the signal and noise functional dependencies on baseline are different, SNR exhibits a peak corresponding to an optimum baseline of ~ 3 – 8 cm for first-order radial gradiometers (10). Magnetometers can be thought of as gradiometers with very long baseline

and are not optimal because they can be overly sensitive to environmental noise. Planar gradiometers have good SNR for shallow brain sources but are suboptimal for deeper sources due to their short baselines resulting in poor depth sensitivity. Too long a baseline can also result in greater sensitivity to noise sources arising from the body itself, such as the magnetic field of the heart that may then contaminate the MEG signal. A detailed comparison of gradiometer design and performance can be found in (10).

Noise Cancellation

Introduction. Since biomagnetic measurements must be made in real world settings, the influence of noise on the measurements is a major concern in the design of biomagnetic instrumentation. Environmental noise affects biomagnetometer systems even when they are operated within shielded rooms. Environmental noise results from moving magnetic objects and currents (cars, trains, elevators, power lines, etc.). These noise sources are many orders of magnitude larger than signals of biomagnetic origin as shown in Fig. 5a. Note also, that only SQUID magnetometers have sufficient sensitivity for measuring biomagnetic signals of interest [atomic magnetometers are not yet suitable for biomagnetic applications (19)]. For MEG applications, the resolution or white noise level of the sensors should be much less than the “noise” level of brain activity ($\sim 30 \text{ fT} \cdot \text{Hz}^{1/2}$). An example of background brain activity is shown in Fig. 5b. Also, certain MEG signal

interpretation methods require the white noise to be as low as possible, however, the noise level cannot be made lower than the contribution of noise from the cryogenic vessel (dewar) itself. As a compromise, the majority of the existing MEG systems exhibit intrinsic noise levels of $< 10 \text{ fT} \cdot \text{Hz}^{1/2}$ (typically $\sim 5 \text{ fT} \cdot \text{Hz}^{1/2}$), yet are able to tolerate unwanted environmental noise many orders of magnitude greater.

Magnetic Shielding. Magnetic shielding is the most straightforward, though most costly method for reduction of environmental noise. A variety of shielded rooms have been used for biomagnetic applications and their relative shielding performance is shown in Fig. 6. The simplest shielding is accomplished through eddy currents by using a thick layer of high conductivity metal (20). Eddy current shielding is not effective at low frequencies, and therefore shielded rooms utilize high permeability μ -metal, which depending on the number of layers, can provide attenuation in the range from ~ 30 to $\sim 10^5$ (21–24). Low frequency attenuation of nearly 10^8 was demonstrated with a whole-body, high T_c superconducting shield (25).

Environmental noise can also be reduced by active shielding, which can be employed either in unshielded environments (26), or in combination with shielded rooms (24,27,28). Active shielding system consists of a reference magnetometer, feedback electronics, and a set of compensating coils. The references measure the environmental noise and provide a signal that is amplified and fed into the

Figure 5. Environmental and brain generated noise. (a) Comparison of biomagnetic fields, environmental noise, and sensitivity in 1 Hz bandwidth of various types of magnetometers. (b) Spontaneous brain activity and the system noise measured in an unshielded environment, noise cancellation by synthetic third-order gradiometer, primary sensors are radial first-order gradiometers with 5 cm baseline. Control trace was collected with no subject in the helmet, large lines correspond to signals due to nearby rotating machinery. Eyes closed and open were collected with the subject in the MEG helmet. The presence of alpha activity (peak at 8 Hz) is visible in the eyes closed condition. (Reproduced with permission from Ref. 18).

Figure 6. Noise attenuation of various shielded rooms as a function of frequency. (a) Eddy current Al rooms. (b) Standard μ -metal rooms used for MEG applications. (c,d) High attenuation μ -metal rooms. (e) Combination of high attenuation m-metal room in “d” and active shielding. (f) Whole-body high temperature superconducting shield. (Adapted with permission from Ref. 18).

compensating coils to reduce the noise. In general, the active shielding reduces the magnetic field noise due to far field sources and is effective only for magnetometers with no noise cancellation, while it has only a small effect on first-order gradiometers or magnetometers with noise cancellation. For higher order gradiometers, active shielding actually degrades system performance since the active coils can produce higher order gradients that are larger than that of the environmental noise.

Noise Reduction Using Higher Order Gradients. Since hardware noise cancellation (shielding or active noise cancellation) is usually not sufficient, additional methods, implemented in software or firmware, are employed. These methods either incorporate information from additional reference sensors or operate directly on the primary sensors. The reference sensors are typically a combination of SQUID magnetometers and gradiometers and the noise is canceled by synthesizing either higher order gradiometers or adaptively minimizing noise. The principle of synthetic gradiometer operation is similar for all gradiometer orders, and the method is illustrated for first-order gradiometer synthesis in Fig. 7a (29). The primary magnetometer

detects the magnetic field component parallel to its coil normal, \mathbf{p} (unit vector). The three reference magnetometers are orthogonal and their vector output, \mathbf{r} , corresponds to the environmental field at the reference location, $\mathbf{r} \approx \mathbf{B}$. Then, if α_p is the primary magnetometer gain and α_r the reference gain (identical for all three references), the synthetic first-order gradiometer, $g^{(1)}$, can be derived as

$$g^{(1)} = m_p - \frac{\alpha_p}{\alpha_r} (\mathbf{p} \cdot \mathbf{r}) \approx \alpha_p \mathbf{p} \cdot \mathbf{G} \cdot \mathbf{b} \quad (1)$$

where \mathbf{b} is the gradiometer baseline (a vector connecting the primary sensor and the reference centers), and \mathbf{G} is the first gradient tensor at the coordinate origin. Equation 1 states that the synthetic first-order gradiometer is a projection of the first-gradient tensor to the primary magnetometer orientation, \mathbf{p} , and the baseline, \mathbf{b} . To synthesize a second-order gradiometer, a primary hardware or synthetic first-order gradiometer, and a tensor first-gradient reference are used (Fig. 7b). Similar to Eq. 1, it can be shown that the synthetic second-order gradiometer output is a projection of the second gradient tensor to the coil orientation \mathbf{p} and the first- and second-order gradiometer baselines \mathbf{b}_1 and \mathbf{b}_2 . Synthesis of third- and higher order gradiometers is similar (29).

Adaptive methods can also be applied in addition to the synthetic gradiometers and can incorporate the same references as the gradiometers, but their coefficients are explicitly computed to minimize correlated noise (29). The advantage of synthesizing higher order gradiometers is that their coefficients are universal, independent of the noise character or sensor orientation (18). In contrast, the coefficients determined to adaptively minimize background noise are not universal because they depend on the noise character and sensor orientations (18) and assume that the noise environment is unchanging.

The noise cancellation achieved by various methods is illustrated in Fig. 8. The upper trace (a) shows the magnetic field noise outside a shielded room; and trace (b) shows the field noise after attenuation by the shielded room. The difference of the two slopes is due to the

Figure 7. An illustration of gradiometer synthesis. (a) Synthesis of a first-order gradiometer from a primary magnetometer sensor and a vector magnetometer reference. (b) Synthesis of a second-order gradiometer from hardware first-order gradiometer and a first-gradient tensor reference. (Adapted from Ref. 30).

(e) Noise reduction by addition of adaptive methods to synthetic third-order gradiometer. (Adapted from Ref. 31).

frequency dependent eddy current shield that is part of the room. Hardware first-order radial gradiometers with 5 cm baseline reduce noise by nearly a factor of 100; and (c) a synthetic third-order gradiometer; (d) reduces the noise by almost another factor of 100. The low frequency environmental noise can further be reduced by adaptive method (e). The combination of all methods in Fig. 8 achieves attenuation of $>10^7$ at low frequencies.

Additional noise reduction methods can be employed in systems with a large number of channels. The simplest method is spatial filtering using Signal Space Projection (SSP) (32–34), which projects out from the measurement the noise components oriented along specific spatial vectors in signal space. The method works best when the signal and noise subspaces are nearly orthogonal. Related to SSP is noise elimination by rotation in signal space (35), which avoids loss of degrees of freedom encountered in SSP. These methods are discussed further in the Signal Interpretation section. More recently Signal Space Separation (SSS) has been proposed as a noise cancellation method in MEG (36). This approach was first proposed by Ioannides et al. (37) and reduces environmental noise by retaining only the “internal” component of the spherical expansion of the measured signal. This method can be applied to a number of problems inherent in biomagnetic measurements, including environmental noise reduction and motion compensation.

Cryogenics

The sensing elements of a biomagnetometer system (SQUIDS, flux transformers, and their interconnections) are superconducting and must be maintained at low temperatures. Since all commercial systems use low temperature superconductors, they must be operated at liquid He temperatures of 4.2 K. These temperatures can be achieved

either with cryocoolers or by a cryogenic bath in contact with the superconducting components. The cryocoolers are attractive because they eliminate the need for periodic refilling of the cryogenic container. However, because they contribute magnetic and electric interference, vibrational noise, thermal fluctuations, and Johnson noise from metallic parts (38), they are not yet commonly used in MEG instrumentation. Present commercial biomagnetometer systems rely on cooling by liquid He bath in a nonmagnetic vessel with an outer vacuum space also referred to as a Dewar. An example of how the components may be organized within the Dewar for an MEG system is shown in Fig. 9a (39). The primary sensing flux transformers are positioned in the Dewar helmet area. The reference system for the noise cancellation is positioned close to the primary sensors and the SQUIDS with their shields are located at some distance from the references, all immersed in liquid He or cold He gas. The Dewar is a complex dynamic device that incorporates various forms of thermal insulation, heat conduction, and radiation shielding, as shown Fig. 9b. Most commercial MEG and MCG systems have reservoirs holding up to 100 L of liquid He and can be operated for periods of several days before refilling. An excellent review of the issues associated with the Dewar construction is presented in (38).

Biomagnetometer Systems: Overview

Even though magnetic fields have been detected from many organs, so far the most important application of biomagnetism has been the detection of neuromagnetic activity of the human brain. This interest led to the development of sophisticated commercial MEG systems. The current generation of these systems consists of helmet shaped multisensor arrays capable of measuring activity

Figure 9. Schematic diagram of cryogenic containers used for whole-cortex MEG. (a) Placement of various MEG components relative to the cryogenic Dewar. (b) Principles of the Dewar operation. Reproduced with permission from (10).

simultaneously from the entire cerebrum. In contrast, multichannel magnetocardiogram (MCG) systems consist of a flat array of radial or vector devices (40–45) or systems with a smaller number of channels operating at liquid N₂ temperatures (46–51) for better placement over the chest directly above the heart. These flat array systems can also be placed over other areas of the body to measure peripheral nerve, gastrointestinal, or muscle activity. These systems can even be placed over the maternal abdomen to measure heart and brain activity of the fetus and a custom shaped multichannel array specifically designed for fetal measurements has recently been introduced (39,52).

MEG Systems. A diagram of a generic MEG system is shown in Fig. 10. The SQUID sensors and their associated flux transformers are mounted within a liquid He dewar suspended in a movable gantry to allow for supine or seated patient position. The patient rests on an adjustable chair or

a bed. All signals are preamplified and transmitted from the shielded room to a central workstation for real-time acquisition and monitoring of the magnetic signals. At present, the majority of MEG installations use magnetically shielded rooms, however, progress is being made toward unshielded operation (18,40). The MEG measurements are often complemented by simultaneous EEG measurements or peripheral measures of muscle activity or eye movement. Most MEG installations have provisions for stimulus delivery in order to study brain responses to sensory stimulation and video and intercom systems in order to interact with the patient from outside the shielded room. Multichannel MEG systems are commercially available from a number of manufacturers (39,53–56).

For MEG localization of brain activity to be useful, particularly in clinical applications, it must be accurately known relative to brain anatomy. The anatomical information is usually obtained by magnetic resonance imaging

Figure 10. Schematic diagram of a typical MEG installation in a magnetically shielded room. (Reproduced with permission from Ref. 10).

(MRI), and the MRI images are required during the MEG interpretation phase. The registration of the MEG sensors to the brain anatomy is performed in two steps. First, the head position relative to the MEG sensor array is determined in order to accurately position MEG sources within a head-based coordinate system. Second, the head position relative to the MRI anatomical image is determined to allow transfer of MEG sources to the anatomical images. There are different methods for such registration. The simplest one uses a small number of anatomical markers positioned on identical locations on the head surface that can be measured both by MEG and MRI (e.g., small coils for MEG and lipid contrast markers for MRI) usually placed at anatomical landmarks near the nose and ears (18). To improve localization accuracy, the head shape can be digitized in the MEG coordinate system by a device mounted on the dewar (57) or by the MEG sensors (10). The surface of the head can also be constructed from segmented MRI and the transformation between the two systems can be determined by alignment of the two surfaces (58–60).

Biosusceptometers. A somewhat different system design is encountered in biomagnetometer systems used for the measurement of magnetic materials in the human body, such as iron content in the liver or magnetic contaminants in the lung. These instruments contain both SQUID sensing coils and a superconducting magnet operated in persistent mode. The system is suspended over the patient's body on a bed with a waterbag placed between the patient and dewar to provide continuity of the diamagnetic properties of body tissue. Figure 11 illustrates the layout of a biosusceptometer system for liver measurements with a patient in a supine position on a moveable bed. The patient

is moved vertically relative to the SQUID gradiometer-magnet system and flux changes due to the susceptibility of the liver are monitored. These measures of magnetic moment can then be used to estimate the concentration of the paramagnetic compounds within the liver (62–64).

Signal Interpretation

Biomagnetometers measure the distribution of magnetic field outside of the body. Although the observed field patterns provide some information about the underlying physiological activity, ideally one would like to invert the magnetic field and provide a detailed image of the current distribution within the body. Such inversion problems are nonunique and ill defined. The nonuniqueness is either physical (65) or mathematical due to being highly underdetermined (i.e., there are many more sources than sensors). In order to determine the current distribution, it is necessary to provide additional information, constraints, or simplified mathematical models of the sources. The field of source modeling in both MEG and MCG has been an intensive area of study over the last 20 years. In the following section we shall review briefly various methods of source analysis as it is applied to MEG, although these methods apply to other biomagnetic measurements such as MCG, with the main difference being the physical geometry of the conductor volumes containing the sources. For detailed reviews of mathematical approaches used in biomagnetism (see 66–69).

Neural Origin of Neuromagnetic Fields. Magnetic fields of the brain measured by MEG are thought to be the primarily due to activation of neurons in the gray matter of the neocortex, whereas action potentials in the underlying fiber tracts (white matter) have been shown to produce only poorly synchronized quadrupolar sources associated with weak fields (70,71). Some subcortical structures have also been shown to produce weak yet measurable magnetic fields, but are difficult to detect without extensive signal processing (72,73). The generation of magnetic fields in the human brain is illustrated in Fig. 12. The neocortex of the brain (shown in Fig. 12a) contains a large number of pyramidal cells arranged in parallel (Fig. 12b) that in their resting state maintain an intracellular potential of ca. -70 mV. Excitatory (or inhibitory) synaptic input near the cell body or at the superficial apical dendrites results in the flow of charged ions across the cell membrane producing a graded depolarization (or hyperpolarization) of the cell. This change in polarization results in current flow inside the cell, called *impressed current* and corresponding return or *volume currents* that flow through the extracellular space in the opposite direction. Studies carried out in the early 1960s (74,75) demonstrated that these extracellular or volume currents are main generators of electrical activity measured in the electroencephalogram or EEG. The combination of excitatory and inhibitory synaptic inputs to different cortical layers can produce a variety of sink and source patterns through the depth of the cortex, each associated with current flow along the axes of elongated pyramidal cells toward or away from the cortical surface.

Figure 12. Origin of the MEG signal. (a) Coronal section of the human brain. The neocortex is indicated by dark outer surface. (b) Pyramidal cells in the cortex have vertically oriented receptive areas (dendrites). Depolarization of the dendrites at the cortical surface due to excitatory synaptic input results in Na^+ ions entering the cell producing a local current source and a current sink at the cell body, resulting in intracellular current flowing toward the cell body (arrow). (c) The cortex has numerous sulci and gyri resulting in currents flowing either tangentially or radially relative to the head surface. (d) Tangential currents will produce magnetic fields that are observable outside the head if modeled as a sphere. (e) Radial currents will not produce magnetic fields outside of the head if modeled as a sphere. (Adapted from Ref. 10).

Synchronous activity in large populations of these cells summate to produce the positive and negative time-varying voltages measured at the scalp surface in the EEG (76).

Okada et al. (77) carried out extensive studies over the last 20 years on the neural origin of evoked magnetic fields using small array “microSQUID” systems to measure directly magnetic fields from *in vitro* preparations in the turtle cerebellum and mammalian hippocampus. These studies have shown that although both extracellular and intracellular currents may contribute to externally measured magnetic fields, it is primarily intracellular or impressed currents flowing along the longitudinal axis of pyramidal cells that are the generators of evoked magnetic fields. A recent review of this work is presented in (78). Note that, since MEG measures mainly intracellular currents and EEG the return volume currents, the pattern of electrical potential over the scalp due to an underlying current source will reflect current flow in opposite direction to that of the magnetic field, as has been demonstrated in physical models (79) and human brain activity (80). In addition, activation of various regions of the enfolded cortical surface (the gyri and sulci) will result in current flow that is either radial or tangential to the scalp surface, respectively (Fig. 12c). If the brain is modeled as a spherical conducting volume, then due to axial symmetry it can be shown that only the tangential currents will produce fields outside the sphere (81) (Fig. 12d and e). Using *in vivo* preparations in the porcine brain, it has been experimentally demonstrated that, in contrast to the EEG, magnetic fields are relatively undistorted by the presence of the skull, and are generated primarily in tangentially oriented tissue (78). It has been recently shown, however, that MEG is insensitive only to a relatively small percentage of the total cortical surface in humans due to this tangential constraint (82). There is some uncertainty as to the extent of cortical activation typically measured by MEG. Current densities in the cortex have been estimated to be on the

order of $50 \text{ pA} \cdot \text{m} \cdot \text{mm}^2$ (83) suggesting that cortical areas of at least 20 mm^2 must be activated in order to produce a sufficiently large external field to be observed outside the head (66,68). However, current densities as high as $1000 \text{ pA} \cdot \text{m} \cdot \text{mm}^2$ have been recorded *in vitro* (77) indicating that much smaller areas of activation may be observed magnetically.

Equivalent Current Dipoles. The equivalent current dipole or ECD (81,84) is the oldest and most frequently used model for brain source activity. It is based on the assumption that activation of a specific cortical region involves populations of functionally interconnected neurons (macrocolumns) within a relatively small area. When measured from a distance, this local population activity can be modeled by a vector sum or “equivalent” current dipole that represents the aggregate activity of these neurons. The ECD analysis proceeds by estimating a priori the number of equivalent dipoles and their approximate locations, and then adjusting the dipole parameters (location and orientation) by a nonlinear search that minimizes differences between the field computed from the dipole model and the measured field (Fig. 13). This can be done at one time sample, or it can be extended to a time segment, where several dipoles are assumed to have fixed positions in space, but variable amplitude. Such models are referred to as “spatiotemporal” dipole models (85). The dipole fit procedures require the calculation of the magnetic field produced by a current dipole at each sensor: also termed the *forward solution*. Since the frequency range of interest for biomagnetic fields is $<1 \text{ kHz}$, the quasistatic approximations of Maxwell’s equations apply. If the head is assumed to be approximately spherical in shape it can be represented by a uniformly conducting sphere and the radial magnetic field of an ECD with magnitude \mathbf{q} , is given by the radial component of the well-known Biot–Savart law, $B_{\text{rad}}(\mathbf{r}) = \mathbf{B}(\mathbf{r}) \cdot \mathbf{r}/|\mathbf{r}|$, where the Biot–Savart

Figure 13. Magnetic fields due to an equivalent current dipole source will exit and reenter the head that can be modeled as a spherical shaped conducting medium. Calculation of the field magnitude (\mathbf{B}_{coil}) measured by a magnetometer coil due to a current dipole \mathbf{q} at location \mathbf{r}_0 inside a sphere is given by the projection of the calculated vector field $\mathbf{B}(\mathbf{r})$ onto the direction normal to the surface area of the coil indicated by the unit vector \mathbf{p} , such that $\mathbf{B}_{\text{coil}} = \mathbf{B}(\mathbf{r}) \cdot \mathbf{p}$. The orientation of \mathbf{q} is assumed to be tangential to the sphere surface. For gradiometer devices, the measured output of the gradiometer can be calculated as the difference between the field magnitudes calculated separately at each of the coils.

vector field, $\mathbf{B}(\mathbf{r})$, is given by

$$\mathbf{B}(\mathbf{r}) = \frac{\mu_0}{4\pi} \frac{\mathbf{q} \times (\mathbf{r} - \mathbf{r}_0)}{|\mathbf{r} - \mathbf{r}_0|^3} \quad (2)$$

where \mathbf{r}_0 is the ECD position and \mathbf{r} is the position where the field is measured. For multiple ECDs or continuously distributed sources, Eq. 2 will also include the sum over all sources or the integral over the volume of the conducting sphere.

Generally, the vector of the external magnetic field is produced by both the primary current density reflecting the impressed (intracellular) currents, and volume currents that produce “secondary sources” on the surface of the volume conductor. For complex shapes, the calculation of the external field also requires knowledge of the conductivity profile of the conducting volume. The assumption of spherical symmetry, however, simplifies the calculation, and the vector field $\mathbf{B}(\mathbf{r})$ due to a current dipole \mathbf{q} in a sphere at location \mathbf{r}_0 (Fig. 13b) is given by Sarvas (81) as

$$\mathbf{B}(\mathbf{r}) = \frac{\mu_0}{4\pi F^2} \{F\mathbf{q} \times \mathbf{r}_0 - [(\mathbf{q} \times \mathbf{r}_0) \cdot \mathbf{r}]\nabla F\} \quad (3a)$$

where

$$F = a(ra + r^2 - \mathbf{r}_0 \cdot \mathbf{r}) \quad (3b)$$

and

$$\nabla F = (r^{-1}a^2 + a^{-1}\mathbf{a} \cdot \mathbf{r} + 2a + 2r)\mathbf{r} - (a + 2r + a^{-1}\mathbf{a} \cdot \mathbf{r})\mathbf{r}_0 \quad (3c)$$

and $\mathbf{a} = \mathbf{r} - \mathbf{r}_0$, $a = |\mathbf{a}|$, $r = |\mathbf{r}|$ and the permeability of free space $\mu_0 = 4\pi \times 10^{-7}$ H · m. The sensing coil measures the component of the vector field $\mathbf{B}(\mathbf{r})$ perpendicular to its surface area as shown in Fig. 13b. If the field is measured only in the radial direction, Eq. 3 simplifies to the radial component of the Biot–Savart law (Eq. 2), and the volume currents do not contribute any field. It can be seen from Fig. 13 that the definition of the origin of the theoretical

sphere relative to the head will influence the calculation of the external magnetic field and thus plays a significant role in the accuracy of the single sphere approach. Since the head is not perfectly spherical, improved accuracy of the forward solution can be achieved by using more realistic models of the conducting surfaces and boundary element methods for the calculation of the magnetic field (69), but these methods are more computationally demanding. A simple improvement over the single sphere model can be achieved by using a multiple-sphere model, where independent spheres are determined for each sensor by evaluating local head curvature in the sensor vicinity (86).

The ECD procedure is very sensitive to the SNR and dc offsets, and therefore works best when applied to averaged brain responses that are well time locked to a sensory or motor event and requires an accurate estimate of signal baseline (e.g., prestimulus activity). This approach has proven useful for modeling simple patterns of focal brain activity, yet is compromised by interaction or “cross-talk” between simultaneously active sources, requiring that the number of dipoles be correctly specified. Also, ECD models do not correctly describe spatially “extended” sources: areas of cortical activity that may extend over an area of several square centimeters.

Minimum Norm. The dipole model assumes that the brain activity is localized in one or several small areas of the brain. Sometimes it is required to obtain a more general solution without an a priori assumption about the source distribution. This can be obtained by minimum norm methods, first proposed for MEG by Hämäläinen and Ilmoniemi (84). This inverse problem is underdetermined, solutions are diffuse, and the unweighted minimum norm favors solutions close to the sensors. The minimum norm method has subsequently been adapted to produce more localized solutions. The algorithm, FOCal Undetermined System Solution (FOCUSS) utilizes a recursive linear estimation based on weighted pseudoinverse solution (87) and the Minimum Current Estimate (MCE) utilizes the L1-norm approach (88). A related method, Magnetic Field Tomography (MFT) (89) utilizes weights and a regularization parameter that are optimized according to the given experimental geometry and noise. Another minimum norm-based method is the algorithm LORETA (LOW Resolution Electromagnetic Tomography) (90). This algorithm introduces a spatial second derivative operator (Laplacian) into the weighting function and seeks the minimum norm solution subject to the maximum smoothness condition. This requirement is justified on a physiological assumption that neighboring points in the brain are likely to be synchronized. The method produces low spatial resolution that is a consequence of the smoothness constraint. Methods based on simulated (surrogate) data have also been proposed for producing distributed, unbiased solutions based on the minimum norm (91).

Bayesian Inference. Bayesian inference has also been applied to the biomagnetic inverse problem, using probability distributions of many possible source solutions. This approach can easily incorporate a priori information that may influence the likelihood of features of the current

distribution based on anatomy, maximum current strength, smoothness, and so on (92,93). This method determines expectation and variance of the a posteriori source current probability distribution given source prior probability distribution and data set (94,95). The model can include probability weightings determined from other imaging techniques such as functional MRI (fMRI) or positron emission tomography (PET) to influence the MEG current images.

Signal Space Projection. Signal space projection. (33,34) and beamformers are spatial filters that can separate signal from noise on the basis of their relationship in signal space (a M -dimensional space, where M is the number of MEG channels). The application of spatial filtering to MEG was first proposed by Robinson and Rose (96). This original article sparked growing interest in spatial filtering by the MEG community that still continues. The spatial filtering depends on the assumption that component vectors corresponding to different neuronal sources have distinct and stable (fixed) directions in signal space, and only their magnitudes are functions of time. If the vectors are defined by modeling the field produced by known dipole sources, SSP can be used as a spatial filter that passes only signals corresponding to these known sources. Thus, we can define the output of a spatial filter as $y_\theta(t) = \mathbf{P}_\parallel \mathbf{m}(t)$, where \mathbf{P}_\parallel is the parallel projection operator (95) constructed from the forward solutions of the dipole source(s) of interest, and $\mathbf{m}(t)$ represents a vector of instantaneous MEG measurement at time t . The output of the spatial filter then provides a time series that is the estimate of changing strength of the dipole source(s) over time. Alternatively, if the vectors associated with artifact patterns are known, SSP can be used to remove these artifacts from the signal using orthogonal projection operators (32). If the signal vectors are determined from patterns in the data, the source model need not even be known. Note that restricting all sources to current dipoles in a known volume conductor model reduces SSP to a multiple dipole approximation (34).

Beamformers. The SSP method does not separate well sources that are not in orthogonal subspaces. To overcome this limitation, source analysis can be done by beamforming (borrowed from radio-communication and radar work). Beamformers utilize spatial and temporal correlations to obtain information about uncorrelated dipolar sources. The Linearly Constrained Minimum Variance (LCMV) beamformer in the form now used in MEG analysis was first described in 1972 (97) and can be used without specific information about source orientation. An introduction to the beamformers may be found in (98) and a relatively recent review of various beamforming techniques in (99). As in the case of SSP, if vector $\mathbf{m}(t)$ represent an instantaneous MEG measurement in M -dimensional space, we can define a spatial filter centered on the location “ θ ” as $y_\theta(t) = \mathbf{W}_\theta^T \mathbf{m}(t)$, where \mathbf{W}_θ is a weight matrix. Only tangential sources contribute to the MEG signal. They can be decomposed into two orthogonal tangential directions and the corresponding forward solutions, $\mathbf{B}_{\theta 1}$ and $\mathbf{B}_{\theta 2}$, can be arranged in a forward solution matrix as $\mathbf{H}_\theta = [\mathbf{B}_{\theta 1}, \mathbf{B}_{\theta 2}]$. The beamformer weights are determined by minimizing

the power projected from the location , $P_\theta = \mathbf{W}_\theta^T \mathbf{C} \mathbf{W}_\theta$, subject to the unity gain condition, $\mathbf{W}_\theta^T \mathbf{H}_\theta = \mathbf{I}$, where \mathbf{C} is the covariance matrix of the measurement and \mathbf{I} is the identity matrix. The weights are given as (100)

$$\mathbf{W}_\theta = \mathbf{C}^{-1} \mathbf{H}_\theta (\mathbf{H}_\theta^T \mathbf{C}^{-1} \mathbf{H}_\theta)^{-1} \quad (4)$$

An alternative approach known as synthetic aperture magnetometry (SAM) defines an optimal dipole orientation for each spatial filter location (101). Only one vector is retained, $\mathbf{H}_\theta = \mathbf{B}_\theta$ simplifying Eq. 6 to $\mathbf{W}_\theta = \mathbf{C}^{-1} \mathbf{B}_\theta (\mathbf{B}_\theta^T \mathbf{C}^{-1} \mathbf{B}_\theta)^{-1}$. This approach produces higher spatial resolution due to less projected sensor noise by the spatial filter (102). The beamformer weights can be used to compute the time course of the dipole magnitude variation or power at a single location in the brain independently of other active sources, provided sources are not highly correlated. An especially useful quantity is the normalized power $Z_\theta^2 = P_\theta / N_\theta$, where $N_\theta^2 = \mathbf{W}_\theta^T \Sigma \mathbf{W}_\theta$ is the sensor noise projected by the beamformer from location ‘ θ ’, and Σ is the sensor noise covariance matrix (100). In contrast to P_θ and N_θ , the parameter Z_θ^2 behaves gracefully through the center of the model sphere and does not exhibit a singularity. A spatial image of brain activity can be obtained by computing the normalized power at individual brain voxels, θ , one at a time over a region of interest.

Multiple Signal Classification. Multiple Signal Classification (MUSIC) is a signal space scanning method and is related to beamforming (103,104). MUSIC requires an initial nonlinear step of partitioning the data covariance matrix into signal and noise subspaces using standard eigendecomposition methods. This partitioning can be more readily determined from the averaged data and as a result the method is more difficult to apply to spontaneous brain activity. Sources are located by scanning of the brain volume and at each location requiring that the dipole forward solution be orthogonal to the noise subspace (or parallel to the signal subspace). A more recent implementation known as recursively applied and projected MUSIC (RAP-MUSIC) projects out each located source and then repeats the scanning procedure (105). Similar to beamforming, MUSIC also assumes there are fewer sources than sensors, the sources are uncorrelated and the noise is white. In the limit of high SNR (e.g., averaged data), a small number of sources, and white noise, the MUSIC localizer function and beamformer based source power estimates differ only by a scaling factor.

Principal Component Analysis. Principal Component Analysis (PCA), for example (106,107), also determines the signal and noise subspaces. The method is based on second order statistics and attempts to fit dipoles into the orthogonal principal spatial vectors of the singular value decomposition of the data. For mixtures of components corresponding to nonorthogonal spatial vectors, the PCA cannot account for the structure of the data (108). The PCA has been shown to be potentially inaccurate, as it can mislocalize dipoles even in noiseless simulations.

Independent Component Analysis. Independent Component Analysis (ICA) is a relatively new technique that

allows separation of sources that are linearly mixed at the sensors. The method is also called blind source separation, because the source signals are not directly observed and nothing is known about their mixture (109,110). The method uses higher order statistics and in realistic situations is often more successful than PCA (108). The mixing model used for the separation is usually stated as $\mathbf{m}(t) = \mathbf{A}\mathbf{s}(t)$, where $\mathbf{m}(t)$ is the instantaneous vector of the measurement, $\mathbf{s}(t)$ is the instantaneous source activity vector, and \mathbf{A} is the mixing matrix. The procedure provides solution for an unmixing matrix \mathbf{B} , such that the estimated source activity is given as $\hat{\mathbf{s}}(t) = \mathbf{B}\mathbf{m}(t)$, where $\hat{\mathbf{s}}$ is the estimate of the source vector \mathbf{s} . The sources are assumed to be statistically independent and the separation is obtained by optimizing a contrast function, that is, a scalar measure of some distributional property of the output $\hat{\mathbf{s}}$. The contrast functions are based on entropy, mutual independence, high order decorrelations, and so on. The ICA has been applied to MEG and EEG to either remove artifacts or extract desired signals (111,112).

APPLICATIONS OF BIOMAGNETIC MEASUREMENTS

Magnetoencephalography: Basic Studies

The most prevalent and rapidly growing application of biomagnetism is the field of magnetoencephalography (MEG): the measurement of human brain activity. This field of basic and clinical research is also referred to as *neuromagnetism* or *magnetic source imaging* (113–117). The latter term is often used to refer to the localization of neural sources with respect to individual brain anatomy by the combination of MEG source modeling with structural imaging techniques such as MRI (see Magnetic Resonance Imaging). As noted in the introduction, the first magnetic fields recorded from the human brain involved the observation of spontaneous alpha rhythm activity. This was soon followed by the application of MEG measurements to the study of *evoked responses* of the human brain: Time-averaged responses to discrete sensory or motor events that provide sufficient SNR to allow for the localization of brain

regions contributing to the externally measured field patterns. Due to its excellent time resolution and ability to measure neuronal function directly, MEG has continued to generate interest within the field of human neuroscience as a complement to other methods of functional brain imaging based on metabolic or hemodynamic changes in brain function, such as fMRI (see Magnetic Resonance Imaging) or PET (see Positron Emission Tomography). Present MEG practice includes measurement of both evoked and spontaneous signals and is used for clinical purposes and for investigation of a wide range of brain processes.

Somatosensory Evoked Fields. Evoked responses to stimulation of the human somatosensory system (somatosensory evoked fields or SEFs) were first reported by Brenner and colleagues in 1987 (118). The observed magnetic brain response to electrical stimulation of the digit was of great interest since it demonstrated a well-characterized dipolar field pattern over the scalp indicative of a single neural generator located in the underlying somatosensory cortex. Subsequent studies have shown that early components of the SEF occurring at latencies of 20–50 ms reflect early activation of the primary somatosensory cortex contralateral to the side of stimulation, and are generally well modeled as single ECD source in these brain regions [see (119) for a recent review]. The earliest component at a poststimulus latency of 20 ms (sometimes referred to as the “M20” or “N20m” since it is considered the magnetic equivalent of the negative N20 potential measured in the EEG) arises from the posterior bank of the central sulcus: a primary somatosensory projection area. By stimulating different body parts, it can be shown that the N20m source reflects the somatotopic or “homuncular” organization of the ascending neural pathways of the somatosensory system to this brain region (120). Figure 14 shows a typical SEF response to stimulation of the median nerve at the wrist and the localization of an ECD model fit to the N20m source in the corresponding somatosensory cortex.

When using extensive signal averaging, MEG recordings also reveal low amplitude high frequency oscillations in the 300–900 Hz range during the period of the N20m

Figure 14. (a) Topographic map (polar projection with nose upwards) of the magnetic field pattern recorded from 151 MEG channels over the scalp at a latency of 20 ms following stimulation of the right median nerve (average of 600 stimuli). White contours indicate outgoing fields and solid contours, ingoing fields. Arrow indicates direction of current flow below the scalp corresponding to the dipolar field pattern over the left hemisphere. (b) Location of a single ECD source corresponding to the magnetic field pattern shown in (a) indicated by white dot with tail indicating direction of current flow superimposed on an axial slice of the individual’s MRI. Location is in the hand region of the primary somatosensory cortex.

response (121). These oscillations have been proposed to reflect the activity of inhibitory interneurons in the somatosensory cortex (122) although cortico-thalamic pathways have also been shown to play a possible role (123). The N20m is followed by reversals of the same pattern at latencies of 30 and 40 ms that appear to reflect additional activation of somatosensory areas. These are followed by more complex and widespread activity from ~80 to 150 ms after stimulation that reflects bilateral activation of secondary somatosensory areas in the parietal operculum and is most likely related to higher order processing of somatosensory input (124). The MEG responses at latencies of 50–70 ms are elicited by mechanical stimulation of the digits (125) and reflect somatotopically organized sources in the primary somatosensory cortex (80). A number of MEG studies have used mechanical SEFs to demonstrate functional reorganization or “plasticity” of the somatosensory cortex resulting from anesthetic block or damage to the peripheral nerves or amputation (126), or even as the result of musical training (127).

Movement Related Fields. The first recordings of magnetic fields accompanying simple finger movements were reported in the early 1980s. Deecke et al. (128) observed slow magnetic field changes over sensorimotor areas of the brain preceding voluntary movements of the digits. These “readiness fields” begin approximately a half a second prior to the onset of a voluntary movement and are thought to represent activation of brain areas involved in motor preparation (129). Dipole source analysis suggests that pre-movement fields arise primarily from bilateral activation of the primary motor cortex (even for unilateral movements) with larger amplitude fields and dipole magnitudes the contralateral to the side of movement (130).

Movement-evoked fields (MEFs) accompany the onset and execution phase of simple movements. The first component (MEFI) is the largest in amplitude and begins ~100 ms after onset of EMG activity in the involved muscles. These responses appear to arise from sources in the postcentral gyrus, most likely reflecting sensory feedback to cortex from proprioceptors in the muscles (131) and are correlated with movement velocity (132). Movements made in response to a sensory cue show a very similar pattern of activity, but with a shorter latency of onset of pre-movement activity (133). Passive movements also elicit magnetic responses thought to reflect activation of the proprioceptive inputs to areas of the postcentral gyrus (134). MEG mapping studies have demonstrated activity in motor cortex during motor imagery providing evidence of the involvement of these brain areas in the simple imagination of movement (135).

MEG–EMG Coherence. By using a single channel magnetometer, Conway et al. (136) made the interesting observation of increased coherence (correlation in the frequency domain) between the surface electromyogram (EMG) in a contracting muscle and MEG recordings made over the contralateral motor areas. Subsequently, there has been a great deal of interest in the relationship between MEG–EMG coherence and the functional relationship between spontaneous cortical rhythms and EMG activity during

movement (137). Interestingly, changes in the frequency of coherence varies with the strength of muscular contraction and recent studies have shown that MEG–EMG coherence may reflect the underlying physiology of tremor in patients with Parkinson’s disease (138) or essential tremor (139).

Sensorimotor Rhythms. The MEG studies have also provided evidence for the functional significance of specific oscillatory brain activity in humans associated with both somatosensory stimulation and motor output. These centrally distributed rhythms were first observed in the EEG, and are predominant at frequencies ~10 Hz (also referred to as the mu rhythm) and in the range of 20–30 Hz. The MEG studies have been able to show that these are functionally independent cortical oscillations that originate from postcentral and precentral regions, respectively (140,141). These sensorimotor rhythms are suppressed during median nerve stimulation, followed by a transient increase or “rebound” of 20–30 Hz rhythms within 500 ms after stimulus onset. A similar pattern of suppression followed by rebound is observed during voluntary movements (142). These rhythmic changes are modulated by sensorimotor tasks such as movement or passive tactile stimulation and motor imagery or even observation of another individual’s movements (140). Rhythmic activity is not amenable to the same signal averaging technique used for evoked fields and therefore the ECD source modeling approach is more difficult to apply. Spatial filtering methods, however, provide a new approach to the localization of frequency dependent power changes in cortical areas using MEG and have been applied to the localization of rhythmic changes induced by somatosensory stimulation (141,143) and voluntary movements of the digits (144).

Visual Evoked Fields. One of the first magnetic evoked responses recorded from the human brain was the visual evoked field or VEF reported by Brenner et al. in 1975 (145). Robust responses can be elicited at latencies of 100–150 ms following visual stimulation using light flashes or visual pattern contrast changes (e.g., reversing checkerboard stimuli). However, early VEF responses pose a challenge in terms of modeling their sources due to the complex enfolded cross-like shape of the primary (striate) visual cortex: also referred to as the “cruciform” model. More recently, investigators have successfully modeled early VEF components in primary visual cortex by stimulating restricted portions of the total visual field using both monochrome (146) and color (147) pattern stimuli and have produced source configurations that reflect the retinotopic organization of the primary visual cortex. Due to the difficulty in applying ECD models to the VEF response, spatial filtering methods such as beamforming have been found to be useful for imaging visual cortex function (148). Figure 15 shows the activation of primary visual cortex by a steady state visual pattern (reversing checkerboard) using the SAM beamforming algorithm. Visual stimuli also activate several nonprimary (extrastriate) visual areas depending on the attributes of the stimulus. A number of MEG studies have shown activation of brain areas related to higher order visual processes such as detection

Figure 15. Images of following response to flickering checkerboard stimulus at $f = 17$ Hz presented to the left or right visual field, using a whole-head MEG recordings and the synthetic aperture magnetometry (SAM) beamformer algorithm. The image shows increased source power as yellow (lighter) colored areas at the posterior portion of the brain, corresponding to increased power at 34 Hz ($2f$) in the primary visual cortex of the contralateral hemisphere. Unpublished data. (Courtesy of K. Singh.)

of coherent motion (149,150). Clinical applications of VEFs have been limited, although abnormal VEFs have been reported in cases of strabismic amblyopia (151).

Auditory Evoked Fields. Auditory evoked fields were first reported by Reite et al. (152) and subsequent MEG mapping studies have demonstrated that responses at latencies of 50 and 100 ms reflect activity of primary auditory cortex in the temporal lobes (153). The largest response occurring ~ 100 ms following stimulus onset, termed the M100, has been the most extensively studied auditory evoked field response. The M100 is bilateral for both binaural and monaural stimuli and has been shown to reflect the frequency specific (tonotopic) organization of the primary auditory cortex (154). These magnetic evoked responses are of interest in the study of the functional organization of the auditory system as they reflect perceptual attributes of auditory stimulation such as perceived pitch or the frequency profiles of complex speech sounds (155,156). Auditory responses to repetitive (steady-state) auditory stimuli show enhanced amplitude in the EEG at presentation rates of ~ 40 Hz and were initially thought to represent volume conducted thalamic responses. However, MEG steady-state auditory responses were shown by Weinberg et al. (157) to reflect oscillations at the stimulus frequency in the auditory cortex. Subsequent studies have suggested that 40 Hz auditory responses reflect thalamocortical networks in the brain responsible for integration of sensory input (158). The 40 Hz MEG response has recently been used to measure temporal integration times in the primary auditory cortex (159).

MEG Studies of Higher Brain Function. Although early MEG studies have provided useful information regarding the early processing of sensory input and motor output, one of the more intriguing potential uses of MEG is the non-invasive study of higher brain function. The EEG studies of

cognitive function have been carried out using event-related potentials (ERPs) for many decades. The MEG measurements using similar paradigms have helped gain a better understanding of the neural basis of many ERP components. Early MEG studies have had some success in measuring brain responses related to short-term memory (160), target detection tasks (161), or selective attention (162). More recently, the use of whole head MEG systems have enabled the study of more complex aspects of cognitive processing in humans, such as face recognition (163) and object naming (164). Basic research on brain mechanisms related to speech and language is also a promising area of application for MEG. Early studies have shown that speech processing is affected by incongruous visual feedback at the level of the auditory cortex (165). More recent studies have attempted to localize magnetic brain responses related to syntactic (166) and semantic (167) language processes as well as the processing of speech sounds (168). The MEG responses have also been used to study abnormal processing of sensory input during reading in dyslexic children (169) and during speech in stutterers (170).

A great deal of progress has been made in studying higher brain function with MEG by applying traditional source analysis methods to ERP components. However, these complex brain processes often involve activation of multiple brain regions complicating the interpretation of the data in terms of simple ECD models. Moreover, many of these processes may not be highly time-locked to specific sensory or motor events. More recent approaches have focused on oscillatory brain activity and synchronization or “phase-locking” between different cortical areas. Accordingly, this has produced increased interest in brain imaging methods with fine temporal resolution such as MEG. Rhythmic activity in the so-called gamma frequency band (30–90 Hz) is of particular interest since it is associated with cognitive processes such as feature binding within a sensory modality that may underlie perception (171). Recent studies have also described changes in neuromagnetic rhythms associated with observation and imitation of other individual’s actions that appear to originate in brain areas associated with learning through imitation (172). Since changes in spontaneous brain rhythms are not necessarily time-locked to a stimulus onset, alternative signal processing techniques are required (173). The combination of spatial filtering source analysis methods and time frequency and phase analysis may be particularly well suited to measure these aspects of higher order brain function (141) and constitute a new and interesting avenue of research in human cognition.

Magnetoencephalography: Clinical Applications

Presurgical Functional Mapping. One of the more prevalent clinical applications of MEG is the localization of so-called “eloquent cortex” (those areas that subservise sensory, motor, speech, and memory function) prior to neurosurgery in order to prevent loss of these functions as a result of the surgical procedure. Due to displacement cortical tissue by space occupying lesions such as tumors, or natural variability in cortical morphology, identification of these brain

areas may not be possible by visual inspection alone and can be aided by functional localization of these areas using MEG. This is achieved by activating primary sensory areas associated with visual, somatosensory and auditory stimulation, and applying ECD models to the early evoked response—a method generally referred to as *presurgical functional mapping* (114,116). For example, the N20m source of the somatosensory evoked field can be consistently and reliably localized in most individuals and used as an estimate of the location of the central sulcus prior to surgical removal of brain tissue in the region of the primary motor or somatosensory cortex (174).

Determination of the language dominant hemisphere is also necessary prior to surgical resection of cortical tissue near language areas of the temporal lobe. This is routinely done through highly invasive procedures such as selective anesthesia of the left and right hemispheres (*Wada test*) or direct cortical stimulation intraoperatively. The use of MEG for the localization of brain areas that are specific to the processing of speech, as distinct from areas associated with the simple processing of auditory input, constitutes a challenging area of research, however, some recent progress has been made in this area (175–177). In addition to using MEG source imaging to identify functional and pathological brain areas in surgical planning, these functional data can also be incorporated into frameless stereotaxic *neuronavigation* systems. These systems allow surgeons to identify the corresponding brain areas in the functional and structural images during the surgical procedure. The MEG-based neuronavigation is rapidly becoming a useful clinical tool for the surgical treatment of epilepsy, tumors and other brain disorders (114,178,179).

Epilepsy. Due to its high temporal resolution and ability to localize focal brain activity, there has been a long interest in the application of MEG to the study of epilepsy. In many cases, intractable seizures can be controlled by the removal of the epileptogenic zone: brain tissue from which seizure activity originates. The identification of this area may be aided by the measurement of abnormal electrical activity between seizures. These interictal (between seizure) spikes arise from an *irritative zone* that may be correlated with the epileptogenic zone in cases of focal epilepsy (180). The localization of ECD sources based on MEG recordings of interictal spiking activity has been shown to be highly correlated with the localization of this zone as identified by other methods such as direct intracranial monitoring from depth or subdural electrode grids [for recent reviews see (181–184)]. Interictal spikes are generally of much larger amplitude than sensory evoked responses and ECD models can be used to localize individual spike events without averaging. However, the area activated may be quite large and exhibit a high degree of spatial variability, and as a result the aggregate locations or clusters of many spike sources are often used to estimate the putative location of the irritative zone. Other methods, such as spatial filtering by beamformers (SAM), are currently being investigated and may help overcome some of the limitations of the single ECD approach to the localization of epileptogenic areas. Even in cases where

the precise location of the epileptogenic zone is not clearly identified, MEG may help to guide the placement of subdural grids, and in some cases may be used to evaluate the propagation of abnormal electrical activity between multiple brain regions. The diagnostic yield of MEG measurements of interictal activity varies with different forms of epilepsy and appears to be highest for neocortical epilepsy (185) and can also aid in the differentiation of different types of epilepsy (186).

Since the site of brain pathology may not be known in advance, particularly in nonlesional epilepsy, the introduction of whole-head MEG systems has drastically improved the feasibility of using MEG as a routine clinical procedure for presurgical epilepsy evaluation allowing the data to be acquired in a more rapid and standardized manner. The main drawbacks to the application of MEG in epilepsy is the inability to measure brain activity during or just prior to seizure onset due to head movement, and the difficulty in performing long-term monitoring of interictal activity, although this is somewhat ameliorated by the introduction of MEG systems that allow recording from patients in the supine position and while asleep. Although there is some debate on the overall usefulness of MEG in the presurgical evaluation of epilepsy (183) comparisons with other modalities such as EEG, functional MRI, and intracranial electrical recordings (114,182) indicate that MEG provides useful complementary, and in some cases unique information for the surgical treatment of epilepsy.

Other Clinical Applications. Although presurgical functional mapping and epilepsy have been the main areas of clinical application of MEG, other brain disorders have been studied. This includes the use of MEG to study changes in electrical brain activity associated with tumors that often manifests as abnormal low frequency activity (187) or other disturbances in brain rhythmic activity (188) and may help identify the functional integrity of surrounding brain tissue (189). Abnormal low frequency activity has been associated with other brain lesions such as those due to stroke and in epilepsy (190). The MEG has also been used to study recovery after stroke due to functional reorganization of the cortex (191) and its relationship to rehabilitation and outcome (192) and in the evaluation of patients with mild head injury (193). Low frequency neuromagnetic activity has been hypothesized to be an index of spreading cortical depression associated with migraine (194).

The MEG studies have focused on pain related brain responses by selectively stimulating the A δ and C fiber systems painful CO₂ laser stimulation of the skin (195) or direct electrical stimulation of nerve fibers (196). This type of somatosensory stimulation produces long latency responses in secondary somatosensory areas located in the parietal operculum, and insula: brain regions known to be involved in the perception of pain. Such studies are promising for the clinical treatment of chronic pain, although are challenging due to the difficulty in discriminating activation of brain areas due to painful versus nonpainful somatosensory input, and the invasiveness of the procedure.

More recently, MEG measures have also been combined with neurochemical imaging methods such as magnetic resonance spectroscopy (MRS). In these studies, correlations have been found between MEG activity and changes in levels of neurotransmitter and other brain metabolites in ischemia or in brain areas harboring tumors (197). Although still a new area of study, there is a great deal of interest in the application of MEG to psychiatric disorders. For example, MEG studies have reported abnormal auditory evoked magnetic fields in schizophrenic patients (198) and patients with Alzheimer's disease (199) or in individuals with developmental disorders such as autism (200).

Magnetocardiography

The first biomagnetic measurements in humans were measurements of the magnetic field of the heart. The field of magnetocardiography or MCG has not expanded as rapidly as that of MEG, although a number of research centers have continued to develop the MCG method for the non-invasive evaluation of cardiac disease. As described in the Instrumentation section, MCG requires instrumentation designed for the adequate sampling of the heart's magnetic field over the chest and a number of instruments have been developed and installed at research centers around the world, including systems based on high temperature SQUIDS. Source modeling based on magnetic field measurements is somewhat simplified in the case of MEG due to the ability to model the head as a spherically shaped conductor, whereas, modeling of the electrical activity of the heart requires realistic models of the conducting properties of the thorax and its influence on the distribution of magnetic fields arising from the heart. As a result, source localization methods in MCG often employ boundary element methods for forward calculations (201). Source localization in MCG is further complicated by the continuous movement of the heart itself. Nevertheless, MCG has been successfully used in the diagnosis of cardiac disease. For recent reviews see (202–204).

Since the 1980s a number of studies have focused on the use of MCG for the 3D localization of the origins of abnormal electrical activity of the heart. This includes abnormal activity underlying cardiac arrhythmias, such as Wolff–Parkinson–White syndrome, which involves abnormal electrical activity (preexcitation) in the accessory pathway. Recent studies have shown that MCG studies provide more accurate localization of the site of pathology than standard multichannel electrocardiogram techniques (205). The identification of the generators of heart arrhythmias is useful in presurgical evaluation for interventional procedures such as catheter ablation therapy, or in the screening of patients at risk for ventricular tachycardia (202) or coronary artery disease (206). Another application of MCG is in the assessment of ischemic areas of the heart after infarction by the detection of regions of low current density (207).

Fetal Studies

One of the more intriguing new applications of biomagnetism is the noninvasive measurement of activity of the fetal

heart and brain. Since the first report of the detection of an evoked response from the fetal brain in 1985 (208) there has been a great of interest in developing instrumentation for the measurement of biomagnetic fields from the human fetus. The main challenges for the measurement of fetal MCG or MEG is the detection of biomagnetic sources that are distant from the detector array, and the difficulty in establishing the position of the fetal heart and brain during measurement. The latter has been partially resolved by the combination of fetal biomagnetic measurements with 3D ultrasound imaging and new instrumentation has been recently designed for optimum placement and sensitivity of the sensory array to detect fetal heart and brain responses.

Fetal MCG. The largest biomagnetic signal arising from the fetus is the fetal magnetocardiogram or fMCG. The first recording of fMCG was demonstrated in 1984 (209). The fMCG signal magnitude is quite large, but due to proximity of the fetus to the mother's heart, signal processing methods are required to first remove the large maternal heart signal, after which the P, QRS, and T segments of the fMCG can be discerned with high reliability in fetuses beyond the twentieth week of gestation (210). Fetal heart rate variability has been shown to be a good indicator of fetal well being (211). This method has been applied to the detection of fetal arrhythmias (212) and may provide a useful diagnostic or screening tool for fetal congenital heart defects (213), or for the assessment of fetal health in high risk pregnancies. An overview of fMCG can be found in (214).

Fetal MEG. Due to the distance of the fetal brain from the surface of the maternal abdomen, the fetal MEG (fMEG) signal is difficult to detect without high sensitivity biomagnetometer with large coverage, large number of channels, and optimal placement of the sensor array. In addition, the fetal brain signals are small in comparison with an adult and their measurement is performed in the presence of strong interference from the maternal and fetal heart signals and various abdominal signals (intestinal electrical activity, uterine contractions, etc.). Measurements of fetal brain responses to sensory stimulation are also hampered by the difficulty in delivering the sensory stimulus to the fetus. However, fetal auditory evoked responses have been successfully recorded by presenting high amplitude auditory stimuli directly to the mother's abdomen (215,216). In order to successfully eliminate the interference due to cardiac signals, which can be >100 times larger than the fMEG, the latter efforts employed various signal extraction methods (spatial filtering, PCA, etc.) in addition to averaging. Magnitudes of fMEG responses to transient tone bursts are in the range of ~8–180 fT and the latencies range from ~125 to nearly 300 ms, decreasing with the increasing gestation age (217). The response is typically observed in not more than about 50% of examined subjects. Fetal responses to steady-state auditory clicks have also been reported (218) as well as spontaneous fetal brain activity in the form of burst suppression (219). The strength of these signals can be

Figure 16. Dedicated system for fetal MEG measurement. (a) Schematic diagram of SQUID Array for Reproductive Assessment (SARA) (52). (b) Layout of 151 sensing channels. (c) Example of flash evoked fMEG response, overlay of 151 SARA channels. The fetus with gestation age of 28 weeks was stimulated by 33 ms duration flashes of 625 nm wavelength light (220). Vertical dashed line corresponds to the flash stimulus onset. (Adapted from Ref. 221).

relatively large, up to 500 fT, and can represent interference during evoked fMEG responses.

Early fMEG experiments used single or multiple-channel probes with relatively small area of coverage, requiring a search for the region with the largest signals. Recently, a dedicated fetal MEG system, the SQUID Array for Reproductive Assessment (SARA), was constructed and operated (52). The SARA system consists of an array of 151 SQUID sensors covering the mother's anterior abdominal surface in late gestation, from the perineum to the top of the uterus as shown in Fig. 16a and b. The primary sensor flux transformers are axial first-order gradiometers, with 8 cm baseline with a nominal SQUID sensor noise density of 4 fT/Hz^{1/2}. The SARA system is now being used routinely and was recently used to measure the first fetal visual evoked field to high intensity light stimuli presented to the maternal abdomen (220). An example of a flash evoked response from the fetal brain is shown in Fig. 16c.

Other Applications

Biosusceptometry. The greatest interest in biosusceptometry has stemmed from its potential to assess noninvasively iron overload in the human liver. This potentially fatal condition arises in individuals with hemoglobinopathies that require frequent blood transfusions (e.g., sickle cell anemia) or involve abnormal production of hemoglobin (hemochromatosis and beta-thalassemia). Standard methods for assessing iron overload can be highly invasive (e.g., liver biopsy) and biosusceptometry offers a safer and potentially more accurate diagnostic tool. Iron, which is normally strongly ferromagnetic, is stored in the liver bound by the proteins ferritin and hemosiderin and exhibits a strong paramagnetic response. As a result, measurement of the magnetic moment produced by placing the liver in a uniform magnetic field will be proportional to the total amount of iron in the liver: a method known as *biomagnetic liver susceptometry* (BLS). The basis for this technique was

first proposed and the first measurements carried out in the late 1970s (222).

Most approaches to the measurement of hepatic iron concentration involve placing the patient's abdomen directly under a magnetic sensor that also contains a field coil that produces a magnetic field, and lowering the patient by a fixed distance to measure the change in field amplitude due to the magnetized liver (Fig. 11). In order to eliminate the effect of the surrounding air, a water-filled bellows is placed between the abdomen and the device to simulate the diamagnetic properties of the other tissues in the body. The main challenge to accurate estimates of hepatic iron content using BLS is the remaining effect of the varying susceptibility of the lungs and air filled compartments in the abdomen. Since this technique requires the application of a dc magnetic field to the body on the order of about 0.1 T, it is a much more invasive technology in comparison to MEG and MCG, and may be contraindicated in patients with implanted medical devices such as pacemakers. A detailed review of the clinical applications of BLS can be found in (223).

Peripheral Nerve Studies. It is known from the pioneering studies of Wikswo and colleagues (70) that the propagation of action potentials in nerve fibers produces quadrupolar like sources that have a rapidly diminishing magnetic field with distance. This is due to the fact that action potentials consist of a traveling wave of depolarization in the axon, followed closely by a wave of repolarization. In addition, due to varying conduction velocities in the peripheral nerves, action potentials in different axons will not necessarily summate to produce coherent synchronous activity. As a result, activation of compound nerve bundles does not produce coherent dipole-like sources as in the case of the neocortex. However, with sufficient signal averaging it is possible to record the magnetic signature of the sensory nerve action potentials noninvasively in the human: a technique

referred to as *magnetoneurography*. These measures have been achieved by placing single channel magnetometers or flat arrays of magnetic sensors over the peripheral nerve pathways and electrically stimulating the nerve. The predicted quadrupolar pattern of traveling action potentials resulting from electrical stimulation of the finger was reported by Hoshiyama et al. (224) using a 12 channel "micro-SQUID" device placed over the wrist. Mackert et al. (225), using a 49 channel flat triangular array of first-order radial gradiometers were able to measure compound action potentials elicited by tibial nerve stimulation in sensory nerves entering the spinal cord at the lower lumbar region, and have recently using this method clinically to demonstrate impaired nerve conduction in the patients with S1 root compression.

Magnetopneumography. Magnetopneumography refers to the measurement of the remanent magnetism of ferromagnetic particles in the lungs. This technique may be used to assess lung contamination encountered in occupations that may involve the inhalation of ferromagnetic dust particles such as arc-welders, coalminers, asbestos, and foundry and steel workers. Similar to liver biosusceptometry, magnetopneumography involves the application of a weak dc magnetic field to the thorax. However, the field is applied for only a short interval in order to produce a remanent magnetization of ferromagnetic material, usually iron oxides such as magnetite. This remanent magnetic field is then measured to assess to total load of ferromagnetic particles in the lung. These measures can be used to evaluate the quantity and clearance rates of these substances (226,227). A related measure is *relaxation*: the decay of the remanent field due to the reorientation of the magnetic particles away from their aligned state after application of the dc field. Relaxation times are thought to reflect cellular processes in the lung associated with clearance or macrophage activity on the foreign particles. Recent studies have used magnetopneumography to study the effect of smoking on clearance times of inhaled magnetic particles (228).

Gastrointestinal System. Biomagnetic measurements have also been applied to other areas of the human body. The human gastrointestinal system produces electrical activity associated with the processes of peristalsis and digestion of food. For example, slow electrical activity at frequencies of ~ 3 cycles/min (0.05 Hz) can be recorded from the human stomach using cutaneous surface electrodes or magnetically: a technique referred to as *magnetogastrography* (MGG). This activity arises from the smooth muscle of the stomach and the detection of changes in frequency with time has been proposed as a method of characterizing gastric disorders (229). Another novel application of biomagnetic instrumentation to gastrointestinal function, is the 3D tracking of the transport of magnetic materials through the gut. This technique has been termed *magnetic marker monitoring* (MMM) and can be used to monitor the passage and disintegration (by measuring decrease in magnetic moment) of magnetically

labeled pharmaceutical substances through the gastrointestinal system (230).

FUTURE DIRECTIONS

Since its inception 40 years ago with the first recording of the magnetic field of the heart, the field of biomagnetism has expanded immensely to become a major field of basic and applied research. The field of magnetoencephalography, or MEG, has in recent years become a recognized neuroimaging technique, with the development of advanced instruments for the measurement of the electrical activity of the brain with exquisite temporal and spatial resolution. Biomagnetic instrumentation is now at a mature state, with commercially developed measurement systems available for a variety of biomagnetic applications. For example, whole head MEG systems are installed worldwide in >100 research laboratories and clinical centres and are now being used in routine clinical diagnostic procedures. Nevertheless, there remain many areas for further improvement of both instrumentation and data analysis approaches and techniques. In terms of instrumentation, biomagnetometer systems with increased number of sensing channels and capable of unshielded operation will likely be developed, and present systems that require frequent refilling with liquid Helium may be replaced by systems with longer hold times and less frequent cryogen replenishment. The latter may be accomplished either by incorporation of cryocoolers, or the use of sensors that do not require liquid He. The last two technical innovations, combined with production of larger numbers of MEG systems will also help reduce the cost of these instruments.

The analysis and interpretation of biomagnetic measurements is possibly the most significant area for continued research and development, and much progress has been made in the implementation of new signal processing algorithms for the extraction of biomagnetic signals, or improving the spatial resolution of source localization methods. There has been recent interest in combining MEG with its high temporal resolution and other functional imaging techniques such as functional MRI. In addition, advanced image processing techniques, such as the automated extraction of the cortical surface of the brain from structural MRI, will allow the use of more precise physical models of biomagnetic sources. Combination of MEG with its counterpart EEG may also help to develop more accurate models of brain activity. These advancements will aid the development of new clinical applications of biomagnetism such as the use of MEG to study psychiatric disorders, or to study the effects of drug treatments on brain processes related to cognitive deficits, or gain insight into the physiological mechanisms underlying various brain disorders in children, for example, learning disabilities, dyslexia, and autism. Finally, novel applications of biomagnetic measurements, for example, the measurement of heart and brain activity in the fetus, will lead to new applications of biomagnetism in clinical medicine and will further drive the development of improved technology. In sum, biomagnetism will continue

to grow as a novel and powerful noninvasive technique for the study of physiological processes in humans in both health and disease.

BIOMATERIALS, ABSORBABLE

MARK BORDEN
 Director of Biomaterials
 Research
 Irvine, California

INTRODUCTION

Historically, the use of implants in orthopedic surgery has originated from fracture repair and joint replacement

applications. During the late 1920s, stainless-steel bone implants such as Kirshner nails and Steinman pins were popularized for the surgical treatment of fractures (1). With the introduction of new surgical materials such as cobalt alloys, polyethylene and poly(tetrafluoroethylene) [Teflon], surgeons and engineers began working toward the design and fabrication of artificial joints. The advent of new high strength implant materials allowed researchers such Dr. John Charnley to begin pioneering work in total hip replacement surgery in the late 1930s (1,2). As advances in chemistry, metallurgy, and ceramics progressed throughout the years, a large variety of implants have entered the orthopedic market. Today, orthopedic implants are composed of specialized metals, ceramics, polymers, and composites that possess a large range in properties. Although these materials have been successfully fabricated into a variety of implants, one common issue has remained. Once the device has performed its required function and is no longer needed, it remains as a bystander in the now healthy tissue. The issue is that the long-term presence of an implant in the body can result in implant-related complications such as loosening, migration, mechanical breakdown and fatigue, generation of wear particles, and other negative effects (3–6). With prolonged patient life spans and higher activity levels, more and more people are now outliving the lifetime of their implants.

The potential for long-term implant problems has driven researchers to look to a unique category of materials that are capable of being completely resorbed by the body. These bioresorbable or biodegradable materials are characterized by the ability to be chemically broken down into harmless byproducts that are metabolized or excreted by the body. Materials of this type offer a great advantage over conventional nonresorbable implant materials. Bioresorbable implants provide their required function until the tissue is healed, and once their role is complete, the implant is completely resorbed by the body. The end result is healthy tissue with no signs that an implant was ever present. As the implant is completely gone from the site, long-term complications associated with nonresorbable devices do not exist.

ORTHOPEDIC APPLICATIONS OF RESORBABLE IMPLANTS

The ability of a resorbable implant to provide temporary fixation followed by complete resorption is a desirable property for a large variety of surgical applications. In relation to orthopedic surgery, this behavior is particularly useful based on the goal of restoring physiological function to the tissues and joints of the skeleton. In general, orthopedic surgery is often compared with carpentry in that the surgeon's instruments often consist of hammers, drills, and saws. Similar to carpentry, specialized screws, plates, pins, and nails are used to fix one material to another. In orthopedics, this fixation can be categorized into two main areas: bone-to-bone fixation and soft tissue-to-bone fixation. Bone fixation is used in the treatment of complex fractures and in reconstructive procedures of the skeleton. The implants used in these surgeries are designed to

maintain the position of the bone fragments, to stabilize the site, and to allow for eventual fusion of the fracture. As a result of the fracture healing process, the bone is remodeled so effectively that it is often difficult to locate the initial injury. With nonresorbable implants, the long-term presence of the device only serves as a source for potential complications. Resorbable implants, on the other hand, alleviate this concern by fully resorbing and allowing the bone to completely remodel into its normal physiological state.

In addition to bone fixation, soft tissue fixation is also an excellent application of resorbable implants. This type of reconstruction is often the result of trauma to joints such as the knee and shoulder. Typically developing from sports injuries or accidents, the goal is to restore stability to the joint by replacing or reconstructing the ligament or tendon interface to bone. In the knee, for example, the reconstruction of a torn anterior cruciate ligament (ACL) is a common sports medicine procedure. This type of surgical reconstruction consists of replacing the torn ACL with a bone-tendon-bone graft taken from the patient's patella and fixing the graft across the joint. During the procedure, the bony portion of the ACL graft is fixed in bone tunnels drilled into the tibia and femur. In order to stabilize the graft and aid in the formation of a stable bone-to-ligament interface, interference screws are used to fix the graft to the site. Once bone has been incorporated into the graft, the device is no longer needed.

Another example of soft tissue reconstruction is the repair of a tear in the rotator cuff tendon of the shoulder. This type of injury requires reestablishing the tendon-to-bone interface. To facilitate this process and restore stability to the shoulder, implants called suture anchors are used to provide a means to affix the torn tendon to the bone of the humerus. Just as the name describes, these implants function by providing an anchor in bone that allows the attached suture to tighten down on the tendon and pull it in contact with bone. As healing progresses, a stable interface develops and joint function is restored. Similar to other fixation applications, once the interface has fully healed, the implant is no longer needed.

FUNCTION OF A RESORBABLE IMPLANT

As seen from the various types of tissue fixation procedures within orthopedic surgery, resorbable implants are exposed to a variety of healing environments. Out of the currently used materials in orthopedic surgery, only the polymer and ceramic groups contain resorbable biomaterials. It is the specific properties of these materials that allow them to be used as resorbable devices. In evaluating a material for potential use as an implant, the key properties include implant biocompatibility, resorbability, and mechanical properties. The first criteria, biocompatibility, refers to the ability of the material to be implanted into the body without negatively affecting the surrounding tissue, which includes the absence of inflammation, toxicity (materials that kill surrounding cells), carcinogenicity (materials that can cause cancer), genotoxicity (materials that damage the DNA of sur-

Figure 1. Optimal stress transfer profile for resorbable implants demonstrating the load-sharing properties of the implant.

rounding cells), and mutagenicity (materials that cause genetic mutations within the cell). More specifically related to bone, the implant must also be osteocompatible, which means the material does not interfere with the normal bone healing process (7).

Although biocompatibility has a direct effect on how the tissue surrounding the device heals and is an important property of the implant, the main criteria related to implant function are the resorbability and mechanical properties. Once the device is implanted, it provides immediate mechanical stabilization to the site while the tissue heals. As the regenerating bone, ligaments, or tendons become stronger over time, the implant site becomes less dependent on the device and more dependent on the healing tissue. This concept is shown in Fig. 1. In this situation, the implant provides all of the mechanical support immediately following placement. As the device begins to degrade, the mechanical properties decrease over time and are gradually transferred to the new tissue. During this period, the regenerating tissue responds to the gradual loads and begins to remodel and become stronger. In the healing of musculoskeletal tissue, the sharing of the load between the implant and the tissue results in further regeneration. Once healing is complete, the load is fully transitioned to the tissue, which is now mechanically independent from the implant. Upon final resorption of the device, the site is left fully functional and entirely free of any implant material.

The ability to gradually transfer load to regenerating tissue is an important part of the musculoskeletal healing process. This characteristic is only found in resorbable materials. Although metallic implants offer effective load-bearing properties in applications such as joint replacement and certain spinal surgeries, these high strength materials do not resorb and do not effectively transfer loads to the implant site. Due to the high strength of metals, these implants bear the majority of the force at the site and can shield the surrounding tissues from any load. This phenomenon is called stress shielding and can actually cause bone to resorb in certain areas around the implant (8,9). The stress-shielding effect is based on a concept called Wolff's Law, which describes the ability of bone to

dynamically respond to the presence or lack of stress by changing its density and strength.

When bone is subjected to new loads, the additional stress stimulates bone formation and the tissue increases in strength and density. When the remodeling process is complete, the stronger tissue can now fully support the added load. However, when a high strength material such as metal is placed in bone, the bone surrounding the implant is shielded from the normal stresses, which results in a decrease in the strength and density of this tissue and possible bone resorption. This phenomenon can cause complications such as implant loosening or fracture of the implant site. Polymer and ceramic materials, on the other hand, have mechanical properties that are similar to bone, which allows them to share the stresses with newly regenerating tissue thereby preventing resorption and other stress-shielding complications (10–12).

Although load transfer and strength retention are common properties of all resorbable implants, not all surgical sites heal at the same rate. In fracture fixation applications where bone-to-bone contact is maintained, healing can be as short as 6–8 weeks. However, in applications such as spinal fusion where significant amounts of tissue need to be formed in the intervertebral space, the healing process can take up to 6–12 months. Based on the dependence of implant function on the surgical site, the material choice becomes an important part of implant development. The challenge in designing an implant lies in choosing a material that correctly matches the function and strength requirements of the surgical application, which can be accomplished through a thorough understanding of the function of the implant, the load requirements of the implant site, and the properties of the material.

RESORBABLE POLYMERS

One of the most versatile materials used in orthopedic surgery are polymers. Polymers are a group of materials that are produced through a chemical reaction that results in a long chain of repeating molecules called monomers. In addition to polymers composed of a single monomer repeating unit, there are other materials, called copolymers, that have two or more monomer repeating units. By combining different monomers, the properties of the resultant copolymer can be specifically modified to serve a certain purpose. This versatility can also be achieved by modifying the polymerization reaction and the postprocessing techniques used to create polymer implants. Table 1 shows a few

Table 1. Range of Common Properties Found in Orthopedic Polymers

Property	Range	
Resorbability	Fully Resorbable	Nonresorbable
Strength	Low Strength	High Strength
Moldability	Flexible	Rigid
Physical State	Gel/Liquid	Solid
Temperature Sensitivity	Flexible at higher Temperature	Rigid at all Temperatures
Radiation Resistance	Low	High

examples of the many properties that characterize polymers. These characteristics can be altered by changing the molecular weight, chemical structure, and morphology of the polymer or copolymer.

The molecular weight of a polymer is a measurement of the number of repeating units found in the entire molecule. During the formation of polymers and copolymers, the length of the molecule can be controlled to give a variety of molecular weights. The length of the polymer chain can be as small as a few thousand repeating units or as large as a million, which can have a significant effect on the degradation properties of the polymer. When a polymer breaks down, it occurs through random cleavage of the chemical bonds along the polymer chain. It is not until the polymer finally fragments into its monomer form that the material is absorbed by the surrounding tissue. Therefore, longer polymers chains with higher molecular weights will take a longer time to degrade because more bonds exist to the cleaved.

Additionally, the chemical structure can also affect degradation. As described previously, the backbone of a polymer consists of a long, continuous chain of monomer units linked together. In all resorbable polymers, it is the backbone of the polymer where degradation occurs. The typical linkage that allows polymers to break down is a carbon–oxygen–carbon (C-O-C) bond. This bond is found in ester, carbonate, carboxylic acid, and amide-based polymers. The degradation process occurs at this bond when the material is exposed to water. In a process called hydrolytic degradation, water molecules chemically react with the C-O-C bonds causing them to break apart at random areas throughout the polymer chain. The chemical structure of the polymer dictates the ability of the water molecules to access these bonds and start the degradation reaction. If the polymer is characterized by large bulky side chains or strong C-O-C bonds, it becomes difficult for the water molecule to penetrate the polymer chains to react with the backbone, which results in a prolonged degradation period. The opposite is true for polymers that tend to absorb water and do not have any large side chains. In these polymers, the water molecules can easily access the backbone and the degradation process proceeds at a relatively fast rate.

The final characteristic that can affect the degradation and strength of a polymer is the morphology. The morphology of the polymer refers to the orientation of the long polymer chains throughout the material. Polymer morphology can be classified into three groups: crystalline polymers, semicrystalline polymers, and amorphous polymers. The crystallinity of a polymer develops from areas within the material where the polymer chains are aligned and tightly packed together. This type of orientation forms dense crystalline regions within the random arrangement of the polymer chains. A highly organized polymer is considered crystalline, whereas a completely random orientation is considered amorphous. Semicrystalline polymers fall between these two extremes and exist with varying degrees of crystallinity (Fig. 2).

The effect of crystallinity on the degradation of the polymer is due to the tight orientation between the polymer chains in the crystalline regions. With highly crystalline

Figure 2. Semicrystalline polymer showing orientation of amorphous regions and crystalline regions.

polymers, the degradation rate is very slow due to the difficulty of water gaining access to the C-O-C bonds. These polymers degrade at a rate much slower than polymers that are completely amorphous with no crystalline regions (13). The crystallinity also affects the mechanical properties of the polymer. The dense, organized areas within crystalline polymer make these regions stronger than the unorganized, amorphous regions. As a result, an increase in crystallinity translates into an increase in mechanical properties.

The ability to alter the properties of a polymer has resulted in thousands of different materials used in a wide range of applications. However, only a few of these polymers can be effectively used as medical implants due to the strict requirements of surgical implants. The following sections describe some of the polymers currently used in orthopedic surgery.

Poly(hydroxy acids)

Poly(hydroxy acids) were the first group of resorbable materials to be used in surgery (14). The main polymers in this family are poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and the copolymer poly(lactide-*co*-glycolide) (PLG). The basic chemical structure of these materials is shown in Fig. 3. Originally, PLA and PGA were initially used as a degradable sutures (15–18). However, since their initial success in the wound closure field, both of these polymers have been fabricated into several orthopedic implants including screws (19,20), plates (19,21), pins (22–25), suture anchors (26), and bone grafting scaffolds (27–30). In addition, several new devices composed of the PLG copolymer have been developed over the past 10 years (31–35).

Although the chemical structure of PLA and PGA is somewhat similar, the presence of a methyl group ($-\text{CH}_3$) in PLA significantly changes its physical properties compared with PGA. Comparatively, PGA has a lower strength and degrades in approximately 3–6 months, whereas certain forms of PLA can take 3–5 years to fully degrade. Although only a single methyl group differentiating PLA from PGA exists, the location of this side group close to the C-O-C bond makes it difficult for the water molecules to gain access to cleavage site, thereby prolonging degradation.

POLY (LACTIC ACID)

POLY (GLYCOLIC ACID)

POLY (LACTIDE-*co*-GLYCOLIDE)

Figure 3. Chemical structure of poly(lactic acid), poly(glycolic acid), and the copolymer poly(lactide-*co*-glycolide).

In addition, the methyl group in PLA also gives the polymer a unique chemical orientation. As a monomer, lactic acid is a molecule that can have two different molecular orientations: L-lactic acid and D-lactic acid. These isomers are based on the orientation of the methyl and hydrogen groups on the molecule. Figure 4 shows the chiral nature of the lactic acid molecule and the resulting stereoregular polymers: poly(L-lactic acid) (PLLA), poly(D-lactic acid) (PDLA), and poly(D,L-lactic acid) (PDLLA). Although three forms of PLA exist, in the medical field, poly(L-lactic acid) is used more often than poly(D-lactic acid) because the degradation product is the same as naturally occurring L-lactic acid (13).

Using the various forms of PLA, polymers with significantly different properties can be synthesized. The effect of the starting isomer on the physical properties of the material is dramatically seen in the properties of PLLA and PDLLA. In Fig. 4, the chemical structure of poly(L-lactic acid) is represented by a long chain with all of the $-\text{CH}_3$ groups on one side. This uniformity allows the chains to pack tightly together resulting in a highly crystalline material that has a high strength and long degradation period (3–5 years). Poly(D,L lactic acid), on the other hand, is characterized by either a random or alternating arrangement of the $-\text{CH}_3$ groups and $-\text{H}$ groups. This molecule orientation prevents the polymer chains from packing together, resulting in a completely amorphous polymer with a lower strength and shorter degradation profile (9–12 months). In addition, the polymerization of L-lactic acid and D,L-lactic acid together results in a copolymer with properties in between PLLA and PDLLA. In recent years, the 70:30 combination of poly(L/D,L lactic acid) has gained popularity in orthopedic applications due to its ability to retain its strength for 9–12 months while being completely resorbed within 1.5–2 years (36–38). This copolymer appears to provide the best

Figure 4. The optically active center in lactic acid allows it to have two different molecular orientations. These orientations result in three types of stereoregular polymers.

of both worlds in that it has the strength retention of PLLA but has a degradation period only slightly longer than PDLLA.

In addition to the lactic acid-based copolymers, a combination of PLA and PGA has also been shown to be an effective implant material (31–35). Due to the large differences in the degradation properties of PLA and PGA, the poly(lactide-*co*-glycolide) (PLG) copolymer can be modified based on the PLA to PGA ratio to provide varying degradation periods. Common PLG copolymers used in orthopedic surgery have PLA/PGA ratios of 50:50, 75:25, and 85:15. This combination not only provides both slow and fast resorbing monomer units but also eliminates any crystallinity, making the copolymer completely amorphous. These materials have been commonly used as fracture implants due to the shorter 6–12 month degradation period.

Although PLA and PGA polymers have been successfully used in patients for several years, there have been certain cases where the abundance of acidic monomers at the site has caused inflammation and bone resorption (39–48). When PLA and PGA polymers near the end of degradation, they release lactic acid and glycolic acid, respectively. Although these degradation products can be metabolized by the body, if the surrounding tissue cannot absorb the acid in a timely manner, the build up of acid and resultant drop in pH at the implant site can cause bone to resorb. Historically, this effect has mainly been seen in the fast-resorbing PGA implants; however, a few cases have been reported with PLA (43,46,49,50). Although the bone resorption complication is detrimental to the healing of the implant site, the complication rate has been relatively low. In a review of over 2000 patients by Bostman, only 5% of the patients have shown implant-associated reactions (44).

Additionally, the copolymers PLG and PLDLLA have been shown to possess a more osteocompatible degradation profile due to a gradual release of the acidic byproducts (36,51–56), which has minimized acid dumping and the

associated bone resorption complications. In a study by Eppley et al. (35), 1883 patients treated with PLG plates and screws for bone fixation in craniofacial procedures showed an implant-related complication rate of only 0.5%, which was well below the 5% rate reported by Bostman for PGA and PLA implants. Overall, the PLG and PLDLLA copolymers have been shown to be effective devices for fracture fixation, bone graft containment, and soft tissue fixation, and have begun to replace the outdated PLA and PGA devices (37,38,57,58).

Polycarbonates

Another group of resorbable polymers are the polycarbonates. Although the majority of the polymers and copolymers within the polycarbonate family are nonresorbable plastics used for industrial applications, a select few exist that are resorbable and can be used as orthopedic implants. One group of medical-grade polycarbonates are the copolymers based off of poly(trimethylene-carbonate) (PTMC) and poly(glycolic acid) or poly(lactic acid). These combinations offer the combined advantage of the processing versatility of PTMC and the resorbability and strength of PLA and PGA. The PTMC copolymers have been used for soft tissue fixation in shoulder surgery as suture anchors and soft tissue tacks (59–61).

Although the PTMC copolymers with PGA and PLA offer improved implant properties compared with PTMC alone, the degradation of the material still produces acidic monomers. In order to avoid the issues with glycolic acid- and lactic acid-based polymers and copolymers, an amino acid-based polycarbonate was developed by Joachim Kohn at Rutgers University. Designed specifically for orthopedic applications, the amino acid poly(carbonates) combine the biocompatibility of individual amino acids with the strength and processability of standard industrial poly(carbonates) (62–64). One such promising polymer, poly(DTE carbonate), is derived from the amino acid

tyrosine and has been shown to have excellent strength-retention properties, an optimal degradation profile, and biocompatible degradation products (65–68). Based on large amount of characterization data, a material safety file has been recently established at the U.S. Food and Drug Administration (FDA) that allows manufacturers to begin development of poly(DTE carbonate) implants. Due to the advantages of poly(DTE carbonate) over conventional resorbable polymers, amino acid-based poly(carbonate) implants may soon be a common sight in orthopedic operating rooms.

Other Resorbable Polymers

In addition to the widely used PLA and PGA polymers and the up-and-coming amino acid-based poly(carbonates), several other polymers have applications as medical devices. Although not specifically used in orthopedics, the poly(anhydride) family of polymers developed by Robert Langer at MIT has been effectively used as drug-delivery vehicles (69–73). The function of these resorbable implants is to provide a sustained and controlled release of drugs to a specific implant site. The device functions by releasing molecules entrapped within the implant as it degrades. Another polymer, poly(dioxanone), has been used as a resorbable suture material for several years (74–80). The flexibility of this polymer enables it to be used as a monofilament suture instead of the typical braided fiber of PGA, which provides the suture with an improved ability to move through tissue with less friction, thereby minimizing the tearing and pulling of the surrounding areas (81,82). Looking specifically at orthopedic applications, additional polymers currently in development include poly(caprolactone) (83–86), poly(hydroxybutyrate) (87–89), polyurethanes (90–93), and poly(phosphazenes) (94–96).

RESORBABLE CALCIUM CERAMICS

Aside from the polymers, the other group of resorbable implant materials are the calcium-based ceramics. Due to the similarity of these materials with the mineral content of bone, hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$, calcium ceramics are highly biocompatible and osteocompatible materials that have a long history of clinical use. These materials are typically used in orthopedic surgery to fill voids in bone as self-setting cements or as porous blocks and granules.

Calcium Sulfate

One of the first materials to ever be used as a filler for bone defects was calcium sulfate (Plaster of Paris) (97). In its dehydrated form (calcium sulfate hemihydrate), this material undergoes a chemical reaction when mixed with water that allows it to function as a resorbable cement. As the cement reacts, it transforms from a slurry, to a paste, to a dough, and then fully sets into its final hardened form (calcium sulfate dihydrate). This reaction is exothermic in that it produces heat; however, the increase in temperature is only slightly above body temp (37°C). Figure 5 shows a

Figure 5. Typical setting reaction and phase changes for a calcium sulfate cement.

typical timeline of the calcium sulfate setting reaction. In the slurry and paste form, the calcium sulfate is able to be added to a syringe and injected to the bone graft site. Near the end of the reaction, the cement becomes much thicker and has a putty-like consistency. During this phase, the doughy cement can be molded into a variety of shapes and provides a custom fit when placed directly at the implant site. Once the cement has fully hardened, it can be shaped by using powered surgical instruments such as osteotomes, burrs, and drills.

The resorption of calcium sulfate graft materials is based on the microstructure of the fully hardened cement. Figure 6 shows electron micrographs of the surface of fully reacted calcium sulfate dihydrate. These high magnification images show small calcium sulfate crystals packed together in a microporous structure. Upon implantation, the presence of these small pores allows the calcium sulfate to absorb water throughout the cement. Unlike polymers, which undergo active breakdown of the polymer chains, calcium sulfate materials are slowly dissolved by the water. As the material dissolves, Ca^{2+} and SO_4^{-3} ions are released over a 6–8 week period. During healing, bone formation initially begins on the outer area of the calcium sulfate and progresses inward as the cement slowly breaks apart. During the resorption process, the dissolution of the calcium sulfate material aids bone formation by providing a direct source Ca^{2+} ions to the surrounding osteoblasts. These cells absorb the calcium and use it during the mineralization phase of bone regeneration. From a mechanical standpoint, the hardened cement can provide initial stabilization to the site, but quickly loses its strength as the calcium sulfate begins to fragment. Although the strength of the calcium sulfate quickly decreases within the first few weeks, additional bone regeneration takes place within the cement and the implant site becomes mechanically stable. At the 6–8 week period, the majority of the calcium sulfate is resorbed by the body and has been replaced by bone.

In general, calcium sulfate cements and implants offer an effective means to fill small voids in bone resulting from cysts, tumors, or fractures (98–101). The initial strength

Figure 6. High magnification scanning electron micrographs of fully reacted calcium sulfate dihydrate showing crystalline structure and microporosity (1000X and 2000X magnification).

can also help maintain the spacing of fracture fragments and aid in placement of additional hardware. The moldability of the cement allows a custom fit to the defect site and makes the material easy to use. However, due to the quick resorption time and quick loss in strength, this material can not be effectively used in large defects or in areas under high mechanical loads. In these applications, supplemental hardware and grafting materials are needed to ensure complete bone regeneration (102,103). From a commercial standpoint, calcium sulfate graft materials are available in a cement form (requires mixing at the time of surgery) or in a preformed pellet form (fully reacted calcium sulfate dihydrate).

Calcium Phosphate. Calcium phosphates are another class of calcium containing bone graft materials that offer different properties than the calcium sulfates. As the name describes, these material are composed of varying amounts of calcium (Ca^{2+}) and phosphate (PO_4^{-3}). One of the first calcium phosphate materials to be used as a bone graft was hydroxyapatite, which was chosen because it is the main inorganic component of bone accounting for 40% of its

weight. Most calcium phosphate graft materials are produced synthetically and can be chemically altered to create materials with different properties. By slightly varying the calcium-to-phosphate ratio, the resorption times and mechanical properties of these materials can be significantly altered. Hydroxyapatite [$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$] with a Ca/P ratio of 1.67 has slow resorption rate, which, depending on crystallinity, can be as little as 2–5% resorption per year. Tricalcium phosphate $\text{Ca}_3(\text{PO}_4)_2$ has a ratio of 1.5, which results in a much faster resorption time of 9–12 months.

Due to the chemical composition of calcium phosphates, the mechanism of resorption is different than the dissolution mechanism seen with calcium sulfates. The chemical similarity of calcium phosphates to bone results in a cell-mediated resorption profile. During healing, bone-resorbing cells called osteoclasts migrate to the surface of the calcium phosphate ceramics. Once activated, the osteoclasts release specific enzymes that dissolve the calcium phosphate into its base ions. As the osteoclasts tunnel through the calcium phosphate, bone-forming cells called osteoblasts trail behind filling in the region with new tissue. Similar to calcium sulfate, the calcium ions resulting from the resorption process are transported to the osteoblasts, which create new mineralized bone. Over time, the entire structure is slowly dissolved by the osteoclasts and replaced with new bone.

To facilitate this type of resorption process, many of the calcium phosphate bone graft materials exist as porous scaffolds (104–109). A typical example of an osteoconductive calcium phosphate bone graft scaffold is shown in Fig. 7. This material, called Pro Osteon (developed and manufactured by Interpore Cross), was one of the first porous calcium phosphates used in orthopedics (110–113). Derived from sea coral, it is fabricated by chemically converting the calcium carbonate skeleton of the coral into hydroxyapatite. This reaction can be run to completion to give a implant composed entirely of hydroxyapatite or intentionally stopped to result in an implant with a thin (4–10 μm) surface of hydroxyapatite over the calcium carbonate skeleton. The conversion of coral to Pro Osteon

Figure 7. Photographs of two commercially available calcium phosphate scaffolds derived from coral (Interpore Cross, Irvine, CA).

allows the relatively short degradation time of calcium carbonate (6–8 weeks) to be prolonged to 8–18 months for Pro Osteon R (HA layer on the calcium carbonate skeleton) and to 3–5 years for Pro Osteon HA (fully converted hydroxyapatite). With a natural pore structure similar to cancellous bone, the Pro Osteon graft materials offer an effective scaffold for new bone growth. Since development of the Pro Osteon bone graft materials, several other porous calcium phosphates have entered the market. These materials are synthetically made to mimic the porosity of cancellous bone, which is done through various foaming and void creation techniques.

In contrast to calcium sulfate graft materials, the slower resorption profile of porous calcium phosphate ceramics allow these material to be used in larger defects. In this scenario, the graft serves as a cellular “bridge” for continued bone growth. In bone grafting surgery, once a defect reaches a size when it can no longer completely heal itself, it is called a critical-sized defect. Typical bone regeneration can bridge empty gaps of up to 4 mm, but anything larger will not fill in with bone. A porous ceramic scaffold alleviates this problem by providing the means for bone to grow across the entire defect.

This effect was demonstrated in a study by Holmes who implanted a block of Pro Osteon 500R (calcium carbonate scaffold with an HA coating) into a rabbit tibial defect (114). The healing sequence of the this scaffold is shown in Fig. 8. As seen from cross sectional image of the implant before implantation (Fig. 8a), the structure is characterized by an open pore structure (black regions) within areas of calcium carbonate/HA ceramic (light-gray regions). After initial placement of the porous ceramic, cells migrated to the graft site and began to infiltrate the pore system. At the same time, proteins were released from surrounding bone and blood cells to stimulate the bone regeneration process, which was seen in the 6 week histology of the Pro Osteon 500R implant (Fig. 8b). In this

Figure 8. Typical healing mechanism of a porous ceramic implanted into a rabbit tibial defect. (Figure A – 0 weeks; Figure B – 6 weeks; Figure C – 12 weeks; Figure D – 24 weeks).

image, bone formation was evident within the porosity of the scaffold, and osteoclasts were seen resorbing the scaffold (arrows). By 12 weeks, further bone growth was seen within the porosity, and significant portions of the scaffold were replaced by bone. At the 24 week time point, the scaffold was fully replaced by bone with the exception of the thin HA layer that once covered the calcium carbonate. As seen from this study, porous ceramics are capable of functioning as a scaffold for bone growth. The pore system allowed for immediate bone regeneration and the resorbability allowed the implant to be completely replaced by bone.

In addition to porous blocks and granules, calcium phosphates are also used in cement form (115–119). In this application, the base components that create calcium phosphates are provided in an unreacted form. With the addition of water, dilute acid, or other initiators, a chemical reaction takes place, and the components are converted to calcium phosphate. The result is a moldable paste or putty that can be shaped to the graft site and hardens into a solid mass. Although these cements have longer resorption times than calcium sulfate cements and can be used in broader applications, the resulting hardened cement does not possess the porosity to function as a scaffold for bone repair, which has limited the use of calcium phosphate cements because surgeons prefer the porous blocks and granules over the self-setting cements.

RESORBABLE COMPOSITES

As discussed, both polymers and ceramics have properties suitable for fabricating orthopedic implants. However, certain drawbacks exist with these materials that can not be avoided no matter how the material is fabricated or chemically altered. One technique for combining the desirable properties of two or more materials is the fabrication of a composite. Composites used in the medical device area are fabricated by physically mixing two or more resorbable materials. One of the most common composite combinations is the creation of a polymer-ceramic composite. On their own, ceramics are excellent substrates for new bone growth due to the chemical similarity with bone mineral. However, their brittleness limits their use in load-bearing applications. Polymers, on the other hand, are elastomeric materials that can flex under deformation without major structural collapse. The combination of these two materials results in a high strength, yet ductile composite that allows for direct bone attachment on its surface. In this combination, the polymer adds to the overall mechanical properties of the composite, whereas the ceramic allows for bone formation directly on the ceramic phase.

The fabrication of a composite is a relatively straightforward process. Typically, ceramic particles in the shape of spheres or fibers are added to the polymer during processing. The various orientations of the particles within a polymer are shown in Fig. 9. As seen from these illustrations, each particle is surrounded by the polymer and serves to reinforce the polymer phase and improve its mechanical properties. Once fabricated in a block or rod

Figure 9. Orientation of various types of polymer-ceramic composites (ceramic is depicted as the black particles).

form, composites of these different types can be machined into a variety of implants such as fracture screws, pins, and plates. During the machining process, the ceramic on the outer surfaces of the implant are exposed. From a bone implant standpoint, the presence of the exposed calcium ceramic particles on the surface of the polymer aids in creating a solid bone-to-implant interface. In comparison, pure polymer implants typically heal with limited bone contact or a continuous layer of fibrous tissue usually covering the surface. Although the implant can still provide stabilization, it is not directly bonded to the surrounding bone. A composite implant improves on the stabilizing effect of the device through this bone-bonding ability.

In addition to the particulate ceramic composites, a new type of composite has recently been developed by Interpore Cross (Irvine, CA). This novel material consists of two intact, continuous phases of polymer and ceramic. Shown in Fig. 10, a continuous phase composite (CPC) is the result of infiltrating a porous ceramic block with polymer. The

Figure 10. A continuous phase composite is formed when a polymer is infiltrated into the porosity of a porous, ceramic scaffold. The result is a solid block with an intact polymer and ceramic phase.

Figure 11. Backscattered electron microscope images demonstrating bone and blood vessel in-growth into a CPC implant (bone is shown in gray, ceramic is white, and polymer is black).

end result is a composite material with continuous seams of ceramic running through the polymer. Similar to the particulate composites, the CPC material will allow for bone growth on the surface and into the ceramic regions. However, the continuity of the ceramic phase throughout the composite gives the material a unique ability to allow for bone to penetrate into the center of a CPC implant. Figure 11 shows the histology of a CPC implant composed of the Pro Osteon porous ceramic infiltrated with poly(L/D,L lactic acid) implanted in a sheep femur at 9 months. This backscattered electron microscope image shows the ability of a CPC implant to support bone and blood vessel in-growth into the center of the implant wall. In addition to acting as a structural implant, a CPC device also functions as an eventual scaffold for bone in-growth. From a healing standpoint, this type of composite will result in more bone formation at the site. Additionally, the presence of bone and blood vessels within the implant wall significantly improves the ability of the tissue to absorb the degradation products. Typically occurring at the surface of polymer implants, the presence of bone within the CPC material allows resorption throughout the entire device. This new

composite is currently being investigated for use as spinal fusion implants, fracture screws and plates, interference screws, and suture anchors.

CONCLUSION

As seen from this article, resorbable polymers and ceramics possess the desired properties needed for orthopedic implants. They have been shown to be versatile materials with a range in degradation rates and mechanical properties. The resorbable nature of these devices allows them to provide temporary stabilization and mechanical support. Combined with the ability to be completely resorbed by the body and replaced by natural tissue, these implants are highly desirable alternatives to their nonresorbing counterparts. The elimination of long-term implant complications and the ability to share load with regenerating tissues are large driving forces behind the use of these implants in orthopedics. With further advancements in biomaterial research, resorbable implants may soon become the standard of care.

BIOMATERIALS: AN OVERVIEW

BRANDON L. SEAL
 ALYSSA PANITCH
 Arizona State University
 Tempe, Arizona

INTRODUCTION

Biomaterials are materials that are used or that have been designed for use in medical devices or in contact with the body. Traditionally, they consist of metallic, ceramic, or synthetic polymeric materials, but more recent develop-

ments in biomaterials design have attempted to incorporate materials derived from or inspired by biological materials (e.g., silk and collagen). Often, the use of biomaterials focuses on the augmentation, replacement, or restoration of diseased or damaged tissues and organs. The prevalence of biomaterials within society is most evident within medical and dental offices, pharmacies, and hospitals. However, the influence of biomaterials has reached into many households with examples ranging from increasingly common news media coverage of medical breakthroughs to the availability of custom color non-corrective contact lenses.

The evolving character of the discipline of biomaterials is evidenced by how the term biomaterial has been defined. In 1974, the Clemson Advisory Board, in response to a request by the World Health Organization (WHO), stated that a biomaterial is a “systemically pharmacologically inert substance designed for implantation within or incorporation with living tissue” (1). Dr. Jonathan Black further modified this definition to state that a biomaterial is “any pharmacologically inert material, viable or nonviable, natural product or manmade, that is part of or is capable of interacting in a beneficial way with a living organism” (1). An National Institute of Health (NIH) consensus definition appeared in 1983 and defined biomaterials as “any substance (other than a drug) or combination of substances, synthetic or natural in origin, which can be used for any period of time, as a whole or as a part of a system that treats, augments, or replaces any tissue, organ, or function of the body” (2). Thus, relatively newer definitions of the term biomaterial recognize that more modern medical and diagnostic devices will rely increasingly upon direct biological interaction between biological molecules, cells, and tissues and the materials from which these devices are manufactured.

HISTORY OF BIOMATERIALS

Compared with the much larger field of materials science, the field of biomaterials is relatively new. Although there exist recorded cases of glass eyes and metallic or wooden dental implants (some of which can be dated back to ancient Egypt), the modern age of biomaterials could not have existed without the adoption of aseptic surgical techniques pioneered by Sir Joseph Lister in the mid-nineteenth century and indeed, did not fully emerge as an industry or discipline until after the development of synthetic polymers just prior to, during, and following World War II. Prior to World War II, implanted biomaterials consisted primarily of metals (e.g., steel, used in pins and plates for bone fixation, joint replacements, and the covering of bone defects). In the late 1940s, Harold Ridley observed that shards of poly(methyl methacrylate) (PMMA), from airplane cockpit windshields, embedded within the eyes of World War II aviators did not provoke much of an inflammatory response (3). This observation led not only to the development of PMMA intraocular lenses, but also to greater experimentation of available materials, especially polymers, as biomaterials that could be placed in direct contact with living tissue.

As the fields of cellular, molecular, and developmental biology began to grow during the 1970s and 1980s, new insights into the organization, function, and properties of biological systems, tissues, and interactions led to a greater understanding of how cells respond to their environment. This wealth of biological information allowed the field of biomaterials to undergo a paradigm shift. Instead of focusing primarily on replacing an organ or a tissue with a synthetic, usually nondegradable biomaterial, a new branch of biomaterials would attempt to combine biologically active molecules, therapeutics, and motifs into existing and novel biomaterial systems derived from both synthetic and natural sources (4–6). Although there exist many examples of successful, commercially available biomaterials consisting of metallic and ceramic bases, the focus of biomaterials research has shifted to the development of polymeric or composite materials with biologically sensitive or environmentally controlled properties. This change has resulted largely due to the reactivity and variety of chemical moieties that are found in or that can be engineered into natural and synthetic polymers. Indeed, by viewing biomaterials as materials designed to interact with biology rather than being inert substances, the field of biomaterials has exploded with innovative designs that promote cell attachment, encapsulation, proliferation, differentiation, migration, and apoptosis, and that allow the biomaterial to polymerize, swell, and degrade under a variety of environmental conditions and biological stimuli. Evidence of this polymer and composite revolution is the dramatic increase in the number of publications relating to biomaterials research. Figure 1 shows a plot of the number of journal articles with biomaterial or biomaterials in their title, abstract, or keyword as a function of publication year as searched in the Web of Science database. As seen in Fig. 1, publications matching the search criteria have increased exponentially starting around the early 1990s and continuing until the present. The number of scientific journals, shown in Table 1, related

Figure 1. A plot of the number of publications (○) containing the word biomaterial or biomaterials in the title, abstract, or keywords, as searched in the Web of Science database, as a function of the publication year as well as a plot of the number of bioengineering or biomedical engineering departments (BME departments) within the United States as a function of time (■).

to research in the field of biomaterials has also grown. Although the number of journal articles related to biomaterials research may have resulted primarily from the large increase in the number of biomaterials-related scientific journals, the exponential growth of biomaterials is evidenced further by the growth of the number of bioengineering or biomedical engineering departments (the department in which most biomaterials programs reside) established at universities throughout the United States (Fig. 1).

MARKET SIZE AND TYPES OF APPLICATIONS

The field of biomaterials, by nature, is interdisciplinary. Successful biomaterial designs have involved talents, knowledge, and expertise provided by physicians and clinicians, materials scientists, engineers, chemists, biologists, and physicists. As a result, it is not surprising that the biomaterials industry is both relatively young and very diversified. The diversity of this industry has resulted from the types of products created and marketed, the size and location of involved companies, and the types of regulatory policies imposed by government agencies and third party reimbursement organizations. Specifically, the biomaterials industry is part of the Medical Device and Diagnostic Industry, a multibillion dollar industry comprised of organizations that design, fabricate, and/or manufacture materials that are used in the health and life science fields. The end use applications are medical and dental devices, prostheses, personal hygiene products, diagnostic devices, drug delivery vehicles, and biotechnology systems. Some examples of these applications include full and hybrid artificial organs, biosensors, vascular grafts, pacemakers, catheters, insulin pumps, cochlear implants, contact lenses, intraocular lenses, artificial joints and bones, burn dressings, and sutures. Table 2 shows a list of some common medical devices that require various biomaterials, and Table 3 displays a list of the prevalence and market potential of a few of these applications (7).

GOVERNMENT REGULATION

Within the United States, in a research only environment, biomaterials by themselves do not necessarily require government regulation. However, if any biomaterial is used within a medical or diagnostic device designed and destined for commercialization, the biomaterials used within the medical device (as well as the device itself) are subject to the jurisdiction of the U.S. Food and Drug Administration (FDA) as set forth in the Federal Food, Drug, and Cosmetic Act of 1938, the Medical Device Amendments of 1976, and the Food and Drug Administration Modernization Act of 1997. These laws have empowered the FDA to regulate conditions involving premarket controls, postmarket reporting, production involving Good Manufacturing Practices, and the registration and listing of medical devices. Any biomaterial within a marketed medical device prior to the Medical Device Amendments of 1976 were grandfathered and are considered approved materials. Modifications to these materials or

^aThe date of first publication is listed in parentheses following the name of each journal.

new materials are subject to controls established by the FDA. These controls consist of obtaining an Investigational Device Exemption for the medical device, including the biomaterials used within the device, prior to conducting clinical trials.

In addition, biomaterials can be considered part of a Class I, II, or III device depending on FDA classifications and depending on whether or not the biomaterial is considered to be part of a biologic, drug, or medical device. Class I devices are generally considered those devices needing the least amount of regulatory control since they do not present a great risk for a patient. Examples include tongue depressors and surgical drills. Class II devices represent a moderate risk to patients and require additional regulation (e.g., mandatory performance standards, additional labeling requirements, and postmarket surveillance). Some examples include X-ray systems and cardiac mapping catheters. Class III devices (e.g., cardiovascular stents and heart valves), represent those devices with the highest risk to patients and require extensive regulatory control. Usually, for biomaterials in direct contact with tissue within the body, devices are considered Class III devices and are subject to a Premarket Approval process before they can be sold within the United States. In general, for most biomaterials, some of the tests the FDA reviews to evaluate biomaterial safety includes tests

Table 2. Some Common Uses for Biomaterials

Organ/Procedure	Associated Medical Devices
Bladder	Catheters
Bone	Bone plates, joint replacements (metallic and ceramic)
Brain	Deep brain stimulator, hydrocephalus shunt, drug eluting polymers
Cardiovascular	Polymer grafts, metallic stents, drug eluting grafts
Cosmetic enhancement	Breast implants, injectable collagen
Eye	Intraocular lenses, contact lenses
Ear	Artificial cochlea, artificial stapes
Heart	Artificial heart, ventricular assist devices, heart valves, pacemakers
Kidney	Hemodialysis instrumentation
Knee	Metallic knee replacements
Lung	Blood oxygenator
Reproductive system	Hormone replacement patches, contraceptives
Skin	Artificial skin, living skin equivalents
Surgical	Scalpels, retractors, drills
Tissue repair	Sutures, bandages

Table 3. A Summary of the Prevalence and Economic Cost of Some of the Healthcare Treatments Requiring Biomaterials for the Year 2000

Medical Application ^a	Incident Patient Population ^a	Prevalent Patient Population ^a	Total Therapy Cost (Billions of US Dollars) ^a
Dialysis	188,000	1,030,000	\$67
Cardiovascular			
Bypass grafts	733,000	6,000,000	\$65
Valves	245,000	2,400,000	\$27
Pacemakers	670,000	5,500,000	\$44
Stents	1,750,000	2,500,000	\$48
Joint replacement	1,285,000	7,000,000	\$41
Hips	610,000		
Knees	675,000		

^aAll data taken from that reported by Lysaght and O'Loughlin (7).

involving cellular toxicity (both direct and indirect), acute and chronic inflammation, debris and degradation byproducts and associated clearance events, carcinogenicity, mutagenicity, fatigue, creep, tribology, and corrosion. Further information regarding FDA approval for medical devices can be found on the FDA webpage, www.fda.gov.

Many FDA approved biomaterials continue to be monitored for efficacy and safety in an effort not only to protect patients, but also to improve biocompatibility and reduce material failure. Perhaps the best known example of an FDA regulated biomaterial is silicone. Silicone had been used since the early 1960s in breast implants. As a result, silicone breast implants were grandfathered into the Medical Device Amendments of 1976. During the 1980s, some concerns regarding the safety of silicone breast implants arose and prompted the FDA to request, in 1990, additional safety data from manufacturers of breast implants. Due to fears of connective tissue disease, multiple sclerosis, and other ailments resulting from ruptured silicone implants, the FDA banned silicone breast implants in 1992. Recently, however, manufacturers (e.g., the Mentor Corporation) have applied for and received premarket approval for the sale of silicone breast implants contingent on the compliance of various conditions (8). Thus, silicone is a good example of the complexity surrounding the testing of both efficacy and safety for biomaterials.

TYPES OF BIOMATERIALS

Similar to the field of materials science, the field of biomaterials focuses on four major types of materials: metals, ceramics, polymers, and composites. Examples of a few selected medical devices made from these materials are shown in Fig. 2. The materials selected for any particular application depend on the properties desired for a particular function or set of functions. In all materials applications, the structure, properties, and processing of the selected material will affect performance. As a result, physicians, scientists and engineers who design biomaterials need to understand not only mechanical and physical properties of materials, but also biological properties of materials. Mechanical and physical properties include strength, fatigue, creep resistance, flexibility, permeability

Figure 2. A representation of a few medical devices made from various biomaterials. From the upper left corner and moving clockwise, this picture shows a kidney hemodialyzer, two pacemakers, a hip replacement, an articulating wrist joint, a heart valve, and a vascular graft.

to gases and liquids, thermal and electrical properties, chemical reactivity, and degradation. Biological properties of materials largely focus on biocompatibility issues related to toxicity, immune system reactivity, thrombus formation, tribology, inflammation, carcinogenic and teratogenic potential, integration with tissues and cells, and the ability to be sterilized. Regardless of the material, recent approaches to biomaterials research has focused on directing specific tissue interaction by using materials to introduce chemical bonds with the surrounding tissue, to act as scaffolds for tissue ingrowth, to introduce an inductive signal that will influence the behavior of surrounding cells or matrix, or to form new tissue when incubated or presented to transplanted cells.

Metals

Metals have been used as biomaterials for centuries. Although some fields (e.g., dentistry) continue to use amalgams, gold, and silver, most modern metallic biomaterials consist of iron, cobalt, titanium, or platinum bases. Since they are strong, metals are most often employed as biomaterials in orthopedic or fracture fixation medical devices; however, metals are also excellent conductors, and are therefore used for electrical stimulation of the heart, brain, nerves, muscle, and spinal cord. The most common alloys for orthopedic applications include stainless steel, cobalt, and titanium alloys. These alloys have enjoyed frequent use in medical procedures related to the function of joints and load-bearing. For example, metal alloys are commonly found in medical devices for knee replacement as well as in the femoral stem used in total hip replacements. Since all metals are subject to corrosion, especially in the salty, aqueous environment within the body, metals used as biomaterials often require an external oxide layer to protect against pitting and corrosion. These electrochemically inert oxide layers consist of Cr_2O_3 for stainless steel, Cr_2O_3 for cobalt alloys, and TiO_2 for

Figure 3. Photographs of stainless steel (a), cobalt–chromium (b), and titanium alloy (Ti6Al4V) (c) hip implants. (All three photographs are used with permission from the Department of Materials at Queen Mary University of London.)

titanium alloys. Figure 3 displays examples of three types of metallic hip replacements.

Stainless Steel Alloys. The stainless steel most commonly used as orthopedic biomaterials is classified 316L by the American Iron and Steel Institute. This particular austenitic alloy contains a very low carbon content (a maximum of 0.03%) and chromium content of 17–20%. The added chromium will react with oxygen to produce a corrosion-resistant chromium oxide layer. The 316L grade of stainless steel is a casting alloy, and its relatively high ductility makes this alloy amenable to extensive postcasting mechanical processing. Compared to cobalt and titanium alloys, stainless steel has a moderate yield and ultimate strength, but high ductility. Furthermore, it may be fabricated by virtually all machining and finishing processes and is generally the least expensive of the three major metallic alloys (4,5,9).

Cobalt Alloys. Cobalt alloys have been used since the early twentieth century as dental alloys and in heavily loaded joint applications. For use as a biomaterial, cobalt alloys are either cast (i.e., primarily formed within a mold) or wrought (i.e., worked into a final form from a large ingot). Two examples of cobalt alloys include Vitallium (designated F 75 by ASTM International), a cast alloy that consists of 27–30% chromium and >34% cobalt, and the wrought cobalt alloy MP35N (designated F 563 by ASTM International), which consists of 18–22% chromium, 15–25% nickel, and >34% cobalt. Compared to Vitallium, the MP35N alloy has demonstrated superior fatigue resistance, larger ultimate tensile strength, and a higher degree of corrosion resistance to chlorine. Consequently, this particular alloy is good for applications requiring long service life without fracture or stress fatigue. Compared to stainless steel alloys, cobalt-based alloys have slightly higher tensile moduli, but lower ductility. In addition, they are more expensive to manufacture and more difficult to machine. However, relative to stainless steel and titanium, cobalt-based alloys can offer the most useful balance of corrosion resistance, fatigue resistance, and strength (4,5,9).

Titanium Alloys. The most recent of the major orthopedic metallic alloys to be employed as biomaterials are titanium alloys. Although pure titanium is relatively weak and ductile, titanium can be stabilized by adding elements (e.g., aluminum and vanadium) to the alloy. Often, pure titanium (designated F 67 by ASTM International) is pri-

marily used as a surface coating for orthopedic medical devices. For load-bearing applications, the alloy Ti6Al4V (designated F 136 by ASTM International) is much more widely used in implant manufacturing. As in the case of stainless steel and cobalt alloys, titanium contains an outer oxide layer, composed of TiO_2 , that protects the implant from corrosion. In fact, of the three major orthopedic alloys, titanium shows the lowest rate of corrosion. Moreover, the density of titanium is almost half that of stainless steel and cobalt alloys. As a result, implants made from titanium are lighter and reduce patient awareness of the implant; however, titanium alloys are among the most expensive metallic biomaterials. Relative to stainless steel and cobalt alloys, titanium has a lower Young's modulus, which can aid in reducing the stresses around the implant by flexing with the bone. Titanium has a lower ductility than the other alloys, but does demonstrate high strength. These properties allow titanium alloys to play a diverse role as a biomaterial. Titanium alloys are used in parts for total joint replacements, screws, nails, pacemaker cases, and leads for implantable electrical stimulators (4,5,9).

Despite the reduced weight and improved mechanical match of titanium alloy implants to bone relative to stainless steel and chromium alloy implants, titanium alloy implants still exhibit issues with regard to mechanical mismatch. This problem stems from the large differences in properties (e.g., elastic moduli) between bone, metals, and polymers used as acetabular cups. For example, metals have elastic moduli ranging from ~ 100 to 200 GPa, ultrahigh molecular weight polyethylene has an elastic modulus of 1–2 GPa, and the elastic modulus of cortical bone is ~ 12 GPa (10). In addition, it is difficult to produce a titanium implant surface that is conducive to bone ingrowth or attachment. Novel titanium foams have been investigated as a method for reducing implant weight, better matching tissue mechanics, and improving bone ingrowth. The process involves mixing titanium powder with ammonium hydrogen carbonate powder and compressing and heating the mixture to form foams with densities varying from 0.2 to 0.65 times the density of solid titanium. These densities are close to those of cancellous bone (0.2–0.3 times the density of solid titanium) and cortical bone (0.5–0.65 times the density of solid titanium) (11). While they are preliminary, studies with novel materials such as these titanium foams illustrate a trend toward the development of materials that better mimic the properties of the native tissue they are designed to replace.

Figure 4. A photograph of the SMARTeR nitinol stent developed by the Cordis Corporation. (Reprinted from Ref. 12, with permission from Royal College of Radiologists.)

Other Metals. Besides stainless steel, cobalt alloys, and titanium alloys, there exist other examples of metals used as biomaterials. Some examples include nitinol, a single-phase nickel/titanium shape memory alloy, tantalum, a very dense, chemically inert, weak, but fatigue-resistant metal, and platinum, a very expensive metal used by itself or with iridium as a corrosion-resistant electrical conductor for electrode applications. Nitinol stents (e.g., that seen in Fig. 4) (12) and drug-eluting nitinol stents used for cardiovascular applications recently have seen enormous medical and commercial success. Indeed, metallic stents have significantly changed the way coronary blockages are treated (4,5,9).

Ceramics

Of the major types of materials used as biomaterials, ceramics have not been used as frequently as metals, polymers, or composites. However, ceramics continue to enjoy widespread use in certain bone-related applications (e.g., dentistry and joint replacement surgeries), due to their high compressive strength, high degree of hardness, excellent biocompatibility, superior tribological properties, and chemical inertness. Although they are very strong in compression, ceramics are susceptible to mechanical and thermal loading, have lower tensile strengths relative to other materials, and are very brittle in tension; this brittleness limits potential biomaterials applications.

Ceramics consist of a network of metal and nonmetal ions, with the general structure $X_m Y_n$, arranged in a repeating structure. This structure depends on the relative size of the ions as well as the number of counterions needed to balance total charge. For example, if $m = n = 1$, and both ions are approximately the same size, then the structure would be of a simple cubic nature (e.g., CsCl or CsI); if the anion is much larger than the cation, then typically, a face centered cubic (fcc) structure would emerge (e.g., ZnS or CdS). If $m = 2$ and $n = 3$, as is the case with oxide ceramics (e.g., Al_2O_3), then a hexagonal closed pack structure would often result (13).

Ceramics used as biomaterials can be classified by processing–manufacturing methods, by chemical reactivity, or by ionic composition. Regarding chemical reactivity, ceramics can be bioinert, bioactive, or bioresorbable. Bio-

inert or nonresorbable ceramics are either porous or nonporous and are essentially not affected by the environment at the implant site. Bioactive or reactive ceramics are designed with specific surface properties that are intended to react with the local host environment and to elicit a desired tissue response. Bioresorbable ceramics dissolve over some prescribed period of time *in vivo* mediated by physiochemical processes. If one considers the application of bone replacement, then there would be about four ways for ceramics to interact with and attach to bone. First, a nonporous, inert ceramic material could be attached via glues, surface irregularities, or press-filling methods. Second, a porous, inert ceramic could be designed to have an optimal pore size, which promotes direct mechanical attachment of bone through bone ingrowth. Third, a nonporous, inert ceramic with a reactive surface could direct bone attachment via chemical bonding. Fourth, a nonporous or porous, resorbable ceramic could eventually be replaced by bone. When describing real examples of ceramics used as biomaterials, it is more useful to classify the ceramics based on ionic composition. This type of classification reveals a few major bioceramic groups: oxide ceramics, multiple oxides of calcium and phosphorus, glasses and glass ceramics, and carbon.

Oxide Ceramics. As their name implies, oxide ceramics consist of oxygen bound to a metallic species. Oxide ceramics are chemically inert, but can be nonporous or porous. One example of a nonporous oxide ceramic used as a biomaterial is aluminum oxide, Al_2O_3 . Highly pure aluminum oxide (F 603 as designated by ASTM International), or alumina, has high corrosion resistance, good biocompatibility, high wear resistance, and good mechanical properties due to high density and small grain size. Aluminum oxide has been manufactured as an acetabular cup for total hip replacement. In comparison with metal or ultrahigh molecular weight polyethylene, Al_2O_3 provides better tribological properties by greatly decreasing friction within the joint and substantially increasing wear resistance. Recently, the FDA approved ceramic on ceramic hip replacements made from alumina and marketed by companies such as Wright Medical Technology and Stryker Osteonics. This ceramic on ceramic design is very resistant to wear and results in a much smaller amount of wear debris than traditional metal–polymer joints. With better wear properties and longer useful lifespan, ceramic on ceramic hip replacements likely will provide an attractive alternative to other biomaterial options, especially for younger patients that need better long-term solutions for joint replacements (4,5,9).

Ceramic oxides can also be porous. In bone formation, these pores are useful for allowing bone ingrowth, which will stabilize the mechanical properties of the implant without sacrificing the chemical inertness of the ceramic material. In general, there are three ways to make a porous ceramic oxide. First, a soluble metal or salt can be mixed with the ceramic and etched away. Second, a foaming agent that evolves gases during heating (e.g., calcium carbonate) can be mixed with the ceramic powder prior to firing. Third, the microstructure of corals can be used as a template to create a ceramic with a high degree

Figure 5. Photographs of (a) a cross-section of human cancellous bone and (b) coral of the genus *Porites*. These images illustrate how biologically derived materials (e.g., coral) can be used as scaffolds to create ceramic biomaterials that mimic the structure and porosity of natural bone. (Both photographs are used with permission from Biocoral, Inc.)

of interconnectivity and uniform pore size. In this third approach, coral is machined into the desired shape. Then, the coral is heated up to drive off carbon dioxide. The remaining calcium oxide provides a scaffold around which the ceramic material is deposited. After firing, the calcium oxide can be dissolved using hydrochloric acid. This dissolved calcium oxide will leave behind a very uniform and highly interconnected porous structure. Interestingly, the type of coral used will affect the pore size of the resulting ceramic. For example, if the genus *Porites* is used, then the pore size will range from 140 to 160 μm ; the genus *Goniopora* will result in a pore size of 200–1000 μm (5). Porous ceramics do have many advantages for bone ingrowth, especially since the porous structure more closely mimics that of cancellous bone (see Fig. 5). However, the porous structure does result in a loss of strength and a tremendous increase in surface area that interacts with an *in vivo* saline environment.

Multiple Oxides of Calcium and Phosphorus. Aside from many types of proteins, the extracellular environment of bone contains a large concentration of organic mineral deposits known as hydroxyapatite. Chemically, hydroxyapatite generally has the following composition: $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$. Since hydroxyapatite is a naturally occurring ceramic produced by osteoblasts, it seemed reasonable to apply hydroxyapatite as filler or as a coating to allow better integration with existing bone. Coatings of hydroxyapatite have been applied (usually by plasma spraying) to metallic implants used in applications requiring bone ingrowth to provide a tight fit between bone and the implanted device, to minimize loosening over time, and to provide some measure of isolation from the foreign body response. Although hydroxyapatite is the most commonly used bioceramic containing calcium and phosphorus, there do exist other forms of calcium and phosphorus oxides including tricalcium phosphate, $\text{Ca}_3(\text{PO}_4)_2$, and octacalcium phosphate, $\text{Ca}_8\text{H}_2\text{PO}_4 \cdot 5\text{H}_2\text{O}$ (4,5,9,14).

Glasses and Glass Ceramics. Just as in the case of traditional glass, glass ceramics used as biomaterials contain large amounts of silica, SiO_2 . Glass ceramics are formed using controlled crystallization techniques during

which silica is cooled down at rate slow enough to allow the formation of a hexagonal crystal structure with small, crystalline grains ($\sim 1 \mu\text{m}$) surrounded by an amorphous phase. Bioactive glass ceramics have been studied as biomaterials because they can attach directly to tissue via chemical bonds, they have a low thermal coefficient of expansion, they have good compressive mechanical strength, the mechanical strength of the glass–tissue interface is close to that of tissue, and they resist scratching and abrasion. Unfortunately, as with all ceramics, bioactive glasses are very brittle. Two well-known examples of commercially available glass ceramics include Bioglass, which consists of SiO_2 , Na_2O , CaO , and P_2O_5 , and Ceravital, which contains SiO_2 , Na_2O , CaO , P_2O_5 , K_2O , and MgO . Relative to traditional soda lime glass, bioactive glass ceramics contain lower amounts of SiO_2 and higher amounts of Na_2O and CaO . The high ratio of CaO to P_2O_5 in bioactive ceramics allows the rapid formation of a hydroxycarbonate apatite (HCA) layer at alkaline pH. For example, a 50 nm layer of HCA can form from Bioglass 45S5 after 1 h. The release of calcium, phosphorus, and sodium ions from bioactive ceramics also allows the formation of a water-rich gel near the ceramic surface. This cationic-rich environment creates a locally alkaline pH that helps to form HCA layers and provide areas of adhesion for biological molecules and cells (4,5,9).

Carbon. Processed carbon has been used in biomaterials applications as a bioceramic coating. Although carbon can exist in several forms (e.g., graphite, diamond), bioceramic carbons consist primarily of low temperature isotropic (LTI) and ultralow temperature isotropic (ULTI) carbon. This form of carbon is synthesized through the pyrolysis of hydrocarbon gases resulting in the deposition of isotropic carbon in a layer $\sim 4 \text{ mm}$ thick. Advantages to LTI and ULTI carbon include high strength, an elastic modulus close to that of bone, resistance to fatigue compared with other materials, excellent resistance to thrombosis, superior tribological properties, and excellent bond strength with metallic substances. The LTI carbon has been used as a coating for heart valves; however, applications remain limited primarily to coatings due to processing methods (4,5,9).

Polymers

Since the early to mid-twentieth century, the discovery of organic polymerization schemes and the advent of new polymeric species have fueled an incredible interest in the research of biomaterials. The popularity of polymers as potential biomaterials likely stems from the fact that polymers exist in a seemingly endless variety, can be easily fabricated into many forms, can be chemically modified or synthesized with chemically reactive moieties that interact with biological molecules or living tissues and cells, and can have physical properties that resemble that of natural tissues. Some disadvantages to polymeric biomaterials include relatively low moduli, instability following certain forms of sterilization, lot-to-lot variability, a lack of well-defined standards related to manufacturing, processing, and evaluating, and, for some polymers, hydrolytic instability, the need to add potentially toxic polymerization catalysts, and tissue biocompatibility of both the polymer and potential degradation byproducts. There also exist some characteristics of polymers that can be advantageous or disadvantageous depending on the application and type of polymer. Some of these characteristics include polymer degradation, chemical reactivity, polymer crystallinity, and viscoelastic behavior. Early examples of polymeric biomaterials included nylon for sutures and cellulose for kidney dialysis membranes, but more recent developments in the design of polymeric biomaterials are leading the field of biomaterials to embrace cellular and tissue interactions in order to directly induce tissue repair or regeneration.

Polymers consist of an organic backbone from which other pendant molecules extend. As their name implies, polymers consist of repeating units of one or more "mers". For example, polyethylene consists of repeating units of ethylene; nylon is comprised of repeating units of a diamine and a diacid. In general, polymers used as biomaterials are made in one of two ways: condensation or addition reactions. In condensation reactions, two precursors are combined to form larger molecules by eliminating a small molecule (e.g., water). Examples of condensation polymeric biomaterials include nylon, poly(ethylene terephthalate) (Dacron), poly(lactic acid), poly(glycolic acid), and polyurethane. In addition to synthetic polymers, biological polymers (e.g., cellulose and proteins) are formed through condensation-like polymerization mechanisms. The other major polymerization mechanism used to synthesize polymers is addition polymerization. In addition polymerization, an initiator or catalyst (e.g., free radical, heat, light, or certain ions) is used to promote a rapid polymerization reaction involving unsaturated bonds. Unlike condensation reactions, addition polymerization does not result in small molecular byproducts. Furthermore, polymers can be formed using only one type of monomer or a combination of several monomers susceptible to free radical initiation and propagation. Some examples of addition reaction polymeric biomaterials include polyethylene, poly(ethylene glycol) (PEG), poly(*N*-isopropylacrylamide), and poly(hydroxyethyl methacrylate) (HEMA). The chemical structure of various synthetic and natural polymers used as biomaterials are shown in Figs. 6a and b (15).

The properties of polymers are affected greatly by chemical composition and molecular weight. In general, as polymer chains become longer, their mobility decreases, but their strength and thermal stability increases. The tacticity and size of pendant chains off the backbone will affect temperature-dependent physical properties. For example, small side groups that are regularly oriented in an isotactic or syndiotactic arrangement will allow the polymer to crystallize much more readily than a polymer containing an atactic arrangement of bulky side groups. The crystalline and glass transition temperatures of polymers will affect properties (e.g., stiffness, mechanical moduli, and thermal stability) *in vivo* and will consequently influence the potential application and utility of the polymer system as a biomaterial. When the functionality of a monomer exceeds two, then the polymer will become branched upon polymerization. If a sufficient number of these high functionality monomers exist within the material, then the main chains of the polymer will become chemically cross-linked. Cross-linked polymers can be much stronger and more rigid than noncross-linked polymers. However, like linear and branched polymers, cross-linked polymers can be designed such that they degrade through hydrolytic or enzymatic mechanisms.

Due to their weaker moduli compared with that of metals or ceramics, polymers are not often used in load-bearing biomaterial applications. One exception to this observation is the example of ultrahigh molecular weight polyethylene (UHMWPE), which has a molecular weight $\sim 2,000,000 \text{ g}\cdot\text{mol}^{-1}$ and has a higher modulus of elasticity than high or low density polyethylene. Additionally, UHMWPE is tough and ductile and demonstrates good wear properties and low friction. As a result, UHMWPE has been used extensively in the manufacturing of acetabular cups for total hip replacements. As an acetabular cup, UHMWPE is used in conjunction with metallic femoral stems to act as a load-bearing, low wear and friction interface. Some drawbacks to using UHMWPE include water absorption, cyclic fatigue, and a somewhat significant creep rate (4,5,9). Part of the problems surrounding UHMWPE involves its lower elastic modulus ($\sim 1\text{--}2 \text{ GPa}$) relative to bone ($\sim 12 \text{ GPa}$) and metallic implants ($\sim 100\text{--}200 \text{ GPa}$).

Polymers in Sutures. One of the first widespread uses of polymers as biomaterials involved sutures. In particular, polyamides and polyesters are among the most common suture materials. Nylons, an example of a polyamide, have an increased fiber strength due to a high degree of crystallinity resulting from interchain hydrogen bonding between atoms of the amide group. Nylon can be attacked by proteolytic enzymes *in vivo* and can absorb water. As a result, nylon has been used more as a short-term biomaterial. Polyester sutures, such as poly(glycolic acid), poly(lactic acid), and poly(lactic-co-glycolic acid) are readily degraded through hydrolytic mechanisms *in vivo*. Since one side chain of lactic acid contains a bulky hydrophobic methyl group (relative to the hydrogen side group of glycolic acid), polyesters comprised principally of lactic acid degrade at a rate slower than that of polyesters consisting mostly of glycolic acid. The degradation rate of copolymers

(Reprinted from Ref. 15 with permission from Elsevier.)

Figure 7. A photograph of a Carboflo vascular graft made out of expanded polytetrafluoroethylene (ePTFE) impregnated with carbon and marketed by Bard Peripheral Vascular, Inc.

of glycolic and lactic acid can be tailored based on the relative molar ratios of each monomer. Although the local pH of degrading polyesters can cause local inflammation concerns, the degradation byproducts of glycolic and lactic acid can be readily cleared through existing biochemical pathways. As a result, polyester sutures are commonly used within the body in applications where removal of sutures would warrant an invasive procedure (4,5,16).

Polymers in Cardiovascular Applications. Poly(ethylene terephthalate) (Dacron) and expanded polytetrafluoroethylene (Teflon) have been used for decades as vascular grafts. An example of a Teflon vascular graft is shown in Fig. 7. Both of these polymers have excellent burst strengths and can be sutured directly to existing vasculature. For applications involving large diameter vascular grafts (> 6 mm), these two materials have worked well. However, neointimal hyperplasia and thrombus formation severely limit the patency of all known polymeric materials used for small diameter vascular grafts (17). Most current strategies to improve vascular graft patency involves chemically modifying the polymers used as vascular grafts to include the anticoagulant heparin, endothelial binding peptide analogues, and growth factors to stimulate endothelialization and minimize proliferation of smooth muscle into the lumen of the graft (15,18).

Polymers for Tissue Engineering. For many *in vivo* applications, researchers continue to evaluate a variety of polymeric biomaterials. Some more recent additions to the repertoire of biomaterials include naturally derived or recombinantly produced biological polymers. As an example, in the case of articular cartilage repair, it is evident that many types of polymers can be designed, modified, or combined with other materials to create new generations of biomaterials that promote healing and/or restore biological function. For example, synthetic polymers, such as poly(vinyl alcohol) (PVA), PMMA, poly(hydroxyethyl methacrylate), poly(*N*-isopropylacrylamide), polyethylene, poly(lactic acid), poly(glycolic acid), poly(lactic-co-glycolic

acid), and poly(ethylene glycol) and naturally derived polymers (e.g., alginate, agarose, chitosan, hyaluronic acid, collagen, and fibrin) have been studied extensively with and without biochemical modifications to replace cartilage function or to promote neocartilage formation (15,19,20). These and other polymeric biomaterials have been used in studies related to liver, nerve, cardiovascular, bone, ophthalmic, skin, and pancreatic repair or restoration (15,21).

Hydrogels. As the name implies, hydrogels are polymer networks that contain large amounts of water (up to or > 90% water). As a result, hydrogels generally are hydrophilic materials, although, the presence of hydrophobic domains within the hydrogel backbone can enhance mechanical properties. To avoid dissolution into the aqueous phase, the polymeric component of the hydrogel must contain cross-links. The majority of hydrogel systems use chemical cross-links, such as covalent bonds to create a three-dimensional (3D) network; however, some hydrogels exist that rely on physical interactions to maintain gel integrity.

The high water content of hydrogels provides many benefits. First, of all the materials within materials science, the physical and mechanical properties of hydrogels most closely resemble those of biological tissue. Due to their polymeric content, hydrogels exhibit viscoelastic behavior. The elastic modulus, G' , of many gel compositions reaches 1 MPa, but some hydrogels can be as strong as 20 MPa. These mechanical properties match well with those reported for many tissues. Second, the large presence of water within hydrogels can limit nonspecific interactions within the body, can shield the polymer from leukocytes and can decrease frictional effects at the site of implantation. Third, the relatively low concentration of polymer within the hydrogel can result in materials with higher porosities. Consequently, it is possible not only for cells to migrate within the hydrogel structure, but also for nutrients and waste products to diffuse into and out of the gel structure (15,22,23).

In addition to high water content, hydrogels possess other characteristics that are beneficial for biomedical applications. For example, chemical composition of polymers used in hydrogel formulations is amenable to chemical modification of the backbone and/or side group structures. These polymer derivatives allow the incorporation of various gelation chemistries, degradation rates and biologically active molecules. Although not a complete list, some of the polymers used as biomaterial hydrogels include poly(ethylene glycol), PVA, poly(hydroxyethyl methacrylate) PHEMA, poly(*N*-isopropylacrylamide), poly(vinyl pyrrolidone), dextran, alginate, chitosan, and collagen. These hydrogels, in addition to many others, are currently being explored as materials for use in cartilage, skin, liver, nerve, muscle, cardiovascular, and bone tissue engineering applications.

Poly(ethylene glycol). One of the most widely studied hydrogel materials is PEG, which contains repeats of the monomer $\text{CH}_2\text{CH}_2\text{O}$ and exhibits a large radius of hydration due to its high hydrophilicity. As a result, PEG

can avoid detection by the body, and often is coupled to pharmaceuticals or other molecules to extend circulation half-life within the body. Of all the materials used in biomedical research, few polymers have better biocompatibility properties than PEG. Also, the chemical structure of PEG is fairly stable within aqueous environments, although hydrolytic degradation can occur. Furthermore, removal of PEG from the body is not a major concern since PEG, with a molecular weight $< 20,000 \text{ g}\cdot\text{mol}^{-1}$, can be cleared readily by the kidneys. Traditionally, PEG hydrogels have been cross-linked through chemical initiators, however, other work has shown that photoinitiators can be used to gel PEG *in situ*. Recently, more attention has focused on the use of star PEG, which contain a central core out of which proceeds several linear PEG arms. Consequently, these materials offer improved control over mechanical properties and biological interactions since each molecule of polymer contains many more potential sites for cross-linking or for incorporating biologically active molecules. Cell adhesion peptides, polysaccharides, and polysaccharide ligands have all been coupled to various PEG molecules and studied as biomaterials (15,23,24).

Acrylics. One of the greatest success stories involving polymeric biomaterials involves PMMA and PHEMA. Many polymers have not yet been approved by the FDA. However, many polymers of the acrylic family (e.g., PMMA used for bone cement and intraocular lenses) were grandfathered into the Medical Device Amendments of 1976 as approved materials. The PHEMA polymer allows for sufficient gas exchange, and both PHEMA and PMMA have excellent optical properties and a good degree of hydration. As a result, intraocular lenses, hard, and soft contact lenses (see Fig. 8) made in whole or in part from these polymers are commercially available (3,5). Even though contact lenses only touch the eye on one side, the polymers that comprise the contact lenses are still bathed in tears and are therefore subject to protein deposition. This protein deposition can cause eye irritation and lead to contact lens failure if the contacts are not properly cleaned. With

Figure 8. A photograph of a disposable contact lens made from PHEMA.

the development of disposable contact lenses, however, the problem of protein buildup can be minimized since the useful lifespan of each contact lens does not have to extend very long.

Biomimetic Materials. Recently, the field of biomaterials has started to incorporate features found within mechanisms involved in biomolecular assembly and interaction (24). These biomimetic materials show great promise since assembly is directed through biological affinity, recognition and/or interactions. As a result, these materials often have properties more similar to those of natural materials. Biomimetic materials exist as polymer scaffolds and hydrogels, but can also consist of ceramic and metallic materials machined or chemically modified to mimic porous structure of tissue (e.g., bone). Further elucidation of mechanisms responsible for biological self-assembly most likely will lead to improved biomaterials that are capable of interacting very specifically with an environment containing cells, tissue, or ECM molecules. In addition, many researchers are borrowing biological concepts to provide appropriate signals for cellular proliferation or differentiation and to deliver pharmaceuticals in a much more controlled manner. The scanning electron micrograph (SEM) shown in Fig. 9 illustrates a biologically oriented approach of using a biomaterial like chitosan–collagen as a scaffold on which cells can adhere (25).

Drug Delivery. Applications involving biomaterials have evolved from those focused on mostly structural requirements to those combining multiple design considerations including structure, mechanics, degradation, and drug delivery. The latest trend in biomaterials design is to promote healing, repair, or regeneration via the delivery of pharmaceutical agents, drugs, or growth factors. There exist many examples of biomaterials used as delivery vehicles or as drugs (22); however, many of these examples

Figure 9. A SEM showing chondrocytes (denoted by white arrows) attached to a biomaterial scaffold comprised of chitosan-based hyaluronic acid hybrid polymer fibers. (Reprinted from Ref. 25 with permission from Elsevier.)

are just beginning to transition from research materials into commercially available products. One example of a commercially available drug delivery biomaterial is known as Gliadel, made by Guilford Pharmaceuticals. Gliadel wafers consist of a polyanhydride polymer loaded with carmustine, a chemotherapeutic drug. This system is intended as a treatment for malignant gliomas. Following removal of the tumor, the Gliadel wafers are added to the cavity and allowed to degrade and release the carmustine in order to kill remaining tumor cells. In addition to cancer treatments, biomaterials as drug delivery vehicles have been extensively employed in cardiovascular applications. Recently, FDA approval was granted to several types of drug eluting metallic stents. Among these include the Sirolimus-eluting CYPHER stent manufactured by the Cordis Corporation, the TAXUS Express² Paclitaxel-eluting stent manufactured by the Boston Scientific Corporation. The purpose behind releasing the drugs from the stents is to decrease the occurrence of restenosis, or the renarrowing of vessels treated by the stent. As a result of the drug delivery aspect of the system, the stents are expected to have better long-term viability. Several more examples of drug delivery and biomaterial hybrid systems exist; however, a comprehensive review of biomaterials as drug delivery systems is beyond the scope of this article. It is important to note that more interest and attention have been given to modify biomaterials so that the material is more integrally involved in interacting with and manipulating organ and tissue biology.

FACTORS CONTRIBUTING TO BIOMATERIAL FAILURE

Although there exists a multitude of commercially available and successful metallic, ceramic, and polymeric biomaterials, biomaterials have and will continue to fail. The human body is a very hostile environment for synthetic and natural materials. In some instances, like orthopedic applications, it is much easier to understand why materials can fail since no material can survive cyclical loading indefinitely without showing signs of fatigue or wear. However, for most biomaterial failures, the exact reason for failure is still not well understood. Some factors contributing to the failure of a biomaterial include corrosion, wear, degradation, and biological interactions.

Corrosion

By weight, more than one-half of the human body consists of water. As a result, all implanted biomaterials will encounter an aqueous environment. Moreover, this aqueous environment is also very saline due to the presence of a relatively large concentration of extracellular salts. The aqueous and saline conditions of physiological solutions create favorable conditions for metallic corrosion. Corrosion involves oxidation and reduction reactions between a metal, ions, and species (e.g., dissolved oxygen). In fact, the lowest free energy state of many metals in and oxygenated and hydrated environment is an oxide. Most corrosion reactions are electrochemical. For example, if zinc metal is placed in an acidic environment (e.g., hydrochloric acid),

hydrogen gas will evolve as the zinc become cationic and binds to chloride ions. The actual reaction consists of two half reactions. In the first reaction, zinc metal is oxidized to a Zn^{2+} state; the second reaction involves the reduction of hydrogen ions to hydrogen gas. During this process, the newly formed metal ions diffuse into solution. Both the oxidation and reduction reactions must occur at the same time to avoid charge buildup within the material. This process occurs at the surface and exposed pore of metals, and, in an attempt to passivate the surface to avoid this process, corrosion resistant oxides have been incorporated into an implant surface (13). Care must be taken, however, to ensure that the protective oxide coating is not damaged during processing, packaging, or surgical procedure.

In addition to oxidative corrosion, bimetallic or galvanic corrosion is a concern with implants composed of more than one type of metal, such as alloys with mixing defects and implants containing parts made from distinct metals. Galvanic corrosion can occur because all metals have a different tendency to corrode. If two distinct metals are in contact with one another through a conductive medium, oxidation of one metal will occur while reduction of the other occurs. In both oxidative corrosion and bimetallic corrosion, bits of metal, metal ions, and oxidative debris can enter the surrounding tissue and even travel to distant body parts. This can result in inflammation and even in metal toxicity.

Wear

In addition to corrosion, metal, as well as other materials can wear as a result of friction. For example, in hip implants, the acetabular cup is in contact with the ball of the metal or ceramic stem. Every time a movement occurs within the joint, rubbing between the ball and cup occurs and small wear particles of metal and polymer are left behind (see Fig. 10). More often than not, the particles are shed from the softer surface (e.g., ultrahigh molecular weight polyethylene); however, metal particles are also produced. The particles range in size from

Figure 10. A photograph of some worn biomaterials. Examples in this photograph include screws, a femoral head replacement, and a polyethylene acetabular cup. (Used with permission from the Department of Materials at Queen Mary University of London.)

nanometers to microns with the smaller particles able to enter the lymph fluid and travel to distant parts of the body. The small particles increase the surface area of the material, and this increased surface area can result in increased corrosion (5,13). Thus, wear can lead to deleterious effects (e.g., corrosion), described above, and inflammation, as will be discussed below.

Degradation

Although not affected by corrosion, certain bioactive ceramics and polymers are susceptible to degradation. In the case of bioactive ceramics, however, this process is relatively slow compared with the potential rate of bone regeneration. For polymers, degradation can occur via hydrolytic or, in some cases, enzymatic mechanisms. The chemical structures of both polyamides and polyesters lend themselves toward enzymatic degradation. For polyesters, acidic or alkaline conditions will lead to a deesterification reaction that will eventually destroy the backbone of the polymer. The degradation rate varies greatly depending on the composition of the polymer. For example, within the body, poly(lactic acid) will degrade over many months to years, but poly(glycolic acid) can degrade over a few days or weeks. The degradation rate of polyamides is slower than that of polyesters, but is still an important design consideration when choosing a polymeric biomaterial for a specific application. For applications (e.g., sutures), degradation of the material is a beneficial property since the sutures only need to remain in place for a few days to weeks until the native tissue heals. For applications needing a material with a longer lifespan, degradation poses a larger problem.

Increasingly, degradable polymers or polymers with degradable cross-links are being studied as biomaterials. This interest in degradable systems stems largely from more current research involving tissue engineering and drug delivery (15,16,22,24,26,27). The philosophy of tissue engineering holds that the polymeric biomaterial acts as a scaffold with or without viable cells or biological molecules to promote tissue ingrowth. As cells proliferate and migrate within these scaffolds and begin to create new tissue, the material can and should degrade to leave, ultimately, regenerated or repaired tissue in its place. One of the engineering design constraints, therefore, is to balance the rate of degradation with that of tissue ingrowth. If the biomaterial degrades too rapidly and the newly formed tissue cannot provide the necessary mechanical support, then the biomaterial will have failed. At the same time, if the biomaterial degrades too slowly, then the process of tissue ingrowth may become inhibited or may not occur at all. To this end, more recent research has attempted to include enzymatically sensitive cross-links, usually made from synthetic peptide analogues of enzyme substrates, within polymer networks. Instead of relying upon relatively uncontrolled hydrolytic degradation, the polymeric biomaterial would degrade at a rate controlled by migrating cells. Thus, the cells themselves could degrade the material and produce new tissue in a much more controlled and physiologically relevant manner.

Biological Interactions

Most modern biomaterials are intended to come into direct contact with living tissue and biological fluids. This interaction often makes the biomaterial a target for the protective mechanisms within the body. These protective mechanisms include protein adsorption, hemostasis, inflammation and the foreign body response, and the immune response. Although it has been well established that all types of tissue-contacting biomaterials invoke some degree of biological response, it has only been during the past decade or so when investigations have revealed that all implanted tissue-containing biomaterials invoke an almost identical inflammatory and foreign body response regardless of whether the biomaterial is of metallic, ceramic, polymeric, or composite origin. Although future research in the field of biomaterials aims to better understand and to eventually mitigate the biological interactions that currently result in the failure of many biomaterials, the following biological responses remain of great importance when considering the design and potential applications of any biomaterial. In fact, most current obstacles related to the design of biomaterials involve the interaction of biomaterials with the body and the reaction of the body to biomaterials. As a result, current biomaterial research trends aim to provide an environment that allows the body to invade, remodel, and degrade the implanted material (23,27,28).

Protein Adsorption. As soon as a biomaterial comes into contact with biological fluid (e.g., blood) the material becomes coated with adsorbed proteins. This adsorption is very rapid and is based primarily on noncovalent interactions between various hydrophilic and hydrophobic domains within the adsorbed proteins and the surface of the implanted biomaterial. Initially, the composition of the protein layer depends on the relative concentration of various proteins within the biological fluid. Certain proteins (e.g., albumin) are very abundant in serum and will initially be found abundantly in the adsorbed protein layer. However, over time the adsorbed protein layer will change its composition as proteins with higher affinities for the surface of the material, but lower serum concentrations will displace proteins with lower affinities and higher serum concentrations. This rearrangement and equilibration of the protein layer is known as the Vroman effect. When biomaterials become coated with proteins, surrounding cells no longer see the surface of the material. Instead, they see a layer of serum-soluble proteins. Increasingly, biomaterials design has focused on optimizing surface chemistries and incorporating selective reactive domains that will promote a specific biological response. In reality, these engineered surfaces become masked by a nonspecific protein layer, and it is this protein layer that drives the biological response to an implanted biomaterial. Some successful examples of surface modifications aimed at reducing nonspecific protein adsorption involve the use of nonfouling hydrophilic polymers (e.g., PEG and dextran), the pretreatment of the biomaterial with a specific protein, and the replacement of certain chemically reactive functional groups with others. Time, however, remains the

Figure 11. A schematic representing the temporal events involved in acute and chronic inflammation as well as the foreign body response. (Adopted from Anderson et al. as found in Ref. 5.)

largest obstacle with any of these surface treatments. Often, surface treatments will only function for a limited time before serum and other extracellular proteins becomes adsorbed. Once adsorbed, proteins can undergo conformational changes that expose cryptic sites, allow autoactivation, or that influence the behavior of other proteins or cells (5,6,18).

Blood Contact. Direct contact with blood is a major concern of all biomaterials regardless of whether or not they were designed for cardiovascular applications. During surgical implantation, blood vessels are broken, which results in an increased probability that the biomaterial will contact blood. Although exact mechanisms remain unclear, serum proteins (e.g., Factor XII, Factor XI, plasma prekallikrein, and high molecular weight kininogen) interact to initiate contact activation of the coagulation cascade through the intrinsic pathway. This calcium- and platelet-dependent cyclic network involves the activation of thrombin, which ultimately cleaves specific protein domains within fibrinogen and Factor XIII. Activated Factor XIIIa and fibrinogen then react to form a cross-linked fibrin clot. The formation of blood clots as well as the activation of various serum proteins and platelets can lead to local inflammation. Recent approaches have attempted to passivate the blood contact response of implanted biomaterials by incorporating heparin or other antithrombotic agents on the biomaterial surface (5,6,18).

Inflammation and the Foreign Body Response. The human body is well equipped to handle injuries that affect hemostasis. During trauma, proteins within blood can initiate a relatively large biological response lasting days, weeks, and even months. Initially, the area around a trauma site, including the implantation of a biomaterial, becomes inflamed. Inflammation is a normal process involved with healing that is characterized by four major events: swelling, pain, redness, and heat. The vasculature around an injury will become leaky to allow extravasation of various leukocytes (e.g., neutrophils and macrophages). With the presence of cytokines and other growth factors, leukocytes, primarily macrophages, are stimulated to remove bacteria and foreign material. Macrophages also

recruit fibroblasts and other cells to the injury site to aid in healing by forming granulation tissue. Over the course of several days or weeks, this initial granulation tissue is remodeled and replaced with restored, functional tissue or, more commonly, scar tissue (Fig. 11).

In the case of implanted biomaterials, the implantation site is the injury site and will become inflamed. As a result, macrophages will be recruited to the site and attempt to remove the "foreign" biomaterial. Unlike smaller injuries, macrophages are unable to remove biomaterials through phagocytosis. When they become frustrated, macrophages will fuse together to form foreign body giant cells. These foreign body giant cells can secrete superoxides and free radicals, which can damage biomaterials, but these cells usually cannot completely remove the foreign biomaterial. In the event that the body cannot eliminate a foreign object through phagocytosis, activated macrophages and foreign body giant cells remain around the implant and can promote a chronic localized area of inflammation. Remaining fibroblasts and other cells around the biomaterial then will begin to secrete a layer of avascular collagen around the biomaterial to effectively encapsulate it and wall it off from the rest of the body (5,6,18). Although the function of some biomaterials is not affected by this foreign body response, biomaterials ranging from sensors to orthopedic implants to soft tissue replacements are adversely affected by this biological reaction. To date, it is not known how to minimize or eliminate an inflammation or foreign body reaction. However, a great deal of research is attempting to create biomaterials that do not evoke a tremendous inflammatory response or that degrade in a way that allows the restoration or repair of native tissue without the adverse affects of chronic inflammation.

Immune Response. The innate and adaptive immune responses of the body also pose a challenge for biomaterials designed for long-term applications. Increasingly, new biomaterials have attempted to incorporate cellular components in an attempt to create new tissues *in vitro* or to seed materials with autologous, allogeneic, or xenogenic cells, including stem cells, to promote tissue repair. Unfortunately, the adaptive immune response will actively eliminate allogeneic or xenogenic cell types. As a result,

biomaterials have been designed to act as barriers that limit lymphocyte activation. Often, cells are encapsulated in microspheres made from various polymers or layers of polymers. For example, pancreatic Islets of Langerhans from animal and human donors have been encapsulated within polymers [e.g., polysulfones, poly(*N*-isopropylacrylamide)] and alginates, to provide an immunoisolated environment that still retains enough permeability to allow for the diffusion of insulin. One of the major complications of this type of biomaterials design is to balance the creation of volume within the microsphere to accommodate enough Islets to allow for sufficient insulin production with the need to provide appropriate diffusion rates so that the cells within the center of the microsphere remain viable. As more polymeric biomaterials incorporate or consist of peptide and protein motifs, there remains a concern as to whether or not these motifs might elicit an adaptive immune response. Even if protein domains derived from human proteins are incorporated into biomaterials, these domains might not be presented the same way to lymphocytes. As a result, the body may start producing antibodies against these domains, which might also lead to certain forms of autoimmune diseases (29).

Although the adaptive immune system is playing an increasingly important role in the rejection of new types of biomaterials, the innate immune system remains a very large threat to the success of a biomaterial. As mentioned above, proteins bind to biomaterials upon implantation. One of the most abundant proteins within the blood is the complement protein C3. Within the blood, C3 can spontaneously hydrolyze to form an active convertase complex, which can cleave C3 into C3a and C3b. Although C3b is rapidly inactivated within the blood, it can remain active if it binds to a surface (e.g., a biomaterial). As a result, the alternative pathway of the complement system can be activated very rapidly leading to formation of membrane-attack complexes but more importantly, the formation of the soluble anaphylotoxins C3a, C4a, and C5a. These anaphylotoxins induce smooth muscle contraction, increase vascular permeability, recruit phagocytic cells, and promote opsonization by phagocytic cells. These phagocytic cells (e.g., macrophages) have receptors recognizing C3b. As a result, macrophages will attempt to engulf the C3b-coated biomaterial. When this fails, the macrophages will form foreign body giant cells, and the body will attempt to encapsulate the biomaterial in a manner similar to that described above for the inflammation and foreign body response (29). Overall, all of the above mentioned biological responses can affect the performance of any biomaterial, and active biomaterials research is striving not only to better understand the mechanisms of inflammation, protein adsorption, hemostasis, and innate and adaptive immune responses, but also to develop strategies to minimize, eliminate, evade, or alter adverse biological responses to materials.

BIOCOMPATIBILITY

Since biomaterials are intended for direct contact with biologically viable tissue, all biomaterials need to possess

some degree of biocompatibility. In a manner similar to that of the term biomaterials, the term biocompatibility has experienced many changing definitions over the past several decades. Initially, biocompatibility implied that the biomaterial remained inert to its surroundings in order to refrain from being toxic, carcinogenic, or allergenic. As the definition of biomaterials evolved to include biologically derived materials and molecules, the term biocompatibility needed to encompass these changes. In 1987, David Williams suggested that biocompatibility is “the ability of a material to perform with an appropriate host response in a specific application” (30). Although there does not yet exist a universal consensus with regard to the definition of the term biocompatibility, the definition proposed by Williams provides enough generality to serve as an adequate and accurate description of biocompatibility.

Instead of remaining inert, biomaterials are becoming increasingly reliant on biochemical reactions and physiological processes in order to serve a useful function. In some cases (e.g., in the case of bone plates and artificial joints), biomaterials can remain inert and still provide satisfactory performance. In other instances (e.g., drug delivery vehicles), tissue engineering applications, and *in vivo* organ replacement therapies, biomaterials not only need to actively minimize or adapt to the surrounding biological responses (e.g., inflammation and foreign body responses), but also need to depend on interactions with surrounding tissues and cells in order to provide a useful function (15,22,24–27). In addition, the performance of traditionally inert biomaterials is being enhanced by incorporating chemical or mechanical modifications that interact with biology at the cellular level. For example, the bone-contacting surfaces of metallic femoral stems, for hip replacement, have been modified to contain bioactive ceramic porous networks or hydroxyapatite crystal networks. These ceramic networks allow better osteointegration of the implant with the host tissue and, in some cases, eliminate the need to use bone sealants (e.g., PMMA).

Obviously, if a successful biomaterial needs to show some level of biocompatibility, then there must exist various testing conditions and manufacturing standards to establish safety controls. Organizations [e.g., ASTM International and the International Organization for Standardization (ISO)] do have guidelines and standards for the testing and evaluation of biomaterial biocompatibility. These regulations include tests include the measuring of cytotoxicity, sensitization, skin irritation, intracutaneous reactivity, acute systemic toxicity, genotoxicity, macroscopic and microscopic evaluation of implanted materials and devices, hemocompatibility, subchronic and chronic toxicity, carcinogenicity, the effect of degradation byproducts, and the effect of sterilization (31). For many of these parameters, the associated standards dictate the size and shape of the material to be tested, appropriate *in vitro* testing procedures and analysis schemes, and relevant testing and evaluation protocols for *in vivo* experimentation. Although standards related to the manufacturing and performance of some biomaterials exist, there remains a lack of uniform biocompatibility testing standards for new classes of biomaterials that rely heavily upon cellular and tissue interactions or that contain biologically active

molecules. New developments in biologically active biomaterials have resulted in not only nonuniform approaches to biocompatibility testing, but also confusions related to the regulatory classification of new types of biomaterials.

FUTURE DIRECTIONS

As more information becomes available regarding biological responses to materials, mechanisms that control embryonic development and early wound healing, and matrix biology, materials will be designed to more adequately address, promote or inhibit biological responses as needed. As a result, the field of biomaterials will not only incorporate principles from materials science and engineering, but also rely increasingly upon design constraints governed by biology (see Fig. 12). Recent trends in biomaterial research show an increased emphasis in designing materials that better match the biological environment with respect to mechanics and biological signals. Materials promote cell attachment using biologically derived signals, degrade through relevant enzymatic degradation and release and store bioactive factors using methods derived from biology. Continued adaptation of materials to more appropriately interact with the living system will result in devices that work with the body to promote tissue regeneration and healing.

Factors to Consider When Designing a New Biomaterial

Figure 12. An illustration depicting the various engineering and biological factors that need to be considered in the design of modern biomaterials. Successful, new biomaterials will require the optimization of a variety of parameters and the cooperation of interdisciplinary scientists, engineers, and clinicians. BIOMATERIALS: BIOCERAMICS

JULIAN R. JONES
LARRY L. HENCH
Imperial College London

INTRODUCTION

During the last century, there has been a revolution in orthopedics with a shift in emphasis from palliative treatment of infection in bone to interventional treatment of chronic age-related ailments. The evolution of stable metallic fixation devices, and the systematic development

of reliable total joint prostheses were critical to this revolution in health care. Two alternative pathways of treatment for patients with chronic bone and joint defects are now possible: (1) transplantation or (2) implantation. Figure 1 shows how approaches to tissue repair have changed and how we think they need to develop.

At present the “gold standard” for the clinical repair of large bone defects is the harvesting of the patient’s tissue from a donor site and transplanting it to a host site, often maintaining blood supply. This type of tissue graft (an *autograft*) has limitations; limited availability, morbidity at the donor site, tendency toward resorption, and a compromise in biomechanical properties compared to the host tissue.

A partial solution to some of these limitations is use of transplant tissue from a human donor, a *homograft*, either as a living transplant (heart, heart-lung, kidney, liver, retina) or from cadavers (freeze-dried bone). Availability, the requirement for lifetime use of immunosuppressant drugs, the concern for viral or prion contamination, ethical, and religious concerns all limit the use of homografts.

The first organ transplant (homograft) was carried out in Harvard in 1954. In the United States alone, there are now >80,000 organs needed for transplantation at one time, only a quarter of which will be found. The shortage of donors increases every year.

A third option for tissue replacement is provided by transplants (living or nonliving) from other species called *heterografts* or *xenografts*. Nonliving, chemically treated xenografts are routinely used as heart valve replacements (porcine) with ~50% survivability after 10 years. Bovine bone grafts are still in use, but concern of transmission of prions (disease transmission) is growing.

The second line of attack in the revolution to replace tissues was the development of manmade materials to interface with living, host tissues (e.g., implants or prostheses made from biomaterials). There are important advantages of implants over transplants, including

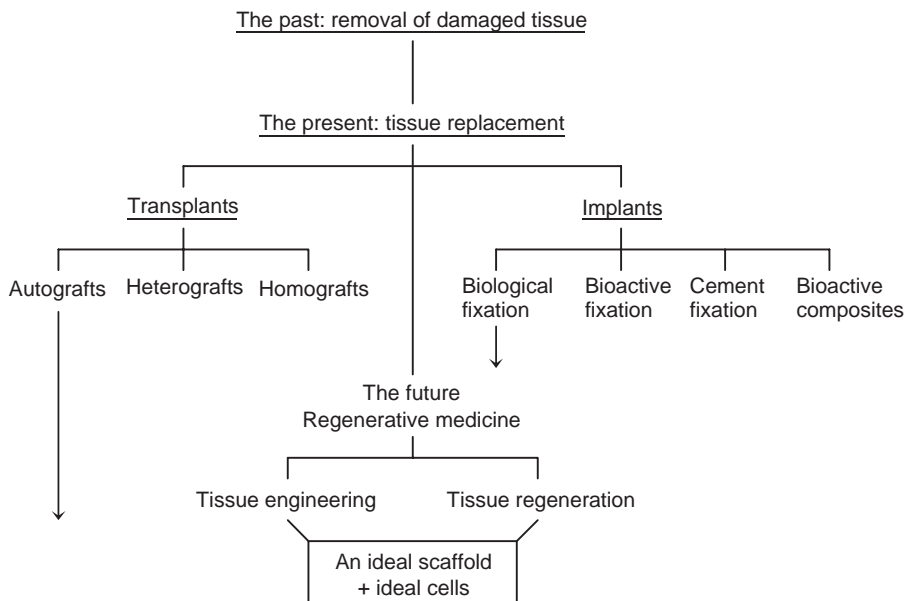

Figure 1. Schematic of the past, present and future of the treatment for diseased and damaged tissue.

availability, reproducibility, and reliability. Failure rate of the materials used in most prostheses are very low, at $<0.01\%$ (1). As a result, survivability of orthopedic implants such as the Charnley low friction metal–polyethylene total hip replacement is very high up to 15 years (2).

Many implants in use today continue to suffer from problems of interfacial stability with host tissues, biomechanical mismatch of elastic moduli, production of wear debris, and maintenance of a stable blood supply. These problems lead to accelerated wear rates, loosening and fracture of the bone, interface or device that become worse as the patient ages (3). Repair of failed devices, called revision surgery, also becomes more difficult as the patient ages due to decreased quality of bone, reduced mobility, and poorer circulation of blood. In addition, all present day orthopedic implants lack two of the most critical characteristics of living tissues: (1) ability to self-repair; and (2) ability to modify their structure and properties in response to environmental factors such as mechanical load. The consequences of these limitations are profound. All implants have limited lifetimes. Many years of research and development have led to only marginal improvements in the survivability of orthopedic implants for >15 years.

Ideally, artificial implants or devices should be designed to stimulate and guide cells in the body to regenerate tissues and organs to a healthy and natural state. We need to shift our thinking toward regenerative medicine (Fig. 1) (4).

BIOCERAMICS AS MEDICAL DEVICES

A bioceramic is a ceramic that can be implanted into a patient without causing a toxic response. Bioceramics can be classified into three categories; resorbable (e.g., tricalcium phosphate), bioactive (e.g., bioactive glass, hydroxyapatite), and nearly inert materials (e.g., alumina and zirconia) (5). A bioactive material is defined as a material that elicits a specific biological response at the interface of the material, which results in a formation of a bond between the tissue and that material (6). Bioceramics can be polycrystalline (alumina or hydroxyapatite), bioactive glass, bioactive glass–ceramic (apatite/wollastonite, A/W), or used in bioactive composites such as polyethylene–hydroxyapatite.

This article begins with examples of successful bioceramics used clinically that improve the length and quality of life for patients. Developments of porous bioceramic and composite scaffolds for tissue engineering applications are then discussed. The article ends by discussing how bioactive ceramics may be the future of regenerative medicine due to their potential for guiding tissue regeneration by stimulating cells at the genetic level (Fig. 1).

NEARLY INERT BIOCERAMICS

High density, high purity α -alumina (Al_2O_3) was the first bioceramic widely used clinically, as the articulating surfaces of the ball and socket joints of total hip replacements because of its combination of low friction, high wear

resistance, excellent corrosion resistance, good biocompatibility, and high strength (7). The physical properties of alumina depend on the grain size. Medical grade alumina exhibits an average grain size $<4\ \mu m$, a compressive strength of 4.5 GPa and a Young's modulus of 400 GPa (8). Other clinical applications of Al_2O_3 include bone screws, jaw and maxillofacial reconstructions, middle ear bone substitutions, and dental implants.

Zirconia is a bioinert ceramic that has higher flexural strength and fracture toughness and a lower Young's modulus than alumina. Zirconia may therefore be suitable for bearing surfaces in total hip prostheses, however, there are concerns over the wear rate and radioactivity of the material in the body (9).

When an almost inert implant is implanted into soft or hard tissue, a nonadherent fibrous capsule surrounds the implant. If the implant is loaded such that interfacial movement can occur, the fibrous capsule can become several hundred micrometers thick and cause loosening of the implant, which will eventually lead to clinical failure (8).

An improved interface between nearly inert implants and tissue can be achieved by using an implant containing pores in excess of $100\ \mu m$ in diameter. The fibrous connective (scar) tissue grows into these pores and anchors the implant in place. This technique is termed "biological fixation" (10). Viable bone requires pores of $>200\ \mu m$. However, connective tissue still allows some movement of the prosthesis, which will increase with age and cause bone resorption.

THE CHALLENGE FOR BIOCERAMICS

Bone is a natural composite of collagen (type I) fibers, noncollagenous proteins, and mineralized bone. It is a rigid material that exhibits a hierarchical structure with an outer layer of dense cortical bone and an internal structure of porous cancellous and trabecular (spongy) bone. Trabecular bone is orientated spongy bone that is found at the end of long bones and in vertebrae (11). This structure provides excellent mechanical properties: cortical bone exhibits a compressive strength of 100–230 MPa and a Young's modulus of 7–30 GPa; cancellous bone exhibits a compressive strength of 2–12 MPa and a Young's modulus of 0.05–0.5 GPa (8). Bone is generated by cells called osteoblasts and resorbed by cells called osteoclasts, which remodel the bone in response to external stimuli such as mechanical load (11). In order to regenerate bone, the implant should exhibit a Young's modulus similar to that of the bone. If the modulus of the implant is higher than the bone then stress shielding can occur, where the stem supports the total load. If this occurs, osteoclasts resorb bone from the implant interface (12). An example of this is the use of alumina as in total hip replacements. Alumina exhibits a modulus 10–50 times higher than cortical bone. If the modulus of the implant is substantially lower than the bone, the implant is unlikely to be able to withstand the loading environment and will fracture.

Ceramics have the potential to prevent stress-shielding and have many properties that can aid bone regeneration (8). Therefore, we will concentrate on the use of bioceramics

in orthopedics, but will also describe adaption for soft tissue applications.

Osteoporosis is a condition where the density and strength of the trabecular bone decreases (13), due to osteoblasts becoming progressively less active and the pore walls (trabeculae) in the internal spongy bone are reduced in thickness and number causing spinal problems, hip fracture, and subsequent hip replacement operations.

The challenge for bioceramics is to replace old, deteriorating bone with a material that can function for as long as is needed, which may be > 20 years. There are two options to satisfy increasing needs for orthopedic repair in the new millennium: (1) improve implant survivability by 10–20 years; or (2) develop alternative devices that can regenerate tissues to their natural form and function. Decades of research have not been able to achieve the first, discussion of the second, the application of bioactive bioceramics, and their role in regenerative medicine, particularly in bone regeneration follows.

RESORBABLE BIOCERAMICS

Tricalcium phosphate (TCP) resorbs on contact with body fluid. Resorbable materials are designed to dissolve at the same rate that a tissue grows, so that they eventually are totally replaced by the natural host tissue. However, matching the resorption rate of TCP with bone growth is difficult and since TCP ceramics exhibit low mechanical strength, so they cannot be used in load bearing applications (14).

THE BIOACTIVE ALTERNATIVE

During the last decade, considerable attention has been directed toward the use of bioceramic implants with bioactive fixation, where bioactive fixation is defined as interfacial bonding of an implant to tissue by means of formation of a biologically active hydroxyapatite layer on the surface of the implant. This layer bonds to the biological apatite in bone (8).

An important advantage of bioactive fixation is that a bioactive bond forms at the implant–bone interface with a strength equal to, or greater than, bone after 3–6 months. The level of bioactivity of a specific material can be related to the time taken for > 50% of the interface to bond to bone ($t_{0.5bb}$) (15);

$$\text{Bioactivity index, } I_B = 100/t_{0.5bb} \quad (1)$$

Materials exhibiting an I_B value > 8 (class A), will bond to both soft and hard tissue. Materials with an I_B value < 8 (class B), but > 0, will bond only to bone. Biological fixation is capable of withstanding more-complex stress states than implants that only achieve morphological fixation, that is surface fixation to roughness (15). There are a number of bioactive bioceramics.

SYNTHETIC HYDROXYAPATITE

Synthetic hydroxyapatite (HA) $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ has been developed to match the biological apatite in bone.

Biological apatite, although similar, exhibits different stoichiometry, composition, and crystallinity to pure HA. Biological apatites are usually calcium deficient and carbonate substituted (primarily for phosphate groups) (16). Hydroxyapatite is a class B bioactive material, that is, it bonds only to bone and promotes bone growth along its surface (osteoconduction). The mechanism for bone bonding involves the development of a cellular bone matrix on the surface of the HA, producing an electron dense band 3–5 μm wide. Collagen bundles appear between this area and the cells. On contact with body fluid, a dissolution–precipitation process occurs at the HA surface resulting in the formation of carbonated apatite microcrystals, which are similar to biological HA and are incorporated into the collagen. As the site matures, collagen fibrils mineralize and the interfacial layer decreases in thickness as crystallites of the growing bone align with those of the implant. Commercial production methods for synthetic HA usually involve a dropwise addition of phosphoric acid to a stirring suspension of calcium hydroxide in water, which causes an apatite precipitate to form. Ammonia is added to keep the pH very alkaline and to ensure formation of HA when the precipitate is sintered at 1250 °C. Commercial dense HA exhibits a compressive strength in excess of 400 MPa and a Young's modulus of 12 GPa. There are many clinical applications for HA implants including the repair of bony defects and tooth root replacement (16).

Hydroxyapatite has also been used as a plasma-sprayed coating on porous metallic implants in total hip replacements, allowing a bond to form between the bone and the implant (17). Initial bone ingrowth is more rapid than uncoated porous metallic implants, but the long-term survivability of the implants will not be known until after 10-year follow-up clinical trails have been completed.

BIOACTIVE GLASSES

Bioactive glasses are class A bioactive materials (I_B value > 8) that bond to soft and hard tissue and are osteoconductive, which means that bioactive glass implants stimulate bone formation on the implant away from the host bone–implant interface (15). Bioactive glasses undergo surface dissolution in a physiological environment in order to form a hydroxycarbonate apatite (HCA) layer. This is very similar to the carbonate-substituted apatite in bone. The higher the solubility of a bioactive glass, the more pronounced is the effect of bone tissue growth. The structures of bioactive glasses are based on a cross-linked silica network modified by cations. The original bioactive glasses were developed by Hench and colleagues in the early 1970s (18) and were produced using conventional glass melt-processing techniques with a composition of 45S5, 46.1% SiO_2 , 24.4% NaO , 26.9% CaO , and 2.6% P_2O_5 , in mol percent. This composition was given the name Bioglass.

MECHANISM OF BIOACTIVITY OF BIOACTIVE GLASSES

When a glass reacts with an aqueous solution, both chemical and structural kinetic changes occur as a function of time within the glass surface (8). Accumulation of

dissolution products causes both the chemical composition and pH of solution to change. The formation of HCA on bioactive glasses and the release of soluble silica to the surrounding tissue are key factors in the rapid bonding of these glasses to tissue and the stimulation of tissue growth.

There are 11 stages in process of complete bonding of bioactive glass to bone. Stages 1–5 are chemical; stages 6–11 are biological (4,15);

1. Rapid exchange of Na^+ and Ca^{2+} with H^+ or H_3O^+ from solution (diffusion controlled with a $t^{1/2}$ dependence, causing hydrolysis of the silica groups, which creates silanols;

The pH of the solution increases as a result of H^+ ions in the solution being replaced by cations.

2. The cation exchange increases the hydroxyl concentration of the solution, which leads to attack of the silica glass network. Soluble silica is lost in the form of $\text{Si}(\text{OH})_4$ to the solution, resulting from the breaking of Si-O-Si bonds and the continued formation of Si-OH (silanols) at the glass solution interface:

This stage is an interface-controlled reaction with a $t^{1.0}$ dependence.

3. Condensation and repolymerization of a SiO_2 -rich layer on the surface, depleted in alkalis and alkali earth cations:
4. Migration of Ca^{2+} and PO_4^{3-} groups to the surface through the SiO_2 -rich layer, forming a $\text{CaO-P}_2\text{O}_5$ -rich film on top of the SiO_2 -rich layer, followed by growth of the amorphous $\text{CaO-P}_2\text{O}_5$ -rich film by incorporation of soluble calcium and phosphates from solution.
5. Crystallization of the amorphous $\text{CaO-P}_2\text{O}_5$ film by incorporation of OH^- and CO_3^{2-} anions from solution to form a mixed-HCA layer.
6. Adsorption and desorption of biological growth factors, in the HCA layer (continues throughout the process) to activate differentiation of stem cells.
7. Action of macrophages to remove debris from the site.
8. Attachment of stem cells on the bioactive surface.
9. Differentiation of stem cells to form bone growing cells, such as osteoblasts.
10. Generation of extra cellular matrix by the osteoblasts to form bone.
11. Crystallization of inorganic calcium phosphate matrix to enclose bone cells in a living composite structure.

Interfacial bonding occurs with bone because of the biological equivalence of the inorganic portion of bone and the growing HCA layer on the bioactive implant. For soft tissues, the collagen fibrils are chemisorbed on the porous SiO_2 -rich layer via electrostatic, ionic and/or hydrogen bonding, and HCA is precipitated and crystallized on the collagen fiber and glass surfaces.

Reaction stages one and two are responsible for the dissolution of a bioactive glass, and therefore greatly influence the rate of HCA formation. Studies have shown that the leaching of silicon and sodium to solution, from melt-derived bioactive glasses, is initially rapid, following a parabolic relationship with time for the first 6 h of reaction, then stabilizes, following a linear dependence on time, which agree with the dissolution kinetics of soda lime-silica glasses:

$$Q = Kt^\gamma \quad \text{for total diffusion, or more generally} \quad (2)$$

$$Q = at^\gamma + bt \quad \text{for total diffusion and selective leaching} \quad (3)$$

where Q is the quantity of alkali ions from the glass, t is the duration of experiment, a, b are empirically determined constants, K is the reaction rate constant, assuming constant glass area and temperature, and $\gamma = 1/2$ (for stage 1) or 1 (for stage 2); as $t \rightarrow 0$ $\gamma = 1/2$, as $t \rightarrow \infty$ $\gamma = 1$ (19).

Phosphorous and calcium contents of the solution follow a similar parabolic trend over the first few hours, after which they decrease, corresponding with the formation of the Ca-P-rich film (stage 4). The pH change of the solution mirrors dissolution rates. An initial rapid increase of pH is a result of ion exchange of cations such as Na^+ from the glass with H^+ from solution during the first minutes of reaction at the bioactive glass surface. As release rate of cations decreases, the solution pH value tends toward a constant value.

For bioactive implants, it is necessary to control the solubility (dissolution rate) of the material. A low solubility material is needed if the implant is designed to have a long life, for example, a coating on orthopedic metals, such as synthetic hydroxyapatite on a titanium alloy femoral stem. A high solubility implant is required if it is designed to aid bone formation, such as 45S5 Bioglass powders for bone graft augmentation. A fundamental understanding of factors influencing solubility and bioreactivity is required when developing new materials for *in situ* tissue regeneration and tissue engineering.

FACTORS AFFECTING THE DISSOLUTION AND BIOACTIVITY OF GLASSES

Many factors affect the dissolution rate, and therefore bioactivity of bioactive glasses. The composition, initial pH, ionic concentration, and temperature of the aqueous environment have a large effect on the dissolution of the glass. The presence of proteins in the solution has been found to reduce dissolution rates due to the adsorption of serum proteins onto the surface of the bioactive glass, which form a barrier to nucleation of the HCA layer (19).

A change in geometry and surface texture of an implant will generally mean a change in the surface area/solution volume ratio (SA/V). An increase in the SA/V generally causes an increase in the dissolution rate, as the amount of surface exposed to solution for ion exchange increases. An increase in SA/V can be caused by a decrease in particle size or by an increase in surface roughness or porosity (19). A

similar effect occurs if the volume of surrounding solution increases (20).

If silicate glasses are considered to be inorganic polymers of silicon cross-linked by oxygen, the network connectivity is defined as the average number of cross-linking bonds for elements other than oxygen that form the backbone of a silicate glass network. The network connectivity can be used to predict solubility (21). Calculation of network connectivity is based on the relative numbers of network forming oxide species (those that contribute to cross-linking or bridging) and network-modifiers (nonbridging) present. Silicate structural units in a glass of low network connectivity are probably of low molecular mass and capable of going into solution. Consequently, glass solubility increases as network connectivity is reduced. The network connectivity can be used to predict bioactivity. Crystallization of a glass inhibits its bioactive properties, because ion exchange is inhibited by crystalline phases, and interferes with network connectivity.

Slight deviations in glass composition can radically alter the dissolution kinetics and the basic mechanisms of bonding. It is widely accepted that increasing silica content of melt-derived glass decreases dissolution rates by reducing the availability of modifier ions such as Ca^{2+} and HPO_4^{4-} to the solution and the inhibiting development of a silica-gel layer on the surface. The result is the reduction and eventual elimination of the bioactivity of the melt-derived bioactive glasses as the silica content approaches 60%. The addition of multivalent cations, such as alumina, stabilizes the glass structure by eliminating nonbridging oxygen bonds reducing the rate of break-up of the silica network and reducing the rate of HCA formation. Melt-derived glasses with > 60 mol% silica are not bioactive. In order to obtain bioactivity at silica levels > 60 mol%, the sol-gel process is used, which is a novel processing technique for the synthesis of tertiary bioactive glasses.

CLINICAL APPLICATIONS OF MELT-DERIVED BIOACTIVE GLASSES

Bioactive glasses have been used for >15 years to replace the small bones of the middle ear (ossicles) damaged by chronic infection (22). The glass bonds to the soft tissue of the eardrum and to the remaining bone of the stapes footplate, anchoring both ends of the implant without the formation of fibrous (scar) tissue.

In 1993, particulate bioactive glass, 45S5 Bioglass was cleared in the United States for clinical use as a bone graft material for the repair of periodontal osseous defects (Perioglas, USBiomaterials Alachua, Florida). The glass powder is inserted into the cavities in the bone between the tooth and the periodontal membrane and the tooth, which have eroded due to periodontitis. New bone is rapidly formed around the particles restoring the anchorage of the tooth in place (23). Since 1993, numerous oral and maxillofacial clinical studies have been conducted to expand the use of this material. More than 2,000,000 reconstructive surgeries in the jaw have been done using Perioglas. The same material has been used by several orthopedic surgeons to fill a variety of osseous defects and for clinical use

in orthopedics, now termed NovaBone, it is now approved for clinical use worldwide.

GLASS-CERAMICS

Bioactive glasses and sintered HA do not have mechanical properties as high as that of cortical bone. Kokubo et al. (24) developed dense apatite/wollastonite (A/W) glass-ceramics by heating crushed quenched melt-derived glass (MgO 4.6, CaO 44.7, SiO_2 34.0, P_2O_5 6.2, CaF_2 0.5 wt%) to 1050°C at a rate of $5^\circ\text{C}\cdot\text{min}$. Oxyapatite (38 wt%) and β -wollastonite (34 wt%) precipitated and were homogeneously dispersed in a glassy matrix (28 wt%). A/W glass-ceramic (Cerabone) has a compressive strength of 1080 MPa and a Young's modulus of 118 GPa, an order of magnitude higher than cortical bone. On contact with body fluid, the A/W glass-ceramic forms a surface layer of carbonated apatite (HCA) similar to biological apatite. The release of calcium to solution causes a hydrated silica layer to form on the glass phase, providing nucleation sites for the HCA layer. Figure 2 shows how A/W glass-ceramics bond to bone more rapidly than sintered HA, but less rapidly than Bioglass. The A/W glass-ceramics are not resorbable, but due to the high compressive strengths A/W glass-ceramics are used as replacement vertebrae, iliac prostheses and in a granular form as bone defect fillers.

SOL-GEL-DERIVED BIOACTIVE GLASSES

Until the late 1980s, bioactive glasses were generally melt-derived, with the majority of research aimed at the 45S5 Bioglass composition (46.1% SiO_2 , 24.4% NaO, 26.9% CaO,

Figure 2. Graph of rate of bone ingrowth into the spaces between bioactive ceramic particles (diameters $300\text{--}500\ \mu\text{m}$) as a function of implantation time for Bioglass (BG), A/W glass-ceramics (A/W) and sintered hydroxyapatite (s-HA).

and 2.6% P₂O₅, in mol%) and apatite-wollastonite (A/W) glass-ceramics. The recognition that the silica gel layer plays a role in HCA nucleation and crystallization led to the development of the bioactive three component CaO–P₂O₅–SiO₂ sol–gel-derived glasses by Li et al. (25).

A sol is a dispersion of colloidal particles (solid particles with diameters 1–100 nm) in a liquid. A gel is an interconnected, rigid network of polymeric chains with average lengths > 1 μm in a continuous fluid phase and pores of submicrometer dimensions.

There are three methods that are used to produce sol–gel monoliths (26):

1. Network growth of discrete colloidal powders in solution.
2. Simultaneous hydrolysis and polycondensation of alkoxide or nitrate precursors, followed by hypercritical point drying of gels.
3. Simultaneous hydrolysis and polycondensation of alkoxide precursors, followed by ageing and drying under ambient conditions.

The pore liquid is removed from the three-dimensional (3D) network as a gas phase. A gel is defined as dried when the physically absorbed water is completely evacuated. This occurs between 100 and 180 °C. Homogeneous gel-glasses are only obtained when a sol–gel method using alkoxide precursors is employed (i.e., methods 2 or 3).

Liquid alkoxide precursors, such as Si(OR)₄, where R is CH₃, C₂H₅, and so on, are mixed with a solvent (usually water) and a catalyst. Tetraethylorthosilicate (TEOS) and tetramethylorthosilicate (TMOS) are the alkoxide precursors most commonly used for sol–gel derived silica. Hydrolysis and condensation (aqueous and alcoholic) reactions follow, forming a 3D SiO₂ network of continuous Si–O–Si links that span throughout the solvent medium. When sufficient interconnected Si–O–Si bonds are formed in a region, they respond cooperatively as a sol. A silica network is formed by the condensation reactions and the sol becomes a gel when it becomes rigid and it can support a stress elastically. The gel point is characterized by a steep increase in elastic and viscous moduli. A highly interconnected 3D gel network is obtained, composed of (SiO₄)₄ tetrahedra bonded either to neighboring silica tetrahedra via bridging oxygen (BO) bonds or by Si–O–Ca or Si–O–P nonbridging (NBO) bonds. The gel consists of interpenetrating solid and liquid phases: the liquid (a byproduct of the polycondensation reactions) prevents the solid network from collapsing and the solid network prevents the liquid from escaping. The gel is aged at ~60 °C to allow cross-linking of silica species and further network formation. The liquid is then removed from the interconnected pore network by evaporation of the solvent at elevated temperature to form a “xerogel”. During this stage, the gel network undergoes considerable shrinkage and weight loss. This stage is critical in obtaining crack-free bodies as large capillary stresses can develop due to solvent evaporation through the pore network. To prevent cracking, the drying process must be controlled by decreasing liquid surface energy, by controlling the rates of hydrolysis and

condensation using the precursors, and controlling the thermal drying conditions carefully. Extending the ageing time can help prevent cracking during drying (27). However, even under optimum conditions it is difficult to produce multicomponent crack-free silica-based glasses with diameters in excess of 10 mm.

Dried xerogels have a very large concentration of silanols on the surface of the pores, which renders them chemically unstable at room temperature. The gel is stabilized by sintering at > 500 °C, which removes chemically active surface groups (such as silanols or trisiloxane rings) from the pore network, so that the surface does not rehydroxylate in use. Thermal methods are most common, but chemical methods, involving replacing silanols with more hydrophobic and less reactive species are also possible.

In multicomponent systems, the stabilization process also decomposes other species in the gel such as nitrates or organics. In this thesis nitrates are present after drying. Such species are a source of inhomogeneity and are biologically toxic. Pure Ca(NO₃)₂ decomposes at 561 °C, therefore thermal stabilization must be carried out above this temperature.

Sol–gel derived bioactive glasses exhibit a mesoporous texture, that is, pores with diameters in the range 2–50 nm that are inherent to the sol–gel process. The textural properties of the glass are affected by each stage of the sol–gel process, that is, temperature, sol composition, ageing, drying rate, and stabilization temperatures and rates.

Advantages of Sol–Gel-Derived Glasses

There are several advantages of a sol–gel-derived glass over a melt-derived glass, which are important for biomedical applications. Sol–gel-derived glasses have (26):

1. Lower processing temperatures (600–700 °C for gel-glasses compared to 1100–1300 °C for melt-derived glasses).
2. The potential of improved purity, required for optimal bioactivity due to low processing temperatures and high silica and low alkali content.
3. Improved homogeneity.
4. Wider compositions can be used (up to 90 mol% SiO₂) while maintaining bioactivity.
5. Better control of bioactivity by changing composition or microstructure.
6. Structural variation can be produced without compositional changes by control of hydrolysis and polycondensation reactions during synthesis.
7. A greater ease of powder production.
8. Interconnected nanometer scale porosity that can be varied to control dissolution kinetics or be impregnated with biologically active phases such as growth factors.
9. A higher bioactivity due to the textural porosity (SA/V ratio two orders of magnitude higher than melt-derived glasses).
10. Gel-glasses are resorbable and the resorption rate can be controlled by controlling the mesoporosity.

11. Can be foamed to provide interconnected pores of 10–200 μm , mimicking the architecture of trabecular bone.

The mechanism for HCA formation on bioactive glasses follows most of the same 11 stages as those for melt-derived glasses except that dissolution rates are much higher due to the mesoporous texture which creates a higher SA/V ratio, increasing the area of surface exposed for cation exchange (stage 1) and silica network break-up (stage 2). There are also more sites available for HCA layer formation (19).

FEATURES OF CLASS A BIOACTIVE MATERIALS

An important feature of Class A bioactive materials is that they are osteoproliferative as well as osteoconductive. In contrast, Class B bioactive materials exhibit only *osteoproliferative*, defined as the characteristic of bone growth and bonding along a surface. Dense synthetic HA ceramic implants exhibit Class B bioactivity. *Osteoproliferation* occurs when bone proliferates on the surfaces of a material due to enhanced osteoblast activity. Enhanced proliferation and differentiation of osteoprogenitor cells, stimulated by slow resorption of the Class A bioactive particles, are responsible for osteoproliferation.

Is Bioactive Fixation the Solution?

During the last decade, it has been assumed that improved interfacial stability achieved with bioactive fixation would improve implant survivability. Clinical trials have shown this to often not be the case. Replacement of the roots of extracted teeth with dense HA ceramic cones to preserve the edentulous alveolar ridge of denture wearers resulted in generally <50% survived at only 5 years. Early use of HA-coated orthopedic implants seldom survived 10 years >85% figure for cemented total hip prostheses (1). However, long-term success rates of bioactive HA coatings have improved during the last decade due to greater control of the coating process. The survivability of HA coated femoral stems is now equivalent at 10 years to cemented prostheses. It will take another 5 years to know if survivability is superior when HA coatings are used.

Why is bioactive fixation not a panacea to hip implant survivability? There are three primary reasons: (1) metallic prostheses with a bioactive coating still have a mismatch in mechanical properties with host bone, and therefore less than optimal biomechanical and bioelectric stimuli, at the bonded interface; (2) the bioactive bonded interface is unable to remodel in response to applied load; and (3) use of bioactive materials does not solve the problem of osteolysis due to wear debris generated from the polyethylene cups. Use of alumina–alumina bearing surfaces eliminates most wear debris from total hip prostheses, but increases the cost of the prosthesis by 200–300%. For younger patients the cost is acceptable, but for the general population it often is considered to be too expensive.

Most biomaterials in use today and the prostheses made from the materials have evolved from trial and error

experiments. Optimal biochemical and biomechanical features that match living tissues have not been achieved, so it also is not surprising that long-term implant survivability has not been improved very much during the last 15 years.

THE BIOCOSCOMPOSITES ALTERNATIVE

Bone is a natural composite of collagen fibers (polymer) and mineral (ceramic). Therefore to create an implant that mimics the mechanical properties of bone, a composite should provide high toughness, tensile strength, fatigue resistance, and flexibility while maintaining modulus similar to bone. Biocomposites are being developed to eliminate elastic modulus mismatch and stress shielding of bone. Two approaches have been tried. Bioinert composites, such as carbon–carbon fiber composite materials, are routinely used in aerospace and automotive applications. These lightweight, strong, and low modulus materials would seem to offer great potential for load-bearing orthopedic devices. However, delamination can occur under cyclic loading that releases carbon fibers into the interfacial tissues. The carbon fibers can give rise to a chronic inflammatory response. Thus, bioinert composites are not widely used and are unlikely to be a fruitful direction for development in the next decade.

BIOACTIVE COMPOSITES

The second approach is to make a bioactive composite that does not degrade, such as pioneered by at the IRC in Biomedical Materials, University of London. Bonfield and co-workers (28) increased the stiffness of a biocompatible polymer (polyethylene) from 1 to 8 GPa by adding a secondary phase with higher modulus (HA). The compressive strength of the composite, now called HAPEX, was 26 MPa. Addition of HA also meant that the composite would also bond to bone. Applications for HAPEX have included ossicular replacement prostheses and the repair of orbital floors in the eye socket. Ideally, it is possible to match the properties of both cancellous and cortical bone, although this is seldom achieved by the biocomposites available today. A challenge for the next decade is to use advanced materials processing technology to improve the interfacial bonding between the phases and reduce the size of the second-phase particles, thereby increasing the strength and fracture toughness of these new materials.

Another option is to use a resorbable polymer matrix for a biocomposite that will be replaced with mineralizing bone as the load on the device is increased. Work in this area is in progress, but it is difficult to maintain structural integrity as resorption occurs. The tissue engineering alternative is based upon this concept (29). Further details on biomedical composites can be found in a review by Thompson and Hench (30).

A NEW REVOLUTION IN ORTHOPEDICS?

We suggest that the orthopedics revolution of the last 30 years, the revolution of replacement of tissues by transplants and implants, has run its course. It has led to a

remarkable increase in the quality of life for millions of patients; total joint prostheses provide excellent performance and survivability for 15–20 years. Prostheses will still be the treatment of choice for many years to come for patients of 70 years or older. However, continuing the same approach of the last century; that is, modification of implant materials and designs is not likely to reach a goal of 25–30 years implant survivability, an increasing need of our ageing population. We need a change in emphasis in orthopedic materials research; in fact, we need a new revolution.

BIOCERAMICS IN REGENERATIVE MEDICINE

The challenge for the next millennium in bioceramics and biomedical materials in general is to shift the emphasis of research toward assisting or enhancing the body's own reparative capacity. We must recognize that within our cells lies the genetic information needed to replicate or repair any tissue. We need to learn how to activate the genes to initiate repair at the right site.

Our goal of regeneration of tissues should involve the restoration of metabolic and biochemical behavior at the defect site, which would lead to restoration of biomechanical performance, by means of restoration of the tissue structure leading to restoration of physiological function.

The concept requires that we develop biomaterials that behave in a manner equivalent to an autograft, that is, what we seek is a *regenerative allograft* or *scaffold*. This is a great challenge. However, the time is ripe for such a revolution in thinking and priorities. Regenerative medicine encompasses many fields. We concentrate here on the use of bioceramics in tissue engineering and regeneration applications that require scaffolds to promote tissue repair. Tissue regeneration techniques involve the use of a scaffold that can be implanted into a defect to guide and stimulate tissue regrowth *in situ*. The scaffold should resorb as the tissue grows, leaving no trace. In tissue engineering applications, the scaffolds are seeded with cells *in vitro* to produce the basis of a tissue before implantation; cells extracted from a patient, seeded on a scaffold of the desired architecture and the replacement tissue grown in the laboratory, ready for implantation. The use of the patient's own cells from the same patient would eliminate any chance of immunorejection (31).

GENETIC CONTROL BY BIOACTIVE MATERIALS

We have now discovered the genes involved in phenotype expression and bone and joint morphogenesis, and thus are on the way toward learning the correct combination of extracellular and intracellular chemical concentration gradients, cellular attachment complexes, and other stimuli required to activate tissue regeneration *in situ*. Professor Julia Polak's group at the Imperial College London Centre for Tissue Engineering and Regenerative Medicine has recently shown that seven families of genes are up- and down-regulated by bioactive glass extracts during proliferation and differentiation of primary human osteoblasts *in vitro* (32). These findings should make it possible to design a new generation of bioactive materials for

regeneration of bone. The significant new finding is that low levels of dissolution of the bioactive glass particles in the physiological environment exert a genetic control over osteoblast cell cycle and rapid expression of genes that regulate osteogenesis and the production of growth factors.

Xynos et al. (33) showed that within 48 h a group of genes was activated including genes encoding nuclear transcription factors and potent growth factors. These results were obtained using cultures of human osteoblasts, obtained from excised femoral heads of patients (50–70 years) undergoing total hip arthroplasty.

In particular, insulin-like growth factor (IGF) II, IGF-binding proteins, and proteases that cleave IGF-II from their binding proteins were identified (34). The activation of numerous early response genes and synthesis of growth factors was shown to modulate the cell cycle response of osteoblasts to the bioactive glasses and their ionic dissolution products. These results indicate that bioactive glasses enhance osteogenesis through a direct control over genes that regulate cell cycle induction and progression. However, these molecular biological results also confirm that the osteoprogenitor cells must be in a chemical environment suitable for passing checkpoints in the cell cycle toward the synthesis and mitosis phases. Only a select number of cells from a population are capable of dividing and becoming mature osteoblasts. The others are switched into apoptosis and cell death. The number of progenitor cells capable of being stimulated by a bioactive medium decreases as a patient ages, which may account for the time delay in formation of new bone in augmented sites.

Enormous advances have been made in developmental biology, genetic engineering, cellular and tissue engineering, imaging and diagnosis, and in microoptical and micro-mechanical surgery and repair. Few of these advances have, as yet, been incorporated with the molecular design of new biomaterials. This must be a high priority for the next two decades of research. However, for large defects a scaffold is required to guide tissue regeneration in 3D. Ideally, the scaffold should also release active agents that can also stimulate the cells within the tissue.

AN IDEAL SCAFFOLD

An ideal scaffold is one that mimics the extracellular matrix of the tissue that is to be replaced so that it can act as a 3D template on which cells attach, multiply, migrate, and function. The criteria for an ideal scaffold for bone regeneration are that it (35,36):

1. Is made from a material that is biocompatible (i.e., not cytotoxic).
2. Acts as template for tissue growth in 3D.
3. Has an interconnected macroporous network containing pores with diameters in excess of 100 μm for cell penetration, tissue ingrowth and vascularization, and nutrient delivery to the center of the regenerating tissue on implantation.
4. Bonds to the host tissue without the formation of scar tissue (i.e., is made from an bioactive and osteoconductive–osteoproduative material).

5. Exhibits a surface texture that promotes cell adhesion, adsorption of biological metabolites.
6. Influences the genes in the bone generating cells to enable efficient cell differentiation and proliferation.
7. Resorbs at the same rate as the tissue is regenerated, with degradation products that are nontoxic and that can be easily be excreted by the body, for example, via the respiratory or urinary systems. Is made from a processing technique that can produce irregular shapes to match that of the defect in the patient. Has the potential to be commercially producible to the required ISO (International Standards Organization) or FDA (Food and Drug Administration) standards.
8. Can be sterilized and maintained as a sterile product to the patient.
9. Can be produced economically to be covered by national and/ or private healthcare insurances.

For *in situ* bone regeneration applications, the mechanical properties of the scaffold are also critical and the modulus and elastic strength the scaffold should be similar to that of the natural bone. However, for tissue engineering applications only the mechanical properties of the final tissue engineered construct are critical (36).

TYPES OF BIOCERAMIC SCAFFOLD

Many types of porous bioceramics have been developed and are reviewed in Ref. (37). The simplest way to generate porous scaffolds from ceramics such as HA or TCP is to sinter particles. Particles are usually mixed with a wetting solution, such as poly(vinyl alcohol), and compacted by cold isostatic pressing to form a "green" body, which is sintered (heated to $\sim 1200^\circ\text{C}$) to improve mechanical properties. Porosity can be increased by adding fillers such as sucrose to the powder and the wetting solution, which burnout on sintering. Komlev et al. (38) produced porous HA scaffolds with interconnected interparticle pore diameters of $\sim 100\ \mu\text{m}$, and a tensile strength of $\sim 0.9\ \text{MPa}$ by sintering HA spheres $500\ \mu\text{m}$ in diameter.

Other techniques include adding a combustible organic material to a ceramic powder burned away during sintering leaving closed pores; freeze drying where ice crystals are formed in ceramic slurries and then sublimation of the ice leaves pores; polymer foam replication where the ceramic slurry is poured into a polymer foam, which is then burnt out on sintering leaving a pore network. Most of these techniques produced porous ceramics that were not suitable for tissue engineering applications. Typical problems were either that the pore diameters were too low, the pores were closed, the pore distributions were very heterogeneous or mechanical strengths were very low.

Recently, rapid prototyping has been adapted for producing scaffolds with controlled and homogeneous interconnected porosity (39). Rapid prototyping is a generic term for a processing technique that produces materials in a shape determined by CAD (computer aided design) software on a computer. Such materials are usually built up layer-by-layer using a liquid phase or slurry of the

material that cures or sets on contact with a substrate. Specific techniques include stereolithography, selective laser sintering, fused deposition modeling and ink-jet printing. It is a challenge to apply these techniques to direct processing of bioactive ceramic scaffolds.

Perhaps the most successful technique for synthesis of porous HA that could be produced in any size of shape, with interconnected macropore diameters in excess of $100\ \mu\text{m}$ is the gel-casting process.

GEL-CASTING OF HA

In the gel-casting of HA, aqueous suspensions of HA particles, dispersing agents, and organic monomers (6 wt% acrylate/diene) are foamed. The organic monomers must be water soluble and retain a high reactivity. Foaming is the incorporation of air into a ceramic to produce a porous material. Once the slurry has foamed, *in situ* polymerization of the monomers is initiated and cross-linking occurs, forming a 3D polymeric network (gel), which produces strong green bodies. Foaming is achieved by vigorous agitation at 900 rpm with the addition of a surfactant (Tergitol TMN10; polyethylene glycol trimethylnonyl ether) under a nitrogen atmosphere (40). Surfactants are macromolecules composed of two parts, one hydrophobic and one hydrophilic. Owing to this configuration, surfactants tend to adsorb onto gas-liquid interfaces with the hydrophobic part being expelled from the solvent and a hydrophilic part remaining in contact with the liquid. This behavior lowers the surface tension of the gas-liquid interfaces, making the foam films thermodynamically stable, which would otherwise collapse in the absence of surfactant (41). Once stable bubble formation is achieved, the polymerization process is initiated using ammonium persulphate and a catalyst (TEMED, *N,N,N',N'*-tetramethylethylenediamine) and the viscous foam is cast into moulds immediately prior to gelation. The surfactant stabilises the air bubbles until gelation provides permanent stability (40).

The porous green bodies are then sintered to provide mechanical strength and to burnout the organic solvents. Foam volume (and hence porosity) can be controlled by the surfactant concentration in the slurry. The materials produced exhibited interconnected pores of maximum diameter of $100\text{--}200\ \mu\text{m}$, which is ideal for tissue engineering applications.

The gel-cast HA scaffolds satisfy many of the criteria of the ideal scaffold, however, the criteria of controlled resorbability and genetic stimulation are not fulfilled. A bioactive glass scaffold would fulfil these criteria and also be able to bond to soft tissue. However, producing a 3D macroporous scaffold from a glass is difficult.

POROUS MELT-DERIVED BIOACTIVE GLASSES

Theoretically, the gel-casting process could be applied to melt-derived bioactive glass powders. However, such glasses undergo surface reactions on contact with solutions to produce an HCA surface layer and it is desirable to control the reaction before a scaffold is ready for clinical use.

Livingston et al. (42) produced a simple sintered scaffold by mixing 45S5 melt-derived bioactive glass (Bioglass) powders, with a particle size range of 38–75 μm , with 20.2 wt% camphor ($\text{C}_{10}\text{H}_{16}\text{O}$) particles, with particle size range of 210–350 μm . The mixture was dry pressed at 350 MPa and heat treated at 640 °C for 30 min. The camphor decomposed to leave porous Bioglass blocks. Macropores were in the region of 200–300 μm in diameter, however, the total porosity was just 21% as there were large distances between pores.

Yuan et al. (43) produced similar scaffolds by foaming Bioglass 45S5 powder with a dilute H_2O_2 solution and sintered at 1000 °C for 2 h to produce a porous glass-ceramic. The pores were irregular in shape and relatively few in number, implying that interconnectivity was poor, but pore diameters were in the range 100–600 μm . The pores appeared to be more like orientated channels running through the glass, rather than an interconnected network. The samples were implanted into the muscle of dogs and were found for the first time to be osteoinductive. Bone was formed directly on the solid surface and on the surface of crystal layers that formed in the inner pores. Osteogenic cells were observed to aggregate near the material surface and secrete bone matrix, which then calcified to form bone. However, although the implants had a porosity of ~30% only 3% bone was formed. It seems that creating interconnected pore networks in bioactive glasses by sintering is not practical at the present time, although sol-gel derived bioactive glasses may do so.

SOL-GEL DERIVED BIOACTIVE GLASS FOAMS: AN IDEAL SCAFFOLD?

The foaming process has also been applied to sol-gel derived bioactive glasses (44). The resulting scaffolds exhibit the majority of the criteria for an ideal scaffold.

Figure 3 shows an scanning electron microscopy (SEM) micrograph of a typical foam of the 70S30C composition (70 mol% SiO_2 , 30 mol% CaO). The scaffolds have a

Figure 3. An SEM micrograph of a sol-gel derived bioactive glass foam scaffold.

hierarchical pore structure similar to that of trabecular bone, with interconnected macropores with diameters in excess of 100 μm and a textural porosity with diameters in range 10–20 nm (mesopores), which are inherent to the sol-gel process. The scaffolds have the potential to guide tissue growth, with the interconnected macropores providing channels for cell migration, tissue ingrowth, nutrient delivery, and eventually vascularisation (blood vessel ingrowth throughout the regenerated tissue). The mesoporous texture enhances the resorbability and bioactivity of the scaffolds and provides nucleation points for the HCA layer and sites for cell attachment for anchorage dependant cells such as osteoblasts. The bioactive glass composition contributes high bioactivity, controlled resorbability, and the potential for the ionic dissolution products (Si and Ca) to stimulate the genes in bone cells to enhance bone regeneration.

Figure 4 shows a flow chart of the sol-gel foaming process. Sol-gel precursors [e.g., tetraethoxyl orthosilicate (TEOS, $\text{Si}(\text{OC}_2\text{H}_5)_4$)] are mixed in deionized water in the presence of an acidic hydrolysis catalyst. Simultaneous hydrolysis and polycondensation reactions occur beginning with the formation of a silica network. Viscosity of the sol increases as the condensation reaction continues and the network grows. Other alkoxides-salts can be added to introduce network modifiers (e.g., CaO species). On completion of hydrolysis, the sol is foamed by vigorous agitation with the addition of a surfactant. A gelling agent [hydrofluoric acid (HF), a catalyst for polycondensation] is added to induce a rapid increase in viscosity and reduce the gelling time.

The surfactant stabilized the bubbles that were formed by air entrapment during the early stages of foaming by lowering the surface tension of the solution. As viscosity rapidly increased and the gelling point was approached, the solution was cast into airtight moulds. The gelling point is the point at which the meniscus of the foamed sol does not move, even if the mold is tilted. Casting must

Figure 4. Flow chart of the sol-gel foaming process.

take place immediately prior to the gelation point. The gelation process provided permanent stabilization for the bubbles.

A foam scaffold is produced that sits in the liquid mixture of water and alcohol (pore liquor) produced as a byproduct of the polycondensation reaction. The foams are then subjected to the thermal treatments of ageing, drying, and stabilization. Ageing is done at 60 °C, leaving the foam immersed in its pore liquor. Ageing allows further cross-linking of the silica network and a thickening of the pore walls. Pore coarsening also occurs when larger pores grow at the expense of smaller ones.

Drying involves the evaporation of the pore liquor, which is critical and must be carried out under very carefully controlled conditions to prevent cracking under capillary pressure. Silica-based glasses that only contain the textural mesopores cannot be produced as monoliths with diameters in excess of 10 mm due to the high capillary stresses during drying. The formation of interconnected pore channels with large diameters allows efficient evaporation of the pore liquor; therefore very large crack-free scaffolds (in excess of 100 mm diameter) can be made. Thermal stabilization is carried out (again under carefully controlled heating regimes) at a minimum of 600 °C to ensure removal of silanol and nitrate groups from the glass.

The variables in each stage of the foaming process affect the final structure and properties of the foams (45,46). The percentage and pore volume of the textural mesopores can be controlled by the glass composition and the alkoxide: water ratio in initial sol preparation. Therefore the resorbability and bioactivity of the scaffolds can be easily controlled. The macropore diameters are little affected until the sintering temperature increases >800 °C. However, the glass composition, the foaming temperature, the surfactant concentration and type, the gelling agent concentration heavily affect the macropore diameters, and interconnectivity, which are vital for tissue engineering applications.

Three compositions have been successfully foamed; the tertiary 58S (60 mol% SiO₂, 36 mol% CaO, 4 mol% P₂O₅), the binary 70S30C (70 mol% SiO₂, 30 mol% CaO) composition, and 100S silica. The binary composition 70S30C (70 mol% SiO₂, 30 mol% CaO) has been found to be the most suitable to the foaming process, producing crack-free foams scaffolds with porosities in the range 60–95% (depending on the other variables in the process). Macropores were homogeneously distributed with diameters up of up to 600 μm and modal interconnected pore diameters of up to 150 μm.

Due to the nature of the sol–gel process the scaffolds can be produced in many shapes, which are determined simply by the shape of the casting mould. The scaffolds can be produced from various compositions of gel-derived glasses. All foam compositions can be easily cut to a required shape. Figure 5 shows foams produced in various shapes.

The only criterion not addressed is the matching of mechanical properties of the scaffolds to bone for *in situ* bone regeneration applications. The compressive strength of the foams (~2.5 MPa for 70S30C foams sintered at 800 °C) is less than that of trabecular bone (~10 MPa). However, the mechanical properties of these foams should

Figure 5. Sol–gel derived bioactive glass scaffolds. (Courtesy of Dr. P. Sepulveda.)

be sufficient for tissue engineering applications, where bone would be grown on a scaffold in the laboratory before implantation. Work on improving the mechanical properties is ongoing.

BIOLOGICAL RESPONSES TO SOL–GEL DERIVED BIOACTIVE GLASSES

The biological response to bioactive gel–glasses made from the CaO–P₂O₅–SiO₂ system provides evidence that bone regeneration is feasible. An important factor for future research is that the structure and chemistry of bioactive gel–glasses can be tailored at a molecular level by varying the composition (such as SiO₂ content) or the thermal or environmental processing history. The compositional range for Class A bioactive behavior is considerably extended for the bioactive gel–glasses over Class A bioactive glasses and glass–ceramics made by standard high temperature melting or hot pressing. Thus, gel–glasses offer several new degrees of freedom over the influence of cellular differentiation and tissue proliferation. This enhanced biomolecular control will be vital in developing the matrices and scaffolds for engineering of tissues and for the *in vivo* regenerative allograft stimulation of tissue repair.

Evidence of the regenerative capacity of bioactive gel–glasses powders is based on a comparison of the rates of proliferation of trabecular bone in a rabbit femoral defect (47). Melt-derived Class A 45S5 bioactive glass particles exhibit substantially greater rates of trabecular bone growth and a greater final quantity of bone than Class B synthetic HA ceramic or bioactive glass–ceramic particles. The restored trabecular bone has a morphological structure equivalent to the normal host bone after 6 weeks; however, the regenerated bone still contains some of the larger (>90 μm) bioactive glass particles. Wheeler et al. (48) showed that the use of bioactive gel–glass particles in the same animal model produces an even faster rate of trabecular bone regeneration with no residual gel–glass particles of either the 58S or 77S composition. The gel–glass particles resorb more rapidly during proliferation of

trabecular bone. Thus, the criteria of a regenerative allograft cited above appear to have been met. Recent results of *in vivo* subperiosteum implantation of 58S foams on the calvaria of New Zealand rabbits (49) showed that bone regeneration occurred more rapidly for 58S foams compared to 58S powder and that the regeneration was in line with that produced by compacted melt-derived Bioglass powders that are available commercially as PerioGlas and Novabone.

SOFT TISSUE ENGINEERING

The interactions between cells and surfaces play a major biological role in cellular behavior. Cellular interactions with artificial surfaces are mediated through adsorbed proteins. A common strategy in tissue engineering is to modify the biomaterial surface selectively to interact with a cell through biomolecular recognition events. Adsorbed bioactive peptides can allow cell attachment on biomaterials, and allow 3D structures modified with these peptides to preferentially induce tissue formation consistent with the cell-type seeded, either on or within the device (50). The surface of the gel-derived foams has been modified with organic groups and proteins to create scaffolds that have potential for lung tissue engineering (50,51). If cells can recognize the proteins adsorbed on the surface of a biomaterial they can attach to it and start to differentiate, inducing tissue regeneration. However, if cells do not recognize the proteins, an immunogenic response may result, initiating a chronic inflammation that can lead to failure of the device. Besides promoting cell-surface recognition, bioactive peptides can be used to control or promote many aspects of cell physiology, such as adhesion, spreading, activation, migration, proliferation, and differentiation.

Three-dimensional scaffolds have been produced that allow the incorporation and release of biologically active proteins to stimulate cell function. Laminin was adsorbed on the textured surfaces of binary 70S30C (70 mol% SiO₂-30 mol% CaO) and ternary 58S (60 mol% SiO₂-36 mol% CaO-4 mol% P₂O₅) sol-gel derived bioactive foams. The covalent bonds between the binding sites of the protein and the ligands on the scaffolds surface do not denature the protein. *In vitro* studies show that the foams modified with chemical groups and coated with laminin maintained bioactivity, as demonstrated by the formation of the (HCA) layer formed on the surface of the foams on exposure to simulated body fluid (SBF). Sustained and controlled release from the scaffolds over a 30-day period was achieved. The laminin release from the bioactive foams followed the dissolution rate of the material network. These findings suggest that bioactive foams have the potential to act as scaffolds for soft tissue engineering with a controlled release of proteins that can induce tissue formation or regeneration.

The way that proteins or other bioactive peptides interact with surfaces can alter their biological functionality. In order to achieve full functionality, peptides have to adsorb specifically. They also must maintain conformation in order to remain functional biologically. Chemical groups, such as amine and mercaptan groups, are known to control the ability of surfaces to interact with proteins (51). In

addition, these chemical groups can allow protein-surface interactions to occur such that the active domains of the protein can be oriented outward, where they can be maximally effective in triggering biospecific processes. Cell cultures of mouse lung epithelial cells (MLE-12) on modified 58S foam scaffolds showed that cells attached and proliferated best on 58S foam modified with amine groups (using aminopropyltriethoxysilane, APTS) and coated with laminin (52).

SUMMARY

During the last century, a revolution in orthopedics occurred that has led to a remarkably improved quality of life for millions of aged patients. Specially developed bioceramics were a critical component of this revolution. However, survival of prostheses appears to be limited to ~20 years. We conclude that a shift in emphasis from replacement of tissues to regeneration of tissues should be the challenge for orthopedic materials in the new millennium. The emphasis should be on the use of materials to activate the body's own repair mechanisms, that is, regenerative allografts. This concept will combine the understanding of tissue growth at a molecular biological level with the molecular design of a new generation of bioactive scaffolds that stimulate genes to activate the proliferation and differentiation of osteoprogenitor cells and enhance rapid formation of extracellular matrix and growth of new bone *in situ*. The economic and personal benefits of *in situ* regenerative repair of the skeleton on younger patients will be profound.

Medical Carbon Research
Institute
Austin, Texas

INTRODUCTION

Inorganic, elemental carbon is one of the oldest, and yet newest, biomaterials. Carbon utilization began with prehistoric human's use of charcoal and continues today with a variety of applications exploiting the physicochemical, adsorptive, structural, and biocompatible properties of different forms of carbon. To date, the most important carbon biomaterials have been the isotropic pyrolytic carbons (PyC), produced in a fluidized bed, for use as structural blood contacting components for heart valve prostheses and for small joint orthopedic prostheses. Adsorptive properties of activated carbons also find widespread use for the removal of toxins from the body either by direct ingestion, dialysis, or by plasmapheresis.

Other carbons, such as carbon fibers and glassy carbons have been proposed for use in a variety of structural implants, but because of limited strength and durability, have not been generally accepted. However, carbon fibers and glassy carbons are used as electrodes and electronic components in biomedical analytical devices. Diamond-like coatings have been proposed to provide enhanced wear resistance for large orthopedic components, but this technology is still under development. For the future, carbon holds a central focus in nanotechnology with investigations into the use of fullerenes and carbon nanotubes as means of imaging and manipulating nanoscale bioactive molecules, as selective markers, and perhaps as inhibitors to virulent organisms such as the human immunodeficiency virus (HIV).

Elemental carbon is allotropic, meaning that it can exist in two or more forms (1). There are at least two perfectly crystalline allotropic forms: graphite and diamond, and a myriad of intermediate, imperfectly crystalline, amorphous structures (2). This diversity in structure leads to considerable variability in physical and mechanical properties ranging from graphite, one of the softest materials, to diamond, the hardest material known to human. Thus,

carbon rather than being a single material is actually a spectrum of materials (3). For this reason, it is necessary to qualify the use of the term *carbon* as designating a generic material with a carbon elemental composition. A specific carbon material must then be qualified with a description of its structure.

In general, most of the pure carbons are biocompatible in that they are bioinert, do not provoke thrombosis, hemolysis, inflammatory response, nor activate the complement system (4). Furthermore pure carbons are biostable: toxic products are not generated and the materials retain their properties. However, just because a candidate material is a carbon does not mean that its particular microstructure and properties are appropriate for the desired application. For example, structural applications such as cardiovascular and orthopedic prostheses require strength, fatigue resistance, wear resistance, low friction and durability, in addition to tissue compatibility (3). Not all carbons have the appropriate properties needed for structural use.

In order to appreciate the medically important carbons, some of the various forms of elemental carbon, their synthesis, structure, and properties will be presented and briefly discussed. We will then return to the important carbon biomaterials, discuss their utilization, and conclude with speculations as future directions.

BACKGROUND

Structure of Carbons

Diversity in carbon arises from the electronic configuration: $1s^2 2s^2 2p^2; ^3P$, which allows the formation of a number of hybridized atomic orbitals that share four valence electrons to form covalent bonds with directional properties. On the basis of bond structures that arise from the hybridized orbital bonds, carbon compounds are classed as aliphatic and as aromatic (5). Originally, aliphatic meant "fatty" and aromatic meant "fragrant", but these descriptions no longer have any real significance. Aliphatic compounds are further subdivided into alkane, alkenes, alkynes, and cyclic aliphatic. Aromatic compounds are benzenes and compounds that resemble benzene in chemical behavior. With a few exceptions, organic compounds of medical importance tend to be aromatic or benzene-like. Details of electronic structure beyond that given here may be found in standard chemistry and organic chemistry textbooks (1,5).

Naturally Occurring Carbons

Diamond. Diamond is the ultimate polycyclic aliphatic system, but is not a hydrocarbon; rather, it is one of the allotropic forms of elemental carbon. In the diamond allotropic structure, one *s* and three *p* orbitals undergo hybridization to form the sp^3 orbital that has tetrahedral symmetry. This symmetry allows covalent bonds to connect each carbon atom with four others. Bond angles are 109.5° and the carbon-carbon bond length is 0.154 nm. Each carbon is bonded to the original plus three others and this structure propagates throughout the entire crystal forming one giant isotropic molecule of covalently bonded carbons (1,2), as shown in Fig. 1. The diamond crystallographic

Figure 1. Crystallographic structure of diamond with tetrahedral bond angles of 109.5° and bond lengths of 0.154 nm. The unit cell with a length of 0.358 nm is shown by the dashed lines. The spheres represent the location of the atoms and not size.

structure can be visualized as a repetition of the six-carbon cyclohexane “chair” configuration. Because of the large number covalent bonds with an interlocking isotropic orientation, the structure is very rigid. A large amount of energy is required to deform the crystal, hence diamond is the hardest material known.

Graphite. Where diamond is the ultimate polycyclic aliphatic system, graphite is the ultimate polycyclic aromatic system. Graphite has a layered structure consisting of planar arrays in which each carbon atom is bonded by two single bonds and one double bond with its three nearest neighbors. Where diamond can be visualized as a repeated cyclohexane chair, graphite is visualized as a repeated six-carbon benzene ring structure. Within a single plane, each carbon is bonded with a single atomic distance of 0.142 nm to its three nearest neighbors by sp^2 orbitals with hexagonal symmetry and 120° bond angles (1). Three of the four valence electrons are used to form these regular covalent σ (sigma) bonds, which forms the basal planes of hexagonal covalently bonded atoms as shown in Fig. 2. A single basal layer of the hexagonal carbons is known as a *graphene* structure.

The fourth π (pi) electron resonates between valence structures in overlapping p orbitals forming π bond donut-shaped electron clouds with one lying above and one below and perpendicular to the plane of the σ bonded carbons (2). Successive layers of the hexagonal carbons are held together at a distance of 0.34 nm by weak van der Waals forces or by interactions between the π orbitals of the adjacent layers (6,7). Thus the graphite structure is highly anisotropic, consisting of stacked parallel planes of strong covalent in-plane bonded carbons with the planes held together by much weaker van der Waals type forces. Because of weak interlayer forces, the layers are easily separated, which accounts for softness and lubricity of graphite. These weak interlayer forces also account for (a) the tendency of graphitic materials to fracture along

Figure 2. Crystallographic structure of graphite. Basal planes *a* and *b* contain the hexagonal covalently bonded carbons with bond angles of 120° and bond lengths of 0.142 nm. Because of sp^2 coordination, each basal plane is shifted one atomic position relative to one another. The successive basal planes are separated by 0.34 nm in the *c* direction. The distances 0.246 and 0.67 nm are the dimensions of the graphite hexagonal close-packed unit cell.

planes, (b) the formation of interstitial compounds; and (c) the lubricating, compressive, and many other properties of graphite (2,6).

Amorphous Carbons. There are many crystallographically disordered forms of carbon with structures that are intermediate between those of graphite and diamond. The majority tends to be imperfectly layered graphene, turbostratic, and randomly oriented structures (2). X-ray diffraction patterns for amorphous carbons are broad and diffuse because of the small crystallite size, imperfections, and a turbostratic structure (2). In turbostratic structures, there is order within the graphene planes (denoted as *a* and *b*), but no order between planes (denoted as *c* direction) as shown in Fig. 3. Crystallographic defects such as lattice vacancies, kinked or warped layer planes, and possible aliphatic bonds tend to increase the turbostratic layer spacing relative to graphite and inhibit the ability of the layer planes to slip easily as occurs in graphite (2). Like graphite, there is strong in plane covalent bonding, but, because the ability of the planes to slip past one another is inhibited, the materials are much harder and stronger than graphite. Turbostratic carbons occur in a spectrum of amorphous ranging through mixed-amorphous structures and include materials such as soot, pitch, and coals.

Fullerenes. The recently discovered fullerenes (2,8,9) can occur naturally as a constituent of soot. Fullerenes are hollow cage-like structures that can be imagined as graphene sheets that have been folded or rolled into a ball or cylindrical tube. However, the structures are actually formed by the reassociation of individual carbon atoms rather than a folding or rolling of a graphene structure. The most famous fullerene is the ~ 1 nm diameter C_{60}

Figure 3. Turbostratic amorphous structure.

(60 carbon) buckminsterfullerene (bucky ball) with a truncated icosahedron structure that resembles a European football. Because the structure is reminiscent of the geodesic dome designed by the architect Buckminster Fuller, the proposed structure was named after him (8).

Geometrically, the bucky ball has a repeating structure that consists of a pentagon surrounded by five hexagons (see Fig. 4). In order to wrap into a nonplanar ball, the graphitic p orbitals must assume an angle of 101.6° relative to the plane of the C bonds rather than 90° for graphite (9). There are a number of other possible carbon number ball structures, but the smallest sizes are thought to be limited to C_{60} and C_{70} by the molecular strain induced at the edge-sharing pentagons. Although remarkably stable, C_{60} can photodisassociate when pulsed with laser light and loose carbon C_2 pairs down to $\sim C_{32}$, where it explodes into open fragments because of strain energy (10).

Metals can also be inserted into the buckyball cage simply by conducting fullerene synthesis in the presence of metals (11). Such internally substituted endohedral fullerenes are fancifully called “dopyballs” for doped fullerenes (12) and denoted as M_aC_n , where M_a is the metal and C_n the carbon complex. “Fullerite” refers to a solid-state association of individual C_{60} molecules, named by analogy to graphite, in which the bucky balls assume a face-centered cubic (fcc) crystallographic structure with lattice constant $a = 1.417$ nm (13). Treatment of fullerite with 3 equiv of alkali metal, A_3C_{60} , makes it a superconductor at room temperature (14), whereas treatment with 6 equiv of alkali metal, A_6C_{60} , makes it an insulator.

An excellent introduction to fullerenes by Bleeke and Frey, Department of Chemistry, Washington University, St. Louis, MO, is available on the Internet at <http://www.chemistry.wustl.edu/edudev/Fullerene/fullerene.html> (15).

Nanotubes. Although most likely synthetic, because of the basic fullerene structure, nanotubes will be discussed

here. A nanotube consists of a single graphene sheet SWNT (single-wall nanotube) or multiple concentric graphene sheets MWNT (multiwall nanotube) rolled into a cylindrical tube (16). In MWNT, the nested concentric cylinders are separated by the ~ 0.34 – 0.36 nm graphite layer separation distance.

There are several different wrapping symmetries to give chiral, zigzag or arm chair nanotubes and the tubes may be end capped by a bucky ball half-sphere. Lengths range from well > 1 μm and diameters range from 1 nm for SWNT to 50 nm for MWNT. A zigzag SWNT is shown in Fig. 5. Additional information regarding nanotubes can be found at Tomanek’s laboratory, at the University of Michigan. A very informative web page dedicated to nanotubes (17) is at <http://www.pa.msu.edu/cmp/csc/nanotube.html>.

Figure 4. A surface view of a C_{60} structure, buckminsterfullerene (buckyball), with an ~ 1 nm diameter, is shown.

Figure 5. A short section of SWNT with a zigzag chiral symmetry is shown. The arrow indicates the long axis of the tube and bonds on the forward wall are more heavily drawn. Like the buckyball, this SWNT has a diameter of ~ 1 nm.

Synthetic Carbons

Carbon structures can be synthesized through a variety of processes. Because these processes define the resulting materials, both will be presented together. The most important synthesis processes include carbonization or pyrolysis and graphitization (2). Carbonization is a thermal process in which an organic precursor is converted into an all carbon residue with the diffusion of non-carbon volatile compounds to the atmosphere (2,6). The resulting all-carbon residue is known as a coke or a char.

Coke is a graphitizable carbon and chars are nongraphitizing (2). Cokes and chars are amorphous, lacking long-range crystallographic structure (turbostratic), with the degree of structure dependant on the precursor and the particular carbonization process. A coke may then be graphitized. In graphitization, residual non-carbon impurities are removed and the turbostratic structure is converted into a well-ordered graphite crystallographic structure by heating to high temperatures (6). A char, when graphitized retains its disordered turbostratic structure (2).

Synthetic Graphites. These carbons are prepared by grinding or milling a solid precursor material (coke) into fine particles, binding with a material such as coal tar pitch, and then molding into shape (2,6). The resulting material is then carbonized baked and graphitized. Typical milled grain sizes may range from $1 \mu\text{m}$ up to ~ 1 cm. The mixture of filler and binding may be doped or impregnated with the addition of non-carbon elements such as tungsten. The final properties of the molded graphite depend on the degree of graphitization and the grain size (6). Other

important parameters are porosity, anisotropy, and density (6). One synthetic graphite used in medical devices, POCO AXF 5Q, has a grain size of $5 \mu\text{m}$, a pore size of $0.6 \mu\text{m}$, and a 23% volume total porosity. This particular graphite grade is often mixed with 10% by weight fine powdered tungsten before molding and baking to confer radio opacity (6).

Viterous, Glassy Carbons. Carbonization of certain polymer chars produces glassy carbons. These materials are amorphous, turbostratic, and thought to contain some sp^3 character in addition to sp^2 (2). Precursors are polymers such as phenolformaldehyde, poly(furfuryl alcohol) and poly(vinyl alcohol). Shapes are attained by carbonization in molds and are limited to ~ 7 mm thickness because of volumetric shrinkage ($\sim 50\%$) and the need for gases generated during carbonization to diffuse out and not nucleate bubbles (18). The resulting material is hard, brittle, and difficult to machine.

Carbon Fibers. Thomas Edison produced the first carbon fiber in 1879 as a filament of an incandescent lamp and the first patent was issued in 1892 (2,3). Hiram Maxim received a process patent for the production of carbon fibers in 1899 (3). However, prior to the 1950s carbon fibers were of marginal strength and used primarily for their electrical properties.

Carbon fibers are highly oriented, small (with diameters on the order of $7 \mu\text{m}$), crystalline filaments that are prepared by carbonization of polymeric filament precursors and sequential heat treatment. There are three classes of fibers based on the precursor material: PAN (polyacrylonitrile), rayon, and pitch (2). Other precursors and processes exist, but have not been as successful commercially (3). In general, fibers are classified according to structure and degree of crystallite orientation (2): high modulus (345 GPa and above), intermediate modulus (275 GPa), and low modulus (205 GPa and below). Structures are turbostratic and can contain mixed sp^2 and sp^3 bonding (2). Because of their small volume, tensile strengths can be quite high, on the order of 1000–7000 MPa.

Chemical Vapor Deposited (CVD) Carbons. Carbonization of a gaseous or liquid precursor such as gaseous hydrocarbons produces a material known as pyrolytic carbon or pyrolytic graphite (2). Thermal decomposition of hydrocarbons produces carbon free radicals in the vapor phase, which can then polymerize to form coatings on exposed surfaces. Common precursor hydrocarbons are methane, propane, and acetylene. The resulting turbostratic pyrolytic carbons can be isotropic or anisotropic depending on the pyrolysis reaction conditions (19). The coating process can be prolonged so as to produce structural components for heart valve and orthopedic prostheses with coating thickness on the order of 1 mm.

The pyrolytic carbons for medical applications are formed by CVD processes in fluidized-bed reactors (20). Propane is the precursor gas and an inert gas such as nitrogen or helium provides the levitation needed to fluidize a bed of small refractory particles. Graphite preformed substrates (e.g., POCO AXF 5Q) suspended in the fluidized

bed are coated with the pyrolytic carbon (20). The resulting coating structures are turbostratic and isotropic with very small randomly oriented crystallites: These crystallites will henceforth be designated as *isotropic fluidized-bed pyrolytic carbons*. Nonfluidized-bed CVD reactors tend to produce a highly anisotropic coating with column-like, (columnar) crystallites or laminar structures with the basal planes oriented parallel to the deposition surface (2,19).

Highly Oriented Pyrolytic Graphite (HOPG). Columnar and laminar pyrolytic carbons when annealed $>2700^{\circ}\text{C}$ are reordered, the turbostratic imperfections disappear and the resulting structure closely approaches the ideal graphite structure with an angular spread of the crystallite c axes of $<1^{\circ}$ (2).

Vapor-Phase Carbons. Carbon CVD coatings formed from solid precursors carbonized by vaporization are considered vapor-deposited coatings (VPC). Precursors can be graphite or vitreous carbon vaporized by heating to high temperature at low pressure to generate the carbon free radicals. This technique produces line-of-sight coatings of nanometer and micrometer level thickness. The VPC coatings tend to be turbostratic and amorphous (3).

Diamond-Like Carbon. Diamond-like carbon coatings containing mixed sp^3 and sp^2 bonds can be prepared by physical vapor deposition (PVD). These PVD methods produce carbon free radicals by ion beam sputtering, or laser or glow discharge of solid carbon targets. There are also mixed PVD/CVD methods such as plasma or ion beam deposition from hydrocarbon gas precursors (2).

Activation. Activated carbons have large surface areas and large pore volumes that lend to a unique adsorption

capability (21). Activation is a thermal or chemical treatment that increases adsorption capability. The mechanisms for adsorption are complex and include physical and chemical interactions between the carbon surface and the sorbed substances. Activity includes (a) adsorption, (b) mechanical filtration, (c) ion exchange, and (d) surface oxidation (22). Of these, adsorption and surface oxidation are the most important for medical applications. Incompletely bonded basal plane carbons as occur at crystal edges exposed at the surface, as well as defects, are chemically active and can chemisorb substances, particularly oxidizing gases such as carbon monoxide and carbon dioxide (23). Surface oxidation involves the chemisorbance of atmospheric oxygen and further reaction of the sorbed oxygen with other substances (24). Physical adsorbance occurs because of charge interactions, and chemical adsorbance occurs because of reactions between the adsorbant and adsorbate (24).

Any high carbon material can be “activated” by various oxidizing thermal and chemical processes that increase porosity and active surface area, which increases the ability for chemisorption (25). A char is formed and then treated chemically or physically to generate pores and the surface oxidized (21). Surface oxide complexes such as phenols, lactones, carbonyls, carboxylic acids, and quinones form that have a strong affinity for adsorbing many substances such as toxins or impurities (26). Carbon fibers may be activated in order to enhance the ability to bind with a matrix material when used as a filler.

PROPERTIES

Representative physical and mechanical properties of the carbon allotropes are summarized in Table 1 (2,3,27). Materials included span the spectrum from natural diamond to natural graphite. There is considerable variability

Table 1. Representative Mechanical and Physical Properties for Carbon Allotropes

Property	Natural Diamond	Amorphous Carbons	HOPG	Natural Graphite
Density, $\text{g}\cdot\text{cm}^{-3}$	3.5–3.53	1.45–2.1	2.25–2.65	2.25
Young's modulus, GPa	700–1200	17–31	20	4.8
Hardness, mohs	10	2–5		1–2
Hardness, DPH 500 g		150–(>230)		
Flexural strength, MPa		175–520	80 (c) 120 (ab)	
Compressive yield strength, MPa	8680–16530	700–900	100	
Fracture toughness, $\text{MPa}\cdot\text{m}^{1/2}$	3.4	0.5–1.67		
Poisson's ratio	0.1–0.29	0.2–0.28		
Wear resistance	Excellent	Poor to excellent	Poor	Poor
Electrical resistivity, $\Omega\cdot\text{cm}$	2700		0.15–0.25 (c) 3.5×10^{-5} – 4.5×10^{-5} (ab)	0.006
Magnetic susceptibility, $\times 10^6$ emu/mol	–5.9			–6
Melting point, $^{\circ}\text{C}$	3550		3650	3652–3697 (sublimes)
Boiling point, $^{\circ}\text{C}$	4827			4220
CTE linear, $(20^{\circ}\text{C})\mu\text{m}\cdot(\text{m}\cdot^{\circ}\text{C})^{-1}$	1.18	2.6–6.5	–0.1 (ab) 20 (c)	0.6 (ab) 4.3 (c)
Heat capacity, $\text{J/g}\cdot^{\circ}\text{C}$	0.4715			0.69
Thermal conductivity, $\text{W}\cdot(\text{m}\cdot\text{K})^{-1}$	2000	4.6–6.3	16–20 (ab) 0.8 (c)	19.6 (ab) 0.0573 (c)

^aValues from Matweb.com and from Refs. (2,3).

in properties depending on the structure, anisotropy, and crystallinity, particularly in the amorphous carbons. Physical properties such as resistivity, coefficient of thermal expansion, thermal conductivity, and tensile strength (28) show profound sensitivity to direction in the graphitic materials. This anisotropy is most easily seen in HOPG by comparing the *ab* direction, parallel to the σ -bonded basal plane, to the perpendicular *c* direction. For example, the resistivity drops for HOPG because of the mobility of the π -electron clouds in the *ab* direction relative to the *c* direction (2). Diamond, with full covalent bonding, is an insulator.

Thermal conductivity, which occurs by lattice vibration, is related to a mean-free-path length for wave scattering. Little scattering occurs in the near-perfect graphite crystal basal plane, so the scattering path length and thermal conductivity are high in the *ab* direction. In the *c* direction, thermal conductivity is much lower because the amplitude of lattice vibration is considerably lower than for the *ab* direction (2). Thermal expansion is related to the interatomic spacing of the carbon atoms, bond strength, and vibration. As temperature increases, the atoms vibrate and the mean interatomic spacing increases. For weak bonding in the *c* direction, the interatomic vibrational amplitude and dimensional changes are larger than for the strongly bonded *ab* direction (2). The CTE values are stated for room temperature to $\sim 200^\circ\text{C}$; the negative values shown in Table 1 are possibly due to internal stresses and become positive at higher temperatures. Large anisotropic differences in CTE can result in large internal stresses and possible structural problems with heating and cooling over large temperature differences.

BIOCOMPATIBILITY

Pyrolytic carbons used in heart valve and orthopedic prostheses have a successful clinical experience as long-term implant materials for blood and skeletal tissue contact (3,29–31). These isotropic, fluidized-bed, pyrolytic carbons that were originated at General Atomics in the 1960s demonstrate negligible reactions in the standard Tripartite and ISO 10993-1 type biocompatibility tests. Results from such tests are given below in Table 2 (20). This material is so nonreactive that it has been proposed as a negative control for these tests. However, the surface is not totally inert and is capable of adsorption and desorption of a variety of substances including protein (32–39). The mechanism for biocompatibility is yet poorly understood,

but probably consists of a complex, interdependent, and time-dependent series of interactions between the proteins and the carbon surface (32).

Because of the similarity in surface sp^2 and sp^3 character among the various pure carbons, most can be expected to have the tissue compatibility and biostability to perform well in these biocompatibility tests also. Vitreous carbons (40), activated carbons, and diamond-like coatings (41) are known to exhibit tissue compatibility, likewise the fullerenes will probably be found tissue compatible. As an extreme example, in testing the safety of an activated charcoal for hemoperfusion, Hill (42) introduced finely ground charcoal suspensions into the blood stream of rats in varying concentrations up to 20 mg/kg charcoal and observed no differences in survival or growth relative to controls over a 2-year observation period.

A reasonable working definition for biocompatibility has been given by Williams (43) as, “*The ability of a material to perform with an appropriate response in a specific application*”. The important point here is that while many carbons provoke a minimal biological reaction, “*the specific application*” demands a complete set of mechanical and physical properties, in addition to basic cell compatibility. Because there are a number of possible microstructures, each with different properties, a given carbon will probably not have the entire set of properties needed for a specific application. Historically, the clinically successful isotropic, fluidized-bed, pyrolytic carbons required extensive development and tailoring to achieve the set of mechanical and physical properties needed for long-term cardiovascular and orthopedic applications (20,30–32).

Blood compatible glassy carbons, for example, are often proposed for use in heart valves. However, glassy carbons were evaluated in the early 1970s as a replacement for the polymer Delrin in Bjork–Shiley valve occluders and actually found to have inferior wear resistance and durability relative to the polymer (44). Thus, the fact that a material is carbon, a turbostratic carbon, or a pyrolytic carbon and is cell compatible, does not justify its use in a long-term implant devices (3,32,33). The entire range of physical and mechanical properties as dictated by the intended application are required.

MEDICAL APPLICATIONS

Activated Charcoal–Activated Carbons

Charcoal, the residue from burnt organic matter, was probably one of the first materials used for medical and

Table 2. Biological Testing of Pure PyC

Test description	Protocol	Results
Klingman maximization	ISO/CD 10993-10	Grade 1; not significant
Rabbit pyrogen	ISO/ DIS 10993-11	Nonpyrogenic
Intracutaneous injection	ISO 10993-10	Negligible irritant
Systemic injection	ANSI/AAMI/ISO 10993-11	Negative—same as controls
<i>Salmonella typhimurium</i> Reverse mutation assay	ISO 10993-3	Nonmutagenic
Physiochemical	USP XXIII, 1995	Exceeds standards
Hemolysis–rabbit blood	ISO 10993-4/NIH 77-1294	Nonhemolytic
Elution test, L929 mammalian cell culture	ISO 10993-5, USP XXIII, 1995	Noncytotoxic

biocompatible applications. Prehistoric humans knew that pulverized charcoal could be placed under the skin indefinitely without ill effects, thus allowing decorative tattoos (45). Because granulated charcoal has an active surface area, it can adsorb toxins when ingested. Likewise, charcoal has long been used to clear water and other foods. The ancient Egyptians first recorded the medical use of charcoal ~1500 BC (21). During the 1800s, the first formal scientific studies of charcoal as an antidote to treat human poisoning appeared in Europe and The United States. In some of these studies, the researchers demonstrated charcoals effectiveness by personally ingesting charcoal along with an otherwise fatal dose of strychnine or arsenic (21). Activation was discovered ~1900 and activated charcoals were used as the sorbant in World War I gas masks (21).

Today's activated carbons or activated charcoals are derived from a number of precursor organic materials ranging from coal, wood, coconut shells, and bone. Chars are prepared by pyrolyzing the starting organic material using heat in the absence of oxygen. The char is then activated by treatment with chemicals or steam. Activated carbon has remarkable adsorptive properties that vary with the starting material and activation process. Common active surface areas are on the order of 1000–2000 m²/g. Prior to the discovery of activation processes, charcoals were naturally oxidized by exposure to the atmosphere and moisture, as in charcoal, or oxidized in a more controlled activating process (46).

Orally administered activated carbon applications include use as an antidote to poisoning and to drug overdoses, where it acts at the primary site of drug adsorption in the small intestine. There are no contraindications for patients with intact GI tracts. There are numerous advantages and few disadvantages. One of the main disadvantages is that it is unpleasant for the health care professional to use because it can be messy, staining walls, floors, clothing, and so on. It may also be unpleasant to swallow because of a gritty texture (46).

There are extracorporeal, parenteral, methods such as hemoperfusion, hemofiltration, and plasmapheresis where activated carbon is used to remove toxins from a patient's blood. The patient's heparinized blood is passed via an arterial outflow catheter into an extracorporeal filter cartridge containing the activated carbon and then returned to the patient via a venous catheter. These techniques are effective when there is laboratory confirmation of lethal toxin concentrations in the blood and for poorly dialyzable and nondialyzable substances (47).

Pyrolytic Carbons

Isotropic, fluidized-bed PyCs, appropriate for cardiovascular applications originated at General Atomics in the late 1960s as a cooperative effort between an engineer, Jack Bokros, working with pyrolytic carbons as coatings for nuclear fuel particles and a surgeon, Vincent Gott, who was searching for thromboresistant materials for cardiovascular applications (48). Together, they tailored a specific fluidized-bed, isotropic pyrolytic carbon alloy with the biocompatibility, strength and durability needed for long-term structural applications in the

cardiovascular system. The original material was a patented silicon-alloyed pyrolytic carbon given the tradename "Pyrolite" (20).

In the early 1960s, heart valve prostheses constructed from polymers and metal were prone to early failure from wear, thrombosis, and reactions with the biological environment. Prosthesis lifetimes were limited to several years because of wear in one or more of the valve components. Incorporation of PyC as a replacement for the polymeric valve components successfully eliminated wear as an early failure mechanism. Subsequently, in most valve designs, metallic materials were replaced with PyC also (20,29–33,49).

During the 1970s and 1980s Pyrolite was only available from a single source until the original patents expired. Since that time, several other sources have appeared with copies of the original silicon-alloyed General Atomics material. In the early 1990s, the Bokros group revisited the synthesis methods and found that with the then available technology for process control, that a pure carbon pyrolytic carbon could be made with better mechanical properties and potentially better biocompatibility than the original silicon-alloyed Pyrolite (20). This new pure isotropic, fluidized-bed, pyrolytic carbon material was patented and named On-X carbon. On-X carbon is currently utilized in mechanical heart valves and in small joint orthopedic applications.

These PyC materials are turbostratic in structure and isotropic with fine randomly oriented crystallite sizes on the order 2.5–4.0 nm and *c* layer spacing of ~0.348 nm (50–52). Implants are prepared by depositing the hydrocarbon gas precursor coating in a fluidized bed on to a preformed graphite substrate to a thickness of ~0.5 mm (29–32,53). The coatings then may be ground and polished if desired and subjected to a proprietary process that minimizes the degree of surface chemisorbed oxygen.

Some of the mechanical and physical properties of the pure and silicon-alloyed PyC materials appropriate for use in long-term implants are given Table 3 (3,20). A typical glassy carbon and a fine-grained synthetic graphite are also included for comparison. The PyC flexural strength, fatigue, and wear resistance provide adequate structural integrity for a variety of implant applications. The density is low enough to allow components to be actuated by flowing blood. Relative to orthopedic applications, Young's modulus is in the range reported for bone (54,55), which allows for compliance matching and minimizes stress shielding at the prosthesis bone interface. The PyC strain-to-failure is low relative to ductile metals and polymers; but it is high relative to ceramics. Because PyC is a nearly ideal linear elastic material, component design requires the consideration of brittle material design principals. Certain properties such as strength vary with the effective stressed volume, or stressed area as predicted by Weibull theory (56). Table 3 strength levels were measured for specimens tested in four-point bending, third-point loading (57) with an effective stressed volume of 1.93 mm³. The Weibull modulus for PyC is ~10 (57).

Fluidized-bed isotropic PyCs are remarkably fatigue resistant. There is strong evidence for the existence of a fatigue threshold that is very nearly the single cycle

Table 3. Biomedical Fluidized-Bed Pyrolytic Carbon Properties

Property	Pure PyC	Typical Si-Alloyed PyC	Typical Glassy Carbon	POCO Graphite AXF-5Q
Flexural strength, MPa	493.7 ± 12	407.7 ± 14.1	175	90
Young's modulus, GPa	29.4 ± 0.4	30.5 ± 0.65	21	11
Strain-to-failure, %	1.58 ± 0.03	1.28 ± 0.03		0.95
Fracture toughness, MPa · √m	1.68 ± 0.05	1.17 ± 0.17	0.5–0.7	1.5
Hardness, DPH, 500 g load	235.9 ± 3.3	287 ± 10	150	120
Density, g · cm ⁻³	1.93 ± 0.01	2.12 ± 0.01	< 1.54	1.78

Silicon content, %	0	6.58 ± 0.32	0	0
Wear resistance	Excellent	Excellent	Poor	Poor

fracture strength (58–60). Paris-law fatigue crack propagation rate exponents are high; on the order of 80 and da/dN fatigue crack propagation testing displays clear evidence of a fatigue crack propagation threshold (58–63).

Crystallographic mechanisms for fatigue crack initiation and damage accumulation are not significant in the PyC at ambient temperatures (59,61). There have been no clear instances of fatigue failure in a clinical implant during the accumulated 30-year experience (64). Less than 60 out of >4 million implanted PyC components have fractured (65), and these were caused by damage from handling or cavitation (66–68).

The PyC wear resistance is excellent. Wear testing performed in the 1970s identified titanium alloy, cobalt chromium alloy, and PyC as low wear contact materials for use in contact with PyC (69,70). This study determined that wear in PyC occurred due to an abrasive mechanism and interpreted wear resistance as approximately proportional to the ratio $H^2/2E$, where H is the Brinell hardness number and E is Young's modulus. This criteria is related to the amount of elastic energy that can be stored in the wearing surface (70). The greater the amount of stored energy, the greater the wear resistance. Successful low wearing contact couples used for mechanical heart valves include PyC against itself, cobalt chromium alloy, and ELI titanium alloy.

Observed wear in retrieved PyC mechanical heart valve prosthesis implant components utilizing PyC coupled with cobalt chromium alloy is extremely low with PyC wear mark depths of < 2 μm at durations of 17 years (71–73). Wear in the cobalt chromium components was higher, 19 μm at 12 years (71–73). But, wear in the cobalt chromium components was concentrated at fixed contact points instead of being distributed over a large area as for the PyC rotating disk. Wear depths in all PyC prostheses, with fixed contact points are also low, < 3.5 μm at 13 years (74,75). In contrast, the wear depths in valves utilizing polymeric components such as the polyacetyl Delrin in contact with cobalt chromium and titanium alloys are much higher at 267 μm at 17 years (76). Incorporation of PyC in heart valve prostheses has eliminated wear as a failure mode (29,77).

The PyC is often used in contact with metals and behaves as a noble metal in the galvanic series. Testing using mixed potential corrosion theory and potentiostatic polarization has determined that no detrimental effects occur for PyC coupled with titanium or cobalt–chrome alloys (78,79). Use of PyC with stainless steel alloys is not recommended.

To date, PyC has been used in ~25 mechanical heart valve prosthesis designs. One such design, the On-X valve, by Medical Carbon Research Institute, <http://www.mcritx.com>, is shown in Fig. 6.

Pyrolytic carbon has a good potential for orthopedic applications because of advantages over metallic alloys and polymers (3,30,31):

1. A modulus of elasticity similar to bone to minimize stress shielding.
2. Excellent wear characteristics.
3. Excellent fatigue endurance.
4. Low coefficient of friction.
5. Excellent biocompatibility with bone and hard tissue.
6. Excellent biocompatibility with cartilage.
7. Fixation by direct bone apposition.

A brief comparison of PyC properties to those of conventional/orthopedic implant materials is given in Table 4. Pyrolytic carbon coatings for orthopedic implants can reduce wear, wear particle generation, osteolysis aseptic loosening, and thus extend implant useful lifetimes. Furthermore, good PyC compatibility with bone and the native joint capsule enables conservative hemiarthroplasty replacements as an alternative to total joint replacement.

Cook et al. (80) studied hemijoint implants with a PyC femoral head in the canine hip and observed a greater potential for acetabular cartilage survival in PyC than for cobalt–chromium–molybdenum alloy and titanium alloy femoral heads. There were significantly lower levels of gross acetabular wear, fibrillation, eburnation, glycosaminoglycan loss, and subchondral bone change for PyC than the metallic alloys.

Tian et al. (81) surveyed *in vitro* and clinical *in vivo* PyC orthopedic implant studies conducted during the 1970s through the early 1990s and concluded that PyC demonstrated good biocompatibility and good function in clinical applications.

A 10-year follow-up of PyC metacarpophalangeal (MCP) finger joint replacements implanted in patients at the Mayo Clinic, Rochester Minnesota (82) between 1979 and 1987, demonstrated excellent performance. Ascension Orthopedics was able to use these results in part to justify a FDA premarket approval application (PMA) for the semi-constrained, uncemented MCP finger joint replacement, PMA P000057, Nov. 2001.

Figure 6. On-X prosthetic heart valves manufactured by Medical Carbon Research Institute from the elementally pure, fluidized-bed isotropic pyrolytic carbon, On-X carbon. The valves consist of a central flow circular orifice with two semicircular occluder disks. A polymeric sewing cuff is used to attach the valve to the annulus tissue. Aortic and mitral valves with two different sewing cuff designs each are shown.

Currently, Ascension Orthopedics, <http://www.ascensionortho.com>, manufactures PyC prostheses for finger joints: metacarpophalangeal (MCP) and proximal interphalangeal (PIP) in addition to carpometacarpal (CMC) thumb and an elbow radial head (RH) prostheses (see Fig. 7). Because of the excellent PyC compatibility with bone and cartilage, the CMC and radial head are used in hemiarthroplasty directly contacting the native joint capsule and bone. Fixation is by direct bone opposition for all of the prostheses. To date, ~6500 Ascension Orthopedics prostheses have been implanted. Another company, Bioprofile, <http://www.bio-profile.com>, manufactures hemiarthroplasty PyC prostheses for the wrist: scapoid, scapho-trapezo-trapezoid, trapezium bone, capitate head, and an elbow radial head.

Glassy carbons have been proposed as an attractive low cost alternative for a variety of orthopedic and cardiovascular devices (3). However, because of relatively low strength and poor wear resistance it has not been generally accepted as a suitable material for long-term critical implants. An example of poor glassy carbon durability when used for heart valve components was cited earlier in the text (44).

Carbon fibers are popular as high strength fillers for polymers and other material composites and have been proposed for use in tendon and ligament replacements in addition to orthopedic and dental implants (83–86). Spinal interbody fusion cages using PEEK and carbon fibers (86) are an example of an orthopedic application. However, the ultimate properties of the implant depend largely upon the

Table 4. Material Properties of Orthopedic Materials

Property	Unit	PyC	Al ₂ O ₃	TZP	CoCrMo	UHMWPE
Density	g · cm ⁻³	1.93	3.98	6.05	8.52	0.95
Bend strength	MPa	494	595	1000	690, uts	20
Young's modulus, <i>E</i>	GPa	29.4	400	150	226	1.17
Hardness, <i>H</i>	HV	236 ^a	2400	1200	496	NA
Fracture toughness, <i>K</i> _{1c}	MN · m ^{-3/2}	1.68	5	7		
Elongation at failure	%	2	0.15		1	>300
Poisson's ratio		0.28	0.2	0.2	0.3	
<i>H</i> ² / <i>2E</i> ^b		7.6	12.2		1.8	

^aThe hardness value for PyC is a hybrid definition that represents the indentation length at a 500 g load with a diamond penetrant indenter. Because PyC elastically completely recovers the microhardness indentation a replica material such as a cellulose acetate coating, or a thin copper tape is used to "record" the fully recovered indentation length. Although unusual, this operational definition for hardness is a common practice used throughout the PyC heart valve industry.

^bApproximate values, there are no exact conversions.

Figure 7. Ascension Orthopedics small joint PyC prostheses for finger joints.

matrix in which the carbon fibers are included and the geometry and orientation of the fiber inclusions (3).

Diamond-like carbon (DLC) coatings may find use as low friction, wear resistant surfaces for joint articulating surfaces in orthopedic implants (87,88). However, the coating thickness is limited to the micrometer level; the technology is still in development and ultimately may not be competitive with the newer ceramic joint replacement materials.

Buckyballs (fullerenes) and carbon nanotubes are cage-like structures that suggest use as a means to encapsulate and selectively deliver molecules to tissues. Because of their nanometer dimensions, fullerenes can potentially travel throughout the body. Some current biomedical applications under study involve functionalizing fullerenes with

a number of substances including DNA and peptides that can specifically target, mark, or interfere with active sites on enzymes and perhaps inhibit virulent organisms such as the human immunodeficiency virus (89–93). They may also be used to selectively block ion channels on membranes (94). Fullerenes are synthesized by CVD and PVD techniques and can have a variety of novel properties depending on preparation. Currently, there are production difficulties with separation and isolation of fullerenes from the rest of soot-like materials that can occur during synthesis. However, bulk separation methods have been developed and some commercial sources have appeared. See <http://www.chemistry.wustl.edu/~edudev/Fullerene/fullerene.html#index> and <http://www.pa.msu.edu/cmp/csc/nanotube.html>. There is a wealth of information available on

the Internet that is readily accessed. Medical applications of fullerenes are currently a topic of intense interest and activity and hold much promise for future developments.

CONCLUSION

Uses of carbon as a biomaterial range from burnt toast, as mother's first aid remedy for suspected poisoning, to the newly discovered fullerene nanomaterials as a possible means to treat disease on a molecular level. The most successful and widespread medical applications have been the use of activated carbons for detoxification and the use of the General Atomics family of isotropic, fluidized-bed, pyrolytic carbons for structural components of long-term critical implants. However, the successful biomedical application of carbon requires an understanding that carbon is a spectrum of materials with wide variations in structure and properties. While a given carbon may be biocompatible, it may not have the mechanical and physical properties needed for the intended application.

As for the future, additional applications of the biomedical PyC materials to orthopedic applications in larger joints and in the spine can be expected, especially if successful long-term hemiarthroplasty devices can be demonstrated. New cardiovascular devices can be expected, such as components for venous shunts and venous valves. The most exciting new developments will probably occur in nanotechnology with the creation of functional, fullerene type, materials, devices, and systems through control of matter at the scale of 1–100 nm, and the exploitation of novel properties and phenomena at the same scale.

INTRODUCTION

Many materials suffer degradation with time when exposed to aggressive chemical environments within the human body. In metallic biomaterials, degradation results from electrochemical corrosion. Ceramic and polymeric biomaterials may undergo physical or chemical deterioration processes. In addition, mechanical forces may act to increase damage by wear, abrasion, or environment-induced cracking processes.

Corrosion of implants, dental restorations, and other objects placed in the human body may result in degradation of function as a result of loss of mass, decrease in mechanical integrity, or deterioration of aesthetic qualities. The associated release of corrosion products and the flow of the corrosion currents also may cause inflammation, allergic reactions, local necrosis, and many other health problems.

For electronic conductors (e.g., metals), corrosive interaction with ionically conducting liquids (e.g. body fluids) is almost always electrochemical. The degradation of metals is due to an oxidation process that involves the loss of electrons. This process involves a change from a metallic state to an ionic state, in which the ions dissolve or form nonmetallic solid products. For the process to continue, the released electrons must be consumed in a complementary reduction, which usually involves species present in the biological environment (e.g., hydrogen ions or dissolved oxygen). The reaction resulting in oxidation is usually called an anodic process and reaction resulting in reduction is usually called a cathodic process. The metal is referred to as an electrode, and the liquid environment is referred to as an electrolyte.

For many metals, the most important environmental variables are the concentrations of chloride ions, hydrogen ions, and dissolved oxygen. In many human body fluids, the chloride ion concentration varies in a relatively narrow range near $0.1 \text{ mol}\cdot\text{L}^{-1}$; however, it may be variable (e.g., urine) or lower (e.g., saliva) in certain body fluids. The hydrogen ion concentration is expressed as a pH value and is near neutral ($\text{pH} = 7$) for plasma, interstitial fluid, bile, and saliva; however, it is more variable ($\text{pH} = 4\text{--}8$) in urine and very low ($\text{pH} = 1\text{--}3$) in gastric juice (1). The chloride concentration and pH are most important factors determining the rate of oxidation because of their effect on protective oxide passivating films on metals. The dissolved oxygen concentration affects mainly the cathodic process. The usual range of partial pressure of oxygen in body fluids is $\sim 40\text{--}100 \text{ mmHg}$ ($5.33\text{--}13.33 \text{ kPa}$) (1–3).

For electrochemical oxidation to cause clinically relevant degradation of a material, the electrochemical reaction must be energetically possible (thermodynamics) and the reaction rate must be appreciable (kinetics). Oxidation of nickel, for example,

will proceed in the indicated direction if the potential of the electrode on which the reaction occurs is higher (more positive or less negative) than the equilibrium potential for a given electrolyte, and is a function of the energy change involved. The equilibrium potential also depends on temperature, pressure, and activity (\approx concentration) of ions. The values of potentials for reactions between metals and their ions in water are given under standard conditions (temperature 25 °C, pressure 1 atm, and activity of ions equal to 1) and are written in the form of materials reduction. These values, known as standard single electrode potentials, are listed in the so-called electrochemical or electromotive (EM) series (1). Noble metals, which have no tendency to dissolve in water have positive standard single-electrode potentials. On the other hand, active metals with a high tendency to react with water exhibit negative potentials.

While the potential of the anodic process must be above the equilibrium potential for the reaction to proceed as oxidation, for the cathodic process the electrode potential must be below (more negative or less positive) the equilibrium potential for net reduction to occur. For reduction of hydrogen ions,

the equilibrium potential at normal body temperature (37 °C) and pH 7.4 (blood or interstitial fluids) is -0.455 V (SHE) (-0.697 V, SCE), while the equilibrium potential of the other likely cathodic reaction,

is -0.753 V (SHE) (0.511 V, SCE) at 40 mmHg (5.33 kPa) of oxygen partial pressure. Although reaction 3 is more sluggish than reaction 2, for most metals in the human body the electrode potential of reaction 3 is above the equilibrium potential of the hydrogen reaction 2, and reduction of oxygen is the dominant cathodic process.

In spontaneous electrochemical corrosion, at least two reactions occur simultaneously. At least one reaction occurs in the direction of oxidation, and at least one reaction occurs in the direction of reduction. Each reaction has its own equilibrium potential, and this potential difference results in a current flow, as the electrons released in oxidation flow to the sites of reduction and are consumed there. In the absence of a significant electrical resistance in the current path between the reaction sites, a common potential is established, which is known as mixed potential or corrosion potential (E_{corr}). At this potential, both reactions produce the same current in opposite directions in order to preserve electrical neutrality. The value of the oxidation current, which is equal to the absolute value of the reduction current, per unit area at this potential is

known as the corrosion current density (i_{corr}). The oxidation and reduction reactions may be distributed uniformly on the same metal surface; however, there are often some regions of the biomaterial surface that are more favorable for oxidation and other regions that are more favorable for reduction. As a result, either local anodic and cathodic areas or completely separate anodes and cathodes are formed.

The corrosion rate (mass of metal oxidized per unit area and time) is proportional to the corrosion current density. The conversion is given by the Faraday's law, which states that an electric charge of 96,485 C is required to convert 1 equiv weight of the metal into ions, or vice versa. The shift of the potential of a reaction from the equilibrium value to the corrosion potential is called polarization by the flow of the current. The resulting current flowing at corrosion potential depends on the way the current of each reaction varies with the potential. If the current is controlled by the activation energy barrier for the reaction at the electrode surface, then the reaction rate increases exponentially with increasing potential for oxidation reactions and decreases exponentially with increasing potential for reduction reactions. The activation energy controlled current typically increases or decreases ten times for a potential change of ~ 50 – 150 mV. At high reaction rates, the current may become limited by the transport of reaction species to or from the electrodes; eventually, the corrosion process may become completely controlled by diffusion and independent of potential.

The vast majority of uses for metallic biomaterials in the human body are successful due to the phenomenon of passivity. In a passive state, these metals become covered with thin, protective films of stable, poorly soluble oxides or hydroxides when exposed to an aqueous electrolyte. Once this passivating film forms, the current density drops to a very low value and becomes much less dependent on the potential. The variation of the reaction current density with the potential can be illustrated in a polarization diagram. A schematic diagram in Fig. 1 shows some of the main reactions in corrosion and relevant parameters. A straight-line relationship in a semilogarithmic (E vs. $\log I$) diagram indicates that an activation energy-controlled reaction is occurring. This electrochemical activity is known as Tafel behavior, and the slopes of the lines (~ 50 – 150 mV per 10-fold change in the current or current density) are equal to the values of the Tafel constants. When the oxidation reaction of the metal shows this relationship at the corrosion potential, it indicates that the metal is actively corroding. If a metal forms a passivating film when the potential exceeds a critical value in the active corrosion region, then the current density drops from a value called the critical current density for passivation (i_{crp}) at a primary passivation potential (E_{pp}) to a low current density in the passive state (i_{p}). This behavior is illustrated schematically in Fig. 2. For an electrode to maintain a stable passive state, the intersection of the oxidation (anodic) and reduction (cathodic) lines must occur in the region of passivity.

The polarization characteristics of a biomaterial can be experimentally determined using a device called a potentiostat, which maintains the sample potential at a set value

Figure 1. Schematic polarization diagram showing oxidation (anodic) and reduction (cathodic) reactions of a corrosion process, for reactions controlled by activation energy and by mass transport (diffusion). In this figure, e_a and e_c refer to equilibrium potentials of the anodic and cathodic process, respectively, i_{oa} and i_{oc} refer to exchange current densities, E_{corr} refers to mixed corrosion potential, and i_L refers to limiting current density.

versus a reference electrode by passing current between the sample and an auxiliary counterelectrode. A scan generator can be used to vary the controlled potential over a range of interest, and the $E-i$ relationship can be determined. The relationship of main interest is usually the oxidation rate as a function of the potential, which can be depicted in an anodic polarization diagram. Since only a net current (difference between the absolute values of the oxidation and reduction currents) can be measured, the experimental polarization curve shows a value approaching zero at the intersection of the anodic and cathodic polarization curves.

Experimental anodic polarization curves for passivating metals and alloys often do not exhibit the passivation peak

shown in Fig. 2, either because the metal forms an oxide in the electrolyte without undergoing active dissolution or because an oxide film already has formed as a result of exposure to air. More importantly for human body fluids and other chloride-containing electrolytes, the region of passivity is often limited by a localized passivation breakdown above a critical breakdown potential (E_b). When a breakdown occurs, intensive oxidation takes place within localized regions on the biomaterial surface, resulting in sometimes significant pit formation. In an experimental anodic polarization diagram, breakdown appears as a sharp increase in the measured current above the critical breakdown potential. Because of the destructive nature of surface pitting, the determination of critical breakdown potential is one of the most important ways of assessing the suitability of novel metallic biomaterials for use in medical devices.

The high current density in active pits is due to the absence of a passivating film, which results from local chemical and electrochemical reactions that change the electrolyte to become highly acidic and depleted in dissolved oxygen. A similar corrosion mechanism may occur in interstices known as crevices, where the transport of species to and from the localized corrosion cell is difficult. This process, known as crevice corrosion, does not require a potential exceeding the critical breakdown potential for the initiation of corrosion. Both pit and crevice corrosion cells may repassivate if the potential is lowered below a value needed for maintenance of a high oxidation rate on the bare (nonpassivated) metal surface. The potential below which active pits repassivate is called the repassivation or protection potential (E_p). The concept of a protection potential also applies to crevice corrosion. Experimentally, repassivation can be studied by reversing the anodic polarization scan and recording the potential at which the current returns to a passive state value (Fig. 3). Repassivation can also be examined by initiating pitting or crevice corrosion and lowering the potential in steps until the current

Figure 2. Schematic polarization diagram, showing a transition from active to passive state and a breakdown of passivity. In this figure, i_{crp} refers to critical current density for passivation, i_p refers to current density in the passive state, E_{pp} refers to primary passivation potential, and E_b refers to breakdown potential.

Figure 3. Schematic experimental cyclic polarization diagram for a passivating electrode, showing passivity breakdown and repassivation after potential scan reversal. In this figure, E_{prot} refers to protection (repassivation) potential.

shows low values that decrease with time (standard test methods F2129 and F746, respectively, ASTM 2005) (4). The difficulty in finding a reliable protection potential value is due to the fact that the ease of repassivation depends on the extent of pitting or crevice corrosion damage that has occurred before the potential drop.

For some polyvalent metals (e.g., chromium), soluble species (e.g., CrO_4^{2-}) become thermodynamically stable as the valence changes (e.g., from 3 to 6 in chromium) at potentials above those for a stable oxide. This process may result in another region of active dissolution at high potentials in a phenomenon known as transpassivity.

When corrosion is relatively uniform throughout the biomaterial, the most important corrosion parameter is the average corrosion rate. For biomaterials with very low corrosion rates, the average corrosion rate is mostly determined by sensitive electrochemical techniques. The average corrosion current density (i_{corr}) is usually determined either from the results of the polarization scan by extrapolating the anodic and cathodic lines to the corrosion potential or from calculating the value of the polarization resistance. The polarization resistance (R_p) is defined as the slope of the polarization curve at zero current density [$R_p = (dE/di_n)_{i_n=0}$], in which i_n is the net (measured) current density.

When two or more dissimilar metals are placed in contact within an electrolyte, their interaction may cause galvanic corrosion. The oxidation degradation is enhanced for the metal with the lower individual corrosion potential, which becomes the anode of the cell. It is polarized towards a higher potential at the other electrode, which becomes the cathode. Since the oxidation current increase on the anode must be balanced by an identical reduction current increase on the cathode, a combination of a small anode with a large cathode is more detrimental than the reverse situation, since a larger increase in the oxidation current density is produced. In practical situations, resistance in the current path between the electrodes often reduces the galvanic effect. Differences in the concentrations of reaction species at different regions on the metal surface may

result in a potential difference, which leads to additional polarization. An increase in the oxidation current density, a difference in the equilibrium potentials, and a flow of current may result. Differences in concentrations of hydrogen ions, dissolved metal ions, or dissolved oxygen may result in concentration cell corrosion.

Metal parts subjected to mechanical loading in a corrosive environment may fail by environment-induced cracking (EIC). Stress corrosion cracking (SCC) may occur in some biomaterials when they are subjected to static loading under certain environmental conditions. Corrosion fatigue (CF) may result from variable loading in reactive environments. When the failure can be attributed to the entry of hydrogen atoms into the metal, the phenomenon is referred to as hydrogen induced cracking (HIC). Environment-induced cracking may be caused by complex combinations of mechanical, chemical, and electrochemical forces; however, the exact mechanisms of this behavior are subject to significant controversy. In these cases, mechanical factors may play important roles in crack propagation.

Intergranular corrosion occurs when dissolution is confined to a narrow region along the grain boundaries. This process is either due to precipitation of corrosion susceptible phases or due to depletion in elements that provide corrosion protection along the boundaries, which is caused by precipitation of phases rich in those elements. Some stainless steel and nickel-chromium alloys may be sensitized due to precipitation of chromium-rich carbides along grain boundaries when heated to a specific temperature range. Sensitization is normally prevented from occurring in stainless steels currently used in medical devices, which contain very low amounts of carbon.

Passivating films may also be mechanically destroyed in wear-, abrasion-, erosion-, and fretting-corrosion processes. Wear-corrosion involves materials in a friction contact that exhibit substantial relative movement. Fretting occurs in situations in which there are only small relative movements between materials that are essentially fixed with respect to one another. The resulting wear debris may cause abrasion-corrosion behavior. Wear-corrosion may occur in artificial joints, including the metal ball of a hip joint in contact with the polyethylene cup. Fretting may take place between the ball and the stem of multicomponent hip implants. In both forms of corrosion, the narrow gap between contacting surfaces creates crevice conditions. In addition, the destructive effect of friction and abrasion on the protective surface film is superimposed on the corrosion mechanism in the crevice cell. Erosion corrosion may occur on devices exposed to rapidly flowing fluids, including the surfaces of artificial heart valves.

A wide variety of metals and alloys have been used in medical devices. The three most commonly used alloys are stainless steel, cobalt alloys, and titanium alloys (5). Type 316 LVM (low carbon, vacuum-melted) stainless steel is less corrosion resistant than cobalt or titanium alloys, and it is most often used for temporary implants (5–8). This material is referred to as an austenitic steel, because it contains an iron carbide phase called austenite (γ -iron). Implant-grade steel has a nominal composition of 18% chromium, 14% nickel, and 2.5% molybdenum; the

compositional limits and properties are specified by ASTM standards F 138 and F 139 for wrought steel and F 745 for cast steel (ASTM, 2005) (4). Chromium serves to improve corrosion resistance through the formation of a highly protective surface film rich in chromium oxide. Implant-grade steel has a low carbon content in order to prevent sensitization and intergranular corrosion. Alloying with molybdenum further improves the resistance, especially to crevice corrosion and pitting. Nickel serves to stabilize the face-centered cubic (fcc) structure. On the other hand, manganese sulfide inclusions, which contribute to initiation of pitting, are minimized.

The corrosion resistance of stainless steel greatly depends on the surface conditions, and stainless steel implants are almost always electropolished and prepassivated by exposure to nitric acid (standard practice F86, ASTM 2005) (4). The breakdown potential is usually around 0.4 V (SCE), with a large hysteresis loop and a low protection potential (9). Considering that the potential in the human body is not likely to exceed about 0.5 V (SCE) (see Eq. 3 and its equilibrium potential), a well polished and passivated 361 LVM stainless steel is not very susceptible to pitting in the human body, especially for unshielded and undisturbed implant surfaces. Once localized attack is initiated, however, repassivation is difficult. As a result, stainless steel implants are very susceptible to crevice corrosion, especially when the crevice situation is combined with destruction of the surface film (e.g., fretting of bone plates under the screw heads). Small single component stainless steel implants, such as balloon-expandable vascular stents, that are made of high purity precursor materials and are subjected to a high quality surface treatment and inspection can achieve a breakdown potential in excess of 0.8 V (SCE); these materials are considered very resistant to localized corrosion (10). Stainless steel bars [containing 22% chromium, 12.5% nickel, 5% manganese, and 2.5% molybdenum (ASTM F 1586)] and wires [containing 22% chromium, 12.5% nickel, 5% manganese, and 2.5% molybdenum (ASTM F 1314)] strengthened with nitrogen have shown a higher breakdown potential than ASTM F 138 steel (4).

Vitallium and other cobalt–chromium alloys were developed as a corrosion resistant, high strength alternative to stainless steel alloys. These materials were first used in dentistry, and were later introduced to orthopedics and other surgical specialties. The cast cobalt–chromium alloy most commonly used in medical devices (ASTM F 75) contains 28% chromium and 6% molybdenum (4). This alloy was found to be suitable for investment casting into intricate shapes. In addition, it exhibited very good corrosion and excellent wear resistance; however, it possessed low ductility. Alloys with slightly modified compositions were later developed for forgings (ASTM F 799) and wrought bars, rods, and wire (ASTM F 1537) (4). Alloy F75 has shown corrosion resistance superior to stainless steel in the human body. Laboratory studies reported a breakdown potential of 0.5 V (SCE) and protection potential of 0.4 V (SCE) (6,7,9,11). These properties have made it possible to use cobalt–chromium alloys for permanent implants. Cobalt–chromium alloys with porous surfaces have been used for bone ingrowth, although they have

been superseded by even more crevice corrosion resistant and biocompatible titanium alloys. The excellent corrosion resistance of cobalt–chromium alloys can be attributed to a high chromium content and a protective surface film of chromium oxide. Concerns have been raised, however, regarding the release of biologically active hexavalent chromium ions (12). Other cobalt-based wrought surgical alloys include F90 (Co-Cr-W-Ni), F563 (Co-Ni-Cr-Mo-W-Fe), F563 (Co-Ni-Cr-Mo-W-Fe), F1058 (Co-Cr-Ni-Mo), and F688 (Co-Ni-Cr-Mo) (4). These alloys provide good to excellent corrosion behavior and a variety of mechanical properties, which depend on thermomechanical treatment. However, there is some concern regarding metal ion release in these alloys, which contain high nickel concentrations.

Titanium and titanium alloys have been used in orthopedic implants and other medical devices since the 1960s. Their popularity has rapidly increased because they possess high corrosion resistance, adequate mechanical properties, and relatively benign degradation products. Although titanium is thermodynamically one of the least stable structural metals in air and water, it acquires high resistance to corrosion due to a very protective titanium oxide film. Unalloyed titanium (ASTM F67 and F1341) and titanium-6% aluminum, 4% vanadium alloy (ASTM F136 and F1472 for wrought alloy and F1108 for castings) are commonly used in orthopedic prostheses (4). These materials exhibit a breakdown potential in body fluid substitutes well above the physiological range of potentials (several volts vs. SHE). In addition, they readily repassivate in biological fluids, which makes them highly resistant to pitting and crevice corrosion. The high crevice corrosion resistance and biocompatibility of titanium alloys have made it possible to create porous titanium surfaces that allow for bone ingrowth and cementless fixation of implants.

One shortcoming of titanium and titanium alloys is their relatively poor wear resistance (5). Since resistance to corrosion depends on the integrity of the protective oxide film, wear-corrosion remains a problem for titanium alloy prostheses. Surface treatments (including nitrogen diffusion hardening, nitrogen ion implantation, and thin-film deposition) may be used to provide more wear-resistant articulating surfaces. Another solution to titanium wear involves the use of multicomponent implants (e.g., implants that contain smooth surfaces made of cobalt–chromium alloy for articulating components and porous surfaces made out of titanium alloy for bone ingrowth and biological fixation). However, fretting corrosion may occur as a result of micromovement at the taper joints between the components, which may destroy the surface passivating films and increase overall corrosion rates (13–15). In spite of the very successful use of the Ti-6Al-4V alloy orthopedic implants, some concern remains regarding the possible toxicity of the aluminum and vanadium components within this alloy. A variety of vanadium-free or aluminum-, and vanadium-free alloys have been developed, including Ti-15Sn-4Nb-2Ta-0.2Pd, Ti-12Mo-6Zr-2Fe (TMZF), Ti-15Mo, and Ti-13Nb-13Zr (5). Ti-12Mo-6Zr-2Fe (TMZF) and Ti-13Nb-13Zr alloys exhibit lower elastic moduli and higher tensile properties. The alloying

elements also form highly protective oxides, which contribute to the excellent corrosion resistance of these materials (16).

An equiatomic nickel–titanium alloy (Nitinol) has received considerable interest as an implant material because of its shape memory and pseudoelasticity properties, the latter resulting in a very low apparent elastic modulus. This superelastic behavior has allowed the development of self-expandable vascular stents, bendable eyeglass frames, orthodontic dental archwire, and intracranial aneurysm clips. Several studies have shown good biocompatibility of Nitinol; however, clinical failures have also been reported (17–19). Laboratory studies have shown a wide variety of performance, with resistance to the breakdown of passivity ranging from poor to excellent (20–22). Resistance to the initiation of pitting critically depends on the surface conditions. A surface film that consists mostly of titanium oxide results in a high resistance to pitting; however, the presence of elemental nickel or nickel oxide reduces the breakdown potential. In addition, recent studies have shown that strained nickel–titanium alloy exhibits significant improved corrosion resistance over as-prepared materials. Other conditions that may affect corrosion resistance include surface roughness, the presence of inclusions, and the concentration of intermetallic species (23).

Another group of biomaterials is used in restorative dentistry and orthodontics. Materials for restorative dentistry must not only meet corrosion, wear, and compatibility considerations described earlier, but also satisfy aesthetic requirements and must have the capacity to be either precisely cast into intricate shapes or used to directly fill a prepared cavity in a tooth. Dental cast alloys can be roughly divided into three major groups of high noble alloys, seminoble alloys, and base alloys. The high noble alloys include those with a high percentage of gold or other noble metals (e.g., platinum), and derive their corrosion resistance mainly from a low thermodynamic tendency to react with the environment. Seminoble alloys often have complex compositions, and either possess a relatively low noble metal content or contain a significant concentration of silver. These materials possess a higher thermodynamic tendency to react than high noble alloys; however, their kinetics of aqueous corrosion in saliva is sufficiently slow, and allows these materials to provide adequate corrosion resistance under biological conditions. The main corrosion concern for seminoble alloys is their tendency to react with sulfur in food and drinks and form dark metallic sulfide film, resulting in the loss of aesthetic quality. Base dental cast alloys include cast titanium, titanium alloys, and nickel–chromium alloys. These materials lack the aesthetic qualities of noble alloys; however, they are resistant to sulfide tarnishing. Nickel–chromium alloys exhibit passivation behavior and some susceptibility to pitting and crevice corrosion. Cast titanium and titanium alloys exhibit highly protective passive films and high resistance to chloride corrosion; however, they demonstrate some susceptibility to fluoride attack, which is of some concern due to the prophylactic use of fluoride rinses and gels. Direct-filling metallic materials include unalloyed gold and dental amalgams, which are alloys of mercury, silver, tin, copper,

and some other minor elements. Dental amalgams have a higher thermodynamic tendency for reaction with the oral environment than noble and seminoble cast dental alloys. In addition, these materials receive weaker protection by passivating surface films than implant alloys. However, these materials have shown adequate long-term clinical corrosion resistance. This property has been greatly improved by the transition from low copper amalgams, which contain a corrosion susceptible Sn–Hg structural phase, to high copper amalgams, which contain a more corrosion resistant Sn–Cu phase. Low copper amalgams exhibit breakdown of passivity and suffer from selective corrosion of the tin–mercury phase, which penetrates and weakens the structure. On the other hand, high copper amalgams do not show breakdown in laboratory testing and have demonstrated better clinical performance. The use of dental amalgam in dentistry has been on the decline as a result of concerns regarding the release of small amounts of toxic mercury and due to improvements in the performance of nonmetallic dental composites. Recent reviews on dental alloys and their corrosion behavior can be found in Refs. (24) and (25). Materials for orthodontic applications include cobalt–chromium alloys, titanium alloys, nickel–titanium alloys, which exhibit similar corrosion behavior in dental applications and medical applications.

Ceramic materials were first used in medical devices in the early 1970s. These materials are either crystalline or amorphous, and contain atoms linked by highly directional ionic bonds. Alumina (Al_2O_3) and zirconia (ZrO_2) exhibit high passivation tendencies and resistance to breakdown properties. These materials exhibit better corrosion resistance, hardness, stiffness, wear resistance, and biocompatibility properties than metal alloys. Zirconia and alumina used in medical devices exhibit full-densities and uniformly controlled small grain sizes ($<5\ \mu\text{m}$) (26). Full-density ceramics are used in medical devices, because voids may increase stresses and degrade mechanical properties. Ceramics containing uniform small grains are used in order to minimize internal stresses from thermal contraction. In addition, ceramics with small grain sizes exhibit enhanced wear, hardness, and strength properties (27–31). Typical material combinations for ceramic hip prostheses include ceramic-on-ceramic; ceramic-on-metal; and ceramic-on-polymer wear couples.

A ceramic coating material that may provide corrosion resistance to an orthopedic prosthesis is diamond-like carbon (DLC). Diamond-like carbon refers to amorphous carbon materials that contain some component of sp^3 -hybridized atoms. Nano- or microcrystalline graphite regions may also be present within the amorphous matrix. Hydrogen-free diamond-like carbon exhibits atomic number densities $>3.19\ \text{g atom}\cdot\text{cm}^{-3}$. Hydrogenated diamond-like carbon (HDLC) contains up to 30 atomic percent hydrogen and up to 10 atomic percent oxygen within CH_3 and OCH_3 inclusions, which are surrounded by an amorphous carbon matrix. The density of hydrogenated coatings rarely exceeds $2.2\ \text{g}\cdot\text{cm}^{-3}$. Hydrogenated or hydrogen-free diamond-like carbon coatings may provide a medical device with an atomically smooth, low friction, wear resistant, corrosion resistant hermetic seal

between the bulk biomaterial, and the surrounding tissues. Tiainen demonstrated extremely low corrosion rates for diamondlike carbon-coated metals (32). The hydrogen-free diamond-like carbon coated-cobalt–chromium–molybdenum alloy and cobalt–chromium–molybdenum alloy were placed in saline solution equivalent to placement in body fluid for 2 years at a temperature of 37 °C. The DLC-coated cobalt–chromium–molybdenum alloy exhibited 10^5 lower corrosion rate than cobalt–chromium–molybdenum alloy. Similarly, the corrosion rate of DLC-coated titanium–aluminum–vanadium alloy in saline solution has been shown to be extremely low.

Bioactive ceramic materials, which develop a highly adherent interface with bony tissue, have been developed for several medical and dental applications, including coatings for promoting bone ingrowth, grouting agents for hip arthroplasty, and replacements for autologous bone grafts. The most commonly used bioactive ceramics include hydroxyapatite, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, tricalcium phosphate, $\text{Ca}_3(\text{PO}_4)_2$, and $\text{Na}_2\text{OCaOP}_2\text{O}_5\text{SiO}_2$ glasses (e.g., Bioglass). These materials undergo chemical–biochemical processes, which are dependent on several material properties. For example, 45S5 Bioglass, which contains 45 wt% SiO_2 and 5:1 $\text{CaO}:\text{P}_2\text{O}_5$ ratio, forms SiOH bonds, hydrated silica gel, hydroxyl carbonate apatite layer, matrix, and bone at the material/tissue interface. Materials with high (>60 mol%) SiO_2 , low $\text{CaO}:\text{P}_2\text{O}_5$ ratios, and additions of Al_2O_3 , ZrO_2 , or TiO_2 are not highly reactive in aqueous media, and do not demonstrate bonding to bone. For example, Bioglass degradation is highly dependent on composition. The dissolution behavior of calcium phosphate ceramics depends on their composition, crystallinity, and processing parameters. For example, materials with larger surface areas (e.g., powders) and smaller grain sizes resorb more rapidly due to preferential degradation at grain boundaries. Phase is another important factor, with alpha-tricalcium phosphate and beta-tricalcium phosphate degrading more slowly than hydroxyapatite. Hydrated forms of calcium phosphate are more soluble than nonhydrated forms. In addition, ionic substitutions affect resorption rate; CO_3^{2-} , Mg^{2+} , and Sr^{2+} increase and F^- decreases biodegradation. Finally, low pH conditions seen in infection and inflammation can result in locally active dissolution processes.

Polymers used in medicine include polyethylene, poly(methyl methacrylate), poly(dimethylsiloxane), poly(tetrafluoroethylene), and poly(ethyleneterephthalate). These structures contain primarily covalent atomic bonds, and many undergo several *in vivo* degradation processes. Water, oxygen, and lipids may be absorbed by the polymer, which may result in local swelling. Polyamides avidly absorb lipids and undergo a stress-cracking process known as crazing; these materials may swell up to five volume percent, and can serve as locking inserts for screws. Desorption (leaching) of low molecular weight species can occur due to release of species remaining from fabrication or from chain scission processes, including free radical depolymerization and hydrolysis. Hydrolytic- and enzymatic-based degradation processes are also possible. Wettability also has a prominent effect on the degradation rate of polymers. Degradation of hydrophilic polymers occurs by surface recession, and may resemble uniform corrosion of metals. Hydrophobic poly-

mers may absorb water and other polar species. As a result, the amorphous regions may dissolve preferentially to crystalline ones, increasing the surface area and the effective dissolution rate. A process similar to inter-granular corrosion may result, with abrupt loss of integrity and small particle release.

WEAR

Wear is the loss of material as debris when two materials slide against one another, which may result in abrasion, burnishing, delamination, pitting, scratching, or embedding of debris. The study of wear, friction, and lubrication was integrated in a 1966 British Department of Education and Science report into a new branch of science known as tribology. The term biotribology was coined in 1973 by Dowson to describe wear, friction, and lubrication in biological systems (33). Over the past 30 years, biotribologists have considered the wear properties of orthopedic, dental, cardiovascular, ophthalmic, and urologic devices, including artificial joints, dental restorations, artificial vessels, prosthetic heart valves, and urinary catheters.

Much of biotribology research has focused on orthopedic prostheses, including devices that replace the function of the hip, knee, shoulder, and finger joints. Hip prostheses have provided control of pain and restoration of function for patients with hip disease or trauma, including osteoarthritis, rheumatoid arthritis, osteonecrosis, posttraumatic arthritis, ankylosing spondylitis, bone tumors, and hip fractures. Polymers, metals, ceramics, and composites have been used on the bearing surfaces of orthopedic prostheses. At present, there are three material combinations used in hip prostheses: a metallic head articulating with a polymeric acetabular ceramic cup; a metallic head articulating with a metallic acetabular metallic cup; a ceramic head articulating with a ceramic acetabular polymeric cup.

Osteolysis and aseptic loosening (loosening in the absence of infection) are the major causes of hip prosthesis failure. In 1994, the National Institutes of Health concluded that the major issues limiting hip prosthesis lifetime include the long-term fixation of the acetabular component, biological response due to wear debris, and problems related to revision surgery (34). Although problems with acetabular fixation have been significantly reduced in the intervening years, wear and the biological response to wear debris remain major problems that reduce the longevity of hip prostheses.

Wear may affect the longevity and the function of hip and other orthopedic prostheses. Clinical practices, patient-specific factors, design considerations, materials parameters, and tissue-biomaterial interaction all play significant roles in determining implant wear rates (35). The complex interaction between these parameters makes it difficult to determine a relationship between the *in vitro* properties of biomaterials and the *in vivo* wear performance for joint prostheses. For example, particles produced by wear may excite both local and systemic inflammatory responses. In addition, the function of prostheses may be affected by the shape changes that are

caused by uneven wear of surfaces. More effective collaboration among clinicians, material scientists, and biologists is necessary to understand the underlying biological, chemical, mechanical, and patient related parameters associated with wear of prostheses.

Wear may occur via adhesive, abrasive, fatigue, or corrosive mechanisms (30–33). The wear process for a given medical device is usually a combination of these mechanisms; however, one mechanism often plays a dominant role. The most important wear mechanism in orthopedic prostheses is adhesive wear. Adhesive wear is caused by adhesive forces that occur at the junction between rough surfaces. Adhesive wear may occur at asperities, or regions of unevenness, on opposing surfaces. Extremely large local stresses and cold welding processes may occur at the junctions between materials. Material may be transferred from one surface to the other as a result of relative motion at the junction. The transferred fragments may be either temporarily or permanently attached to the counterface surface. During this process, the volume of wear material produced is proportional to both the sliding distance acting on the device and the load. The volume of wear materials produced is also inversely proportional to the hardness of the material. For acetabular hip and tibial knee prostheses, adhesive wear is dependent on the large-strain deformation of polyethylene. For acetabular components under multiaxial loading conditions, plastic strain is locally accumulated until a critical strain is reached. Adhesive wear and submicron wear particle release occurs if this critical value is exceeded (30). Although adhesive wear is the most commonly occurring wear mechanism, it is also the most difficult one to prevent.

Abrasive wear takes place when a harder material ploughs into the surface of a softer material, resulting in the removal of material and the formation of depressions on the surface of the softer material. In general, materials that possess higher hardness values exhibit greater resistance to abrasive wear; however, the relationship between resistance to abrasive wear and hardness is not directly proportional. Abrasive wear is called two-body wear when asperities on one surface plough into and cause abrasion on the counterface surface (36). For example, hip prosthesis simulator testing has shown a positive correlation between the surface roughness of the metallic femoral head and the amount of wear damage to the polyethylene acetabular cup. Isolated scratches on a metallic counterface may also participate in abrasive wear. Three-body wear can also occur if hard, loose particles grind between two opposing surfaces that possess similar hardness values. These loose particles may arise from the material surfaces or from the immediate environment, and may become either trapped between the sliding surfaces or embedded within one of the surfaces. For example, metal, polymer, or tissue (e.g., bone) particles embedded in a polyethylene-bearing surface may act to produce third-body wear in orthopedic prostheses. The overall rate of abrasive wear in polyethylene, metal, and ceramic orthopedic prosthesis components depends both on the surface roughness of the materials and the presence of hard third-body particles.

Fatigue wear is caused by the fracture of materials that results from cyclical loading (fatigue) processes.

Surface cracks created by fatigue may lead to the generation of wear particles. Cracks deeper within the biomaterial may generate larger particles, in a process known as microcracking. This process typically occurs in metal components; however, has been observed in other materials (e.g., polyethylene) as well. Corrosive wear results from chemical or electrochemical reactions at a wear surface. For example, metals may react with oxygen at a wear surface (oxidation). The resulting oxide may have a lower shear strength than the underlying metal, and may exhibit a more rapid wear rate than the surrounding material. The rate of corrosive wear is governed by the reactivity of the biomaterial, the chemical properties of the implant site, and the mechanical activity of the medical device.

A film or layer of lubricant between the two bearing surfaces can serve to reduce frictional forces and wear. Lubrication can be divided into three regimes: full film (hydrodynamic) lubrication, boundary lubrication, and mixed lubrication. In full film lubrication, the sliding surfaces are entirely separated by a lubricant film that is greater in thickness than the roughness of the surfaces. In boundary lubrication, the surfaces are separated by an incomplete lubricant film, which does not prevent contact by asperities on the surfaces. A mixed lubrication is the one that encompasses aspects of full film and boundary lubrication, in which a region of the two surfaces exhibits boundary lubrication, and the remainder exhibits full film lubrication. The healthy synovial joint provides a low wear and low friction environment, which may exhibit combination of these lubrication modes. Under normal conditions, the hip, knee, and shoulder joints exhibit full film lubrication, in which the two opposing surfaces are entirely separated by a lubricant film of synovial fluid, which carries the load of the joint.

Wear testing is an important consideration during the development of novel biomaterials and medical devices. Any changes in biomaterial or implant design parameters, including composition, processing, and finishing, should be accompanied by studies that confirm that these changes provide either equivalent or improved wear performance to the implant under clinical conditions. As mentioned earlier, asperities on the contact surfaces generally have a significant effect on overall wear performance. In addition, wear has been described as an accumulative process, because overall wear behavior is highly dependent on the material and testing history. An isolated event during a wear test (e.g., the presence of a third-body wear particle) may have a significant impact on the behavior that is observed.

Wear can be assessed in several ways, including which involve changes in shape (dimensions), size, weight of the implant, weight of the debris, or location of radioactive tracers (37). A standard parameter, known as a wear factor, can be used to estimate the wear effects obtained from different wear tests. The wear factor (K) is defined as

$$K = V/LX \quad (4)$$

in which V is the volume of wear (mm^3), L is the applied load (N), and X is the sliding distance (m). Many parameters can influence the results of wear testing,

Figure 4. Schematic illustration of geometries in which wear phenomena are likely to occur: (1) pin-on-disk; (2) crossed cylinder; (3) journal bearing; and (4) ball-and-socket bearing (After Ref. 31.)

including test lubricants, test duration, sliding velocity, contact area, alignment, and vibration.

Wear studies fall under three broad categories: (a) screening studies that involve testing of materials with simple geometries under well-controlled conditions; (b) simulator studies that involve testing of partial or complete prostheses; and (c) *in vivo* and retrieval studies of complete implanted devices. Screening studies may provide a basis for comparing novel materials against established materials; however, they can only provide estimations for wear of medical device components. Screening studies involve four general types of geometries: (1) pin-on-disk; (2) crossed cylinder; (3) journal bearing; and (4) spherical or ball and socket bearing. Geometries (3) and (4) are most similar to those encountered in orthopedic prostheses (Fig. 4) (35). Simulator studies can be used to assess biomaterials and compare the wear characteristics of materials within a medical device. Various design and material combinations can be examined prior to animal studies and the clinical trials. Clinical assessments and implant retrieval studies also provide useful information for improving biomaterials, medical device design, and manufacturing protocols.

Much of current biotribology research focuses on the relationship between wear performance and biomaterial properties, including composition, processing, and finishing. However, other parameters have significant impact on the wear performance of the prostheses, including surgical and patient factors. The wear performance of polymer, metal, and ceramic biomaterials is discussed below.

Ultrahigh molecular weight polyethylene is commonly used in load-bearing components of total joint prostheses (38–45). The use of a polyethylene/cobalt–chromium wear couple in orthopedic prosthesis was first advocated by Charnley. In many contemporary total hip prosthesis designs, an ultrahigh molecular weight polyethylene acetabular cup slides against a cobalt–chromium alloy femoral ball. Significant numbers of submicron-sized ultrahigh

molecular weight polyethylene wear particles are commonly released from these prostheses with each movement of the joint. These particles may remain in the synovial fluid that serves to lubricate the joint (and contribute to third-body wear), embed in prosthesis surfaces, or enter lymphatic circulation. Immune cells (e.g., macrophages) may identify these particles as foreign materials and initiate an inflammatory response, which can lead to rapid bone loss (osteolysis), prosthesis loosening, or bone fracture (39). The volume and size of wear particles are critical factors that affect macrophage activation (40). These biological and physical effects of ultra-high molecular weight polyethylene wear particles are presently the leading cause of long term failure for metal-on-polyethylene hip prostheses (41,42).

Several mechanisms have been proposed to describe wear of ultrahigh molecular weight polyethylene prosthesis components. The wear mechanism of ultrahigh molecular weight polyethylene in hip prostheses has been described by Jasty et al. (43). They found that ultrahigh molecular weight polyethylene surfaces of retrieved implants contained numerous elongated fibrils, which were indicative of large strain deformation. This plastic deformation resulted from strain hardening of the material in the sliding direction and weakening of the material in the transverse direction. Once strain deformation of the surface has occurred, the surface will fragment during the relative motion, and micron- and submicron-sized wear particles will be released. Subsurface cracking, pitting, and delamination caused by oxidative embrittlement and subsurface stresses are responsible for wear of ultra-high molecular weight polyethylene tibial knee inserts.

The wear resistance of ultrahigh molecular weight polyethylene can be improved by reducing the plastic-strain deformation and increasing the oxidation stability (30). The large-strain plastic deformation of ultrahigh molecular weight polyethylene can be diminished by increasing the number of covalent bonds between the long molecular chains of the polymer, which reduces the mobility of the polymer chain and minimizes the creep of the polymer. This process can be achieved by chemical methods (e.g., silane reactions) or, more commonly, by exposing polyethylene to ionizing radiation (46–50). Gamma-ray, e-beam, or X-ray radiation is used to cleave C=C and C–H bonds in polyethylene, which leads to the formation of species with unpaired electrons (free radicals). If the carbon-carbon bond is cleaved (chain scission), the polymer molecular weight is reduced. Cross-linking can occur if free radicals from separate chains react with one another, and form an inter-chain covalent bond. If cross-linking occurs as a result of recombination by two radicals cleaved from C–H bonds, it is referred to as an H-type cross-link. If one of the free radicals comes from the cleavage of the C=C bond, it is referred to as a Y-type cross-link. The Y-type cross-linking process can increase the extent of polymer side chain branching (51). The yield of cross-linking processes has been estimated to be three times greater than the yield of chain scission processes for radiation/ultrahigh molecular weight polyethylene interaction. Cross-linking is most significant in amorphous regions of ultrahigh molecular weight polyethylene. An 83% reduction in wear rate has

been reported for ultrahigh molecular weight polyethylene surfaces treated with 5 Mrad radiation (38).

However, not all of the free radicals recombine with other free radicals. In crystalline regions, where the spatial separation between free radicals is large, the residual free radicals become trapped. These species are often confined to the crystalline-amorphous interfaces (52,53). Residual free radicals can cause long-term embrittlement through a series of complex cascade reactions. The residual free radicals first react with oxygen, leading to the formation of oxygen-centered radicals. The oxygen-centered radicals can take a hydrogen atom from a nearby chain to form a hydroperoxide species and another free radical on a chain. This additional free radical can repeat the process by generating another hydroperoxide and forming another free radical on a chain. These unstable species may decay into carbonyl species after exposure to high temperatures or after long periods of time, resulting in lower molecular weights and recrystallization. These processes result in increased stiffness, which is highly undesirable for biotribological applications.

Significant research has been done on reducing the concentration of residual free radicals and limiting the brittleness of irradiated ultrahigh molecular weight polyethylene. One cross-linking postprocessing treatment involved annealing the polymer above its melting transition, which allowed the residual free radicals to be removed through recombination reactions. The polymer recrystallized on cooling; however, the covalent bonds obtained during cross-linking were maintained. Unfortunately, the ultrahigh molecular weight polyethylene exhibited slightly lower crystallinity after this treatment. Another treatment involved annealing the cross-linked polymer at a temperature below the peak melting transition. One advantage of this technique is that a greater degree of crystallinity is retained; however, only a partial reduction in the number of residual free radicals is achieved. Other treatments for residual free radicals include irradiation at room temperature followed by annealing at temperatures below the melting transition; irradiation at room temperature with gamma or electron beams followed by melting; or irradiation at high temperatures followed by melting (34).

The physical properties of the ultrahigh molecular weight polyethylene can be significantly altered by cross-linking and annealing treatments. The effect of these treatments is dependent on the cross-linking parameters (e.g., technique, radiation source, dose, temperature during irradiation) and the annealing parameters (e.g., annealing temperature, annealing time). For example, the ultimate elongation (<45%) and the work to failure for ultrahigh molecular weight polyethylene are reduced as the radiation dose level is increased. Large radiation doses also reduce the yield strength (<30%) and the modulus (<27%) of ultrahigh molecular weight polyethylene (34). In addition, toughness decreases as the radiation dose level is increased, since the energy absorption before failure decreases as the chain mobility is reduced (54).

One alternative to the use of ultrahigh molecular weight polyethylene involves the use of so-called metal-on-metal prostheses, which contain two metallic load-bearing components. The primary motivation for use of these implants

is friction; metal-on-metal bearings generate less frictional torque during simulated gait than metal-on-polyethylene bearings (55–59). A stainless steel metal-on-metal hip prosthesis design was attempted by Wiles in 1938. Cobalt–chromium alloy/cobalt–chromium alloy prostheses designs were later developed by McKee and Watson-Ferrar (55,56). Although many of these early cobalt–chromium alloy metal-on-metal hip prostheses failed relatively soon after implantation, others have remained in place for >20 years (35). These first-generation metal-on-metal prostheses were displaced by ultrahigh molecular weight polyethylene/cobalt–chromium alloy prostheses in the 1970s for several reasons, including seizure of the cast metal surfaces (56). In the 1980s, second generation cobalt–chromium alloy/cobalt–chromium alloy prostheses were developed, which have again attracted interest from biomaterials researchers and prosthesis manufacturers (58). Earlier problems with seizing have been minimized through the use of wrought alloys, which are prepared using a thermal-mechanical forming process. Scholes et al. recently demonstrated using a hip simulator system that the mode of lubrication in metal-on-metal hip prostheses is strongly influenced by the diameter of the femoral head and diameter clearance (42). In small diameter joints, the wear rate increased as the diameter of the femoral head was increased. These results were attributed to the development of mixed lubrication in this system.

Alumina and zirconia have also been considered for use in orthopedic prostheses. Alumina exhibits very high hardness and elastic modulus values of $1900 \text{ kgf} \cdot \text{mm}^{-2}$ (Vickers hardness) and 380 GPa, respectively (60). This material is polished to provide an extremely smooth finish; surface roughness values $<0.005 \mu\text{m}$ are routinely obtained. In addition, alumina surfaces are hydrophilic and may provide prostheses with full film lubrication (35). Fracture toughness and wear resistance can be improved by lowering grain size, increasing grain uniformity, increasing purity, and lowering porosity.

Alumina prostheses have demonstrated wear rates $<1 \text{ mm} \cdot \text{million}^{-1}$ cycles during simulator testing (35). In addition, the *in vivo* wear rate for early alumina-on-alumina hip prostheses was shown to be as low as $1 \text{ mm} \cdot \text{year}$ (61). However, retrieval studies involving early alumina-on-alumina hip prostheses found high rates of wear on some prostheses. Microseparation of the head and cup was shown to be responsible for this *in vivo* wear behavior (62). Insley et al. examined alumina-on-alumina prostheses with a laboratory simulator, and found that many very small ($\sim 40 \text{ nm}$) and some large (100–3000 nm) particles were generated under microseparation conditions (35). Zirconia is harder than alumina, and is used to fabricate smaller components that can withstand higher stresses. Deformation-induced phase transformation has a significant effect on the mechanical properties of zirconia (63). The crystalline phase of a pure zirconium changes from monoclinic to tetragonal during deformation, which is accompanied by volume expansion of $\sim 3\text{--}4\%$. The addition of either yttrium oxide (Y_2O_3) or magnesium oxide (MgO) stabilizes the tetragonal phase at room temperature. However, aging can cause zirconia to return the more stable monoclinic phase, and can limit the lifespan of zirconia

prostheses (64,65). In addition, Sato et al. showed that the tetragonal-monoclinic transformation on the surface of zirconia prostheses can be promoted by the presence of water molecules in the environment (66). The resulting volume change can lead to the generation of surface microcracks and an increase in surface roughness. The failure of some zirconia prostheses has been attributed to this microcracking process. Finally, *in vivo* fracture of some zirconia prostheses has been attributed to variations in sintering.

Thermal oxidation of zirconium alloys has also been used to create biocompatible, corrosion- and wear-resistant surfaces for orthopedic prostheses (67). Wrought zirconium-2.65 weight % niobium alloy contains a two-phase microstructure, which consists of elongated hexagonal alpha-zirconium grains that are bordered by cubic beta-zirconium grains. This material is oxidized for up to 8 h in air at temperatures near 620 °C (the eutectoid temperature). The resulting ~5 μm thick monoclinic ZrO₂ surface contains 40 nm wide × 200 nm long grains that are arranged in a brickwork pattern, which is resilient to grain pull-out and lateral fracture. At the interface between the alloy and the surface oxide, regions of unoxidized niobium in beta-zirconium second-phase grains continue from the alloy into the oxide and serve to anchor the oxide to the alloy. The outermost portion of the oxide surface is burnished to create a smooth bearing surface. The oxide surface provides excellent wear behavior against polyethylene components, with reduced wear particle generation and inflammation.

Diamond-like carbon coatings on orthopedic prostheses can exhibit a wide range of elastic modulus and hardness values, which can be correlated with the fraction of *sp*³-hybridized atoms within the coating (68–71). Collins et al. developed a relation between *sp*³ fraction and Vickers hardness values for hydrogen-free diamond-like carbon coatings. They found that an *sp*³ fraction of 10% corresponded to a hardness value of 2000–3000 Hv, an *sp*³ fraction of 50% corresponded to a hardness value of 7000–8000 Hv, and an *sp*³ fraction of 100% corresponded to a hardness value of 10,000 Hv (72). Schneider et al. found that hydrogen-free and diamond-like carbon films with *sp*³ fractions between 0 and 90% provided elastic modulus values between 300 and 800 GPa. In contrast, typical hardness and elastic modulus values for hydrogenated diamond-like carbon films are <17 and <200 GPa, respectively (73).

The coefficients of friction values for diamond-like carbon coatings depend on ambient humidity, topology, and sliding partner (74). The most important parameter determining the coefficient of friction for hydrogenated diamond-like carbon thin films is relative humidity. Friction values for hydrogenated diamond-like carbon films can be as low as 0.01–0.3 in vacuum conditions, but greatly increase under humid conditions due to incomplete formation of the graphitic transfer surface. This variation in coefficient of friction values can be correlated with hydrogen/carbon ratio in the precursor material. As the hydrogen content in the precursor material increases, the friction coefficient demonstrates a greater positive correlation with ambient humidity. For example, hydrogenated diamond-like carbon films produced from hydrogen-diluted methane demonstrate lower friction coef-

ficients under high humidity conditions than other hydrogenated diamond-like carbon films. On the other hand, hydrogen-free diamond-like carbon thin films maintain low friction coefficients (<0.1) under low and high humidity conditions (75,76).

The combination of high hardness and low coefficient of friction values allows diamond-like carbon coatings to provide significant wear protection to a bulk implant material (71). Hirvonen et al. found that the wear resistance of diamond-like carbon coatings is superior to that of silicon carbide, tungsten carbide–cobalt, silicon nitride, or alumina by factors of 40, 60, 230, and 290, respectively (77). Hydrogen-free diamond-like carbon thin films exhibit wear rates of 10⁻⁹ mm³·N⁻¹·m⁻¹, these values are ~100 times lower than those for hydrogenated diamond-like carbon thin films (10⁻⁷ mm³·N⁻¹·m⁻¹) under similar testing conditions (78). Many diamond-like carbon substrate materials are significantly softer than the diamond-like carbon coatings; high contact pressures can initiate substrate deformation and coating failure. Nitriding processes can harden the substrate surface, reduce subsurface deformation, and extend diamond-like carbon coating lifetimes (79).

The friction and wear properties of diamond-like carbon-coated metal hip prostheses against diamond-like carbon-coated polyethylene cups have been determined using both screening and simulator techniques (80). For example, Tiainen et al. demonstrated extremely low coefficients of friction for prostheses coated with hydrogen-free diamond-like carbon using a pulsed arc discharge method. They demonstrated coefficients of friction for diamond-like carbon/diamond-like carbon and metal–metal pairs of 0.05 and 0.14, respectively. In addition, they found that wear rate in the diamond-like carbon-coated metal/diamond-like carbon-coated metal wear couple was 10⁵–10⁶ times lower than that observed in conventional metal–polyethylene and metal–metal wear couples. They also observed that wear of polyethylene in the diamond-like carbon-coated metal/ultrahigh molecular weight polyethylene wear couple was 10–600 times lower than that observed in conventional metal/ultrahigh molecular weight polyethylene wear couples. On the other hand, other investigators have found little difference in wear rates between diamond-like carbon-coated prosthesis materials and conventional prosthesis materials. For example, Sheeja et al. found little difference in wear rates between cobalt–chromium–molybdenum alloy/ultrahigh molecular weight polyethylene and multilayered diamond-like carbon-coated cobalt–chromium–molybdenum alloy/ultrahigh molecular weight polyethylene wear couples (81,82). The seemingly contradictory results suggest other factors, such as use of lubricant, may play a significant role in determining wear rates (83–85). For example, physiologic lubricants may not allow graphitic layers to form on the surfaces of the test materials. In addition, diamond-like carbon coatings that contain particulates and pits may increase adhesive wear (86).

Adhesion of diamond-like carbon coatings is dependent on several factors, including film stress, film–substrate chemical bonding, and substrate topology (87,88). Large internal compressive stresses (as high as 10 GPa) are typically observed in

diamond-like carbon coatings. These stresses limit maximum diamond-like carbon coating thickness to 0.1–0.2 mm and prevent widespread medical use. Lifshitz et al. attributed these stresses to subplantation (low energy subsurface implantation) of carbon ions during coating formation (89). They suggested that carbon ions with energies between 10 and 1000 eV undergo shallow implantation to depths of 1–10 nm during growth of diamond-like carbon coatings. Carbon species are trapped in subsurface sites due to restricted mobility, leading to the development of very large internal compressive stresses.

Diamond-like carbon can be alloyed with metals in order to reduce internal compressive stresses and promote specific biological responses (90,91). Diamond-like carbon–metal composite coatings retain hardness and wear properties similar to those of unalloyed diamond-like carbon films, and exhibit excellent adhesion to metal alloy substrates (Fig. 5). The metal component can provide additional biological functionality to the implant surface; for example, silver has been shown to possess a wide antimicrobial spectrum against a broad range of Gram-negative bacteria (including *Pseudomonas aeruginosa*),

Figure 5. Wear testing of diamond-like carbon–metal composite coatings using a linear tribometer (screening wear test). (a) Wear track of functionally gradient diamond-like carbon–silver composite film after 10,000 cycles, (b) Wear track of functionally gradient diamond-like carbon–titanium composite film after 10,000 cycles.

Gram-positive bacteria (including methicillin-resistant *Staphylococcus aureus*), fungi, viruses, and yeasts. Films containing both silver and platinum may demonstrate enhanced antimicrobial activity due to formation of a galvanic couple that accelerates silver ion release. Narayan et al. showed that diamond-like carbon–silver–platinum nanocomposite films reduce bacterial colonization rates by 90% compared to uncoated silicon substrates (92).

Corrosion and wear are critical parameters that affect overall success of a biomaterial or a medical device design. The complicated interaction between material-, device-, surgical-, patient-specific parameters has made it difficult to predict clinical behavior of implanted medical devices. In addition, the large variation in measurement techniques for corrosion and wear has led problems in interpreting and comparing the work performed in the biomaterials community. If these issues can be successfully resolved, significant advances in these areas may be achieved in the coming years.

BIOMATERIALS FOR DENTISTRY

STEVE ARMSTRONG
University of Iowa

INTRODUCTION

Gold has been used for dental purposes for at least 2500 years; the fabrication of gold crowns and bridgework flourished in Etruria and Rome as early as 700–500 BC. Gold leaf came into use during the fifteenth century for the restoration of carious teeth. Restorative materials and techniques continued to develop through the nineteenth century including the use of waxes, fused porcelain, “silver paste” amalgam, cements, vulcanite, the angle handpiece, and a gold inlay casting machine. A rapid development in materials and instrumentation has occurred since the 1950s, to include the high speed handpiece, steel and diamond cutting instruments, adhesive techniques to metal, ceramics, enamel and dentin, resin-based compo-

sites, glass ionomers, base-metal alloys for partial dentures, metal-ceramic systems, high-strength all ceramic structures, and titanium alloys for dental implants. This increasing complexity and body of knowledge has led to the establishment of uniform material standards and the recognition of the science of dental materials as a distinct and essential branch of dentistry.

Biomaterials are used in the oral cavity either to restore function, comfort, or aesthetics caused by developmental disorders, disease, or trauma. More elective procedures are being requested and performed purely for aesthetic purposes as the incidence of caries has dropped in certain population groups and as patients have become more aware of various restorative or cosmetic options. However, the replacement of diseased tooth structure or missing teeth accounts for the bulk of work in restorative dentistry. The instruments and materials used in the surgical aspects of oral, maxillofacial and periodontal surgery have much in common with medicine. This article will focus on those commonly used materials in the restoration of individual teeth or the replacement of missing teeth.

Restorative materials include noble and base metal alloys, resin-based composites (RBCs), glass ionomers, ceramics, acrylics, and amalgam alloys. Techniques to apply these materials include both direct and indirect approaches. Materials or “fillings” can be directly placed in a prepared cavity by the use of adhesives and/or retentive-type preparations. Full or partial coverage crowns, bridges, and dentures are fabricated indirectly by dental laboratories or computer aided milling machines and then attached or cemented into the mouth for the coverage of missing or weakened tooth structure or the replacement of missing teeth. Various forms of ceramic or metallic implants can be placed into the upper or lower jaw bones to serve as tooth root substitutes upon which a prosthesis is attached to replace missing teeth. Auxiliary materials, such as waxes, gypsum, and impression materials are also utilized during clinical and laboratory steps but will not be covered in this article.

DIRECTLY PLACED RESTORATIVE MATERIALS: ‘FILLINGS’

Amalgam

Dental amalgam has been very successfully used in dentistry for 150 years and is one of the most technique insensitive dental restorative materials available. Dental amalgams are inexpensive and have demonstrated a relatively long service life. The disadvantages of amalgam are the silver color and the presence of mercury. The presence of mercury requires regulatory control of wastewater effluent and has raised unsubstantiated health concerns regarding mercury toxicity to the individual patient.

Dental amalgam is a mixture of mercury and a solid metal alloy of silver, tin, copper, and sometimes zinc, palladium, indium, and selenium. Once the mercury and alloy is mixed, the plastic mass is condensed into the prepared cavity and carved to required form before hardening. The alloy particles are microspheres of various sizes, irregular lathe-cut particles or mixtures of the two. “High

copper” alloys (13–30%) have essentially replaced the low copper alloys of the past. These high copper alloys, along with the addition of zinc for manufacturing procedures, have improved early clinical strength, lowered creep, and improved corrosion resistance. The mixing of mercury and the alloy is referred to as trituration or amalgamation. A surface reaction occurs between the alloy and liquid mercury that binds the unreacted particles together by a surrounding matrix of reaction products. Increasing the copper content eliminates most of the weakest and most corrosive phase (Sn_{7-8}Hg) from the setting reaction.

After the carious lesion is removed, the plastic dental amalgam is condensed into the prepared cavity before hardening and subsequently retained by the mechanical resistance and retention form of the surgically prepared cavity. An adhesive liner is not required. The material slowly corrodes and the corrosion products “self-seal” the margin between tooth and amalgam, thereby protecting the tooth from leakage of oral fluids and bacteria and their byproducts. Dental amalgam is brittle and undergoes creep at mouth temperature, which can lead to marginal or bulk fracture and clinical failure. However, if the cavity is well designed and the amalgam placed with technical competence, many years of service should be expected. A vast number of studies have shown the safety and efficacy of dental amalgam. When a dentist is faced with a patient’s request to remove amalgam fillings due to a claimed medical malady, the dentist is professionally obligated to explain that the possibility of their medical condition(s) being related to the presence of dental amalgam fillings is extremely remote. These patients typically face a complex problem with biological, psychological, and social components unrelated to mercury intake.

Resin Composites

Modern day resin-based composites placed with dental adhesives have replaced the silicates and acrylic resins of the past and are now widely used throughout dentistry. In addition to the treatment of decay and trauma, RBCs are used in aesthetic or cosmetic dentistry procedures due to their versatility and conservative nature. Discolored, misshapen, or misaligned dentition can be aesthetically treated with cosmetic “bonding”. The RBCs are composed of four main components: (1) a continuous organic polymer matrix, (2) a dispersion of inorganic filler particles, (3) silane coupling agents to bind the filler particles with the polymer matrix, and (4) an initiator–accelerator system. They also contain various pigments for matching tooth shades and ultraviolet (UV) absorbers to minimize oxidative color changes. The two most common oligomers are the dimethacrylates 2,2-bis[4(2-hydroxy-3-methacryloyloxy-propyloxy)-phenyl] (bis-GMA) and urethane dimethacrylate (UDMA). Diluents such as triethylene glycol dimethacrylate (TEGDMA) are added to reduce the viscosity for the addition of filler and to obtain clinically acceptable handling properties. The inorganic filler particles can be of borosilicate, lithium aluminum silicate, barium aluminum silicate, strontium or zinc glasses, quartz, or colloidal silica. The combination of relatively larger glass or quartz particles and a significant addition of

Table 1. Classification of Resin-Based Composites by Filler Particle Size

Class	Particle Size, μm	Filler Loading, vol%
Macrofill	>10	50–70
Midifill	1–10	50–70
Minifill	0.1–1	50–70
Microfill	0.01–0.1	20–50

colloidal silica are referred to as a “hybrid”. A useful classification method is by filler particle size (Table 1) with minifill hybrids and microfills being the most popular types. Recently, using a proprietary process, manufacturers have been able to produce a smaller average silica particle size ($0.02 \mu\text{m}$) as compared with traditional microfills ($0.04 \mu\text{m}$). Marketed as “nanofills”, these smaller silica particles are produced in a nondrying method thereby avoiding agglomeration due to physical forces and thusly enabling a higher degree of filler loading. The microfill RBCs polish to the most enamel-like surface, but lack the strength of the hybrids due to the lower filler volume. Newer formulations of minifill hybrids can be used as “universal” RBCs possessing both the strength for posterior chewing forces and acceptable surface finish for use in aesthetic anterior regions. Clinical studies showed that the long-term wear resistance of RBC restorations placed on posterior teeth is still inferior to the dental amalgam restorations.

Polymerization occurs through either a self-cured free radical initiation when a peroxide–amine system is mixed or through light-activated free radical initiation when a diketone–amine system is exposed to blue light. The photoactivator, most commonly camphoroquinone, is added in small amounts, which forms a free radical when exposed to 467-nm blue light. Dual-cure varieties of RBCs are available as well. Halogen light-curing units are most commonly used, but several other light curing units are currently being marketed to include: plasma-arc, laser and light-emitting diodes. To insure proper polymerization care must be taken to match the unit’s spectral emission and the RBCs spectral requirements. One aspect that all RBCs currently share is 2–4% volumetric shrinkage of the continuous polymeric network upon polymerization. Shrinkage induces residual stress that can disrupt the adhesive bond between the RBC and the tooth structure, damage enamel or the RBC. Incremental placement of light-cured RBCs can help to reduce the net effect of this shrinkage stress. Manufacturer’s are currently working to develop no- or low shrinkage RBCs; several approaches are noted: (1) addition of ring-opening monomers that expand upon polymerization (spiroorthocarbonates, oxiranes, vinylcyclopropanes), (2) low shrinkage cyclopolymerizable di- and multifunctional oligomers synthesized through the reaction of acrylates and formaldehyde, and (3) the addition of strain-absorbing polybutadiene rubber polymer adsorbed onto the fumed silica.

Variations in filler loading, viscosity, and polymerization initiating systems allow RBCs to be used in a wide variety of clinical situations, to include: sealants, cements, crown core buildups, so-called flowables and packables,

provisional restorations, and in a variety of laboratory processed RBCs for adhesive cementation as inlays, onlays, crowns and veneers. Several manufacturer's have promoted fiber reinforced RBCs for use as bridges, as well, but these lack convincing clinical data for their recommended usage.

Glass Ionomers

Smith (1968) developed glass ionomer cements (GIC) by combining the polyacrylic acid from polycarboxylate cement, which is strongly adhesive to tooth structure, and the aluminosilicate glass from the fluoride-containing silicate cements. The GICs form a true chemical bond to the tooth mineral (hydroxyapatite) by ionic bonding between calcium and carboxylic ions and act as chemotherapeutic agents in the treatment and prevention of dental caries through the release of fluoride.

The GIC are composed of a basic ion-leachable aluminosilicate glass powders that, upon exposure to water-soluble homopolymer or copolymers of alkenoic acids, form a matrix of continuous polysalts (polyalkenoates) surrounded by partially solubilized glass filler particles. The clinical placement technique must account for the relatively slow-setting reaction and moisture sensitivity. Fluoride easily passes in and out of the matrix without any degradative effects due to the substitution of carboxyl ions for fluoride within the salt matrix. Fluoride "recharging" has been clearly demonstrated *in vitro* to prevent the demineralization of tooth structure at the margins adjacent to the GIC under an artificial caries challenge. *In vivo* evidence is not as clearly demonstrated, but when evaluating clinical data from high caries risk cohort populations the anticariogenic effect of GIC is elucidated.

Since their development GIC has been modified in a number of different ways to improve their clinical handling properties and durability. A significant development was the addition of water soluble monomers, for example, HEMA, and the grafting of methacrylate side groups on the polyacid polymer. By the addition of visible light initiator-accelerator systems these resin-modified glass ionomers (RMGI) can be command set with a light curing unit while also self-curing through the acid-base reaction. These improvements to the conventional GIC and RMGI have made these materials widely used as restorative materials. The self-adhesive and self-cure properties of GIC, along with improvements in strength have allowed these materials to be used in nontraditional field situations without the luxuries of electricity or modern equipment. Auxiliary personnel have been trained to remove caries with sharp hand instruments with the cavity then filled with a heavier filled GIC. This treatment has aided thousands through a technique termed Atraumatic Restorative Treatment or "ART". These materials are also used as cements and liners.

Adhesives, Cements, and Liners

Adhesive dentistry has become increasingly important as the use of dental amalgam and direct compacted gold foil and cemented gold restorations has declined. Unlike dental amalgam, RBCs require an adhesive liner for placement

and retention. A durable bond of RBCs to enamel can be accomplished by first cleaning and demineralizing the surface with a 30–40% phosphoric acid, followed by a polymerizable methacrylate monomer [bis(GMA), UDMA, TEGDMA], which diffuses into the porosities created by the acid etching. However, bonding to dentin is a much greater challenge due to the compositional differences in dentin relative to enamel and its extremely variable clinical presentation. Dentin contains less inorganic components and more organic components and water than enamel. Dentin is made permeable by tubules that travel from the dental pulp through the dentin to the coronal enamel.

Similar to enamel, the dentin is treated with an acid that removes any smear layer and exposes the collagen fibers by demineralizing the surface. An adhesive primer containing a hydrophilic solvent (water, acetone, ethanol, or HEMA) and an amphipathic monomer (hydrophilic-hydrophobic functionalities) then penetrates the exposed collagen network. After the solvent is evaporated from the primed surface, an adhesive monomer is applied that attaches to the hydrophobic functionality of the primer to create a wetted surface for subsequent copolymerization with the RBC. This bonding process is also approached with so-called "self-etch" adhesives. The initial acid application is eliminated and a water-soluble acidic polymer is included in the primer to simultaneously demineralize the tooth surface while penetrating with the adhesive monomers and oligomers. Regardless of the approach, the adhesive liner penetrates into the exposed collagen network and also partially into the dentinal tubules. The interdiffusion of the synthetic adhesive polymer within the collagen network forms a micromechanical bond and is commonly referred to as a hybrid layer (Fig. 1). In the last 20 years,

Figure 1. Scanning electron micrograph (SEM) image of a total-etch three-step dental adhesive system applied to dentin. A = filled adhesive resin (ceramic filler particles visible within resin matrix), HL = hybrid layer (interdiffusion zone of adhesive polymers and collagen network), T = dentinal tubules, D = laboratory demineralized dentin. Original magnification = 2000X, black bar = 10 μm . (Photomicrograph courtesy of Marcos Vargas, University of Iowa College of Dentistry.)

dentin bonding has improved the clinical success of adhesively placed restorations, but difficulties remain. Completely penetrating the exposed collagen matrix with the adhesive monomers can be hindered by the presence of excess solvent, dentinal fluids, or by physical blockage of the interpenetrating microchannels between collagen fibrils. Even if the adhesive fully wets the dentin surface, suboptimal polymerization may reduce bonding effectiveness. This union of restorative material to enamel and dentin is critical not only for retaining restorations in place, but also for sealing the margin from the passage of bacterial fluids, molecules, or ions. Leakage between the interface of the dental restoration and the wall of the cavity preparation has been associated with marginal discoloration, secondary caries, and pulpal pathology.

Adhesive liners or bonding agents are also used in conjunction with resin-based composite cements when adhesively cementing crowns or other fixed appliances into or onto prepared teeth. The ceramic elements or oxides of the internal surface of dental porcelain-ceramic, metals, and resin-based composite restorative materials are mechanically or chemically roughened before applying a silane coupling agent. The silane bonds to the ceramic surface with both covalent and hydrogen-bonding protecting from hydrolytic degradation while making the surface hydrophobic and organophilic for resin cement wettability and copolymerization. Self-adhesive cements include the glass ionomer and polycarboxylate cements. Zinc phosphate and zinc oxide eugenol are nonadhesive cements that act as mortar or a luting agent.

Additional uses of the above mentioned cements include (1) cavity liners to achieve a physical barrier to bacteria and their products and/or to provide a therapeutic effect, such as fluoride release from glass ionomer or pulpal obtundent with zinc oxide eugenol, (2) cavity bases to block out undercuts in cavity preparations for indirect restorations or for insulating the pulp from thermal changes, and (3) temporary or provisional restorations. The beneficial effects of adhesion to tooth structure and fluoride release obtained from adhesive liners and glass ionomer materials are rapidly replacing the traditional liner, base, and cement materials, that is, zinc phosphate, polycarboxylate, and zinc oxide eugenol.

PROSTHETIC RESTORATIVE MATERIALS: CROWNS, BRIDGES, DENTURES

Metals and Alloys

Noble and base metal alloys are used for (1) crowns and bridges with fused porcelain in esthetic areas, (2) inlays, onlays, crowns, and bridges without porcelain veneering in the posterior or nonaesthetic regions of the mouth, and (3) partial and complete removable denture bases. Base metals commonly used in dental alloys include, nickel, chromium, copper, zinc, gallium, silver, indium, and tin. Silver, a "precious" metal, is not considered a noble metal in dentistry due to its corrosion in the oral cavity. The noble metals utilized in dentistry are gold, platinum, palladium, iridium, rhodium, and ruthenium. Cold-worked or wrought noble and base alloys can be cast with or "soldered"

(brazed) to cast structures as attachments or clasps to removable partial dentures. High purity gold, being soft and malleable, can be cohesively adapted in the form of gold foil into small cavity preparations by careful condensation techniques. This process develops adequate hardness and physical properties through work hardening, resulting in a clinically successful, long-lasting restoration. However, the compacted gold foil restoration is becoming increasingly uncommon due to the success of adhesively bonded tooth colored restorations and the skill and time required to properly place gold foil. Almost all fixed-dental prostheses contained a minimum of 75% gold before the dramatic increase in the price of gold after the United States separated gold from monetary standards in 1969. The increase in gold prices, and rise in palladium prices three decades later, has led to an increased use of alternative alloys containing base metals.

The lost wax technique became common in dentistry after W.H. Taggart introduced his casting machine in 1907. A wax pattern of the desired restoration is fabricated and then invested in a ceramic material (casting investment), which is subsequently heated to burn out the wax pattern, that is "lost wax". A molten metal alloy is then cast into the resultant space previously occupied by the wax. The restoration is recovered, finished, and polished before cementing or delivering to the patient. The investment must be able to expand enough upon setting and heating to compensate for the wax and metal shrinkage if a precise fit is to be obtained.

Alloys should (1) produce no toxic, carcinogenic, or allergic reactions; (2) resist corrosion and physical changes in the oral environment; (3) possess physical properties, that is, strength, fusing temperature, thermal conductivity, and coefficient of thermal expansion, appropriate for the desired application; (4) be able to be fabricated in a technically feasible manner; and (5) be available and relatively inexpensive. The alloys used for metal-ceramic or commonly termed porcelain-fused-to-metal (PFM) restorations must possess a fusion temperature range that is substantially higher ($>100^{\circ}\text{C}$) than the ceramic firing temperature, have sufficient creep resistance at that temperature, and have the ability to form a good bond between its oxide surface and the ceramic veneer.

Wrought stainless steel alloys are used in orthodontic brackets and wires, endodontic instruments, prefabricated temporary crowns and space maintainers. In addition, wrought cobalt-chromium-nickel, nickel-titanium, copper-nickel-titanium, and beta-titanium alloys are also used as orthodontic wires. Nickel-titanium and copper-nickel-titanium orthodontic wires have a unique superelastic (pseudoeelastic) property that delivers a constant low-level force over an extended range of deformation. Nickel-titanium and copper-nickel-titanium alloys are also the shape memory alloy (SMA), that is, they can be deformed plastically below its transition temperature range (TTR), then after heating through and above the TTR, they will return to their original desired shape due to a crystallographic transformation from martensitic phase into austenitic phase. Titanium and titanium alloys, especially due to their thin stable oxide layers, are very important endosseous dental implant materials and, with the

recent refinement in casting techniques, can be used for crowns, partial dentures and complete denture bases.

Ceramics

The first porcelain was developed in the T'ang Dynasty from 618 to 906 AD and the first suggested use of porcelain for dentistry was by Pierre Fauchard in France after the porcelain formula was brought from China by a Jesuit priest. Several developments followed but the current approaches to ceramic-metal crowns and bridges occurred from the 1950s–1960s. High-fusing alloys combined with the development of low-fusing thermally compatible leucitic porcelains permitted the fabrication of ceramic-metal restorations. High expansion leucite was mixed with feldspar glass during manufacturing to refine the coefficient of thermal expansion (α) creating a successful junction between dental porcelain and metal. The combination of which must be thermally compatible for fabrication and so that the veneering materials surface is left in a residual state of compression. The α of the veneering material is generally $\sim 0.5\text{--}1.0 \times 10^{-6} \text{ }^\circ\text{C}^{-1}$ lower than the core material so that upon cooling the inner core will contract more resulting in a residual compressive state resisting crack formation and propagation of the relatively brittle veneering material.

Minor refinements have continued with metal–ceramic systems, but more recently significant advances have occurred in the area of “all-ceramic” systems, in which the metal is replaced with a ceramic core upon which veneering porcelain is fused. This eliminates the masking of the metal with opaquing agents and greatly simplifies the aesthetic technical procedures by the dental technician. However, more tooth structure may need to be removed in preparation for the construction of these all-ceramic restorations and their brittle nature does not yet permit their function in long-span bridges.

Ceramic systems can be classified by their fusion temperature, clinical usage, processing methods, or crystalline phase. Table 2 lists some crystalline types used for the three major applications of ceramics in dentistry: (1) metal–ceramic crowns and fixed-partial dentures

Table 2. Classification of Dental Ceramic Materials

	Fabrication	Crystalline (dispersed) Phase
Ceramic–Metal (PFM)	Sintered	Leucite (KAlSi ₂ O ₆)
All-Ceramic	Machined	Alumina (Al ₂ O ₃)
		Feldspar (KAlSi ₃ O ₈)
	Slip-cast	Mica (KMg _{2.5} Si ₄ O ₁₀ F ₂)
		Alumina (Al ₂ O ₃)
Heat-pressed	Spinel (MgAl ₂ O ₄)	
	Zirconia (ZrO ₂)	
Denture Teeth	Sintered	Leucite (KAlSi ₂ O ₆)
		Lithium disilicate (Li ₂ Si ₂ O ₅)
	Feldspar (KAlSi ₃ O ₈)	

^aAdapted from Ref. (1) p. 553.

(bridges); (2) all-ceramic crowns, inlays, onlays, veneers, and shortspan bridges; and (3) denture teeth.

“Porcelains” are composed of kaolin (clay), feldspar, and quartz (flint), while the dental porcelains being quite similar, are fabricated from silica (SiO₂), soda (NaO₂), potash (K₂O), alumina (Al₂O₃), with the addition of pigments, opacifiers and fluxes. Naturally occurring minerals such as feldspar (K₂O Al₂O₃ 6SiO₂), quartz, and nepheline syenite have been utilized to provide these constituents. The use of feldspar has led to the term feldspathic porcelain, however, feldspar is not necessarily present in the final processed porcelain, nor is it essential to form leucite, the major crystalline phase of the porcelain. Like all dental ceramics, dental porcelain is composed of a glassy (vitreous) matrix phase surrounding a dispersed crystalline phase. The glassy matrix, composing 75–85% of the porcelain, is formed by heating the raw materials into a glassy state then quenching. This pyrochemical reaction produces a supercooled liquid of metastable equilibrium that is quenched then ground into a fine powder. These fine powders or frit can be reheated and will fuse at a lower temperature with little pyroplastic flow giving increased homogeneity, translucency, smoother texture, a lower fusion temperature, and less shrinkage. The temperature at which the surface glassy phase softens allowing the fritted particles to coalesce without further pyrochemical change is called sintering. These sintered dental porcelains, in general, will have little change in the physical, chemical, or optical properties of the glassy matrix upon repeated firings during the necessary steps of the restoration fabrication. However, if improperly fired or over fired, the dispersed leucite crystals can be altered leading to reduced strength or porcelain–metal (core) thermal incompatibilities. During the fritting process the silica matrix is disordered due to the rapid cooling from the molten state and also by the addition of fluxes that break up the silica tetrahedral network by occupying oxygen. These alkali ions reduce the number of cross-linkages between the silicon–oxygen tetrahedra by randomly occupying space in the open network. The net effect of flux (LiO₂, Na₂O, K₂O, BaO, CaO, MgO, ZnO) addition is lower softening or fusion temperature, decreased viscosity, production of glassy phase, increased α , decreased strength, lowered chemical resistance, increased risk of devitrification during repeated firing cycles. The lower fusing temperatures and increased α made possible the modern day metal–ceramic systems. Three components of the porcelain to metal bond are classically described: (1) mechanical interlocking through good wetting of the porcelain on the roughened metal surface, (2) chemical physical bonding between the oxides of the porcelain and the oxides on the metal surface, and (3) a controlled mismatch in α leading to residual compressive forces in the porcelain (described earlier). Any of these may predominate depending on the ceramic system.

Achieving superior esthetics, in general, is simplified by having a ceramic core. However, strength, wear, fit, and longevity must be proven in controlled clinical trials. Increasing the strength of the ceramic core to perform comparably to metal substructures is approached by manipulating the crystalline phase for reinforcement.

Techniques for fabricating all-ceramic systems include (1) sintering with alumina-based, magnesia-based, and leucite-reinforced ceramics; (2) heat-pressed techniques with leucite-reinforced and lithium-disilicate-based ceramics; (3) slip-casting with alumina-, spinel-, and zirconia-based ceramics; and (4) the machining of manufactured ceramic blocks available in several types of ceramic. One method uses computer-aided designing/computer aided machining (CAD/CAM) technology to fabricate inlays, onlays, veneers, and crowns. An "optical" impression is obtained from the prepared tooth with an optical scanner and the computerized image of the restoration is designed by the computer software. Subsequently, a ceramic block is machined in the computer-controlled milling machine according to the design and later cemented into or on the tooth by the dentist.

Slip-cast all-ceramics are fabricated by a process very similar to that used for the production of common objects such as plumbing fixtures and beer steins. Successive layers of ceramic slurry are applied to porous refractory gypsum that draws in the water depositing a solid layer of alumina on its surface. The ceramic buildup is dried then sintered for 4 h at 1100 °C, the porous alumina coping is then carved into the desired shape before infiltrating with a slurry of lanthanum aluminosilicate glass by firing at 1120–1150 °C for 3–5 h. The resultant ceramic is a three-dimensional (3D) interpenetrating network of alumina and glass of high strength due to the presence of densely packed alumina and low porosity. The excess glass is removed and the core is subsequently veneered with a thermally compatible veneering ceramic. Improved translucency (esthetics) can be obtained by glass infiltrating a core composed of magnesium spinel and alumina. The strongest slip-cast material currently available contains tetragonal zirconia along with alumina and glass. When a load is induced on the tetragonal zirconia it absorbs energy by transforming into a monoclinic crystal form accompanied by a volume increase of 3% in a crack arresting manner. Flexural strengths (380–700 MPa) and fracture toughness (2–7 MPa·m^{1/2}) for these core materials are in the following rank order: spinel < alumina < zirconia.

Prosthetic Resin Materials

Poly(methylmethacrylate) was introduced as a denture base material in 1937 and in roughly a decade had virtually replaced the use of vulcanite. Acrylic polymers also enjoy a wide variety of uses in additional prosthetic applications, such as, artificial denture teeth, provisional restorations and temporary crowns, denture base repair, relining and rebasing materials, and obturators for maxillofacial defects.

Denture base materials are typically fabricated from heat-cured poly(methylmethacrylate) and rubber-reinforced poly(methylmethacrylate) and perform surprisingly well. These plastics are supplied in a powder liquid or gel form. The 10 poly(methylmethacrylate) powder is modified with ethyl, butyl, or other alkyl methacrylates for impact resistance and contains benzoyl peroxide or diisobutylazobitrile to initiate polymerization when mixed with the liquid monomer. Pigments are added to obtain natural

tissue appearance, for example, mercuric sulfide, cadmium sulfide, cadmium selenide, ferric oxide, or carbon black. Various glasses, ceramics and polymer fibers have been added as dispersed phases to various products in an attempt to reinforce the acrylic polymers. The liquid component is methyl methacrylate, modified with various other monomers while including an inhibitor such as hydroquinone to prevent premature polymerization for adequate shelf life. The liquid of cold-, self-, or autocuring resins contain tertiary amine or sulfinic acid chemical accelerators to allow the polymerization of the monomer at room temperature. Plasticizers for resilience and cross-linkers for hardness and decreased solubility may also be included. Denture base resins can also be fabricated through pressure, heat and light-activated techniques with compositional modifications for the various initiation reactions and physical handling properties during fabrication. A number of general requirements for denture base resins are outlined in ANSI/ADA Specification No. 12 (ISO 1567) providing guidance to dentists and dental manufacturers.

Denture teeth are also fabricated from acrylic and modified acrylic materials and are generally preferred over porcelain denture teeth due to wear characteristics, phonetics and technical considerations during fabrication and repair. Temporary or provisional restorations are also fabricated from acrylic-based resins, placed during an interim period in or over the coronal aspects of the tooth while a crown or bridge is fabricated in the dental laboratory. Due to ease of fabrication and tooth-like appearance these are much more popular than aluminum shells or polycarbonate crowns that typically must be relined before temporary cementation to the tooth.

Defects of the head and neck resulting from cancer surgery, accidents and congenital deformities have been corrected with a wide variety of maxillofacial resin materials, including poly(methylmethacrylate), plasticized polyvinylchloride, polyurethane, heat-vulcanized and room temperature-vulcanized (RTV) silicone and a whole host of various other elastomers. It is important to use prosthetic resin materials with color stability, ease of fabrication, dimensional stability, edge strength, flexibility, low thermal conductivity, biocompatibility, and surface texture to achieve clinical success and patient acceptance. Silicones are the most widely used materials for facial restorations in the United States, with RTV Silicone MDX-4-4210, possessing surface texture and hardness within the range of human skin. The prosthesis can be held in place by tissue undercuts, the patient's glasses or dentures, medical grade adhesives, magnetic attachment to endosseous implant-retained metallic attachments or bars or through a combination of methods. A mold is made from an impression of the defect upon which a prosthesis is fabricated and color matched by mixing small amounts of pigments into the elastomer. Surface coloration and texturing is completed and the patient returns periodically for esthetic touchups to achieve a lifelike match to the skin.

Implants

The surgical placement of endosseous dental implants to support dental restorations has become a routine aspect of

Figure 2. Dental implant demonstrating osseointegration. I = implant, B = bone. (Courtesy of John Keller, University of Iowa College of Dentistry.)

dental care enjoying a high success rate. Commercially pure titanium (CpTi) and Ti-6Al-4V are the materials most commonly used for endosseous dental implants. The stable oxides surfaces formed on CpTi and Ti-6Al-4V have proven to successfully biointegrate with bone. The terms osseointegration and functional ankylosis are used to describe the direct bone apposition on the implant surface giving evidence to support a direct biochemical bonding (Fig. 2). The clinical success of these implants depends not only on osseointegration, but also the quantity, quality and distribution of bone at the implant site, the technical skill during surgical placement, and the timing and degree of mechanical loading under function. Many other factors play a role but six biological and technical factors are recognized as key to implant success: (1) implant surface texture, (2) biocompatibility, (3) implant design, (4) host tissue condition, (5) surgical technique, and (6) loading conditions.

Lower success is observed in areas of the mouth that may have less cancellous bone or thin cortical plates such as the posterior regions of the maxilla. Therefore, attempts are made to manipulate the osseous response to the implant so that the bone quantity and quality at the implant interface is optimized for the clinical requirements. This will not only help the routine implant but is especially important for those patients with: (1) poor bone

quality, (2) heavy masticatory loading, and (3) the need for multiple tooth replacement. Surgical procedures are also utilized that enhance the osseous tissues at the intended implant site by auto- or allo-grafting.

Implant surface modifications have been heavily investigated with every major manufacturer offering various implant designs and surface textures. Two of the most thoroughly investigated and successful surfaces are machined titanium and titanium plasma-sprayed (TPS) surface, with the latter significantly increasing the surface area for bone contact. These rougher surfaces have been shown to require higher forces to be removed from the bone than do smoother surface implants and may allow: shorter healing periods, the use of less invasive shorter implants and may not require bicortical implant engagement. Improving the bone adaptation through microretentive mechanisms can be divided into those that attempt to enhance the immigration of new bone through surface topography, that is, osteoconduction, and those that attempt to manipulate the type of cell response and growth for new bone formation, that is, osteoinduction. Osteoinductive methods also include the use of the implant as a delivery device for biomolecules for the induction of the desired response. A complex cascade of molecular and cellular processes occur after the placement of the implant into a surgical site, many of which are just now beginning to be understood, leading to the possibility of implant-mediated tissue engineering. Calcium phosphates or "hydroxyapatite" can also be coated on titanium implants and have been documented to create a very intimate bone-to-implant contact with a reduced healing period; however, the long-term results are less favorable than that achieved with TPS due to surface degradation and coating separation problems.

Macroretentive features are also part of the implant design including: screw threads, solid body press-fit designs, and sintered bead technology. These macroretentive features are intended to improve initial implant stability and enhanced bone ingrowth. Without the aid of a periodontal ligament (present between the natural tooth root and bone) the bone responds most favorable to compressive loading, which must accounted for in the implant design.

The original guidelines for implant success have changed over time with an increased use of nonsubmerged (not covered by the gum tissue) and single-staged surgical techniques (immediate abutment placement). These time- and cost-saving changes have come about after studies revealed similar end-results, in terms of "biological width" (composed of junctional epithelial and connective tissue attachment) and clinical survival rates. Considerations such as these are blurring the distinction between the clinical healing period (Phase I) and the functional period (Phase II). Additionally, studies have shown similar clinical predictability using both solely implant supported and mixed tooth-implant-supported fixed partial dentures (bridges), while the use of cemented rather than screw-retained prostheses have reduced technique complications.

Abutments of either titanium or alumina, as compared with those abutments of more "esthetic" quality, such as gold alloys or dental porcelains, are most likely to have favorable soft-tissue healing with formation of a

physiological epithelial and connective tissue attachment without subsequent bone resorption. Therefore, surgical techniques to help hide the prosthesis-abutment in the casual viewing region of a patient's mouth by careful peri-implant soft tissue manipulation with proven implant materials is currently recommended.

As work continues to optimize the osteoconductive (passive) response to implant surfaces, research will also progress toward predictable osteoinductive (active) responses. As hard and soft tissue responses are optimized through surgical protocols and biomaterial influences, healing phases will be shortened, retention rates will be increased, and loading capabilities will be improved, allowing the placement of fewer, less invasive and less expensive implants for predictable long-term, implant supported prostheses.

SUMMARY

This article briefly reviewed those commonly used metal, ceramic, polymer, and composite materials used in dentistry for the restoration of individual teeth or the replacement of missing teeth. Restorative materials include noble and base metals, resin based composites, glass ionomers, ceramics, acrylics, and amalgam alloys. These materials are either directly placed into the prepared tooth cavity or cemented in place after laboratory fabrication. An increasing number of "fillings" are retained by the use of dental adhesives. The dentist, in consult with the patient, must take several factors into consideration in the selection of restorative materials, to include (1) chewing forces, (2) esthetic demands (3) strength of remaining tooth structure, (4) diet, (5) hygiene, and (6) cost. No one material type possesses all the desired physical properties; therefore, several materials are required for successful dental restoration.

Our population is living longer while retaining more of their teeth. With the increased emphasis on preventive dental care, increased awareness and the desire for health, our population will require more partial and single tooth restorations or replacements, especially in the area of root caries and less of a need for removable partial dentures, complete dentures and fixed bridges. Improvements in adhesive dental procedures and direct placed tooth colored resin-based composites will allow more conservative dental care. The interplay of biomaterials and biomolecules may also lead to the predictable regeneration of hard and soft tissues, while tissue engineering may someday lead to the induction of whole tooth regeneration.

INTRODUCTION

Biomaterials are materials of synthetic as well as of natural origin in contact with tissue or biological fluids, including metals, ceramics, polymers, and composites. The main advantages of polymeric biomaterials over ceramics and metals are the variety of composition, properties and available forms (solid, hydrogel, and solution), and ease of fabrication into complex shapes (films, sheets, fibers, powders, etc.) and structures because synthetic polymers are easily tailored to specific applications. In addition, polymeric materials are much lighter than metals and ceramics. Since most natural biomaterials are polymeric, mimicking the function and/or structure of natural materials (e.g., skin) is more easily achieved with polymers or polymeric composites than metals and ceramics. As with other biomaterials, there are some basic requirements for polymeric biomaterials. They must be (1) nontoxic, for example, not causing carcinogenesis, pyrogenicity, hemolysis, sustained inflammation, and allergy; (2) biocompatible, that is, not causing foreign body reactions, such as complement activation, thrombus formation, collagenous tissue encapsulation, calcification, and compatibility with the contact tissue in physical and mechanical properties; (3) sterilizable with autoclave, dry heating, ethylene oxide, gas plasma or γ irradiation, or be produced in a sterile fashion so no postmanufacture sterilization is required (1a).

Synthetic polymers have been widely used in biomedical devices, for example, hard and soft tissue implants, extracorporeal devices, drug delivery systems, and medical disposable supplies. They exhibit diverse properties, ranging from hydrophobic, non-water-absorbing materials (e.g., polyethylene, polypropylene, and polytetrafluoroethylene), to hydrophilic, water-swelling hydrogels [e.g., poly(hydroxyethyl methacrylate)], and to water-soluble materials [e.g.,

poly(vinyl alcohol)] (2a). Biological polymers are obtained from animals, plants, bacteria, or other living creatures. Their remarkable advantages over synthetic polymers include their excellent physiological activities. These activities include cellular activity regulation (e.g., hyaluronic acid), selective cell adhesion (e.g., collagen), and similar properties to natural tissues (3). Most biopolymers are biodegradable, so they are suitable for use in temporary medical devices, drug-delivery systems, and tissue engineering scaffolds.

This section introduces the synthesis methods of generic polymers, and the effect of composition and structure on their properties. Following this, 13 groups of polymers that have found wide biomedical application are reviewed and their properties and uses are discussed.

POLYMERIZATION—SYNTHESIS

Polymers are long molecules made up of a large number of simple repeating units. They are prepared from monomers through a process called polymerization. Small monomer molecules react chemically to form either linear chains or three-dimensional (3D) networks. Conventionally polymerization mechanisms are divided into two main categories: condensation polymerization (also called step-growth polymerization) and addition polymerization (also called chain polymerization).

Condensation or Step-Growth Polymerization

Condensation polymerization occurs between an organic base (e.g., an alcohol and amine) and an organic acid (e.g., carboxylic acid and acid chloride), and a small molecule (e.g., water) is condensed out during the reaction. In a condensation reaction to combine two monomers together to form a dimer, each monomer molecule loses an atom or a group of atoms at the reactive end, leading to the formation of a covalent bond between the two molecules, while the eliminated atoms bond with others to form small molecules. The dimers can react with each other or with unreacted monomers until finally a long molecule is generated. An equilibrium exists between the reactants and products during condensation polymerization. The condensate (e.g., water) should be removed to drive the reaction toward the product direction. A high molecular weight product can be obtained only after a sufficiently long reaction time.

The reaction between a diacid and a dialcohol to produce an ester is a typical condensation polymerization example.

Some condensation polymers used as biomaterials are given in Table 1. They are typically synthesized from reactions of acids and alcohols to produce polyesters, reactions of acids with amines to produce polyamides, or reactions of alcohols or amines with isocyanates to produce polyurethanes or polyurea, respectively.

Synthesis of biopolymers is very complicated, but typically involves enzyme-catalyzed condensation polymerization occurring in animal or plant cells, or in microorganisms via their metabolic pathways (4,5a).

Table 1. Typical Condensation Polymers

Polymer	Repeat Unit
Polyurethane	$-\overset{\text{O}}{\parallel}{\text{C}}-\text{NH}-\text{R}-\text{NH}-\overset{\text{O}}{\parallel}{\text{C}}-\text{O}-(\text{CH}_2)_x-\text{O}-$
Silicone rubber	$-\text{O}-\overset{\text{(CH}_3)_3}{\text{Si}}-$
Polyamide (Nylon 66)	$-\text{HN}-(\text{CH}_2)_6-\text{NH}-\overset{\text{O}}{\parallel}{\text{C}}-(\text{CH}_2)_4-\overset{\text{O}}{\parallel}{\text{C}}-$
Poly(ethylene terephthalate)	$-\text{O}-\text{CH}_2-\text{CH}_2-\text{O}-\overset{\text{O}}{\parallel}{\text{C}}-\text{C}_6\text{H}_4-\overset{\text{O}}{\parallel}{\text{C}}-$
Polycarbonate	$-\text{O}-\text{C}_6\text{H}_4-\overset{\text{CH}_3}{\underset{\text{CH}_3}{\text{C}}}-\text{C}_6\text{H}_4-\text{O}-\overset{\text{O}}{\parallel}{\text{C}}-\text{O}-$
Polyacetal	$-\text{O}-\text{CH}_2-$
Polyglycolic acid (PGA)	$-\text{CH}_2-\overset{\text{O}}{\parallel}{\text{C}}-\text{O}-$
Polylactic acid (PLA)	$-\overset{\text{CH}_3}{\text{CH}}-\overset{\text{O}}{\parallel}{\text{C}}-\text{O}-$

Addition or Chain Polymerization

Addition polymerization occurs among small molecules with double bonds. Polymer chains are formed by opening-up double bonds of unsaturated monomer units and successive addition to a growing chain with an active center. No small molecule byproducts are formed during addition polymerization. Consequently, the composition of the repeating unit of the polymer is identical to that of its monomer. Addition polymerization takes place in three distinct steps: initiation, propagation, and termination. Initiation occurs by an attack on the monomer molecule by a free radical, a cation, an anion, or Ziegler–Natta catalysts; accordingly, addition polymerization can be divided into four types: free-radical polymerization, cationic polymerization, anionic polymerization, and coordination polymerization. No matter how the reaction is initiated, once a reactive center is created, many monomers are added onto it and the molecule chain grows very large within a few seconds or less, so the addition polymer size (i.e., molecular weight) is independent of reaction time. Unlike condensation polymerization, no dimer, trimer, or other intermediates can be found in addition polymerization. Polymerization of ethylene is a typical example of addition polymerization.

Typical addition polymers are listed in Table 2.

Table 2. Typical Addition Polymers

Polymer	Repeat Unit
Polyethylene	$-\text{CH}_2-\text{CH}_2-$
Polypropylene	$-\text{CH}_2-\overset{\text{CH}_3}{\underset{ }{\text{C}}}-$
Polyvinyl chloride	$-\text{CH}_2-\overset{\text{Cl}}{\underset{ }{\text{C}}}-$
Poly(terafluoroethylene) (Teflon)	$-\overset{\text{F}}{\underset{ }{\text{C}}}-\overset{\text{F}}{\underset{ }{\text{C}}}-$
Poly(methyl methacrylate)	$-\text{CH}_2-\overset{\text{CH}_3}{\underset{\text{COOCH}_3}{ }{\text{C}}}-$
Poly(vinyl alcohol)	$-\text{CH}_2-\overset{\text{OH}}{\underset{ }{\text{C}}}-$
Poly(hydroxyethyl methacrylate)	$-\text{CH}_2-\overset{\text{CH}_3}{\underset{\text{COOCH}_2\text{CH}_2\text{OH}}{ }{\text{C}}}-$
Polystyrene	$-\text{CH}_2-\overset{\text{C}_6\text{H}_5}{\underset{ }{\text{C}}}-$

The stereoregularity and branching of addition polymers can be controlled through varying the type of initiator and the reaction conditions (6). Ionic addition polymerization can lead to some control of tacticity and a stereoregular structure. Polymers produced through coordination polymerization have a high degree of stereoregularity. The polyethylene produced with peroxide initiator is highly branched. By using a Ziegler–Natta catalyst, linear, high density polyethylene or ultrahigh molecular weight polyethylene (UHMWPE) can be obtained. Living free-radical polymerization is a newer form of free-radical polymerization. By using rapid initiation, slow propagation, and inhibition of termination and transfer reactions, the molecular structure of polymers can be precisely controlled. This method can be applied to vinyl monomers to produce block, graft, star polymers, polymer brushes, and many other architectures (5a,7).

Molecular Weight and Its Distribution

Almost all polymers consist of molecules (a.k.a., chains) with a variety of lengths, so it is only possible to quote an average value of molecular weight. The length of a polymer molecule is represented by the degree of polymerization (DP), which is equal to the number of repeat units in the chain. The relationship between polymer molecular

weight (MW) and degree of polymerization can be expressed as

$$\text{MW of polymer} = \text{DP} \times \text{MW of repeating units}$$

The number-average molecular weight (M_n) and weight-average molecular weight (M_w) are the most commonly used average values of molecular weight. The number average molecular weight is defined as the sum of the products of the molecular weight of each fraction (M_i) multiplied by its mole fraction (x_i) (Eq. 1), which can be obtained using gel filtration chromatography, light scattering, or ultracentrifugation. Whereas M_w is the sum of the products of the MW of each fraction (M_i) multiplied by its weight fraction (w_i) (Eq. 2), which can be measured with osmometry.

$$M_n = \sum x_i M_i \quad (1)$$

$$M_w = \sum w_i M_i \quad (2)$$

The ratio of M_w/M_n is defined as the polydispersity index (PDI), representing the breadth of the molecular weight distribution. When all the polymer chains have the same length, the ratio is 1. A low polydispersity index is necessary to control physical and mechanical properties of polymers because the short chains usually present when PDI is high degrade properties.

COMPOSITION, STRUCTURE, AND PROPERTIES

The structure and behavior of polymers is strongly temperature dependant. There are two major transition temperatures for polymers: T_g and T_m . The glass-transition temperature is a second-order transition temperature, associated with the amorphous regions of polymers. It marks the onset of significant molecular motion. Above T_g , polymers soften, and become rubber-like and more easily deformed. Below T_g , polymers become hard and brittle, and glass-like. Applications of polymeric biomaterials are related with their T_g values. For example, silicone rubber with a T_g of -127°C is soft and acts as an elastomer at 37°C (human body temperature), while poly(methyl methacrylate) (PMM) used as bone cement with a T_g of 105°C retains high strength, stiffness, and creep resistance at 37°C . The melting temperature is associated with crystalline regions of polymers. It is a first-order transition temperature. Above T_m , the polymer is in a melt liquid state. Polymeric materials with a low T_m value can be melt processed.

Polymer molecules can be linear, branched, or a cross-linked network. Schematic representations are given in Fig. 1. Based on their molecular structure and their mechanical and thermal behavior, polymers are classified into three major categories: thermoplastics, thermosets and elastomers. They are discussed in detail respectively.

Thermoplastics

These polymers soften and harden reversibly with changes in temperature. Both linear and branched polymers are thermoplastic. The properties of thermoplastics can be changed by controlling the following factors.

Figure 1. Schematic representation of different types of polymer molecules.

Molecular Weight. The molecular weight and its distribution have a great effect on the properties of thermoplastics. By increasing molecular weight, the polymer chains become longer and more entangled, resulting in a higher melting temperature and improved strength, including resistance to creep (8a). The strength properties increase with the molecular weight rapidly at first, but level off after reaching a certain point. Uniform molecular length is also important, because short molecules act as plasticizers, which decrease the mechanical properties of polymers. For example, ultrahigh molecular weight polyethylene must have a high molecular weight (MW, $2\text{--}4 \times 10^6 \text{ g}\cdot\text{mol}^{-1}$) and narrow MW distribution (i.e., low PDI) to obtain excellent mechanical properties for orthopedic applications.

Chemical Composition. The changes in the composition of the backbone or side chains also affect the properties of polymers. When atoms that can increase the flexibility of polymer chains (e.g., O and S) are incorporated into the carbon backbone, for example, polyethylene oxide ($\text{CH}_2\text{CH}_2\text{O}$) (T_g : -41°C ; T_m : 69°C), the glass transition and melting temperatures will decrease. On the other hand, the insertion of groups that stiffen the polymer chains markedly raises the T_g and T_m and leads to higher strength and stiffness, as seen in the case of polyethylene

The replacement of pendant hydrogen atoms in polyethylene by other atoms also changes the polymer properties. Large atoms or groups (e.g., methyl groups in polypropylene), hinder the rotation about the backbone, resulting in higher T_g and T_m , strength, and stiffness. Similar results are observed for the polymers with polar pendant atoms or groups [e.g. poly(vinyl chloride), PVC]. van der Waals forces are enforced and even hydrogen bonds may be formed among the chains of these polymers.

Branching. Branching prevents dense packing and crystallization of the polymer chain, and thus reduces the density, melting temperature, strength, and stiffness of polymers. For example, branched low density polyethylene (LDPE) is much weaker than linear high density polyethylene (HDPE).

Tacticity. When the repeat units of a polymer are nonsymmetrical, the location of the side atoms or groups also plays an important role in the structure and proper-

Figure 2. Four types of copolymers.

ties of the polymer. If all the side atoms or groups are on one side of the main chain, the polymer is termed isotactic. In a syndiotactic polymer, the side groups alternatively appear on both sides of the chain. In both cases, the polymer is stereoregular or stereotactic. Polymer chains with stereoregularity are better able to crystallize, resulting in high T_m , stiffness and less solubility. In an atactic polymer, side groups are randomly distributed along the molecular chain. Atactic polymers give poor packing, low density, low stiffness, and strength. A typical example of the importance of tacticity is polypropylene. Isotactic and syndiotactic polypropylene have a high T_m (176°C for isotactic, 150°C for syndiotactic) and good mechanical properties. They are widely used as biomaterials, whereas atactic propylene is an amorphous waxlike polymer without any application in biomedical field (8b,9).

Copolymer. Copolymers contain two or more different types of repeat units. According to the distribution of the repeat units, they are divided into four types (Fig. 2). Copolymers are synthesized to obtain the desirable combination of properties of simple homopolymers.

Temperature and Time. Amorphous thermoplastics exhibit viscoelastic behavior, meaning that their properties are time or temperature dependent. At low temperatures or high rates of loading, the polymers behave in a brittle manner. However, at high temperature or low rates, the materials behave as a viscous liquid with chains easily passing one another. The application temperature of most biomaterials is 37°C , which cannot be changed, but the properties of the materials can be controlled by selecting appropriate T_g .

Thermosets

Thermosets are highly cross-linked 3D molecular networks. High density cross-links between molecules restrict the motion of the chains of thermosets, leading to a high T_g , good strength, stiffness, and hardness, but poor ductility. The hard and stiff thermosetting polymers find uses in hard tissues (e.g., bone and teeth). Poly(carboxylic acid) cross-linked with zinc is a hard and rigid cement used for dental restorations (2a,10a). Epoxy resin is sometime used to fill the cavities of the teeth and provide hardness.

Elastomers

Elastomers are lightly cross-linked macromolecular networks. The cross-linking can be covalent or physical. In

thermoplastic elastomers, the hard and tightly packed domains with high T_g (e.g., the hard isocyanate segments in polyurethane elastomer) act as physical cross-links. The loose cross-links prevent viscous plastic deformation while retaining large elastic deformation, so elastomers can be easily stretched to high extension and will go back to their original position on removal of the stress. To act as a biomedical elastomer, a T_g much lower than 37 °C is required, and the polymer should not easily crystallize.

POLYMERS USED AS BIOMATERIALS

Many polymers have been synthesized for biomedical applications. This section just focuses on 13 groups of polymers most commonly used in clinical practice. Each part of the following deals with one polymer or one group of polymers with similar structures. The synthesis, structure, properties, and applications of these polymers will be discussed. Their trade names and related ASTM standards are listed in Tables 3 and 4, respectively, while the thermal and mechanical properties are summarized in Table 5.

Polyolefins

Polyolefins are a group of thermoplastics polymers derived from simple olefins. The most important polyolefins are polyethylene, polypropylene, and their copolymers.

Polyethylene. Commercially available polyethylene has four major grades: LDPE, linear low density (LLDPE), high density (HDPE), and UHMWPE. These materials have good toughness and excellent chemical resistance, and can be easily processed into products at low cost.

Low density polyethylene is produced through the free-radical polymerization of ethylene gas at high pressure

(100–300 MPa) in the presence of peroxide initiator (5c). The synthesis conditions lead to the highly branched structure, low density (0.915–0.935 g·cm⁻³) and crystallinity of LDPE (11a). By using Ziegler–Natta catalyst, HDPE can be synthesized at a low temperature (60–80 °C) and pressure (~10 MPa). Unlike LDPE, HDPE is linear. The linearity leads to good packing of the molecular chains, high crystallinity, and density (0.94–0.965 g·cm⁻³) of HDPE. The LLDPE is produced by a low pressure process in the presence of metal catalysts. Up to 10% of a 1-alkene (e.g., butene-1, hexene-1, and octane) is used as the comonomer. Unlike LDPE, the side chains of LLDPE are very short, resulting in better properties than LDPE (12). All three types of polyethylene can be melt-processed through extrusion or molding. The LDPE cannot withstand sterilization temperatures, so only HDPE and LLDPE are used for biomedical applications (2a). The HDPE is used in tubing for catheters and drains, and in pharmaceutical bottles and nonwoven fabrics. The LLDPE is frequently used for pouches and bags due to its excellent puncture resistance. Biocompatibility tests for PE used as human tissue contact devices, short-term implantation of 30 days or less and fluid transfer devices are given in ASTM F 639 (not applicable for UHMWPE).

When molecular weights of the linear polyethylene obtained through Ziegler–Natta catalyst are $>1 \times 10^6$ g·mol⁻¹, there is a sudden jump in the properties (13). The melt viscosity becomes extremely high so that the polyethylene cannot be processed with conventional extrusion and injection molding. Also it is practically insoluble in all solvents, so only sintering at high temperature and pressure may be used to fabricate the desired products. The polyethylene has excellent mechanical properties and a very low coefficient of friction and wear. It is termed UHMWPE. The UHMWPE, currently

Table 3. Structures and Trade Names of Polymeric Biomaterials

Polymeric Biomaterials	Structure	Trade Names
Cross-Linked UHMWPE	UHMWPE Cross-Linked through Radiation or Chemical Reactions	Crossfire (Stryker Howmedica Osteonics), Marathon (DePuy Orthopaedics), and Durasul (Sulzer Medica)
Polypropylene	Linear macromolecules	Prolene (Ethicon), Surgipro (Syneture)
PTFE	Linear macromolecules, highly crystalline	Teflon (DuPont)
Expanded PTFE	PTFE with microporous structure	GoreTex (Gore)
PMMA	Atactic, linear macromolecules	Plexiglas (Rohm & Haas), Lucite (DuPont)
Polyurethane	Thermoplastic segmented polyurethane elastomers	Biomer (Ethicon), Pellethane (Dow Chemical), Tecoflex (Thermedics)
Polyamide	Linear macromolecules, strong intermolecular hydrogen bonding	Nylon (DuPont)
PET	Linear, stiff macromolecules	Dacron (DuPont)
Polyacetal	Closely packed, linear molecules	Delrin (DuPont)
Poly(hydroxyethyl methacrylate)	Hydrogel	Hydron (Hydron Technologies)
PGA	Biodegradable polymer	Dexon (American Cyanamid)
PLGA	Biodegradable polymer	Vicryl (Ethicon)

Table 4. Polymeric Biomaterials and Related ASTM Standards

Polymer	ASTM Standards	Scope
Polyethylene	F 639	Specifies requirements and physical/biological test methods for PE plastics used in medical devices (not applicable to UHMWPE).
UHMWPE	F 648	Specifies property requirements for UHMWPE powder and fabricated forms used for surgical implants, such as joint implants.
PVC	F 665	Classifies formulations of PVC plastics used for short-term biomedical application.
PTFE	F 754	Specifies the performance of PTFE in sheet, tube and rod shapes used for surgical implants.
PMMA bone cement	F 451	Specifies composition, physical performance, packaging requirements, and biocompatibility of acrylic bone cement.
	F 2118	Provides test methods to evaluate the fatigue properties of acrylic bone cement.
Polyurethane	F 624	Provides guide to evaluate thermoplastic polyurethane in solid and solution forms for biomedical applications.
Silicone rubbers	F 2038	Provides information about formulation and use of silicone elastomers, gels, and foams used in medical applications.
	F 2042	Provides information about fabrication and processing of silicone elastomers, gels and foams used in medical applications.
Polycarbonates	F 997	Specifies requirements and test methods for polycarbonates used for medical devices.
Polyacetal	F 1855	Specifies requirements and test methods for polyacetal used for medical devices.
L-PLA	F 1925	Specifies requirements for virgin poly(L-lactic-acid) resin used for surgical implants.
	F 1635	Defines testing methods to assess biodegradation rates and changes in material and properties of poly(L-lactic-acid) resin and devices.

used for fabrications of acetabular cups in hip replacements (Fig. 3), tibial plateau and patellar surfaces in knee replacements, sliding core in spinal disk replacements, and glenoid components in shoulder replacements, has a MW $\sim 2-4 \times 10^6$ g·mol⁻¹. The property requirements of UHMWPE for surgical implants are defined by ASTM F648. Before 1995, γ radiation in air was a standard method to sterilize UHMWPE orthopedic implants. However, free radicals within UHMWPE from gamma radiation caused oxidation and property degradation on shelf

aging and *in vivo*. By 1998, all of the major orthopedic manufactures in the United States changed to use gamma radiation in an inert or a reduced oxygen environment, ethylene oxide, or gas plasma to sterilize UHMWPE (14). Despite the recognized success of UHMWPE as loading bearing surfaces in joint arthroplasties, UHMWPE wear debris and associated osteolysis and loosening of implants remains a major obstacle limiting the longevity of current joint replacements. To further improve the wear resistance, highly cross-linked UHMWPE is developed by

cross-linking conventional UHMWPE through chemical reactions, or through gamma or electron beam radiation. Cross-linked UHMWPEs available on the market include Crossfire (Stryker Howmedica Osteonics), Marathon (DePuy Orthopaedics), and Durasul (Sulzer Medica). Both research and clinical applications have demonstrated that cross-linking dramatically reduces the wear rate of UHMWPE (14).

Polypropylene. Like linear polyethylene, syndiotactic and isotactic polypropylene are also polymerized through Ziegler–Natta catalyst. Although polypropylene is similar to polyethylene in structure, polypropylene has a lower density $\sim 0.90 \text{ g}\cdot\text{cm}^{-3}$ and a higher T_g (-12°C) and T_m ($125\text{--}167^\circ\text{C}$). The higher melting temperature makes polypropylene suitable for autoclave sterilization (15). The chemical resistance of polypropylene is similar to high density polyethylene, while its stress-cracking resistance and creep resistance is superior to that of polyethylene. It has an exceptionally long flex life, and thus is used to make integrally molded hinges in finger joint prostheses (11a). Also as a suture material, polypropylene yarn (e.g., Prolene from Ethicon, Surgipro from Syneture) has been used clinically (2a,10b). It causes least fibroblastic response compared with other nondegradable suture materials and does not lose strength after it is implanted.

Poly(vinyl chloride)

Poly(vinyl chloride) is a linear, atactic polymer synthesized through free-radical polymerization. Due to the large volume and high polarity of the chlorine atoms, it is difficult for the molecular chains to rotate and disentangle and hydrogen bonds are formed between adjacent chains, resulting in high strength and stiffness, and T_g (80°C) and T_m (180°C) (10c). Pure PVC is hard and brittle, but with the addition of plasticizers, it becomes soft and flexible. In the medical formulations of PVC, di-2-ethylhexylphthalate (DEHP or DOP) is used as a plasticizer. Plasticized PVC is used in temporary blood storage bags, catheters, cannulae, and dialysis devices. The PVC may pose problems for long-term applications because of possi-

ble extraction of the plasticizer by body fluid. Standard classification for vinyl chloride plastics used in biomedical applications is provided by ASTM F665.

Poly(tetrafluoroethylene)

Poly(tetrafluoroethylene) (PTFE), commonly known as Teflon (DuPont), is made from tetrafluoroethylene through free-radical polymerization in the presence of excess of water for removal of heat. The polymer is highly crystalline ($>94\%$ crystallinity, T_m 327°C), dense ($2.2 \text{ g}\cdot\text{cm}^{-2}$) and insoluble in all common solvents. It is very stable both thermally and chemically, and as a result it is very difficult to process. The PTFE can only be sintered into products at a temperature $>327^\circ\text{C}$ under pressure.

The PTFE has excellent lubricity, its coefficient of friction is very low (0.1), but it is not wear resistant, its modulus of elasticity and tensile strength are very low, and even more importantly it can not maintain shape very well due to the cold-flow (5c). The use of Teflon as the acetabular component material by Charnley (2b) in his total hip replacement design 40 years ago caused a catastrophe. All Teflon cups failed *in vivo*, requiring revision surgery.

Although not suitable for load bearing surfaces, PTFE can be used for other biomedical applications because of its excellent biocompatibility and stability. Standard specifications for the implantable PTFE are given in ASTM F754. Expanded PTFE (ePTFE) vascular grafts, made by stretching paste-extruded PTFE tubes at a temperature $<T_m$ and then sintering, are soft microporous tubes (GoreTex). They show good clinical results as medium diameter (5–11 mm) vessel grafts, (e.g., femoral and popliteal artery replacements) (10d,16a). However, intimal hyperplasia of smooth muscle cells at the anastomosis frequently leads to their failure. The ePTFE grafts are also popular in hemodialysis as an interposition between radial artery and cubital vein. However, thrombosis occurring at the graft venous ends may be a concern (16b). The PTFE fabrics find applications in heart valve prosthesis as suture ring (10b). Sheets or films of PTFE or its composite with graphite are widely used by plastic surgeons in reconstruction of the maxillo-facial areas (10b). The PTFE tubes are used for middle ear drain, while PTFE shunts are used to carry cerebral spinal fluid from brain to venous in the treatment of hydrocephalus.

Poly(methyl methacrylate)

The commercially important poly(methyl methacrylate) (PMMA) is atactic, which is produced by free-radical polymerization of methyl methacrylate monomer (liquid) using initiator, or thermal, or photochemical initiation. Because of the bulky side chains, atactic PMMA is completely amorphous (T_g : 105°C) and has an excellent light transparency (92% transmission) and a high index of refraction (1.49). The transparent material is familiar as Plexiglas or Lucite. For the same side group argument presented above, the strength and stiffness of PMMA are also relatively high. As a hard thermoplastic polymer, PMMA can be easily formed into any desirable shapes by regular cast, molding, or machining.

Figure 4. Chemical formula of bisphenol-A-glycidyl dimethacrylate (a new bone cement).

Poly(methyl methacrylate) is highly biocompatible and chemical resistant. It has been used in a variety of medical applications including hard contact lenses and intraocular lenses, membranes for blood dialysis, cranioplasty, bone cement for joint prostheses fixation, dentures, and maxillofacial implants.

The PMMA resin used for bone cement and dentures are usually formulated from two components: prepolymerized PMMA solid particles and the methyl methacrylate monomer liquid. When the two components are mixed during a clinical procedure, an easily moldable dough is obtained that cures in ~ 10 min. The liquid monomer polymerizes by free-radical reaction and binds the solid particles together. The composition of a commercial bone cement product (Surgical Simplex) is given in Table 6. Dibenzoyl peroxide is included in the solid component to initiate polymerization of the methyl methacrylate monomer. *N, N*-Dimethyl-*p*-toluidine is an activator to promote self-curing of the monomer at room temperature. Hydroquinone is added as an inhibitor to prevent premature polymerization of the monomer during storage. Barium sulfate (BaSO_4) is a radiopacifier. The methyl methacrylate-styrene copolymer is added to adjust the mixing and handling characteristics (e.g., viscosity, exotherm) of the cement. The physical and mechanical properties of the cement can be controlled through changing the composition and relative proportions of the components, solid particle size and its molecular weight. The requirements for PMMA bone cement are given in ASTM F451. The test methods for its fatigue performance are provided in ASTM F2118.

The PMMA bone cement is inert (no bioactivity), and the fatigue failure occurring at the cement-prosthesis and the cement-bone is a main cause of implant loosening (16c). New bioactive bone cements (BABCs) have been developed to improve the bonding strength and

biochemical properties of PMMA bone cement (17a). These BABCs consist of bioactive glass ceramic powder (e.g., $\text{CaOMgOSiO}_2\text{P}_2\text{O}_5\text{CaF}_2$) and a bisphenol-A-glycidyl dimethacrylate-based resin shown in Fig. 4.

Polyurethanes

Polyurethanes are a family of heterogeneous polymers containing the urethane linkage (NHCOO) and frequently the urethane groups are not the predominant functional groups (5d,18). The most common method to synthesize polyurethanes consists of two steps (Fig. 5). The first step involves formation of an isocyanate terminated prepolymer from polyester or polyether polyols and di- or higher isocyanate. Subsequent reaction of the prepolymer with a chain extender, usually a diol or diamine, produces a multiblock copolymer. These two reactions are a step-growth polymerization, but no condensed byproduct is eliminated, so this type of polymerization is often referred to as a polyaddition or rearrangement polymerization. Due to the multiple choices in the chemistry and molecular weight of the various components, polyurethanes exhibit a broad range of physical properties: from hard and brittle thermoset polymers, through thermoplastic elastomers, to viscous materials. Thermoplastic segmented polyurethanes usually are valuable in producing medical devices (e.g., extruded blood tubing), while the cross-linked ones have received more attention for long-term devices and implants. The ASTM F624 provides test methods to evaluate properties of thermoplastic polyurethanes.

Figure 5. Two-step synthesis of polyurethane.

The isocyanates used for linear polyurethane elastomers are aromatic diisocyanates [e.g., toluene diisocyanate (TDI) and 4,4'-diphenylmethane diisocyanate (MDI)], which comprise the hard segments of the thermoplastic elastomers with the chain extenders. The soft segments of the elastomers are blocks of polyether polyols (usually polyethylene glycol PEG) or polyester polyols. These two types of segments tend to aggregate into different domains, resulting in microphase separation with the hard blocks acting as physical crosslinks in the thermoplastic elastomer.

Polyurethane elastomers are good materials for use in medical devices due to their good mechanical properties and blood compatibility. The very high flexural endurance of polyurethanes makes them major candidates for cardiovascular implants. Biomer (Ethicon, NJ), Pellethane (Dow Chemical, TX), and Tecoflex (Thermedics, MA) are all polyurethanes under different trade names. They have been widely used for cardiac guiding catheters, pacemaker lead insulation, vascular prostheses, artificial heart assist devices, blood tubing, and hollow fiber dialysers. Polyurethanes are also used extensively for wound healing. Bioclusive (Johnson and Johnson Medical, Inc.) and Opsite (Smith and Nephew) are two types of nonabsorbent wound dressings made from polyurethane films.

Although these ether-based polyurethanes are stable *in vitro*, environmental stress cracking after implanted makes their long-term biostability questionable. The microcracks caused by biological peroxidation of the ether linkage not only weaken the materials, but also serve as nucleation sites for thrombus formation (19a). To solve the problem, polycarbonate-based polyurethanes have been developed and investigated to provide an unsurpassed combination of biostability, strength, flexibility, and ease of manufacture.

Silicone Rubbers

The basic repeat unit of silicone rubbers is dimethyl siloxane. They are made by vulcanization of silicone prepolymers or by ring-opening polymerization of octamethylcyclotetrasiloxane. Silicone prepolymers are obtained by the hydrolysis of dimethyldichlorosilane with water. The hydrolysis product is dimethylsilanol, which is unstable and condenses to low molecular weight silicone prepolymers in the presence of hydrochloric acid (5d,12,17b) (Fig. 6). Silicone prepolymers are also useful as silicone oil. The vulcanization of the prepolymers can be performed at room or at high temperature. Room temperature vulcanization silicone rubbers are available in two formats: one-component or two-component. The one-component silicone rubbers result from a reaction between atmospheric moisture and a mixture of silicone prepolymers and catalyst, whereas the two-component systems result from a reaction between prepolymers and a cross-linker added to initiate the reaction. In heat vulcanization, peroxides are

used to produce free radicals on heating that react with the side groups of prepolymers to form cross-links. Several copolymer silicone rubbers have been developed to meet diverse biomedical applications. Copolymers made from dimethyl siloxane and a small amount of methylvinyl siloxane result in medium and hard grades of silicone rubbers. Soft grades of silicone rubber are copolymers with phenyl-methyl-siloxane. Requirements for medical grade silicone gels and elastomers are provided in ASTM F2038 and F2042.

Silicone rubbers have many excellent properties, (e.g., extreme inertness, nonadhesion, high oxygen permeability, thermal and oxidative stability, and high flexibility at low temperature). A major disadvantage of silicone rubbers is poor resistance to tearing. Silicone rubbers are one of the widely used polymeric biomaterials in modern medicine. Since Alfred Swanson introduced silicone rubber for small flexible joints in 1960s, > 600,000 silicone rubber hinge or end-bearing prostheses have been implanted to treat arthritic conditions of finger and wrist joints. These silicone implants are successful in relieving pain and restoring motion of joints at initial stage, but their long-term durability and biocompatibility have been questioned. Silicone microparticles from fragmentation or wear may cause immune reactions (20a). The largest use of silicone rubber and gel has been in breast augmentation and reconstruction (19b). Gel bleed, calcified deposit, and autoimmune diseases are concerns related to these gel-filled silicone rubber bag implants. In the earliest prosthetic cage-and-ball heart valves, silicone rubber was used for the ball, but uptake of blood lipids by the silicone led to the swelling and fracturing of the ball after several years of service. Presently, silicone rubber is only used for the suture ring in bioprosthetic heart valves (10d). Other medical applications of silicone rubber include soft contact lenses, catheters and drainage tubing, oxygenator membranes, wound dressings, and facial implants.

Polyamides

Polyamides are known as nylons. They are divided into two types: dyadic nylons and monadic nylons. The dyadic nylons, (e.g., nylon 66 and nylon 610) are made through condensation polymerization of diamine and dicarboxylic acid or its derivatives (Fig. 7a). There are two numbers following the name, the first for the number of carbon atoms in the diamine and the second for that in the diacid. The monadic nylons (e.g., nylon 6 and nylon 11) are made through self-amidation of an amino acid or through ring-opening polymerization of a cyclic lactam (Fig. 7b). The single number following the name represents the number of monomer carbon atoms. These polymers have high crystallinity and very strong intermolecular hydrogen bonding between amide groups. Thus, they have excellent fiber forming properties, and the strength along the fiber

Figure 6. Formation of silicone prepolymer.

Figure 7. Synthesis of nylons: (a) nylon 66, (b) nylon 6.

direction is very high. The number and distribution of amide groups play an important role in determining the properties of nylons. Generally, the T_g and tensile properties increase with increasing the number of amide groups. For example, nylon 66 is stronger than nylon 610 and nylon 6 is stronger than nylon 11 (11a).

Nylon plastics are stiff and tough, and have a high abrasion resistance; but they are sensitive to water. Water adsorption reduces their strength and lowers their T_g . It is the amorphous region of polyamide chains that is sensitive to the attack of water. The greater the degree of crystallinity, the less the water adsorption. Nylons are used as surgical sutures, components of dialysis devices, hypodermic syringes, and intracardiac catheters.

Polyesters

Polyethylene Terephthalate. Polyethylene Terephthalate (PET) is known as Dacron. Commercially, it is manufactured by ester interchange polymerization between dimethyl terephthalate and excess glycol (1:1.7). The reaction has two stages (5d,12) (Fig. 8). In the first stage, methanol is displaced from dimethyl terephthalate by glycol. In the second stage, the excess glycol is driven off under vacuum. The polymer is semicrystalline with a T_m value of 265 °C and a T_g value of 80–120 °C depending on crystallinity. The PET fibers made from melt spinning have high strength and good crease resistance, so they are used as nondegradable surgical sutures. Like PTFE, PET is also hydrophobic and hydrolysis resistant. The knitted or woven PET tubes are widely used for large diameter (12–30 mm) and medium diameter (5–11 mm) vascular grafts. However, Dacron graft devices are not

fully satisfactory. Thrombosis is a major problem. Another drawback of Dacron grafts is the need for preclotting the grafts with autologous blood before implantation to prevent bleeding from their micropores (16a).

Polycarbonates. Bisphenol A polycarbonate is the only commercially significant polycarbonate product, so this material is often referred to as polycarbonate. It is prepared either by the reaction of phosgene with bisphenol A, or by ester interchange of a diphenyl carbonate with bisphenol A (Fig. 9). Polycarbonate is a clear, tough material. It has excellent mechanical and thermal properties (T_g 150 °C). The high transparency and impact strength make polycarbonate useful as lenses for eyeglasses and safety glasses, and housings for oxygenators and heart-lung bypass machines (2a). Requirements for medical grade polycarbonates are given in ASTM F 997.

Polyacetal

Polyacetal, also called poly(oxymethylene) is known as Delrin (DuPont). It is prepared from formaldehyde in an inert hydrocarbon solvent along with an initiator (ring-scission polymerization) (5d). The polymer has a high melting temperature (184 °C) and low glass transition temperature (−82 °C) (5b). It is lubricious, strong, and has good dimensional stability, resistance to creep and fatigue, high abrasion, and chemical resistance. A cementless polyacetal isoelastic femoral stem was introduced in the early 1970s to solve two important problems in total hip replacement (THR): stress shielding and cement disease. The modulus of elasticity of polyacetal (~5–13 GPa) is close to that of bone, thus providing the condition of isoelasticity. However, the prostheses were unsuccessful in clinical practice due to high rate of loosening (20). The successful use of polyacetal in medical devices includes use in the valve disk in Penn State circulatory-assistant devices, which is one of only two approved for heart replacement by the U.S. Food and Drug Administration (FDA) (16d). Specifications for polyacetal are given in ASTM F 1855.

Hydrogels

Hydrogels are 3D networks of hydrophilic polymers held together by chemical or physical crosslinks. Typical methods to prepare hydrogels include irradiation, chemical reactions, and physical association. Hydrogels have inherently weak mechanical properties, so hydrophobic

Figure 8. Synthesis of poly(ethylene terephthalate).

Figure 9. Synthesis of polycarbonate through (a) phosgene, (b) ester interchange.

constituents are often incorporated to improve the mechanical strength. The low interfacial tension with surrounding biological fluids makes hydrogels desirable for nonfouling surfaces (10c). Hydrogels tend to calcify under physiological conditions, limiting the use of hydrogels as implantable biomaterials (17c).

Poly(hydroxyethyl methacrylate) (PHEMA) is the most frequently used hydrogel. It is a rigid acrylic polymer when dry, but it takes up $\sim 40\%$ water when wet and changes into an elastic gel. PHEMA hydrogel is transparent, and thus is used for soft contact lens (17c). Other more hydrophilic hydrogel monomers, such as methacrylic acid and 1-vinyl-2-pyrrolidone, are often copolymerized with hydroxyethyl methacrylate to improve the oxygen permeability coefficient and water adsorption of PHEMA hydrogel. This hydrogel was also the first successfully used for wound dressings under the trade name Hydron (17c).

Poly(vinyl alcohol) is a water-soluble polymer. Solutions of PVA are used as ophthalmic lubricants and viscosity-increasing agents. The solution thickens the natural film of tears in eyes. Poly(vinyl alcohol) can crystallize even in its highly hydrolyzed state, and thus it has a relatively high tensile strength for a hydrogel. The PVA hydrogel is a candidate material for artificial articular cartilage in reconstructive joint surgery, and has been used for releasing bovine serum albumin. Physically cross-linked PVA hydrogels prepared by freeze-thaw processes have been investigated for protein-releasing matrix (17c).

Other synthetic hydrogels of biomedical interest include polyacrylamides, poly(*N*-vinyl-2-pyrrolidone), poly(methacrylic acid), and poly(ethylene oxide).

Biodegradable Synthetic Polymers

The interest in biodegradable polymers has dramatically increased in recent years, because these biomaterials do not permanently leave residuals in the implantation site, do not elicit permanent foreign-body reactions, and avoid second surgeries in the case of temporary implants like fracture fixation devices (10c,11b,17d). The major biome-

dical applications of biodegradable polymers include: temporary scaffolding and barrier, drug delivery matrix, tissue engineering scaffolds, and adhesives. Biodegradable polymers are generally hydrophilic. They degrade either by simple hydrolysis without enzyme catalysis or by enzymatic mechanisms. The degradation products should be inert or a natural metabolite of the body (11b).

The most commercially successful biodegradable polymers are polyglycolide (PGA), polylactide (PLA) and their copolymer poly(glycolide-*co*-lactide) (PLGA). The polymers PGA, PLA, and PLGA are a group of poly α -hydroxy acids belonging to absorbable polyesters. They degrade by bulk hydrolysis of their ester bonds. The hydrolysis byproduct of PLA is lactic acid, which is a normal byproduct of anaerobic metabolism in the human body (17e). The degradation of PGA involves both hydrolytic scission and enzymatic degradation, and the product is glycolic acid that can be eliminated by the metabolic pathway as carbon dioxide and water (1b).

Polylactide is prepared in the solid state through ring-opening polymerization. It has four stereoisomers: *D*-PLA, *L*-PLA, *DL*-PLA, and *meso*-PLA. The most frequently used forms in biomedical practice are *L*-PLA, and *DL*-PLA (2c). The *L*-PLA is a semicrystalline polymer with a T_m of 159–178 °C and T_g of 54–59 °C (17e). Compared with other biodegradable polymers, *L*-PLA exhibits high strength and modulus, and a very slow biodegradation rate. It is suitable for light load-bearing applications (e.g., orthopedic fixation devices, vascular grafts, and surgical meshes). Self-reinforced *L*-PLA bolts, screws, pins and anchors have been used for bone fracture fixation (1b). The *DL*-PLA is an amorphous polymer with a T_g of 51 °C. It degrades very fast, and thus usually is used for drug delivery (11b). The *L*-PLA polymer and its *in vitro* degradation tests are specified in ASTM F 1925 and F 1635, respectively.

Polyglycolide can be synthesized either by direct polycondensation of glycolic acid or by ring-opening polymerization of the cyclic dimers of glycolic acid. Due to tight molecular packing, PGA has a high melting point (225–230 °C). Its T_g ranges from 35 to 40 °C. The PGA degrades

faster than LPLA because it is more hydrophilic (11b) and PGA can be melt spun into fibers and fabricated into sutures, meshes, and surgical products. Dexon (American Cyanamid) is a trade name of polyglycolide products. It has been successfully used for wound closure and sutures (10c,11b). The Properties and degradation rate of PLGA can be controlled by varying the ratio of monomers. Vicryl from Ethicon is a poly(glycolide-L-lactide) random copolymer with 90:10 ratio of glycolide to lactide. It completely degrades *in vivo* after 90 days, and has been successfully used as surgical meshes and sutures, and for wound closure and drug delivery (10c,21b). Several other biodegradable polymers have been developed and investigated for drug delivery, tissue engineering, and medical devices [e.g., polyorthoesters, poly(ϵ -caprolactone), polydioxanone, and polyanhydride] (11b).

The concern with PLA and PGA is that their degradation products (lactic acid and glycolic acid) may significantly lower the local pH in a closed and less body-fluid-buffered region, leading to irritation at the site of polymer implant (11b).

Smart Polymers

Smart polymers are “polymers that respond with large property changes to small physical or chemical stimuli” (22). The most common stimuli are pH values and temperatures. Some polymers [e.g., poly(hydroxypropyl acrylate), poly(*N*-isopropylacrylamide), and poly(ethylene oxide/propylene oxide) copolymers] exhibit thermally induced precipitation and have a lower critical solution temperature (LCST). The polymers are soluble in water below LCST, but precipitate sharply as temperature is raised above LCST. Pluronic F127 (BASF, NJ) is a polyethylene oxide–polypropylene oxide–polyethylene oxide triblock copolymer with a LCST around the physiological temperature. It is used for controlled release of drugs including proteins and liposomes (23).

In general, pH-responsive hydrogels can be prepared from polymers with ionizable groups (e.g., carboxyl, sulfonic, amino, and phosphate groups). The pH change influences the ionization degree of the polymer to govern its solubility in water. Lysozyme (a cationic protein) immobilized within a hydrogel with phosphate groups is released at pH 7.4 (enteric conditions), but is not released at pH 1.4 (gastric conditions), ensuring the drug is delivered to the small intestines, and is not released in the stomach (17f).

Besides drug delivery, smart polymers can be used for sensors, chemical valves, mechanochemical actuators, specialized separation systems, and artificial muscles.

Biopolymers

Biopolymers are polymers of natural origin that can be obtained from animals, plants, and microorganisms. They are produced during the growth cycles of all organisms by enzyme catalyzed stepwise polymerization rather than a chain polymerization (5a). Biopolymers most frequently used for medical applications are polysaccharides and proteins.

Cellulose is a polysaccharide of plant origin. It is the primary structural component of plant cell walls. The molecular chain of cellulose is linear, consisting of D-glucose residues linked by β (1-4) glycoside bonds (Fig. 10a). The strongly hydrogen-bonded structure make cellulose highly crystalline and exceptional in strength, but insoluble in water and most organic solvents, and infusible. Ether and ester derivatives of cellulose, such as cellulose acetate and hydroxyethyl cellulose, have been developed to improve its processability (24). Cellophane (regenerated cellulose) semipermeable membrane was first used for hemodialysis to remove blood waste in the 1960s, and it is still in use today, but mostly in hollow fiber forms. Cellulose acetate (di- and triacetate) membranes and hollow fibers also find in hemodialysis. Hydroxypropylmethylcellulose is the most widely used hydrophilic drug delivery matrix (17f). The matrix tablets can be formed by compression, slugging, or wet granulation. Cellulose and its derivatives are also used as wound dressings.

Hyaluronan (HA) is a natural mucopolysaccharide, present in connective tissues of all vertebrates, which consists of repeating disaccharides of *N*-acetylglucosamine and glucuronic acid (Fig. 10b). Besides inherent biocompatibility, hyaluronan has some other unique properties: viscoelasticity, hydrophilicity, lubricity, and biological activity (regulator of cellular activity) (25). Unlike cellulose, hyaluronan is soluble in water forming a viscous solution, and it is biodegradable. Many derivatives have been developed to improve its residence time in water. Hylan (cross-linked hyaluronan, Biomatrix) and Hyaff (hyaluronan with carboxyl groups esterified by alcohol, Fidia Advanced Biopolymer) are two groups of widely used and commercialized hyaluronan derivatives. Native hyaluronan and Hylan are used for viscosupplementation to treat arthritis, viscosupplementation to prevent adhesion and facilitate wound healing after surgeries, and viscoaugmentation to correct scars and facial wrinkles. Hyaff is widely used for wound dressings as sheets, meshes, or nonwoven fleeces. Hyaluronan and its derivatives have also been investigated for lubricious coatings of biomedical devices, control released drug delivery and tissue engineering scaffolds (26).

Collagens are a family of structural fiber proteins present in all animals (27). They are the most abundant proteins in

Figure 10. Structure of polysaccharides: (a) cellulose, (b) hyaluronan.

vertebrates, widely distributed in pliant connective tissues and tensile structures (e.g., tendon and ligament) as scaffolds to keep their shape, maintain integrity, and support tensile stress. A collagen molecule is composed of three polypeptide chains wound into a triple helix, stabilized by interchain hydrogen bonds. They are subject to degradation by lysosomal enzymes and collagenase. Glutaraldehyde and carbodiimides can be used to crosslink collagens to improve their mechanical properties (10c). Collagens are probably the most common proteins used as biomaterials. They are used in artificial skins, in soft tissue, and plastic surgery to fill up tissue defects, in surgical sutures, vascular grafts, and corneal replacements (11c).

POLYMERIC BIOMATERIALS EVALUATION

Bulk Characterization

Initial characterizations give information about the composition, structure, and physical and mechanical properties of the investigated polymers to examine if the properties match the specific application requirements, and the reproducibility of batch-to-batch properties. Infrared (IR) spectroscopy and nuclear magnetic resonance (NMR) are often used to analyze the chemical composition and structures of polymers. Crystalline and multiphase structures are usually determined using wide- (WAXS) or small-angle (SAXS) X-ray scattering, or transmission electron microscopy (TEM). Differential scanning calorimetry (DSC), and dynamic mechanical analysis (DMA) can provide thermal transition information of polymers (e.g., T_m and T_g). Furthermore, DMA can provide significant insight into the viscoelastic nature of the polymer. The mechanical properties are determined using the standard ASTM methods. A second level of characterizations needs to be made on the candidate materials to investigate if sterilization and physiological environments' exposure significantly change their properties.

Surface Characterization

Biomaterials contact the body through their surface, and thus the surface chemistry and topography determine the host's response to the materials. The surface chemistry of polymers can be characterized with X-ray photoelectron spectroscopy (XPS), attenuated total reflectance Fourier transform infrared (ATR-FTIR) and secondary ion mass spectroscopy (SIMS). Scanning electron microscopy (SEM) and atomic force microscopy (AFM) are typical techniques to determine the surface topography. A contact angle goniometer is used to measure the wettability (i.e., hydrophilicity) of surfaces.

Biocompatibility Assessment

Biocompatibility tests generally include two levels. The first level tests are biosafety testing, while the second level involves biofunctional testing (28). In biosafety tests, the materials or their extracts are tested to see if they are toxic to cultured cells, cause hemolysis or allergic responses, induce heritable genetic alterations, or tissue necrosis after animal implantation. Those materials passing the first

level tests need to be further inspected with the second level tests. This level of testing focuses on the specific functions of a medical device, in which the responses of all the cell and tissue types contacting the device are investigated with both *in vitro* and *in vivo* methods. The functionality of the medical device is also tested during this phase of testing, and changes in material can have significant effects on functionality just as changes in medical device design or function can have significant effects on the biocompatibility of the material.

BIOMATERIALS, SURFACE PROPERTIES OF

SALLY L. McARTHUR
ALEXANDER G. SHARD
University of Sheffield

INTRODUCTION

In the broadest of definitions, biomaterials are nonliving materials that come into contact with biological systems. The point of contact between the two different phases is at the interface, or surface, of the material. It is quite common for the surface of a material to have properties that are not trivially related to the bulk of the material. These differences can arise because of a number of processes, such as surface segregation, surface reactions, contamination, scratching, and phase separation. It should therefore be recognized that the interactions between a biomaterial and the biological medium and in turn, the physical and chemical activity or stability of a medical device, can depend critically upon the properties of the surface.

In general, materials selection for biomedical devices and applications is based on a combination of physical properties, manufacturability, and availability. In many cases, materials are chosen because they have been used previously in medical devices and as such, detailed records of *in vivo* behavior and performance already exist. Due to the costs and time involved with the testing of new materials to meet regulatory standards for safety and efficacy, relatively few materials are currently used in the manufacture of biomedical devices. The most common of these are titanium-based alloys, 316L stainless steels, ultrahigh molecular weight polyethylene (UHMWPE), expanded poly(tetrafluoroethylene) (e-PFTE), poly(ethylene terephthalate) (PET), poly(hydroxyethyl methacrylate) (pHEMA), polyglycolic and lactic acids (PGA and PLA), polystyrene, polyurethanes, hydroxyapatite, alumina, and zirconia.

Of course, mechanical properties are only one of a number of materials characteristics that may be required for biomedical applications. Each biomedical application may desire a range of properties that are directly influenced by the nature of the surface. Specific characteristics and modifications made to biomaterial surfaces include:

1. Orthopedic Devices

Improved wear resistance and frictional properties for joints and bearing surfaces via cross-linking of UHMWPE and the introduction of carbide, nitride and crystalline structures on metallic components.

Bone conductive coatings for improved osseointegration via implantation of specific chemical species (e.g., Ca, P) into metals and deposition of hydroxyapatite coatings

2. Cardiovascular Devices

Improved hemocompatibility via diamond-like carbon (DLC) coatings (e.g., mechanical heart valve leaflets) and via the immobilization of biomolecules to promote epithelialization

Short- and long-term drug delivery via degradable polymeric coatings (e.g., stents).

Polymeric barrier coatings to prevent transmission of electrical signals and improve corrosion resistance (e.g., pacemaker cases and leads).

3. Diagnostics, Sensors and *in vitro* Applications,

Reflective coatings for optical sensors.

Nonfouling coatings to prevent protein and cell attachment and reduce background signal in biological assays and sensors.

Oriented biomolecule immobilization for DNA, protein, and antibody arrays.

Topographical and chemical patterning of microfluidic devices and sensors for the control of fluid flow and chemical mixing.

4. Tissue Engineering

Improved cell proliferation and growth in culture via oxidation of polystyrene to produce a hydrophilic substrate (tissue culture polystyrene, TCPS).

Immobilization of biological ligands for controlled cell adhesion (e.g., RGD and other cell receptor binding domains).

In this article, we intend to provide a broad overview of the basic properties of surfaces, their interactions with biological systems, and how surfaces can be changed to suit particular biomaterial applications. Of particular importance is the requirement for surface characterization. As stated earlier, differences between surface and bulk properties can arise via a number of different processes. However they arise, it is important to ensure that the surface properties of the material are verified before ascribing any biological effect to the material. To complete this article, we provide an outline of the most commonly employed surface characterization techniques and include references to more detailed texts to aid the interested reader.

PROPERTIES OF SURFACES

One of the most important properties of a surface or interface is that it exhibits free energy. This means that if the surface was extended in some way so that it had a larger

area then work would have to be done. If this was not the case, then for fluid interfaces at least, the surface could grow without limit, eventually resulting in a homogenous mixture. The existence of surface energy leads to a tendency for surfaces to contract resulting in a higher pressure on the inside of curved surfaces. Measuring the interfacial energy between liquids and air is relatively trivial, as the surface may be extended without producing a bulk strain. Thus the energy required to extend an area of surface or, more usually, the force of contraction normal to a length of surface can be directly obtained. Liquid surface tensions scale with the strength of intermolecular interactions in the bulk of the liquid, so hydrocarbons typically have surface energies of $\sim 25 \text{ mN} \cdot \text{m}^{-1}$, water has $72 \text{ mN} \cdot \text{m}^{-1}$ due to hydrogen bonding and the metallic bonding in mercury results in a surface energy of over $470 \text{ mN} \cdot \text{m}^{-1}$ (1).

In contrast, the surface energy of solids cannot be obtained directly. There are, however, a variety of methods of estimating it from a series of contact angle experiments and it is found that the surface energies between solids and air are very similar to those of analogous liquids. However, for most biomaterial applications it is the solid–water interfacial energy that is important. One should note that “low energy” hydrophobic surfaces typically have interfacial energies with both air and water of $\sim 30 \text{ mN} \cdot \text{m}^{-1}$. Hydrophilic surfaces, such as clean glass or aluminium, can have high surface energies in air, higher than $80 \text{ mN} \cdot \text{m}^{-1}$, but have negligibly small interfacial energies with water. The difference between the air and water interfacial energies for glass and aluminium is greater than the surface energy of water, and hence water does not form drops, but completely wets these materials. Protein adsorption, described in detail later, can be thought of as being driven by the minimization of surface energy. A comparison of the surface energies for hydrophilic and hydrophobic materials gives an appreciation of the strength and importance of the hydrophobic interaction, described later, during this process.

Other properties of surfaces that are important are chemistry, mechanical properties, and topology. In the context of a biomaterial, the chemistry of a surface will determine the initial interactions with proteins through ionic, hydrogen bonding, and hydrophobic interactions as well as the promotion of specific interactions by the presence of surface bound ligands. It is important to realize that the surface chemistry of a material may bear little or no resemblance to the bulk chemistry. In many cases, this is due to the presence of thin layers of contaminants that naturally accumulate on the surfaces of all materials. The deliberate alteration of biomaterial surface chemistry is carried out to enhance or inhibit certain properties, usually the alteration of protein adsorption and cell attachment. Whether the surface chemistry is a result of contamination or modification, it is important to specifically characterize the surface to ensure that correlations between biomaterial chemistry and performance are correctly obtained. The mechanical properties of a biomaterial surface are also of some importance, particularly for cellular attachment. It is generally found that cells attach more strongly to rigid substrates and will migrate from soft-to-hard materials. Note that the mechanical properties of some materials, in

particular polymers, may be somewhat different at the surface compared to the bulk. It has been observed, for example, that the glass transition temperature of polymers is reduced close to an interface. The topology of a surface is also important as it defines the surface area of the interface, and has been shown to influence cell behavior (2).

The Adsorption of Proteins at Surfaces

One of the most important events that occur in biomaterial applications is the sequestration of proteins from solution to the surface of the material. Proteins are polyamino acids in which, for each protein, there is a predetermined and specific sequence of amino acids. This sequence is termed the primary structure of the protein. The secondary structure consists of a variety of common folding motifs, such as α -helices and β -sheets. The tertiary structure of the protein comprises the folding and packing of the secondary structure into a particular three-dimensional (3D) shape. For most proteins, the tertiary structure creates unique, and often rather small sites of activity that allow the protein to function (e.g., cell-binding domains). In contrast, synthetic macromolecules form random coils because they lack the well-defined structure that allows the strong bonding that occurs between different parts of the protein chain.

When one considers protein adsorption at interfaces, it is common to draw analogies to the adsorption of synthetic macromolecules. While these comparisons are extremely useful, it is important to remember that proteins are capable of site specific and highly selective binding, whereas synthetic macromolecules in general are not. Examples of such selective binding include the much utilized affinity of avidin for biotin and the binding of antigens to antibodies. Protein adsorption occurs primarily due to a number of intermolecular forces. These include ionic and hydrogen bonding and the hydrophobic interaction (3). Although the ionic interaction is rather strong in solid materials, in aqueous media it is diminished due to strong ion-dipole interactions with water, the high dielectric constant of water and the presence of other solvated ions that cause a decrease in the effective range of ionic interactions. Nevertheless, ionic interactions are important at short ranges and can have a strong effect on the rate of adsorption of proteins at surfaces. It is commonly observed, for example, that a protein adsorbs most rapidly to an uncharged surface when it is at its isoelectric point, that is, when it is itself uncharged. The presence of a charged interface can decrease or increase the rate of adsorption depending on whether the protein has a like or an unlike total charge. Furthermore, if the protein has a dipole moment, then it may be possible to influence the orientation of the protein upon adsorption at a charged surface.

Hydrogen bonding is a particularly strong example of a dipole-dipole interaction. A hydrogen atom bound to an electronegative element such as oxygen or nitrogen forms a strong association with a lone pair of electrons on another electronegative atom, which may be part of another molecule. There is no great driving force for the formation of hydrogen bonds in the presence of water, since water very effectively makes such bonds. Without the generation of highly specific geometries of complementary hydrogen donors and acceptors, hydrogen bonding is almost certainly

not a major driving force for adsorption of proteins at interfaces.

The "hydrophobic interaction" is something of a misnomer, since the driving force is in fact the formation of hydrogen bonds in water and not the attraction between two hydrophobic species. Water cannot form hydrogen bonds with regions of predominantly hydrocarbon species, whether these are part of a protein or on a surface. The result is that at such an interface water is in a state of higher free energy than if the interface was not present. Hydrocarbons thus tend to aggregate together to minimize the area of contact between themselves and water and lower the free energy of the system as a whole. These interactions are critical to the folding of proteins, with the interior of the protein generally consisting of hydrophobic amino acids and the exterior of hydrophilic amino acids. It is undoubtedly also an important interaction in the adsorption of proteins at interfaces. While the exterior surface of most globular proteins contain few hydrophobic sites, if the protein can unfold upon the surface (denature) then many more such sites become available.

When a surface is exposed to a solution of a single protein it is generally found that adsorption occurs rapidly and in many cases is diffusion limited. It is usual for adsorption to reach a maximum at a single layer with close contact between adsorbed proteins. Following adsorption, the rate of desorption from the surface is extremely slow. Proteins cannot commonly be removed from surfaces simply by changing the protein solution for pure solvent. However, if other proteins are present there may be exchange between adsorbed and solvated proteins. This includes self-exchange, as has been demonstrated by the exchange of unlabelled proteins with their radiolabeled analogues (4). Different proteins can have different affinities for surfaces, so that one protein may adsorb initially because it is in a high solution concentration, but at later times be displaced by other proteins that have higher affinity, but are in low concentrations. This effect is named after Leo Vroman and the classic example is the adsorption of proteins from serum that occurs in the order albumin, fibrinogen, and high molecular weight kininogen. It is also thought that immunoglobulin G adsorbs transiently between albumin and fibrinogen (5). This exchange can take place in a matter of seconds in pure serum, but may take minutes or hours in diluted serum. It is also noted that the amount of protein that can be exchanged in this manner diminishes the longer the protein is in contact with the surface. This indicates that the initial state of adsorption is metastable and that some activation energy barrier needs to be overcome for an adsorbed protein to reach a free energy minimum. It is possible that this energy barrier relates to the unfolding of tertiary or secondary structure and represents a denaturation of the protein.

Although the precise details of protein adsorption are unclear, it is generally agreed that the stability of adsorbed protein layers derives from the large number of contact points possible between a single protein molecule and a surface. Although each individual contact may be weak and temporarily displaced by smaller molecules the probability of breaking enough bonds for the protein to actually desorb is extremely small. The stability of an adsorbed layer is

therefore related to both the strength of individual interactions with the surface and the number of interactions. One should expect on this basis that, neglecting the detailed interactions and protein conformation, a high molecular weight protein should displace a low molecular weight protein because it is able to form more bonds to the surface. It is instructive to note that this trend is at least partially followed in the Vroman effect, the exception being high molecular weight kininogen that has a slightly lower molecular weight than fibrinogen.

Cell Behavior at Surfaces

In comparison with protein adsorption, the adhesion of cells to a biomaterial surface is a rather slow process. In standard cell culture, the adsorption and equilibration of proteins at the surface will occur much more rapidly than cellular attachment. The behavior of cells at a surface is thought to be governed by the initial layer of protein. Cells with surfaces via interactions of their transmembrane proteins (e.g., integrins) with proteins in the extracellular matrix. One approach to encourage cell adhesion is to incorporate such specific sequences at the surface of the biomaterial. A variety of suitable peptide sequences have been reported. From fibronectin, the RGD sequence mentioned above and also REDV, which targets integrins found in endothelial cells, but not blood platelets. Laminin contains sequences such as YIGSR and SIKVAV, which may be employed to encourage nerve cell growth (6).

If cell attachment and growth is to be discouraged, then the biomaterial surface should adsorb as few proteins as possible or only adsorb proteins that are not implicated in cellular adhesion. In the first alternative, this is typically achieved by using a hydrogel-like polymer layer, such as grafted chains of polyethylene glycol. These highly hydrated films provide few sites for protein attachment and cell attachment is also strongly discouraged. It is commonly observed that cells attach poorly to hydrophobic surfaces; this may indicate that there is a selective adsorption of proteins that do not contain binding domains for cells. The modification of surfaces to promote and inhibit cell attachment is discussed later in this article.

Once a cell has formed attachment points at a surface it will strengthen these by accumulating integrin receptors in the vicinity of each site. These eventually form a focal adhesion that acts as a connection between the actin cytoskeleton of the cell and the surface. As these adhesive contacts are made the cell spreads upon the surface and will then enter the normal cell cycle. The formation of focal adhesions is critical to the survival of the cell, without sufficient spreading a cell will normally die. There are proteins that trigger signals from the focal adhesion to the cellular interior such as focal adhesion kinase, which may be implicated in this decision making process.

The movement of mammalian cells is achieved by crawling. This involves the myosin driven contraction of actin filaments in the cell to supply the mechanical power, the detachment of focal adhesions at the trailing edge of the cell and the formation of new adhesions at the leading edge (7). Cells will generally move in the direction in which they can make the largest number of focal adhesions. The sur-

face of a biomaterial can thus be tailored to concentrate cells in particular locations.

SURFACE MODIFICATION

In many cases, surface characteristics can be modified by designing the chemical constituents of the materials, for example, surface segregating components in polymer blends to alter frictional properties; or induced during the manufacturing process, for example, the introduction of topography via die and mould design. However, it is not always possible or practical to use these approaches and secondary processing capable of inducing specific surface properties without detrimentally affecting the bulk characteristics is often required.

In broad terms, surface modification techniques can be divided into two categories: those that treat the existing surface and those that result in the addition of a surface coating. As shown in Table 1, there are a number of different surface modification techniques that are currently used in industry or applied to bioengineering research. In this section, we give a brief overview of a number of these techniques, discuss their advantages, and limitations and give some specific examples of their application.

Plasma Treatment and Polymerization

Plasma-based modifications have been applied, with varying degrees of success, to biomaterials and biomedical devices since the early 1960s. Also termed radio frequency glow discharge (rfgd), the process involves the volatilization of a liquid or gaseous "monomer" into an evacuated process chamber. An electric field at rf is applied across the vapor, ionizing a fraction of the molecules and generating electrons, ions, free radicals, photons, and molecules in both ground and excited states, within the gas plasma. When the resultant reactive species impinge on a surface within the plasma zone, they create reactive sites resulting in alteration of the surface chemistry and properties.

There are two classes of glow discharge plasma modification, treatment and Polymerization. Plasma treatment results in the introduction of chemical species or physical changes to the surface of the material. Plasma treatments are often used to etch polymeric, metallic and ceramic surfaces, remove contaminants, and improve adhesion and hydrophilicity (8). Chemical modifications resulting from plasma treatments can also be used as an activation step for graft polymerization. Plasma generated radicals can be used to initiate polymerization of monomers in the liquid or gas phase, resulting in surface -grafted polymer layers. Typically "monomers" used for plasma treatment include oxygen, argon, ammonia, air, and water.

Plasma Polymerization occurs when a plasma is struck in an organic vapor and results in the deposition of a polymeric film from the vapor phase. Excitation of the monomer results in reactive species impinging on a surface within the plasma zone creating reactive sites that are then used for the covalent attachment of other species and subsequent growth of a coating of controllable thickness (typically tens of nanometers). A wide range of monomers can be used to produce plasma polymer coatings suitable

for biomaterials applications. Table 2 lists some of the most common monomers and their applications. In general, plasma polymers tend to be highly cross-linked and do not reproduce the chemistry of the monomer. In the last 10 years, there has been increasing interest in the production of plasma polymers with the functionality and specific characteristics of their parent monomer. This can range from simple systems for retaining more amine or acid functionality in coatings (30) to more complex cases such as optimizing the protein resistance of poly(ethylene oxide)-like plasma polymers (31) or the production of thermally responsive *N*-isopropylacrylamide (NIPPAM) surfaces (32).

A range of deposition parameters can be used to manipulate the characteristics of a plasma polymer and encourage coating properties that are commensurate with those of a traditionally synthesized polymer. Lower deposition powers, pulsing of the power supply, and copolymerization have all been used to modify the coating properties (30,33,34). The resulting materials have been shown to retain higher monomer functionality and in some cases specific physicochemical properties normally associated with multi-step polymer grafted surfaces (32).

Ion Implantation and Ion-Beam Assisted Deposition

As is the case with plasma techniques discussed previously, the key difference between these two ion-based

surface modification techniques is that ion implantation is a surface treatment while ion-beam assisted deposition (IBAD), as the name suggests, results in a surface coating. In both cases ionized species are produced via an ion source and accelerated in an electric field to reach the surface with kiloelectronvolt energies. Parameters affecting the process include beam energy, dose, and current density as well as the nature of the ion species (20).

In polymers, ion impacts and interactions induce modifications of the macromolecular structure through gas evolution, formation of double bonds, chain scissions, and cross-linking over a thickness corresponding to the penetration depth of the ions. Factors such as chain scission and cross-linking obviously have diametrically opposing effects on the properties of the polymeric surface. Generally, manufacturers utilize ion-beam implantation to increase cross-link density, a factor that can improve wear properties at load bearing interfaces and create polymers with improved chemical resistance. In metals and ceramics, ion implantation can be used to induce the formation of new surface phases, surface disorder. The formation of hard-phase nitride, carbide, and oxide precipitates via ion implantation has been used to harden the surfaces of Ti and Ti alloy orthopedic implants, improving their wear resistance (35). The application of specific ion species such as nitrogen and calcium enables the generation of specific chemical

Table 2. Common Plasma Polymerization Monomers and the Coating Properties They Produce

Monomer	Coating Properties and Applications
Organosilanes (silanes and disiloxanes)	Thermal and chemical resistance Specific electrical and optical properties
Fluorine (e.g.) and hydrocarbon (octadiene) containing	Hydrophobic coatings Chemical barrier coatings, non cell adhesive.
Acid containing (acrylic acid)	Hydrophilic coatings
Amine containing (heptylamine, allylamine)	Acid and amine functionality used for polymer and biomolecule immobilization Controlled cell attachment and growth
Ethylene oxide containing (glymes, diethylene glycol vinyl ether)	Nonfouling coatings Controlled protein and cell adhesion

changes at the surface. The bone conductivity, corrosion and wear resistance of Ti alloys have all been shown to improve after calcium and phosphorous ion implantation (35). On polymeric materials, nitrogen ion implantation has been used to induce complex crosslinked surfaces with increased solvent and wear resistance (36), while the incorporation of silver (Ag) ions has been used to impart antimicrobial properties on indwelling catheters (21). Ion-beam assisted deposition, combines ion-beam implantation with physical vapor deposition (PVD), producing a low stress, uniform and adherent coating via interactions of the ions from the beam with the coating atoms (20). Ion-beam assisted deposition (IBAD) has been used to produce a variety of metallic and inorganic coatings on Co–Cr and Ti alloys, alumina, and UHMWPE (37). Titanium alloy coatings have been produced on Co–Cr components to improved cellular integration in orthopedic applications (38) and bone conductivity has been improved on a variety of metallic substrates with the deposition of adherent hydroxyapatite coatings. Commercially, IBAD is used to produce DLC coatings that are chemically inert, optically transparent, have a low friction coefficient, and are extremely hard. These DLC coatings are used to treat the bearing surfaces of orthopedic implants to improve wear and friction properties and reduce the incidence of wear debris (39). On polymeric substrates, IBAD is used to produce adhesive silver coatings for antimicrobial applications (40).

Plasma Immersion Ion Implantation

Plasma immersion ion implantation (PIII) has a critical advantage over the standard ion implantation methods discussed in the previous section: it is not a line of sight technique, a factor that enables the modification of complex shapes commonly found in biomedical applications. Unlike ion implantation, PIII samples are pulse-biased to a high negative potential relative to the chamber wall and surrounded by high density plasma. Ions generated in the plasma are accelerated across the sheath formed around the samples and are implanted into the surface. Gaseous plasmas can be induced using a variety of sources including rf and microwave, and combining these gas plasmas with a metallic plasma allows interface mixing that result in metallic coatings with low intrinsic stress, significantly reducing the risk of coating delamination (12). Plasma immersion ion implantation has been used to surface modify skeletal prosthetic implants with Ti alloy coatings (for cell recruitment) while maintaining the mechanical properties of the Co–Cr substrate (41) and to deposit carbon and Ti–N coatings on both metals and polymers for improved wear and scratch resistance (12).

Wet Chemical Techniques

There is a vast array of wet chemical techniques that can be used to modify the surfaces of biomaterials. In their simplest incarnation, wet chemical routes for surface modification can involve the immersion of a device in a chemical bath to adsorb polymer to the surface. The complexity of the modification increases incrementally through the

grafting of polymers to form nonfouling and bioresponsive coatings toward the construction of biomimetic surfaces that attempt to imitate the outer surface of a cell and can contain a range of lipids, proteins, and sugars.

Grafted polymer layers can be used to manipulate both the physical and the chemical characteristics of a surface. Grafting can be achieved via a number of routes including covalent coupling, surface graft polymerization; surface segregation and interpenetration of a substrate. One of the most popular current applications is in the generation of nonfouling surfaces via the immobilization of water-soluble polymers like polyethylene oxide (PEO). While there is considerable debate on the efficacy of these coating, recent reviews on surface modification for nonfouling behavior have detailed the critical roles of polymer molecular weight, graft density, and residual charge on the performance of these types of grafted polymer layers (23,42).

An alternative approach to polymer grafting is the self-assembly of molecules to form monolayers. Self-assembled monolayers (SAMs) can be formed spontaneously via a range of specific molecule–surface interactions. Common systems include alkane thiol on gold or silver and chlorosilanes on hydroxyl-terminated surfaces. By tailoring the headgroup chemistry of the immobilized molecules, surface can be designed with a range of properties. Commercially, these systems are currently used as platforms for biosensors and bioarray technologies (43). The well-defined nature of these systems has resulted in their extensive application in research as model systems for protein and cell–surface interaction studies (42).

Increasing focus on the development of coatings capable of eliciting specific biological responses has seen a significant research focus on the incorporation of peptide sequences, particularly from the receptor-binding domains of adhesion proteins, in order to promote cell adhesion (6,27). In more general terms, there is significant interest in the immobilization of a range of biomolecules. Array and sensor technologies require antibody, protein, and DNA immobilization, while the immobilized proteoglycans such as heparin have been used to modulate hemocompatibility of biomedical devices (44). As illustrated in Fig. 1, immobilization strategies for biomolecules can be as simple as nonspecific adsorption or as complex as molecular imprinting. The adsorption of biomolecules tends to result in coatings with limited functionality as the molecules are randomly oriented and tend to be desorbed from the surface over time. Covalent immobilization can eliminate problems associated with desorption, but there is often little control over conformation or orientation and thus activity of the biomolecule can be limited. The use of spacer polymer chains or amino acid sequences between the surface and the protein can reduce the denaturation of the molecule. Examples of this type of approach are the site specific modification of proteins with cysteine that enable immobilization of the proteins in specific orientations on gold (45). The success of strategies designed to present biological ligands can also be maximized if the immobilized molecule is coupled to a surface capable of preventing nonspecific adsorption. In general terms, biological response is influenced by the presentation, average density and the spatial distribution of the immobilized molecule

Figure 1. A range of immobilization strategies for biomolecules at interfaces.

(1). One of the most challenging applications for wet chemical surface modification lies in the development of surfaces that borrow from structures observed in Nature. Surfaces that mimic the structure of a cell wall are increasingly sought for use in biosensors and as model systems to further investigate cell, protein, and pharmaceutical interactions. These systems generally consist of a lipid bilayer that may contain a range of different lipids, transmembrane and membrane proteins, and in some cases oligosaccharides. Critically, these structures need to retain their fluidity; molecules need to be able to move within and through the structure in order to maintain their activity and function. The most simple cell mimetic surfaces discussed in the literature have been based on transferring lipid bilayers onto glass substrates. Under these conditions, a thin film of water lubricates the interface between the glass and bilayer and allows free lateral diffusion. These types of bilayers generally have poor long-term stability, show limited transmembrane protein activity, and cannot be transferred through the air–water interface without disrupting the structure (46). An alternative approach lies in either the formation of hybrid bilayers, where the inner leaflet is formed from alkane thiol on gold (47), or the deposition of the lipids on a polymer support (46). Hydrogel layers can also be used and act as a hydrated cushion that is both a self-lubricating and a spacer, creating an area for protein insertion without affecting protein function. At present, there are a number

of commercial biosensors that utilize this type of technology for disease diagnosis (48).

SURFACE ANALYSIS

The study of surfaces and coatings is an advanced field and ranges from the investigation of elementary chemical processes on single crystals in ultrahigh vacuum (UHV) to the analysis of rather more “dirty” and real surfaces in engineering applications. The development of techniques suitable for surface science has a long history, the driving force for which has only recently included attempting to understand and control biomaterial surface interactions. Table 3 details some of the more common surface analysis techniques used today in the characterization of biomaterials. The physical principles of all the techniques commonly employed today are well understood and have been for many decades. Many of the approaches described here have their origin in the study of elementary chemical and physical processes, the semiconductor industry, and from engineering disciplines.

When considering the choice of surface analytical tools, it is important to appreciate the questions that require answering. A single technique cannot generally provide a complete picture of the surface characteristics. In this section, a description of some of the most commonly used techniques is provided with reference to more detailed and extensive reviews. It is important to note that the techniques fall into two classes, those that operate inside a vacuum and those that can directly probe the biomaterial–water interface. While it is obviously preferable to use those techniques that can perform under ambient conditions, in general these techniques are either not as informative or not as surface sensitive as the vacuum techniques. For this reason, the vacuum techniques are commonly utilized to provide a detailed characterization, but in doing so it must always be under the assumption that the surface is the same in vacuum as it is under water. This is a rather large assumption, particularly if the material is able to reorganize itself relatively easily. The surface energy change following immersion in water can be rather large, as indicated above, and in mixed biomaterial phases components that are absent at the surface in vacuum may dominate when the material is immersed in an aqueous environment. There is evidence for this kind of surface reorientation in the contact angle hysteresis of water on some polymers.

Hysteresis is the difference in contact angle between a water contact line advancing or receding across a surface. For some polymers, the advancing angle is high and the receding angle is low, indicating that at the polymer–air interface the polymer is hydrophobic and at the polymer–water interface it is hydrophilic. As long as the surface is flat and homogenous, this is evidence of surface reorganization. For some materials it is possible to reduce the rate of reorganization by cooling. This is typically achieved by hydrating the sample in air, and then freezing the sample in liquid nitrogen prior to entry into the vacuum chamber. The sample needs to be held at low temperature while the ice on the surface sublimates and then vacuum techniques

Table 3. Surface Analysis Techniques Used in the Characterization of Biomaterials

Technique	Sampling Depth/Height (Spatial Resolution)	Information Obtained	References
Ultrahigh Vacuum			
Static secondary ion mass spectrometry	<5 nm (500 Å)	Chemical	49,50
X-ray photoelectron spectroscopy	2–10 nm (5 μm)	Spectroscopy and Imaging Elemental, chemical Spectroscopy and Imaging	51
Ambient Techniques			
Attenuated total reflectance Fourier transform Infrared (ATR/FTIR) spectrometry	> 100 nm (1 μm)	Chemical	52
Contact angle measurement	<1 nm (1 mm)	Surface free energy, wettability	53
Atomic force microscopy (AFM) Imaging	Atomic = 20 μm Å = μm	Topography, coverage, atomic structure	54
Surface force measurement		Chemical, conformational, structural	
Ellipsometry	Å = 300 nm	Layer thickness, adsorption kinetics	55,56
Streaming potential measurements/electroosmosis	Not applicable	Electrokinetics	57
Surface plasmon resonance	~300 nm	Adsorbed mass and adsorption kinetics	58

can be applied to the surface, which should not have reorganized from the hydrated state (59).

Vacuum Techniques

Traditional surface analysis techniques are usually based on ultrahigh vacuum instrumentation. One of the reasons for this was that much of the initial interest in the field was concentrated upon extremely clean and often highly reactive surfaces. To maintain the surface in this state during the analysis it is important to prevent undesired gas or vapor molecules sticking to the surface and changing its characteristics. This is only possible in ultrahigh vacuum (<10⁻⁹ mbar or so). A second important reason is that to study just the surface and eliminate contributions from the bulk of the material it is necessary to use probe species that strongly interact with matter, such as ions and electrons. These cannot penetrate through more than a few atomic layers, and hence provide highly surface sensitive information. However, the detection of such species normally requires that they travel a considerable distance from the surface. At atmospheric pressure the average distance traveled prior to interaction with gaseous species is too short for the detection systems to work. A vacuum of, typically, 10⁻⁷ mbar or better is required for the techniques described here to operate. In addition, many of the components necessary for the production and detection of probe species can only be operated in vacuum; at atmospheric pressure, they would be irreparably damaged. We will now briefly describe some of the key surface analysis techniques used in the characterization of biomaterials. More detailed information and discussion on the interpretation of these techniques can be found in books by Vickerman (54) and Watts (51).

X-Ray Photoelectron Spectroscopy

During X-ray photoelectron spectroscopy (XPS) analysis, the sample is illuminated with X rays of a particular energy

that causes electrons to be emitted from the sample. This phenomenon is called the photoelectric effect and it is generally found that an X-ray photon imparts all of its energy to a single electron during the process. Since the electrons are bound in orbitals of well-defined energy (binding energy) that are characteristic of the material, the outgoing electrons have a kinetic energy that is essentially the difference between the photon and binding energies. For core level electrons, this binding energy is characteristic of the nucleus to which the electron is closely bound. Only those electrons that are generated close to the surface can escape from the sample without loss of energy due to inelastic collisions with other atoms. Thus, by analyzing the number of electrons emitted from the surface as a function of electron kinetic energy it becomes possible to identify the elements present on, or near to, the material surface. As long as the photon energy is significantly larger than the binding energy of the electron, the probability of generating a photoelectron from a core level is independent of the chemical situation of the element. This means that it is possible not only to identify the elements present but, with appropriate sensitivity factors, quantify the relative amounts of each element.

The chemical situation of the element may, however, have an influence on the binding energy of the core level electron. Chemical bonds to different elements may cause some charge to accumulate on the element of interest, this will directly affect the binding energy of the core electrons. This change in the binding energy is termed the “chemical shift” by analogy to nuclear magnetic resonance (NMR) spectroscopy. The appearance of a chemical shift is extremely useful in surface analysis as it can provide information on how the various elements in the surface are bonded to each other. Where the same element is in a range of chemical environments it is often possible to deduce the fraction of atoms in each environment by careful curve fitting of the spectrum. An example of these types of chemical shifts is illustrated in Fig. 2. In this case, there are chemical shifts evident in a high resolution carbon 1s

Figure 2. The XPS high resolution C1s spectrum of a HEMA contact lens. The figure illustrates the various chemical shifts associated with the chemical bonds in the polymer chain.

(C1s) spectrum due to the various chemical bonds present in poly(hydroxyethylmethacrylate), pHEMA, a common soft contact lens material.

The surface sensitivity of XPS is dependent on the angle at which electrons are emitted from the sample. For smooth, flat samples it is possible to enhance the surface sensitivity by analyzing electrons which are emitted at a grazing incidence from the sample. By collecting at a number of different angles it is possible to obtain information on the depth distribution of components close to the material surface. This depth profiling capability is particularly important when thin films and coatings of < 10 nm thickness are being studied.

The XPS has been utilized to chemically characterize biomaterials in four principal areas: identification and characterization of the surface chemistry of bulk polymers; characterization of surface specific modifications; characterization of coatings; detection of biomolecules. Factors that are commonly investigated using XPS include: surface oxidation and reorientation of polymer segments; surface segregation (blooming) of plasticizers, additives, and low molecular weight fragments; adventitious contaminants such as silicones and protein adsorption.

Secondary Ion Mass Spectrometry

The impact of a high kinetic energy (typically 1–100 keV) ion, atom, or molecule causes material to be sputtered from a surface. The origin of the vast majority of ejected species is from the topmost layer of the sample. Therefore analysis of the sputtered fragments can provide information on the composition of the material surface. A small proportion of the ejected atomic and molecular fragments are ionized, these are called the secondary ions. Secondary ion mass spectrometry (SIMS) is the application of mass spectrometry to the secondary ions. Note that SIMS is an ablative, destructive technique and this can be used to advantage in

generating a depth profile of layered surfaces. The use of SIMS for depth profiling is termed “dynamic” SIMS and is most often employed in the study of layered materials in which the elemental composition of the layers is of interest, for example, doping levels in semiconductors. It is not possible to obtain more detailed chemical information using dynamic SIMS because of the damage induced by the high energy primary ions. In contrast, “static” SIMS employs a low density, low dose ion bombardment such that the probability of two ion impacts occurring at the same place on the sample is negligibly small ($< 10^{13}$ ions \cdot cm $^{-2}$). The mass spectrum then contains information that is characteristic of the undamaged surface. This information is particularly useful in the analysis of organic materials, when the normal rules of organic mass spectrometry can be applied to the interpretation of SIMS data. Most modern static SIMS instruments are based on time-of-flight mass analyzers (TOF-SIMS), which have a far greater combined sensitivity and mass resolution than quadrupole or magnetic sector detectors. The probability of ion generation is influenced by a daunting range of factors and thus SIMS is regarded as a nonquantitative technique. However, it is commonly found that in a range of similar materials the characteristic ion intensities are approximately proportional to the concentration of species from which they are generated. With a suitable set of calibration data it is then possible to use SIMS in a quantitative manner. The application of TOF-SIMS in the analysis of biomaterials and biological interfaces has historically revolved around the characterization of polymeric interfaces. This has included the study of degradation pathways for biodegradable polymers, the monitoring of coating chemistries, detection of surface contamination and surface chemical characterization of copolymer systems. The surface sensitivity of TOF-SIMS has led to its application in the detection and identification of biomolecules adsorbed at interfaces. The process is not without its problems though as the largest ions detected from any protein are the immonium ions ($^+\text{NH}_2\text{=CHR}$) from each amino acid (MW < 200). As a result of this fragmentation, the identification of proteins is often more like a jigsaw puzzle, where the amino acid fragments have to be pieced together using pattern recognition or multivariate analysis techniques, to identify and quantify the parent molecules (60). These types of statistical analysis are being increasingly used to analyze, compare and reconstruct data collected in TOF-SIMS.

In addition to spectroscopy, TOF-SIMS can be used in an imaging mode to chemically map the surface of a material. There is always a trade off between high spatial resolution and high mass resolution, but with the advent of liquid metal ion sources (e.g., Ga $^+$ and In $^+$), systems are typically capable of spatial resolution of < 10 μ m, while retaining atomic mass resolution. As a result there is increasing application of TOF-SIMS for the chemical imaging of a range of biomaterial surfaces. Significantly, developments in ion sources have shown that polyatomic (e.g., Au $_3$) and cluster ion (C $_{60}$) sources can significantly improve the molecular ion yield of both biological and polymeric materials. With the development of integrated freeze hydration stages for sample preparation, this has

lead to increased activity in the application of TOF-SIMS in the analysis of cell membranes and other hydrated biological systems (49).

AMBIENT TECHNIQUES

Atomic Force Microscopy

Atomic force microscopy (AFM) can be utilized to characterize surfaces via either an imaging or a spectroscopic mode. There are two common methods of imaging utilized in AFM, contact, and tapping mode. Both can be performed in either air or liquid, a factor that makes AFM particularly attractive in biomaterial research. In contact mode, the tip is scraped across the surface, while in tapping mode, the tip is in intermittent contact with the surface and as such, there is limited substrate disturbance. As a result, tapping mode AFM is more common for the characterization of biomaterials and biological surfaces. Common applications of AFM to biomaterial surfaces include: surface topography and coating continuity assessment, measurement and monitoring of coating thickness (see Fig. 3) and phase imaging. The last application is an extension of tapping mode imaging that gives nanometer-scale two-dimensional (2D) information about surface structure. It can be used to locate and characterize the distribution of discrete phases within polymer blends such as polyurethane-urea, and a range of other polymers of biological importance. There is also considerable interest in using AFM to image the surfaces of cells and biomolecules on surfaces (61,62).

Surface Force Measurements

The forces that act between particles and surfaces determine a wide range of interactions. They control the stability of dispersions and emulsions; determine the adhesion of colloids onto surfaces and the adsorption properties of proteins and cells at surfaces. Surface force measurements are used in variety of industries and increasingly there is interest in the application of surface force analysis to biomaterials. with the aim of characterizing protein-protein, cell-protein, protein-surface and cell-surface interactions.

There are a number of techniques that can be used to measure force interactions between surfaces. They are divided into two classes based on the method used to determine surface separation. Absolute surface separation can only be determined using an interferometric technique such as the surface force apparatus (SFA). These techniques are limited by the need for a transparent substrate and specific geometric configuration. In response, noninterferometric techniques have been developed that can employ a wider variety of substrates, and that rely on indirect determination of the surface separation rather than interferometry. One of these is AFM surface force measurement.

Force measurements can be made with an AFM using both a bare tip and a tip modified with a probe particle. If the results from these measurements are to be quantitative, knowledge of the radius of curvature for the probe or tip is critical. While it is possible to measure the nominal

Figure 3. The AFM tapping mode image of a 40 nm step between coated and uncoated regions on a silicon wafer. The step is produced by masking a section of the sample surface prior to plasma polymerization. Once the coating is deposited, the mask is removed and surface imaged. This enables the plasma polymer thickness to be measured with nm resolution. (Image courtesy of Dr. P.G. Hartley, CSIRO Molecular Science, Australia.)

radius of a bare AFM tip, the indirect nature of the measurement adds to the error associated with the resulting force calculations (63). The Derjaguin approximation is only valid when the radius is much larger than the surface separation, which is not necessarily the case if an unmodified tip is used. If a colloid probe is utilized, the radius of curvature can be measured easily and accurately using scanning electron microscope (SEM) or optical microscopy.

The zero surface separation for noninterferometric techniques are set at the hard wall encountered when the two surfaces are forced together. Termed the constant compliance regime, this is the region of the force curve in which the displacement of the colloid probe is linear with respect to the surface motion. This assumption of hard wall contact is an inherent limitation of these techniques, particularly if the surface deforms or compresses under pressure, as is often the case with polymer surfaces. The compression of a polymer layer can have a number of effects on the force curve. In the first instance, compression of a dense polymer layer can result in a compliance line mimicking hard wall contact, with a layer of compressed polymer between the probe and the substrate. If the polymer is less densely

packed, the probe may displace the material, squeezing the polymer out of the gap between the probe and the surface. This results in discontinuities in the compliance region as the force increases and the probe pushes through the polymer layers (63). As a result, conclusions about absolute layer thickness cannot be inferred from this data.

While XPS is able to characterize the chemistry of a surface in the dry state, surface force measurements are well suited to characterizing the intermolecular forces and stability in a variety of environments. A number of studies have investigated the surface force characteristics of rfgd films, grafted polymer layers, and adsorbed protein films in a variety of media (64). Other studies have used surface force measurements to characterize the interactions of polymer modified surfaces in an attempt to elucidate parameters that control the structure of the polymer layer (64). Surface force techniques have been used to investigate the effects of molecular weight, ionic strength, charge density, and polymer concentration on the interaction forces of adsorbed and grafted polymers layers. Increasingly, strategies to eliminate protein adsorption are based on the characterization and modification of the surfaces and thus the interaction forces that govern protein adsorption (65). A number of theoretical studies have also used surface force interactions as design parameters when modeling polymer coatings capable of resisting protein adsorption (66).

In addition to these standard modes of operation, by chemically modifying the AFM cantilever it is possible to map specific interactions between the tip and the surface. Depending on the type of modification made to the cantilever, a range of interactions can be investigated. With a cantilever modified with a receptor specific integrin, dynamic force spectroscopy can be used to identify and map receptor sites on a cell surface (67). By modifying the cantilever with specific chemical functional groups, differences in frictional properties and the distribution of different phases can be probed where there is no topographical variation (68).

Optical Techniques

The refractive index close to an interface can be measured by a number of optical techniques. The two most commonly employed for this purpose are surface plasmon resonance (SPR) (58) and ellipsometry (55,56). Since proteins have a higher refractive index (~ 1.55) than water (~ 1.33) it is possible to monitor the amount of protein adsorption at an interface through a measurement of the refractive index and thickness of the adsorbed layer. These techniques have found utility in a wide range of areas relevant to biomaterials research, such as the study of protein adsorption to biomaterials, ligand-receptor interactions and the dissolution and swelling of polymers. The advantage over traditional approaches such as enzyme linked immunosorbent assay (ELISA), fluorescent labeling or radiolabeling is that the proteins under study do not have to be chemically altered in any way.

The disadvantages of these techniques are that the substrate must be flat and conform to a number of optical requirements for the techniques. Additionally, these tech-

niques cannot directly distinguish between different proteins, since all proteins have roughly equivalent optical densities. To determine the identity of proteins adsorbed from a mixed solution it is necessary to subsequently expose the surface to antibodies specific to each protein of interest. Binding of the antibody can be monitored as an increase in the adsorbed layer thickness, however, this approach is difficult to employ quantitatively as there may be nonspecific and competitive adsorption of the antibody as well as a limited availability of binding sites on the adsorbed target protein.

Surface Plasmon Resonance

A surface plasmon is a collective oscillation of electrons that can be excited in certain metals such as silver and gold. The frequency of this oscillation depends on the refractive index of the dielectric material close to the metal interface. If the metal is a thin film it is possible to excite surface plasmons by reflecting light of a wavelength greater than the thickness of the metal from the reverse side of the film. The ability to cause this excitation depends on the wavelength of light, the refractive index of the material through which the light travels (which remains constant in this geometry) and the angle of reflection. When the conditions are correct, light is absorbed. In the usual set up for surface plasmon resonance (SPR) instruments the light undergoes total internal reflection at the interface and the angle at which light is absorbed is monitored. If there is a change in the refractive index close to the interface then a corresponding shift in the angle at which light is absorbed can be followed. The sensitivity of SPR decreases exponentially in distance from the surface with a decay length of the order of the wavelength of the light. If the layer to be analysed is significantly smaller than the decay length, which is usual for protein adsorption, then it can be assumed that any change in refractive index is proportional to the mass of adsorbed protein.

Ellipsometry

When light is reflected at an oblique angle from a planar surface it commonly undergoes a change in polarization. By analyzing these changes, it is possible to infer both the optical properties and thickness of thin films on the surface. To obtain the most complete characterization, a large number of different wavelengths of light or different angles of incidence must be studied. The measured data is then compared to the expected polarization changes calculated from a model, and parameters in the model changed (such as thickness or refractive index) to find a fit between the two. The sensitivity of ellipsometry is comparable to SPR ($\sim 0.01/\text{g}\cdot\text{cm}^2$), however, it is able to analyze comparatively thick layers of material.

CONCLUSION

While materials selection for most biomedical devices needs to be based upon bulk properties, in this article we have provided a broad overview of the basic properties of surfaces, and introduced some of the reasons why the surface properties may significantly influence the efficacy of biomaterials

and biomedical devices. Surface modification aims to tailor the surface characteristics of a material for a specific application without detrimentally affecting the bulk properties. Throughout this article we have shown how a range of physical, chemical, and biological modifications can be made to surfaces and used to manipulate surface characteristics. Finally, we discussed a range of highly sensitive surface analytical methods that can be utilized to investigate both the nature of an interface and its interactions with biological environments. As is always the case with review articles of this type, it is impossible to give detailed accounts of all of the material being discussed. We have included a range of references (*Reading List*) to aid the reader in further developing their understanding of each of the specific concepts and techniques. Additionally, we have included a list of more general references that cover many of the fundamental concepts discussed within this article.
