Arterial blood pressure (BP) is one of the most important cardiovascular parameters. Long-term monitoring of BP is used for the detection and management of chronic hypertension, which is a known major risk factor for heart disease. In this case, it is appropriate to obtain the instantaneous BP at certain intervals, such as days, weeks, or months, because of the slow progression of the disease.

In an acute care situation, such as during surgery or in intensive care, continuous BP measurements are desired to monitor heart function of the patients. The following sections describe the most important techniques.

Instantaneous BP Measurements

The most widely used approach is the auscultatory method, or method of Korotkoff, a Russian military physician, who developed the measurement in 1905. A pressure cuff is inflated to ~ 30 mmHg (3.99 kPa) above systolic pressure on the upper extremity. While subsequently deflating the cuff at a rate of ~ 2 (0.26)–3 mmHg (0.39 kPa) (1), the operator uses a stethoscope to listen to arterial sounds that indicate the points at which cuff pressure equals the systolic and diastolic pressure. The first is indicated by appearance of a “tapping” sound, while the latter is identified by the change from a muffled to vanishing sound.

A second widespread BP measurement technique is the oscillatory method. Here, the cuff contains a pressure sensor that is capable of measuring cuff pressure oscillations induced by the arterial pulse. The cuff is first inflated to achieve arterial occlusion, and then deflated at rate similar to that for the auscultatory method. During deflation, the sensor registers the onset of oscillations followed by a steady amplitude increase, which reaches maximum when the cuff pressure equals the mean ABP. Beyond that, oscillations subside and eventually vanish. Systolic and diastolic pressure are given by the cuff pressure values at which the oscillatory signal amplitude is 55 and 85% of the maximum amplitude, respectively. These objective criteria, based on population studies, make this method superior to the auscultatory method, which relies on the subjective judgment of changes in sounds. Oscillatory measurements are typically used in automated BP monitors.

Continuous BP Monitoring

Currently, the standard of care for obtaining continuous central blood pressure is the insertion of a Swan–Ganz catheter into the pulmonary artery. The device has to be placed by a trained surgeon, and its use is restricted to the intensive care unit. In addition, besides bearing the risk of serious complications, the procedure is costly. There is clearly a need for noninvasive continuous blood pressure monitoring methods, which could be more widely applied, and which would reduce the patient risk. In the following, we describe two such techniques, the vascular unloading method of Peñáz, and arterial tonometry, both of which have been developed into commercial products.

Vascular Unloading. Many noninvasive BP measurements rely on vascular unloading (i.e., the application of distributed external pressure to the exterior of a limb to counter the internal pressure of the blood vessels). Typically, this is achieved with an inflatable pressure cuff under manual or automated control. Because tissue can be assumed essentially incompressible, the applied pressure is transmitted onto the underlying vessels, where it results in altered transmural (i.e., external minus internal) pressure. If the external pressure P_{ext} exceeds the internal pressure P_{int} , the vessel collapses. For the case $P_{\text{ext}} = P_{\text{int}}$ the vessel is said to be unloaded (1).

In 1973, Czech physiologist Jan Peñáz proposed a noninvasive continuous BP monitoring method based on the vascular unloading principle (2). The approach, which was first realized by Wesseling in 1985, employs a servo-controlled finger pressure cuff with integrated photoplethysmography (see below) to measure digital arterial volume changes (3). The device uses a feedback mechanism to counter volume changes in the digital arteries through constant adjustment of cuff pressure, hence establishing a pressure balance that keeps the arteries in a permanently unloaded state. The applied cuff pressure serves as a measure of the internal arterial pressure. The cuff pressure is controlled with a bandwidth of at least 40 Hz to allow adequate reaction to the pulse wave (4). The method was commercialized in the late 1980s under the name Finapres. The instrument has a portable front end, which is worn on the wrist and contains an electropneumatic pressure valve, the cuff, and the PPG sensor. This part connects to a desktop unit containing the control, air pressure system, and data display–output. Two successor products are now available, one of which is a completely portable system.

One problem of this method is that the digital BP can significantly differ from brachial artery pressure (BAP) in shape, because of distortions due to pulse wave reflections, as well as in amplitude because of flow resistance in the small arteries. The former effect is corrected by introducing a digital filter that equalizes pressure wave distortions. The second problem is addressed by introducing a correction factor and calibrating the pressure with an independent return-to-flow BP measurement. It has been demonstrated that the achievable BP accuracy lies well within the American Association for Medical Instrumentation (AAMI) standards (5).

Figure 1. Applanation tonometry principle. (a) Single-element transducer. (b) Sensor array with pneumatic contact pressure control.

Applanation Tonometry. First conceived and implemented by Pressman and Newgard in the early 1960s, applanation tonometry (AT) measures the pulse pressure wave of a superficial artery with an externally applied transducer (6). The method requires the artery to be supported by an underlying rigid (i.e., bone) structure. Therefore, the method has been applied mainly to the temporal and the radial arteries; the last one being by far the most frequently employed measurement site. Figure 1a shows the general principle of the method. A pressure transducer is placed over the artery, and appropriate pressure is applied so as to partially flatten, or applanate, the artery. This ensures that the vessel wall does not exert any elastic forces perpendicular to the sensor face; therefore the sensor receives only internal arterial pressure changes caused by the arterial pulse. To obtain an accurate measurement it is crucial that the transducer is precisely centered over the artery, and that it is has stable support with respect to the surrounding tissue.

The original design used a single transducer that consisted of a rod of 2.5 mm^2 cross-sectional area, which was pressed against the artery, and which transmitted arterial pressure to a strain gauge above it. This early design suffered from practical difficulties in establishing and maintaining adequate sensor position. In addition, Drzewiecki has shown that for accurate pressure readings, the transducer area needs to be small compared to artery diameter (ideally, $< 1 \text{ mm}$ wide), a requirement that early designs did not meet (1).

The development of miniaturized pressure sensor arrays in the late 1970s has alleviated these difficulties, leading to the development of commercial AT instruments by Colin Medical Instruments Corp., San Antonio, TX. These sensor arrays use piezoresistive elements, which essentially are membranes of doped silicon (Si) that show a change in electrical resistance when subjected to

mechanical stress. Piezoresistivity is a quantum mechanical effect rooted in the dependence of charge carrier motility on mechanical changes in the crystal structure. Pressure-induced resistance changes in a monocrytalline semiconductor are substantially greater than in other available strain gauges. This sensitivity together with the possibility of using semiconductor fabrication techniques to create miniaturized structures makes piezoresistive elements ideal candidates for AT applications. The change in resistance is measured with a Wheatstone bridge (e.g., pictured in Fig. 2), which, together with suitable amplification, can be integrated on the same chip as the sensing element. While piezoresistance shows linear change with strain, the devices are strongly influenced by ambient temperature. Therefore, appropriate compensation measures have to be taken.

Figure 1b shows the schematic of a modern AT pressure sensor. Thirty-one piezoresistive elements form the $4.1 \times 10 \text{ mm}$ large sensor array, which is created from a monolithic Si substrate. After placing the sensor roughly over the artery, the signal from each element is measured to determine whether the transducer is appropriately centered with respect to the vessel. If necessary, its lateral position is automatically adjusted with a micromotor drive. The sensor contact pressure is pneumatically adjusted to achieve appropriate artery applanation. To provide probe stability suitable for long-term studies, the device is strapped to the wrist together with a brace that immobilizes the hand in a slightly overextended position so as to achieve better artery exposure to the sensor field.

Because AT can accurately measure the pulse wave shape, not its absolute amplitude, the AT signal is calibrated with a separate oscillatory BP measurement on the ipsilateral arm. Calibration is performed automatically at predetermined intervals.

Figure 2. (a) Wheatstone bridge for sensitive detection of resistor changes; gauge lead resistance disturbs measurement. (b) Four-wire strain gauge measurement; influence of lead resistance is eliminated.

In addition to fully automated long-term monitoring devices, simpler single-element transducers are offered for clinical and research applications (PulsePen by Dia-Tecne, Milan, Italy and SPT-301 by Millar Instruments, Inc., Houston, TX).

Plethysmography

Plethysmography (derived from the Greek words for “inflating” and “recording”) is the general name of an investigative method that measures volume change of the body, or a part of it, in response to physiologic stimulation or activity. Specifically, it allows measuring dynamics of blood flow to/from the extremities for the diagnosis of peripheral vascular diseases.

Different approaches have been conceived to measure volume change of a limb, the earliest of which, reaching back to the end of the nineteenth century, were based on measuring the volume displacement in a water filled vessel in which the limb was sealed in (7,8). Even though accurate in principle, the method suffers from practical limitations associated with the need to create a satisfactory watertight seal; it has therefore largely been supplanted by other approaches. The most important methods currently used are strain gauge PG, impedance PG, and photo PG. The working principles and applications of each of these methods will be described in the following sections.

Strain Gauge Plethysmography. Introduced by Whitney in 1953 (9), strain gauge plethysmography (SPG) measures changes in limb circumference to deduce volume variations caused by blood flow activity. The strain gauge is a stretchable device whose electrical resistance depends on its length; for SPG, it is fitted under tension in a loop around the limb of interest. Pulsatile and venous blood volume changes induce stretching/relaxing of the gauge, which is translated into a measurable resistance variation. Measurement interpretation is based on the premise that the local circumference variation is representative of the overall change in limb volume.

Whitney introduced a strain gauge consisting of flexible tubing of length l made from silastic, a silicone-based elastomer, filled with mercury. Stretching of the tubing increases the length and decreases the cross-sectional area a of the mercury-filled space, leading to an increase in its resistance R according to

$$R = \rho_m \frac{l^2}{v} \quad (1)$$

where ρ_m denotes mercury’s resistivity (96 $\mu\Omega$ cm), and v is the mercury volume, $v = l a$. Differentiation of Eq. 1. shows that the gauge’s change in resistance is proportional to its length variation (10):

$$\frac{\Delta R}{R} = 2 \frac{\Delta l}{l} \quad (2)$$

Whitney’s original strain gauge design is still the most commonly used in SPG. Because of typical gauge dimensions and mercury’s resistivity, the devices have rather small resistance values, in the range of 0.5–5 Ω .

The measured limb is often approximated as a cylinder of radius r , circumference C , length L , and volume V . By expressing the cylinder volume in terms of its circumference, $V = C^2 L / (4\pi)$, and then differentiating V with respect to C , it is shown that the fractional volume change is proportional to relative variations in circumference:

$$\frac{dV}{V} = 2 \frac{dC}{C} \quad (3)$$

Because changes in C are measured by the strain gauge according to Eq. 1, the arm circumference is proportional to the tubing length, and so the following relationship holds:

$$\frac{\Delta V}{V} = \frac{\Delta R}{R} \quad (4)$$

Whitney used a Wheatstone bridge, a measurement circuit of inherently great sensitivity, to detect changes in gauge resistance. In this configuration, shown in Fig. 2a, three resistors of known value together with the strain gauge form a network, which is connected to a voltage source and a sensitive voltmeter in such a manner that zero voltage is detected when $R_1/R_2 = R_3/R$. In this case, the bridge is said to be balanced. Changes in strain, and therefore R , cause the circuit to become unbalanced, and a nonzero voltage develops between points B and D according to

$$\frac{V_{BD}}{V_{AC}} = \frac{R_2}{R_1 + R_2} - \frac{R}{R_3 + R} \quad (5)$$

One disadvantage of the circuit is its nonlinear voltage response with respect to variations in R . For small changes, however, these nonlinearities remain small, and negligible errors are introduced by assuming a linear relationship.

A more significant shortcoming of the Wheatstone setup is that the measurement is influenced by the voltage drop across the lead resistance; especially for small values of R , such as those encountered in SPG applications, this can be a significant source of error. Therefore, modern SPG instruments use a so-called four-wire configuration, which excludes influences of lead resistance entirely. Figure 2b shows the concept. An electronic source is connected to the strain gauge with two excitation leads of resistance R_{ex1} , R_{ex2} , sending a constant current I through the strain gauge. Two probing leads with resistances R_{pr1} , R_{pr2} connect the device to an instrumentation amplifier of high impedance $R_{amp} \gg R_{pr1}$, R_{pr2} , which measures the voltage drop $V_{SG} = I \times R$ across the strain gauge. Because V_{SG} is independent of R_{ex1} and R_{ex2} , and there is negligible voltage drop across R_{pr1} and R_{pr2} , lead resistances do not influence the measurement of R .

Recently, a new type of plethysmography strain gauge has been introduced, which measures circumference variations in a special band that is worn around the limb of interest. The band, which has a flexible zigzag structure to allow longitudinal stretching, supports a nonstretching nylon loop, whose ends are connected to an electro-mechanical length transducer. Changes in circumference are thus translated into translational motion, which the transducer measures on an inductive basis, with 5 μm

accuracy (11). In evaluation studies, the new design performed comparable to traditional strain gauge designs (12).

Impedance Plethysmography. Electrical conductivity measurements on the human body for the evaluation of cardiac parameters were performed as early as the 1930s and 1940s. Nyboer is widely credited with the development of Impedance Plethysmography (IPG) for the measurement of blood flow to organs, and its introduction into clinical use (13–15).

The frequency-dependent, complex electrical impedance $Z(f)$ of tissue is determined by the resistance of the inter- and intracellular spaces, as well as the capacitance across cell membranes and tissue boundaries. The IPG measurements are performed at a single frequency in the 50–100 kHz range, and only the impedance magnitude Z (not the phase information) is measured. Therefore, Z can be obtained by applying Ohms law

$$Z = \frac{\hat{V}}{\hat{I}} \tag{6}$$

where \hat{V} and \hat{I} denote voltage and current amplitude values, respectively.

In the mentioned frequency range, the resistivity of different tissues varies by about a factor of 100, from $\sim 1.6 \Omega\cdot\text{m}$ for blood to $\sim 170 \Omega\cdot\text{m}$ for bone. Tissue can be considered a linear, approximately isotropic, piecewise electrically homogeneous volume conductor. Some organs, however, notably the brain, heart and skeletal muscles, show highly anisotropic conductivity (16).

Figure 3 shows a schematic for a typical four-electrode IPG setup. Two electrodes are used to inject a defined current into the body part under investigation, and two separate electrodes between the injection points measure the voltage drop that develops across the section of interest. The impedance magnitude Z is obtained, via Eq. 6, from the known current amplitude and the measured voltage amplitude. The four-electrode arrangement is used to eliminate the influence of the high skin impedance ($Z_{s1} = Z_{s4}$), which is $\sim 2\text{--}10$ times greater than that of the underlying body

tissue (17). If the same two electrodes were used to inject the current as well as to pick up the voltage drop, the skin resistance would account for most of the signal and distort the information sought.

The current source generates a sinusoidal output in the described frequency range and maintains a constant amplitude of typically 1 mA. This provides sufficient signal noise ratio (SNR) to detect physiologic activity of interest but is ~ 50 times below the pain threshold for the employed frequency range, and therefore well below potentially hazardous levels.

The voltage difference between the pick-up electrodes is measured with an instrumentation amplifier, whose input impedance is much greater than that of skin or underlying tissue. Therefore, the influence of skin impedance can be neglected, and the measurement yields the voltage drop caused by the tissue of interest. The output of the instrumentation amplifier is a sinusoidal voltage with amplitude proportional to the impedance of interest. The signal needs to be demodulated, that is, stripped of its carrier frequency, to determine the instantaneous amplitude value. This is done with a synchronous rectifier followed by a low pass filter, a technique also known as synchronous, lock-in, or homodyne detection. Figure 3 shows a possible analog circuit implementation; a discriminator, or zero-crossing detector, actuates a switch that, synchronously with the modulation frequency, alternately connects the buffered or inverted measured signal to a low pass filter. If phase delays over transmission lines can be neglected, this will generate a noninverted signal during one-half of a wave, say the positive half, and an inverted signal during the negative half wave. As a result, the carrier frequency is rectified. The low pass filter averages the signal to remove ripple and generates a signal proportional to the carrier frequency amplitude. Inspection shows that frequencies other than the carrier frequency (and its odd harmonics) will produce zero output.

Increasingly, the measured voltage is digitized by an analog-to-digital converter, and demodulation is achieved by a microprocessor through digital signal processing.

The measured impedance is composed of a large direct current (DC), component onto which a small (0.1–1%)

Figure 3. Four-lead tissue impedance measurement; the configuration mitigates influence of skin resistance (A_1 , instrumentation amplifier). Synchronous detection removes carrier signal.

time-varying component is superimposed. The former is the constant impedance of the immobile tissue components, such as bone, fat, and muscle, and the latter represents impedance variations induced by volume changes in the fluid tissue components: most significantly, blood volume fluctuations in the vascular component. To obtain a quantitative relationship between measured impedance variations ΔZ and the change in blood volume, a simple electrical tissue equivalent may be considered, consisting of two separate, parallel-connected volume conductors of equal length L . One of these represents the immobile tissue components of impedance Z_0 . The other is assigned resistivity ρ and a variable cross-sectional area A , thereby modeling impedance changes caused by variations in its volume V according to the relationship

$$Z_v = \rho \frac{L}{A} = \rho \frac{L^2}{V} \quad (7)$$

Here Z_v denotes the variable compartment's impedance, which is generally much greater than that of the immobile constituents. Therefore, the parallel impedance of both conductors can be approximated $Z \approx Z_0 - Z_v$. To obtain a functional relationship between the measured changes in impedance ΔZ and variations in blood volume ΔV , Eq. 7 is solved for V and differentiated with respect to Z . Making use of $Z \approx Z_0$ and $dZ \approx -dZ_v$ yields

$$\Delta V = -\frac{\rho L^2}{Z_0^2} \Delta Z_v \quad (8)$$

The IPG measurements do not allow independent determination of Z_0 and Z_v ; however, the dc component of the IPG signal serves as a good approximation to Z_0 , while the ac part closely reflects changes in Z_v . Low pass filtering of the IPG signal extracts the slowly varying dc components. Electronic subtraction of the dc part from the original signal leaves a residual that reflects physiologic impedance variations. The ac/dc separation can be implemented with analog circuitry. Alternatively, digital signal processing may be employed for this task. Digital methods help alleviate some of the shortcomings of analog circuits, especially the occurrence of slow signal drifts. In addition, software-based signal conditioning affords easy adjusting of processing characteristics, such as the frequency response, to specific applications.

Air Plethysmography. Air plethysmography (APG), also referred to as pneumoplethysmography, uses inflatable pressure cuffs with integrated pressure sensors to sense limb volume changes. The cuff is inflated to a preselected volume, at which it has snug fit, but at which interference with blood flow is minimal. Limb volume changes due to arterial pulsations, or in response to occlusion maneuvers with a separate cuff, cause changes in the measurement cuff internal pressure, which the transducer translates into electrical signals. The volume change is given by

$$\Delta V = V \frac{\Delta P}{P} \quad (9)$$

The APG measurements can be calibrated with a bladder that is inserted between the limb and the cuff, which is filled with a defined amount of water. Because temperature changes influence air pressure inside the cuff, and it needs to be worn for a few minutes after inflation before starting the measurement, so the air volume can reach thermal equilibrium.

Photoplethysmography. Optical spectroscopic investigations of human tissue and blood reach back as far as the late nineteenth and early twentieth century, and Hertzman is widely credited with introducing photoplethysmography (PPG) in 1937 (18). The PPG estimates tissue volume changes based on variations in the light intensity transmitted or reflected by tissue.

Light transport in tissue is governed by two principle interaction processes; elastic scattering, that is, the random redirection of photons by the microscopic interfaces of the cellular and subcellular structures; second, photoelectric absorption by molecules. The scattering power of tissue is much greater (at least tenfold, depending on wavelength) than is the absorption, and the combination of both interactions cause strong dampening of the propagating light intensity, which decays exponentially with increasing distance from the illumination point. The greatest penetration depth is achieved for wavelengths in the 700–1000 nm range, where the combined absorption of hemoglobin (Hb) and other molecules show a broad minimum. Figure 4 shows the absorption spectra of Hb in its oxygenated (HbO_2) and reduced, or deoxygenated, forms.

The PPG measurements in transmission are only feasible only for tissue thickness of up to a few centimeters. For thicker structures, the detectable light signal is too faint to produce a satisfactory SNR. Transmission mode measurements are typically performed on digits and the earlobes.

Whenever tissue is illuminated, a large fraction of the light is backscattered and exits the tissue in the vicinity of the illumination point. Backreflected photons that are detected at a distance from the light source are likely to have descended into the tissue and probed deeper lying structures (Fig. 5). As a general rule, the probing depth

Figure 4. Hemoglobin spectra; typical PPG wavelength for oxygen saturation measurement are 660 and 940 nm.

Figure 5. Schematic of the probed tissue volume in PPG reflection geometry.

equals about half the source-detector separation distance. The separation represents a tradeoff between probing volume and SNR; typical values are on the order of a few millimeters to a few centimeters. Reflection-geometry PPG can be applied to any site of the body.

Originally, incandescent light sources were used for PPG. These have been replaced with light emitting diodes (LED), owing to the latter devices' superior lifetime, more efficient operation (less heat produced), and desirable spectral properties. The LED technology has vastly evolved over the last 20 years, with a wide range of wavelengths—from the near-infrared (NIR) to the ultraviolet (UV)—and optical power of up to a tens of milliwatts currently available. These devices have a fairly narrow emission bandwidth, $\sim 20\text{--}30$ nm, which allows spectroscopic evaluation of the tissue. The light-emitting diode (LEDs) are operated in forward biased mode, and the produced light intensity is proportional to the conducted current, which typically is on the order of tens of milliamps. Because in this configuration, the device essentially presents a short circuit to any voltage greater than its forward drop V_{LED} (typically 1–2 V), some form of current control or limiting circuitry is

required. In the simplest case, this is a current-limiting resistor R_{lim} in series with the diode (Fig. 6a). The value of R_{lim} is chosen so that $I_{LED} = (V_{cc} - V_{LED})/R_{lim}$ is sufficient to drive the LED, typically on the order of tens of milliamps, but does not exceed the maximum permissible value. Depending on the voltage source, this results in adequate output stability. Often, there is a requirement to modulate or adjust the diode output intensity. In this case, an active current source is better suited to drive the LED. Figure 6b shows the example of a voltage-controlled current source with a boost field effect transistor. Here, the light output is linearly dependent on the input voltage from zero to maximum current; the latter is determined by LEDs thermal damage threshold.

Either phototransistors (PT) or photodiodes (PD) are used as light sensors for PPG. Both are semiconductor devices with an optically exposed pn junction. Photons are absorbed in the semiconductor material, where they create free charges through internal photoelectric effect. The charges are separated by the junction potential, giving rise to a photocurrent I_p proportional to the illumination intensity. While a PD has no internal gain mechanism and requires external circuitry to create a suitable signal, the PT (like any transistor) achieves internal current amplification h_{FE} , typically by a factor of ~ 100 . Figure 7a shows how a load resistor is used to convert the PT output current to voltage that is approximately proportional to

Figure 6. LED drive circuits. (a) Simple current limiting resistor. (b) Voltage controlled current source.

Figure 7. Light detection circuits. (a) Phototransistor operation (V_{CE} = collector-emitter voltage). (b) Use of photodiode with current-to-voltage converter (transimpedance amplifier).

the incident light according to

$$V_L = I_{CE}R_L = h_{FE}I_pR_L \quad (10)$$

h_{FE} unavoidably depends on a number of factors including I_p and V_{CE} , thus introducing a nonlinear circuit response. In addition, the PT response tends to be temperature sensitive. The light sensitivity of a PT is limited by its dark current, that is, the output at zero illumination, and the associated noise. The largest measurable amount of light is determined by PT saturation, that is, when V_L approaches V_{cc} . The device's dynamic range, that is, the ratio between the largest and the smallest detectable signal is on the order of three-to-four orders of magnitude.

Figure 7b shows the use of a PD with photoamplifier. The operational amplifier is configured as a current-to-voltage converter and produces an output voltage

$$V_o = I_pR_f \quad (11)$$

Capacitor C_f is required to reduce circuit instabilities. Even though compared to (a) this circuit is more costly and bulky because of the greater number of components involved, it has considerable advantages in terms of temperature stability, dynamic range, and linearity. The PD current varies linearly with illumination intensity over seven-to-nine orders of magnitude. The circuit's dynamic range is determined by the amplifier's electronic noise and its saturation, respectively, and is on the order of four decades. Proper choice of R determines the circuit's working range; values in the 10–100 M Ω range are not uncommon.

It is clear from considering the strong light scattering in tissue that the PPG signal contains volume-integrated information. Many models of light propagation in tissue based on photon transport theory have been developed that are capable of computing realistic light distributions even in inhomogeneous tissues, such as the finger (19). However, it is, difficult, if not impossible, to exactly identify the sampled PPG volume because this depends critically on the encountered optical properties as well as the boundary conditions given by the exact probe placement, digit size and geometry, and so. These factors vary between individuals, and even on the same subject are difficult to quantify or even to reproduce. Therefore, PPG methods do generally not employ a model-based approach, and the origin of the PPG signal as well as its physiologic interpretation has been an area of active research (20–23).

The PPG signals are analyzed based on their temporal signatures, and how those relate to known physiology and empirical observations. The detected light intensity has a static, or dc component, as well as a time-varying ac part. The former is the consequence of light interacting with static tissues, such as skin, bone, and muscle, while the latter is caused by vascular activity. Different signal components allow extraction of specific anatomical and physiological information. For example, the signal component showing cardiac pulsation, also called the digital volume pulse (DVP), can be assumed to primarily originate in the arterial bed, a premise on which pulse oximetry, by far the most widely used PPG application, is based. This method obtains two PPG signals simultaneously at two wave-

lengths that are spectrally located on either side of the isosbestic point. The ratio of the DVP peak amplitudes for each wavelength, normalized by their respective dc components, allows assessment of quantitative arterial oxygen saturation.

A number of other applications of the DVP signal have been proposed or are under investigation. For example, the DVP waveform is known to be related to the arterial blood pressure (ABP) pulse. Using empirically determined transfer functions, it is possible to derive the ABP pulse from PPG measurements (24).

Another potential use of arterial PPG is the assessment of arterial occlusive disease (AOD). It is known that the arterial pulse form carries information about mechanical properties of the peripheral arteries, and PPG has been investigated as a means to noninvasively assess arterial stiffness. To better discriminate features in the PPG signal shape, the second derivative of the signal is analyzed (second-derivative plethysmography, SDPTG) (23).

The PPG is furthermore used for noninvasive peripheral BP monitoring in the vascular unloading technique.

Continuous Wave Doppler Ultrasound

Doppler ultrasound (US) methods are capable of measuring blood flow velocity and direction by detecting the Doppler shift in the ultrasound frequency that is reflected by the moving red blood cells. The acoustic Doppler effect is the change in frequency of a sound wave that an observer perceives who is in relative motion with respect to the sound source. The amount of shift Δf in the US Doppler signal is given by (25)

$$\Delta f = \frac{2f_0v_b\cos\Theta}{c} \quad (12)$$

where f_0 is the US frequency, v_b is the red blood cell velocity, Θ is the angle between the directions of US wave propagation and blood flow, and c is the speed of sound in tissue. Equation 12 demonstrates a linear relationship between blood flow and US Doppler shift. It is also seen that the shift vanishes if the transducer is perpendicular to the vessel because there is no blood velocity component in the direction of wave propagation. The algebraic sign of the shift depends on the flow direction (toward/away from) with respect to the transducer and is hence influenced by angle Θ . A factor of two appears in Eq. 12 because the Doppler effect takes place twice; the first occurs when the red blood cell perceives a shift in the incoming US wave, and the second shift takes place when this frequency is backreflected toward the transducer. Using typical values for the quantities in Eq. 12 ($f_0 = 5$ MHz, $v_b = 50$ cm·s⁻¹, $\Theta = 45^\circ$) yield frequency shifts of 2.3 kHz, which falls within the audible range (25).

Because the shift is added to the US frequency, electronic signal processing is used to remove the high frequency carrier wave. Analog demodulation has been used for this purpose; by mixing, that is, multiplying, the measured frequency with the original US frequency and low pass filtering the result, the carrier wave is removed, and audio-range shift frequencies are extracted. In so-called quadrature detection, this demodulation process yields two

separate signals, one for flow components toward the detector, and one for flow away from it. Modern instruments typically employ digital signal processing, such as fast Fourier transformation (FFT), to accomplish this.

Continuous wave (CW) Doppler refers to the fact that the measurement is performed with a constant, nonmodulated US wave (i.e., infinite sine-wave). This technology does not create echo pulses, and hence does not allow any form of depth-profiling or imaging. Its advantages are its simplified technology, and that it is not restricted to a limited depth or blood velocity. Because the signal is generated continuously, CW transducers require two separate crystals, one for sound generation, and one for detection. The two elements are separated by a small distance and are inclined toward each other. The distance and angle between the elements determine the overlap of their respective characteristics, and thus determine the sensitive volume. All blood flow velocity components within this volume contribute to the Doppler signal.

In the simplest case, the measured frequency shift is made audible through amplification and a loudspeaker, and the operator judges blood velocity from the pitch of the tone (higher pitch = faster blood movement). These devices are used in cuff-based arterial pressure measurements, to detect the onset of pulsation. They also permit qualitative assessment of arterial stenosis and venous thrombosis. More sophisticated instruments display the changing frequency content of the signal as a waveform (velocity spectral display). Doppler spectra are a powerful tool for the assessment of local blood flow in the major vessels, especially when combined with anatomical US images (Duplex imaging, see section on imaging methods).

Peripheral Vascular Measurements

The following is a description of peripheral vascular measures that can be derived with the nonimaging techniques described in the preceding sections.

Assessment Of Peripheral Arterial Occlusive Disease.

Peripheral arterial occlusive disease (PAOD) is among the most common peripheral arterial diseases (26), with a reported prevalence as high as 29% (27). The PAOD is usually caused by atherosclerosis, which is characterized by plaque buildup on the inner-vessel wall, leading to congestion, and hence increased blood flow resistance. Risk factors for PAOD are highly correlated with those for coronary artery disease, and include hypertension, smoking, diabetes, hyperlipidemia, age, and male sex (27–29). A symptom of PAOD is intermittent claudication, that is, the experience of fatigue, pain, and cramping of the legs during exertion, which subsides after rest. Ischemic pain at rest, gangrene, and ulceration frequently occur in advanced stages of the disease (29,30).

Ankle Brachial Index Test. The Ankle Brachial Index (ABI) is a simple and reliable indicator of PAOD (31), with a detection sensitivity of 90% and specificity of 98% for stenoses of >50% in a major leg artery (27,29). The ABI for each leg is obtained by dividing the higher of the posterior and anterior tibial artery systolic pressures for

Table 1. Ankle-Brachial Index (ABI) staging after ()

AB Ratio Range	Stage
1.0–1.1	Normal
< 1.0	Abnormal, possibly asymptomatic
0.5–0.9	Claudication
0.3–0.5	Claudication, rest pain, severe occlusive disease
< 0.2	Ischemia, gangrenes

that leg by the greater of the left- and right-brachial artery systolic pressures. In normal individuals both systolic values should be nearly equal, and ABIs of 1.0–1.1 are considered normal. In PAOD, the increased peripheral arterial resistance of the occluded vessels causes a drop in blood pressure, thus diminishing the ABI. Because of measurement uncertainties, ABI values of < 0.9 generally are considered indicative of PAOD (27,29). Table 1 shows a scheme for staging of disease severity according to ABI values, as recommended by the Society of Interventional Radiology (SIR) (32).

The ABI test is performed with the patient in a supine position, and inflatable pressure cuffs are used to occlude the extremities in the aforementioned locations. The systolic pressure is determined by deflating the cuff and noting the pressure at which pulse sounds reappear. The audio signal from a CW Doppler instrument is used to determine the onset of arterial pulse sounds. Although the test can be performed manually with a sphygmomanometer, there are dedicated vascular lab instruments that automatically control the pressure cuff, register the pressure values, and calculate the ABI. Such instruments are commercially available, for example, from BioMedix, MN, Hokanson, WA, and Parks Medical Electronics, OR.

The primary limitation of the ABI test is that arterial calcifications, such as are common in diabetics, can resist cuff pressure thus causing elevated pressure readings. In those patients, the toe pressure as determined by PPG or SPG may be used because the smaller digital arteries do not develop calcifications (29). The normal toe systolic pressure (TSP) ranges from 90 mmHg to 100 mmHg, or 80% to 90% brachial pressure. The TSP < 30 mmHg (3.99 kPa) is indicative of critical ischemia (33). Also, pulse volume recordings (PVR, see below) are not affected by calcifications (26).

Segmental Systolic Pressure. Segmental Systolic Pressure (SSP) testing is an extension of the ABI method, wherein the arterial systolic pressure is measured at multiple points on the leg, and the respective ratios are formed with the higher of the brachial systolic readings. As is the case for ABI testing, a low ratio for a leg segment indicates occlusion proximal to the segment. By comparing pressures in adjacent segments, and with the contralateral side, SSP measurements offer a way to locate pressure drops and thus roughly localize occlusions. Typically, three to four cuffs are placed on each leg; one or two on the thigh, one below the knee, and one at the ankle.

The SSP technique suffers from the same limitation as does the ABI test, that is, it produces falsely elevated readings for calcified arteries. Again, TSP and PVR are

advised for patients where calcifications might be expected because of known predisposition (e.g., diabetics), or unusual high ABI (> 1.5) (26).

Pulse Volume Recording/Pulse Wave Analysis. Pulse volume recording (PVR), a plethysmographic measurement, is usually combined with the ABI or SSP test. Either the pressure cuffs used in these measurements are equipped with a pressure sensor so they are suitable for recording volume changes due to arterial pulsation, or additional strain gauge sensors are used to obtain segmental volume pulsation. In addition to the leg positions, sensors may be located on the feet, and PPG sensors may be applied to toes. Multiple waveforms are recorded to obtain a representative measurement; for example, the Society for Vascular Ultrasound (SVU) recommends a minimum of three pulse recordings (34). The recorded pulse amplitudes reflect the local arterial pressure, and the mean amplitude, obtained by integrating the pulse, is a measure of the pulse volume. The pulsatility index, the ratio of pulse amplitude over mean pulse volume serves as an index for PAOD, with low values indicating disease (26).

Besides its amplitude and area, the pulse contour can be evaluated for indications of PAOD in a method referred to as pulse wave analysis (PWA). The normal pulse has a steep (anacrotic) rise toward the systolic peak, and a slower downward slope, representing the flow following the end of the heart's left ventricular contraction. The falling slope is interrupted by a short valley (the dicrotic notch), which is caused by the closing of the aortic valve. The details of the pulse shape are the result of the superposition of the incoming arterial pulse and backward-traveling reflections from arterial branchings and from the resistance caused by the small arterioles, as well as from atherosclerotic vessels (35). The pulse shape distal to occlusions tends to be damped and more rounded, and loses the dicrotic wave. Combined SSP and PVR recording has been reported over 90% accurate for predicting the level and extent of PAD (26).

Recently, PWA has increasingly been used to infer central, that is, aortic, arterial parameters from peripheral arterial measures, typically obtained from tonometric measures on the radial artery. These methods, which are commercialized for example by Atcor Medical, Australia and Hypertension Diagnostics, Inc, MN, rely on analytic modeling of transfer functions that describe the shaping of the pulse from the aorta to the periphery. These analytical functions are typically based on models mimicking the mechanical properties of the arterial tree by equivalent circuits (so-called Windkessel models) representing vascular resistances, capacitances, and inductances (36–38). From the derived aortic waveform, parameters are extracted that indicate pathologic states, such as hypertension and central arterial stiffness. One example is the augmentation index, the pressure difference in the first and second systolic peak in the aorta (39,40).

Pulse wave velocity (PWV) depends on arterial stiffness, which is known to correlate with increased cardiovascular risks. The PWV is established by measuring pulse waves on more than one site simultaneously, and dividing their respective separation difference from the heart by the time difference between the arrivals of comparable wave form

features. Peripheral PWV measurements on toes and fingers have been conducted with PPG (41).

It was recently shown that arterial stiffness assessed from PWA and PVA on multisite peripheral tonometric recording correlates with endothelial function. The latter was assessed by US measurements of brachial arterial diameter changes in response to a reactive hyperemia maneuver (42). There is increasing clinical evidence that PWA can serve as a diagnostic tool for hypertension and as a cardiac disease predictor (43).

CW Doppler Assessment. Velocity spectral waveform CW Doppler is useful for assessing peripheral arterial stenoses. The Doppler waveform obtained from a normal artery shows a triphasic shape; there is a strong systolic peak, followed by a short period of low amplitude reversed flow, reversing again to a small anterograde value during mid-diastole. Measuring at a stenosis location shows a waveform of increased velocity and bi- or monophasic behavior. Measurements distal to stenosis appear monophasic and dampened (26,33).

Venous Congestion Plethysmography. The described PG methods are most valuable for the assessment of peripheral vascular blood flow parameters for the diagnosis of peripheral vascular diseases (PVD). Venous congestion PG (VCP), also called venous occlusion PG (VOP), allows the measurement of a variety of important vascular parameters including arterial blood flow (Q_a), venous outflow (Q_{vo}), venous pressure (P_v), venous capacitance (C_v), venous compliance (C), and microvascular filtration. In VCP, a pressure cuff is rapidly inflated on the limb under investigation to a pressure, typically between 10 (1.33 kPa) and 50 mmHg (6.66 kPa), sufficient to cause venous occlusion, but below the diastolic pressure so that arterial flow is not affected. Blocking the venous return in this fashion causes blood pooling in the tissue distal to the cuff, an effect that can be quantified by measuring volume swelling over time with PG. Figure 8 sketches a typical

Figure 8. Schematic of typical VCP response curve. (1), asymptotic arterial blood flow; (2), asymptotic venous outflow; (3), swelling due to filtration; (4), effect of venous blood pooling only, obtained by subtracting the filtration component (3); C_v , venous capacitance.

volume response curve. Upon cuff inflation, an exponential increase in volume is observed, which is caused by the filling of postcapillary compliance vessels, and for which the time constant is ~ 15 s in healthy individuals (44). The initial rate of swelling (indicated by asymptote 1), expressed in $(\text{mL}\cdot\text{min}^{-1})$, is a measure of the arterial blood flow. When the venous pressure reaches the cuff pressure, blood can again flow out, and the relative volume increase reaches a plateau, which equals C_v . If C_v is measured for different occlusion pressure values, the slope of the C_v versus pressure curve yields C (in $\text{mL}\cdot\text{mmHg}^{-1} \times 10^{-2}$). Upon cuff release, the VCP curve shows fast exponential decay (on the orders of seconds), whose initial rate (indicated by asymptote 2) is a measure for Q_{vo} (45,46). With rising venous pressure an increase in fluid leakage, or filtration, takes place from the veins into the interstitial space, leading to additional tissue volume increase. Therefore, the PG response shows a second slow exponential component with a time constant on the order of 800 s (asymptote 3), from which can be deduced the capillary filtration capacity *CFC* (11).

Another application of VCP is the noninvasive diagnosis of deep vein thrombosis (DVT). The presence of venous blood clots impacts on venous capacitance and outflow characteristics. It has been shown that the combined measurement of C_v and Q_{vo} may serve as a diagnostic discriminator for the presence of DVT (45). A computerized SPG instrument is available (Venometer, Amtec Medical Ltd, Antrim, Northern Ireland), which performs a fully automated VCP measurement and data analysis for the detection of DVT (47).

Laser Doppler Flowmetry

Laser Doppler flowmetry (LDF) is a relatively young method of assessing the perfusion of the superficial microvasculature. It is based on the fact that when light enters tissue it is scattered by the moving red blood cells (RBC) in the superficial vessels (see PPG illustration in Fig. 5), and as a result the backscattered light experiences a frequency (Doppler) shift. For an individual scattering event, the shift magnitude can be described exactly; it depends on the photon scattering angle and the RBCs velocity, and it is furthermore related to the angular orientation of blood flow with respect the path directions of the photon before and after the scattering event. In actual tissue measurements, it is impossible to discern individual scattering events, and the obtained signals reflect stochastic distributions of scattering angles and RBC flow directions and velocities present in the interrogated volume.

In its simplest form, an LDF measurement is obtained by punctual illumination of the tissue of interest with a laser source, and by detecting the light that is backscattered at (or close to) the illumination site with a photodetector, typically a photodiode. The laser is a highly coherent light source, that is, its radiation has a very narrow spectral bandwidth. The spectrum of the backscattered light is broadened because it contains light at Doppler frequencies corresponding to all scattering angles and RBC motions occurring in the illuminated volume. Because of typical flow speeds encountered in vessels, the maximum

Doppler shifts encountered are on the order of 20 kHz, which corresponds to a relative frequency variation of $\sim 10^{-10}$. Frequency changes this small can be detected because the shifted light components interfere with the unscattered portion of the light, causing a “beat signal” at the Doppler frequency. This frequency, which falls roughly in the audio range, is extracted from the photodetector signal and further processed. The small amount of frequency shift induced by cell motion is the reason that spectrally narrow, high quality laser sources (e.g., HeNe gas lasers or single-mode laser diodes) are required for LDF measurements.

The basic restriction of LDF is its limited penetration depth. The method relies on interference, an effect that requires photon coherence. Multiple scattering, however, such as experienced by photons in biological tissues, strongly disturbs coherence. For typical tissues, coherence is lost after a few millimeters of tissue. The sensitive volume of single-point LDF measurements is therefore on the order of 1 mm^3 .

Single-point LDF measurements are usually performed with a fiberoptic probe, which consist of one transmitting fiber and one adjacent receiving fiber. Typical distances between these are from a few tenths of a millimeter to > 2 mm. According to light propagation theory (see section on PPG), farther separations result in deeper probing depths, however, because of coherence loss, the SNR decreases exponentially with increasing distance, limiting the maximum usable separation.

The use of a probe makes a contact-based single-point measurement very convenient. Fiber-based probe have been developed that implement several receivers at different distances from the source (48). This allows a degree of depth discrimination of the measured signals, within the aforementioned limits.

The LDF signal is analyzed by calculation the frequency power spectrum of the measured detector signal, usually after band-pass filtering to exclude low frequency artifacts and high frequency noise. From this the so-called flux or perfusion value—a quantity proportional to the number of RBCs and their root-mean-squared velocity, stated in arbitrary units—is obtained. It has been shown that the flux is proportional to the width the measured Doppler power spectrum, normalized to optical power fluctuations in the setup (49).

Laser Doppler imaging (LDI) is an extension of the LDF technique that allows the instantaneous interrogation of extended tissue areas up to tens of centimeters on each side. Two approaches exist. In one implementation, the laser beam is scanned across the desired field of view, and a photodetector registers the signal that is backreflected at each scanning step. In another technology, the field of view is broadly illuminated with one expanded laser beam, and a fast CMOS camera is used to measure the intensity fluctuations in each pixel, thus creating an image. This second approach, while currently in a stage of relative infancy, shows the potential for faster frame rates than the scanning imagers, and it has the advantage of avoiding mechanical components, such as optical scanners (50).

The LDF/LDI applications include the assessment of burn wounds, skin flaps, and peripheral vascular perfusion

problems, such as in Raynaud's disease or diabetes. The vascular response to heating (51) and the evaluation of carpal tunnel syndrome also have been studied (52).

IMAGING METHODS

This section provides an overview of existing medical imaging methods, and how they relate to vascular assessment. Included here are imaging modalities that involve the use of contrast agents or of radioactive markers, even though these methods are not considered noninvasive in the strictest sense of the word.

Ultrasound Imaging

Structural US imaging, especially when combined with Doppler US methods, is at present the most important imaging technique employed in the detection of PVD.

Improvements in ultrasound imaging technology and data analysis methods have brought about a state in which ultrasonic images can, in some circumstances, provide a level of anatomical detail comparable to that obtained in structural X-ray CT images or MRIs (53,54). At the same time, dynamic ultrasound imaging modalities can readily produce images of dynamic properties of macroscopic blood vessels (55,56). The physical phenomenon underlying all the blood-flow-sensitive types of ultrasound imaging is the Doppler effect, wherein the frequency of detected ultrasonic energy is different from that of the source, owing to the interactions of the energy with moving fluid and blood cells as it propagates through tissue. Several different varieties have become clinically important.

The earliest, most basic version of dynamic ultrasound imaging is referred to as color flow imaging (CFI) or color Doppler flow imaging (CDFI). Here, the false color value assigned to each image pixel is a function of the average frequency shift in that pixel, and the resulting image usually is superimposed upon a coregistered anatomic image to facilitate its interpretation. Interpretation of a CDFI image is complicated by, among other factors, the dependence of the frequency shift on the angle between the transducer and the blood vessels in its field of view. In addition, signal/noise level considerations make it difficult to measure low but clinically interesting flow rates. Many of these drawbacks were significantly ameliorated by a subsequently developed imaging modality known as either power flow imaging (PFI) or power Doppler imaging (PDI) (57). The key distinction between PDI and CDFI is that the former uses only the amplitude, or power, of ultrasonic energy reflected from erythrocytes as its image-forming information; in consequence, the entire contents of a vessel lumen have a nearly uniform appearance in the resulting displayed image (58).

The greatest value of Doppler imaging lies in the detection and assessment of stenoses of the larger arteries, as well as in the detection of DVT.

An increasingly employed approach to enhancing ultrasound images, at the cost of making the technique minimally invasive, is by introducing a contrast agent. The relevant contrast agents are microbubbles, which are microscopic, hollow, gas-filled polymer shells that remain

confined in the vascular space and strongly scatter ultrasonic energy (59). It has been found that use of microbubbles permits a novel type of Doppler-shift-based ultrasound imaging, called contrast harmonic imaging (CHI). The incident ultrasound can, under the correct conditions, itself induce oscillatory motions by the microbubbles, which then return reflections to the transducer at not only the original ultrasonic frequency, but also at its second and higher harmonics. While these signals are not high in amplitude, bandpass filtering produces a high SNR, with the passed signal basically originating exclusively from the vascular compartment of tissue (60). The resulting images can have substantially lower levels of "clutter" arising from nonvascular tissue, in comparison to standard CDFI or PDI methods.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is certainly the most versatile of the imaging modalities, and give the user the ability to study and quantify the vasculature at different levels. That is, depending on the details of the measurement, the resulting image may principally confer information about bulk blood flow (i.e., rates and volumes of blood transport in macroscopic arteries and veins), or about perfusion (i.e., amount of blood delivered to capillary beds within a defined time interval). The methods commonly employed to perform each of these functions are given the names magnetic resonance angiography (MRA) and perfusion MRI, respectively. As is the case for the other types of imaging treated here, each can be performed either with or without administration of exogenous contrast agents, that is, in either a noninvasive or a minimally invasive manner (61,62).

Magnetic Resonance Angiography. The MRA methods fall into two broad categories. The basic physical principle for one is flow-related enhancement (FRE), in which the pulse sequence employed has the effect of saturating the spins of ^1H nuclei in the nonmoving portion of the selected slice (63,64). Blood flow that has a large component of motion perpendicular to that slice remains significantly less saturated. Consequently, more intense MR signals arise from the blood than from the stationary tissues, and the contents of blood vessels are enhanced in the resulting image. Subtraction of a static image obtained near the start of the data collection sequence permits even greater enhancement of the blood vessel contents. A drawback of this approach is that vessels that lie within the selected slice, with the direction of blood flow basically parallel to it, do not experience the same enhancement.

A phase contrast mechanism is the basic physical principle for the second category of MRA techniques (65,66). Position-selective phase shifts are induced in ^1H nuclei of the selected slice via the sequential imposition of at least two transverse gradients that sum to a constant value across the slice. The effect is to induce zero net phase shifts among nuclei that were stationary during the gradient sequence, but a nonzero, velocity-dependent net phase shift on those that were in motion. The net phase shifts associated with the flowing blood are revealed in the

resulting image, again, especially following subtraction of an image derived from data collected before the phase contrast procedure.

Perfusion MRI. Early developments in this field necessarily involved injection of a MR contrast agent that has the effect of inducing a sharp transient drop in signal detected as the contrast bolus passes through the selected slice (67). As with many dynamic MRI techniques, the bulk of the published work is geared toward studies of the brain, where, provided that the blood–brain barrier is intact, the method’s implicit assumption that the contrast agent remains exclusively within the vascular space usually is justified. A sufficiently rapid pulse sequence allows the operator to generate curves of signal intensity vs. time, and from these one can deduce physiological parameters of interest, such as the cerebral blood flow (CBF), cerebral blood volume (CBV), and mean transit time (MTT) (67,68).

The minimally invasive approach described in the preceding paragraph remains the most common clinically applied type of perfusion MRI. A noninvasive alternative would have advantages in terms of permissible frequency of use, and would be of particular value in situations where pathology or injury has disrupted the blood–brain barrier. It also would make it possible to obtain perfusion images of other parts of the body than just the brain. Such an alternative exists, in the form of a set of methods known collectively as arterial spin labeling (ASL) (67) or arterial spin tagging (69). The common feature of all these techniques is that the water component of the blood is itself used as a contrast agent, by applying a field gradient that inverts the spins of ^1H nuclei of arterial blood before they enter the slice selected for imaging. The signal change induced by this process is smaller than that resulting from injection of a contrast agent, however, so that requirements for high SNRs are more exacting, and subtraction of a control image a more necessary step.

An increasingly popular and important functional MRI technique is blood-oxygen-level-dependent (BOLD) imaging (67,70). This type of imaging produces spatial maps determined by temporal fluctuations in the concentration of deoxygenated hemoglobin, which serves as an endogenous, intravascular, paramagnetic contrast agent. The physiological importance of BOLD images is that they reveal spatial patterns of tissue metabolism, and especially of neuronal activity of the brain. However, careful examination of the BOLD signal indicates that it depends, in a complex way, on many vascular and non-vascular tissue parameters (67,71). As such, it is not (yet) a readily interpretable method for specifically studying peripheral vasculature.

Fast X Ray Computed Tomography

As data acquisition speeds, and consequently repetition rates, for X ray computed tomography (CT) imaging have increased over the last couple of decades, previously unthinkable dynamic imaging applications have become a reality. The most direct approach taken along these lines is to rapidly acquire sequences of images of a slice or

volume of interest and then examine and interpret, at any desired level of mathematical sophistication, temporal variations in the appearance of tissue structures in the images. Of course this approach is well suited to studying only organs whose functionality entails changes in shape or volume, such as the heart and lungs, and these have been the subject of many fast CT studies.

The functioning of many other organs, such as the kidneys (72), is related to the flow of blood and/or locally formed fluids, but does not involve gross changes in size or shape. In these cases it is necessary to introduce one or more boluses of X ray contrast agents, and to use fast CT to monitor their transit (73). While these methods violate the strict definition of noninvasive procedure, we include them in this synopsis out of consideration of the fact that the health risks associated with the contrast agents ordinarily are minor in relation to those imposed by the ionizing radiation that forms the CT images. For quantitation of regional blood flow and other dynamic vascular parameters, these techniques invariably employ some version of indicator dilution theory (73).

Indicator Dilution Approach

In one clinically important example, it has been found that the detected X ray CT signal changes in a quantifiable manner following inhalation of a gas mixture containing appreciable levels of nonradioactive isotopes of xenon (typically 33% Xe and 67% O_2 , or 30% Xe, 60% O_2 , 10% air) (75–77). A variety of techniques based on this phenomenon, and referred to as stable xenon-enhanced CT or $^{\text{sXe}}$ -CT, were subsequently developed. The common feature is inhalation of a Xe-enriched gas mixture followed by repetitive scanning to monitor the wash-in and/or wash-out of the Xe-affected signal (75). However, while negative side effects are uncommon, they are known to occur (77). Consequently, the $^{\text{sXe}}$ /CT technique is applied almost exclusively to cerebral vascular imaging studies, in cases where there is a diagnosed injury or pathology (75).

Qualitatively similar approaches, known collectively as perfusion CT, that are based on monitoring the time course of passage of an injected bolus of an iodinated contrast agent, also have been developed (74,78,79). Of course, these are even more invasive than the approaches based on inhalation an inert gas. Conflicting assertions (80) have been made regarding which of two approaches, injection or inhalation based, give superior results.

Positron Emission Tomography with ^{15}O

Strictly speaking, all forms of positron emission tomography (PET) imaging (as do all other nuclear medicine procedures) violate the formal definition of noninvasive measurements. The 2.1 min half-life of the isotope ^{15}O , which is brief relative to those of the other commonly used positron emitters, makes ^{15}O -labeled water a useful indicator of blood flow in dynamic PET measurements (81,82). Of course, as a practical matter radioisotope imaging methods cannot be used on a large scale for research or for clinical screening purposes. Medical literature on ^{15}O -PET-based vascular studies, understandably, also focuses

almost exclusively on studies of circulation in the brain, in subjects with diagnosed vascular pathologies such as arteriovenous malformations (81).

Temporal-Spectral Imaging

A new area of investigation and technology development involving assessment of blood delivery to the periphery includes the use of optical array measurements combined with image formation and analysis capabilities. The basic concept, referred to as temporal-spectral imaging (TSI) (83), considers the functional interactions between peripheral tissues and their blood supply, and the added information that is attainable from a time series of volumetric images of tissue, where the latter are reconstructed from optical measurements of the hemoglobin signal. The information content of the measurement comprises three elements: first, expected differential response properties of tissues as a consequence of their varying blood supply and responses to internal and external stimuli; second, added information available from analysis of a time series, such as measures of rates, time delays, frequency content, and so on; third, further information available from a spatial deconvolution of diffusely scattered optical signals arising from deep tissue structures, to provide a volumetric image. In combination, the method provides for the assignment of multiple characteristics to each tissue type, and these can serve to distinguish one tissue from another, and healthy from diseased tissues. Because the supporting technology can be made compact, it is feasible to consider performing the optical array measurements on multiple sites of the body simultaneously in order to identify regional redistribution of blood, as can occur, for example, in response to shock.

The TSI approach builds upon an expanding investigative field known as diffuse optical tomography (DOT), which was first introduced late 1980s (84–88), and later extended to explore time-varying states (89,90). The DOT

technology, unlike laser Doppler techniques, is suitable for exploring deep tissue structures and, similar to PPG, employs near-IR optical sources to assess the hemoglobin signal. In the backreflection mode, penetration depths of 3–4 cm are possible, depending on the tissue type. In the transmission mode, greater penetration is possible, including up to 12 cm of breast tissue and 6–8 cm in the forearm. For larger structures, for example, involving the lower extremities, full transmission measurements are not feasible, although off-axis measures partially inscribing the structure can be made.

The DOT measurements are made using an array of optical emitters and detectors that measure the light field reemitted from tissue over a relatively broad area. Measurements encompassing many tens of square centimeters of tissue surface, with interrogation of subsurface structures to the depths indicated above, are achievable. In practice, the DOT technique can be applied to explore the full volume of a breast, or partial volumes of the head, limbs or portions of the torso.

An example of the DOT approach extended to include TSI is presented below. First, however, it is useful to appreciate how DOT is accomplished. Figure 9 shows a schematic of the measurement strategy applied to time-series DOT. Being a tomographic technique, the DOT employs a multisource, multidetector measurement covering a relative wide area of tissue. Although light migrating in tissue is randomly scattered, predictions can be made as to the volume distribution of paths taken by photons propagating between any one source and detector. These take the shape of a fuzzy banana, and are conceptually similar to the linear trajectories taken by X rays as applied to CT imaging. Collectively, an array measurement can be processed to produce a cross-sectional or volumetric image which, when measured over time, produces a time series of images.

The TSI extends the time-series DOT technique in two ways. First, as noted, it recognizes that a wealth of differential information is available due to the significant

Figure 9. Temporal Spectral Imaging principle. (a) A NIR light source (S1) illuminates the target of interest in a specific location, and the reflected and transmitted light is measured at several locations (D1–D4). The source moves on to the next location (S2), and the measurement is repeated (b). After one full scan, a tomographic image can be reconstructed (c). Steps (a–c) are repeated to obtain successive image frames that show target dynamics, such as local changes in blood volume and oxygenation.

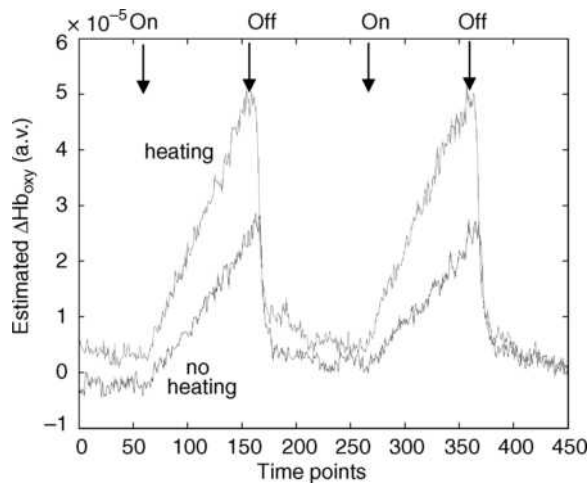

Figure 10. Time course of computed average oxyhemoglobin response to two cycles of mild venous occlusion in the forearm. Dark curve, no heat applied; light curve, with heat. [Reprinted with permission from R.L. Barbour et al., Functional imaging of vascular bed by dynamic optical tomography. Proceedings of SPIE, vol. 5369, in Physiology, Function, and Structure from Medical Images, 2004.]

variations in vascular density among the different tissue types, and in their responses to stimuli. Second, it also recognizes that for any given tissue, multiple response characteristics can be defined that serve to discriminate, as noted, one tissue type from another, or healthy from diseased. An example of this discriminatory capability is the following.

Shown in Fig. 10 is the response to partial cuff occlusion, applied to the arm in order to induce venous engorgement as recorded from a representative site about the forearm. Also shown is an enhanced response to a similar maneuver when the forearm was warmed by a thermal

blanket prior to the measurement. We interpret the enhanced response as evidence of a decrease in local peripheral vascular resistance due to vasodilatation. Using the response curve shown in Fig. 10, it is possible to identify where similar behavior is seen in the corresponding cross-sectional image time series. This is shown in Fig. 11, together with an MR map of the forearm for comparison to anatomy. Regions of high correlation to the response curve are seen in many areas, with distinctively lower correlation occurring in regions that correspond to the ulna and radius, a finding consistent with known differences between soft tissue and interosseous hemodynamics (see overlay in e).

Additional discriminatory information about the considered stimulus can be gleaned from other analyses of the image time series. Motivating the approach taken is knowledge that any measure of bulk tissue properties is actually a composite of multiple overlapping features due to known differences, for example, in vascular compliance attributable to the principal elements of the vascular tree (i.e., arteries, veins and microvessels). Separation of the individual components comprising the whole is attainable using a class of methods known as blind source separation techniques.

Data in Figure 12 is an example of use of these methods, applied to four consecutive mild inflation–deflation cycles of the type illustrated in Fig. 10. The dark curve corresponds to the first principal component (PC) and accounts for ~ 80% of the signal variance. The light curve is the second PC, accounting for ~ 10% of total variance. Inspection reveals that the time courses of the two functions differ, and that they change from one application of mild occlusion to another. In the case of the first PC, it is seen that Hb_{oxy} levels increase promptly upon inflation. Also seen is that the magnitude of this response increases modestly following the second challenge. We interpret this to represent blood volume changes in the venous

Figure 11. (a) MR cross-section of arm. (b) Cross-correlation (CC) map between (dark) model function in Fig. 10 with Hb image time series. (c) Overlay of a and b. tree, as these distend most easily relative to the other elements of the vascular tree. The response seen in the second PC is more complex. Early on in the inflation cycle, a decline is observed, followed by an accelerated increase relative to the first PC, with proportionally greater responses upon subsequent challenges. It is believed this signal originates primarily from the microvascular bed. The initial decline in Hb_{oxy} is consistent with blood pooling, allowing for greater oxygen extraction. Following this, dilation occurs, perhaps in response to a buildup of local metabolic factors. The finding that the rate and extent of change in this signal increases in subsequent challenges suggests that insufficient time had elapsed between cycles to allow for complete washout of tissue factors. Support of this assignment is given in Fig. 13. In Fig. 13a it is seen that the signal associated with the first PC is mainly seen in the periphery (red regions), roughly in agreement with the location of near-surface veins. In contrast the signal associated with the second PC in Fig. 13b is found mainly in the ventral aspect

of the forearm, which is dominated by well-perfused muscle.

Development of DOT technology is proceeding at a brisk pace, with new system designs being reported on a regular basis (91). As depicted here, TSI can be explored using time-series DOT. This, however, is not the only modality by which optical measures of peripheral vascular dynamics can be studied. Judging from advances made with photoacoustics (92), this approach may also prove useful (93,94). Additionally, the method could be extended further, to include use of injectable fluorescent probes or other forms of optical contrast media (95).

SUMMARY

Knowledge about the physiological and pathological state of the peripheral vasculature is extremely useful in the detection and staging of PVD, which occur with high prevalence and are associated with significant morbidity and mortality rates. Noninvasive measurements of those parameters are desirable because they can be performed more easily, are more cost effective, and are better suited for use as general screening tools than are invasive techniques. Volume-integrated dynamic flow measures can be obtained with a variety of available plethysmography methods. Measuring the flow response to occlusion maneuvers allows extraction of vessel flow and compliance values. In addition, plethysmography allows pulse volume recording in different locations on the extremities, and the interpretation of pulse wave contours and velocities permits drawing of inferences regarding peripheral, and even central, arterial health. Ultrasound methods, both structural and Doppler flow measurements, are valuable tools for diagnosing stenoses and thromboses. Laser Doppler flowmetry is a relatively new method for investigating the superficial microvessels.

Several imaging modalities are available for the assessment of blood flow and the vasculature. Most of these rely on contrast agents, and therefore can not strictly be considered noninvasive. The degree of invasiveness, however, seems small enough to justify their mentioning in the context of this article. Besides the conventional imaging methods, which include X ray CT, various MRI methods, and PET, the new noninvasive imaging technique of temporal spectral imaging, and in particular its

INTRODUCTION

What is Phantom?

Radiation has both particle and electromagnetic wave nature. Radiation carries energy; hence, upon striking the human body, radiation deposits the energy in the human tissue. This interaction consequently can damage the tissue by causing strand breaks in genetic molecules called deoxyribonucleic acid (DNA) in nucleus of living cells. Such damages are considered a major cause of cancers.

Radiation, such as X rays, (γ rays, electrons (or β -particles), helium ions (or α -particles), and neutrons were

discovered in late nineteenth century to early twentieth century. Since that time scientists and engineers invented and developed beneficial applications of radiation by taking advantages of the penetrating and damaging power of the radiation. Medical uses are the most noticeable applications of radiation. Radiation is used to diagnose and cure human illness.

Radiologists use X rays and other particulate radiation in hospitals and clinics to diagnose disease through imaging diseased sites. Radiation oncologists use X rays, electrons, and other forms of radiation available in radiation oncology centers to cure cancer.

While radiation is useful, careless use of radiation can lead to harmful effects on the health of people. Therefore, it is quite important to carefully evaluate the distribution of radiation energy absorbed by human tissue (or dose) during the radiological procedures. If the potential radiation damage is not well understood, clinical uses of new radiation sources without careful and thorough evaluation must be avoided. Placement of radiation measurement instrumentation in the human body is not easy, thus hampering precise dose measurements. Therefore, radiation scientists developed simulated human bodies or organs, herein called phantoms, to evaluate actual radiation doses. The phantoms are used to estimate radiation dose and transmission (or attenuation) of radiation in the human body for radiological studies.

Phantom materials for radiology should mimic the radiological characteristics of tissues. The homogeneity of radiological characteristics over the phantom is very important. Often the shape of the phantom should mimic the shape of a human body or a part of the body. Hence, the material should be easily made into various shapes and it should be easy to machine the material. The materials should maintain the mechanical integrity and the radiological characteristics for a long time.

Historical Background

To simulate radiation transport processes in human body, scientists developed phantoms made of tissue mimicking materials. The phantom should be made of material that absorbs and scatter radiation in the same way as the real tissue. Spires showed that the phantom material should have the same density as tissue and contain the same number of electrons per gram (1).

Water was the first material to be used as a tissue substitute in radiation measurements by Kienbock (2). Baumeister introduced wax in 1923 (3). The first formulated solid, called Siemen's Wax, composed of paraffin wax and magnesium oxide as a corrective filter, was reported by Ott in 1937 (4). Several similar wax-based products were subsequently introduced in Europe and North America, including MixD (5), Harris Wax (6), and M3 (7). Many phantoms comprised of either simple stacked sheets or more complex body-like structures have been constructed from these latter materials.

Plastics and rubbers have found an increasing application in the specialty of tissue simulation. From the polyethylene-based Markite (8) stemmed the conducting

plastics of Shonka et al. (9) and polyurethane systems of Griffith et al. (10). The last three products have been used in the manufacture of elaborate anthropomorphic body phantoms with airways, simulated lungs, and embedded skeletons. An important elementally equivalent liquid system was introduced by Rossi and Failla (8). A mixture of water, glycerol, urea, and sucrose was used to match an approximate formula for soft tissue. This mixture was simplified by Goodman (11) and extended to more complex elemental formulas (12). Of the tissue substitutes introduced before 1970, only a handful had radiation absorption and scattering characteristics within $\pm 5\%$ of those of the corresponding real tissues over extended energy range, and these included most of the above-mentioned phantom materials. The most important of them was water. Fortunately, it was readily available and cheap. An extensive program of research and development was initiated at St. Bartholomew's Hospital in London in 1970. Over 160 tissue substitutes were formulated, simulating a wide range of body tissues. Liquid, gel, solid, and particulate systems were produced for use with photon and particulate radiations (13–16). Other groups also developed tissue equivalent materials. Herman et al. used polyethylene to develop water-equivalent material, as well as fat and muscle materials in 1980s (17–19). Homolka et al. used polymer powders together with suitable additives to adjust photon attenuation (20,21). They created adipose, muscle, bone, and water equivalent materials, which simulate radiological characteristics of tissues for low energy photons, that is, energy < 100 keV for diagnostic X rays. Latest work includes development of tissue equivalent materials for pediatric radiology by Bloch et al. (22). Suess et al. manufactured a phantom material based on polyurethane resin for low contrast resolution measurements of computed tomography (CT) scanners (23). Iwashita used polyurethane resin mixed with CaCO_3 to create cortical and cancellous bones (24). Burmeister et al. made brain tissue equivalent conducting plastic for low-energy neutron applications (25).

Physics Background

Medical Radiation. Radiologists and radiation oncologists use radiation in several forms for diagnostics and therapy. The most common radiation is photons, which can be produced by X-ray generators and linear accelerators or are emitted by radioactive source. The photon energy used for medical applications ranges from 10 keV to 20 MeV. Electrons are another common form of radiation for medical uses. Positively charged electron or positrons are used for diagnostic purpose with positron emission tomography (PET) scanners. Heavier particles are also employed for therapeutic radiology. Protons, alpha particles, pi-mesons, neutrons, and heavy charged particles, such as carbonions were used in the past or are being introduced into clinic.

Interaction of Radiation with Matter. Photons interact with matter in three main physical processes: photoelectric absorption, Compton scattering, and pair production.

Depending on the photon energy, one of three interactions play major role. Electrons in the energy range of interest collide with electrons in atoms–molecules of the material. Electrostatic force is the major interaction mechanism. Protons and heavy charged particles go through electrodynamic interactions similar to electrons. Neutrons do not carry electric charge; hence, those interact mostly with the nucleus of atoms.

Photon interaction probability is represented by the attenuation coefficient, which is the loss rate of photon particles per unit length from the original photon flight path. Electron scattering is quantified by stopping power, which represents electron energy loss rate per unit path. Energy absorption of radiation in tissue is considered per unit mass of tissue. The unit of radiation dose is joules per kilogram (J/kg) or gray (Gy). Mass attenuation coefficient and mass stopping power are often used to describe the effectiveness of material to attenuate photons and electrons.

Radiological Equivalence of Material to Tissue. Ideally, a phantom material should have the same mass attenuation coefficient for photons and the same mass stopping power for electrons as the tissue it simulates. If the phantom can have the same atomic composition as tissue, those parameters of the phantom are the same as those of tissue. However, making the atomic composition of phantom exactly the same as tissue is not easily achievable. Hence, as a guideline of tissue equivalent material, physicists expect that the material has a similar mass density, effective atomic number, and electron density as the real tissue. The reasoning for this approach is the following. As mentioned before, photons interact with matter through three physical mechanisms. The magnitude of the photoelectric interaction is approximately proportional to a certain power of the atomic number of the atom. The concept of the effective atomic number is introduced to present how close a material is to another material for photons in the energy range in which the photoelectric effect dominates as the main interaction process. Such energy range is generally < 100 keV. The Compton interaction and pair-production are essentially proportional to the number of electrons in the material. Electron stopping power is also proportional to the number of electrons since electrons directly interact with electrons in the material. Hence, the electron density of the material is another important parameter to represent the radiological characteristics of each material.

Outline

There is concern about the materials used to manufacture phantoms for radiology applications. The next section gives extensive discussion on the materials mainly developed by White, Constantinou, and their co-workers. More detailed discussion can be found in an ICRU report (26) and relevant references by those authors. The third section presents how those materials are used for radiation dosimetry, radiation therapy, and diagnostic radiology. The discussion on applications will be limited to photons and electrons, since most medical applications utilize those

particles. The last section is devoted to speculative discussion on what types of phantom material will be developed in the near future.

PHANTOM MATERIALS: SIMULATED TISSUES AND CRITICAL TISSUE ELEMENTS

The tissue substitutes produced before 1970 were designed to simulate predominantly muscle, bone, lung, and fat. The sources of reliable data on elemental composition and mass densities of real tissues were limited. The main sources included the reports of Woodard (27), giving the elemental composition of cortical bone, and a report by the International Commission on Radiological Units and Measurements (28), giving the elemental composition of striated muscle and compact bone (femur). Unfortunately, there was a disagreement between the above sources on the composition of bone, which made bone simulation work more difficult.

The publication of the *Reference Man* data by the International Commission on Radiological Protection (ICRP) (29) in 1975 and the improvement in available equipment and technology enabled the formulation of new tissue substitutes for 15 different tissues that are described here. The *Reference Man* publication included tabulations of the concentrations of 51 elements in 81 organs, tissues, and tissue components. It also included the mass densities and the ratio of water/fat/protein contents in each one of them. Based on the above information, White and Constantinou developed substitutes for the following categories of tissues and body organs:

1. Principal soft tissues, namely, muscle, blood, adipose tissue, and skin. Adipose tissues are defined by ICRP as composed of 70% fat, 15% water, and 15% protein by mass.
2. Principal skeletal tissues, namely, cortical bone, inner bone, and red marrow. Yellow marrow is very close to adipose tissue and was not included. The formula given by Woodard (27) was adopted as more correct. This reference gives 55.8% Ca plus P, 12.5% water, 25.2% protein, and 6.5% sugar by mass for cortical bone.
3. Body organs, namely brain, kidneys, liver, lung, and thyroid. The elemental data for these organs were obtained from the ICRP Reference Man document.
4. Average tissues, which included average breast, total soft tissue, and total skeleton. The latter two formulas were derived from the ICRP source, while the formulas for average breast were based on 50% fat and 50% water by mass (13). Other formulas for average breast described in the literature (14,30) are based on 25% fat-75% muscle, 50% fat-50% muscle, and 75% fat - 25% muscle, referring to young, middle-aged, and older breast, respectively.

The percentage by mass for the elements H, C, N, O, Na, Mg, P, S, Cl, K, and Ca in each real tissue is given in Table 1 with information on mass densities and additional elements when appropriate. New tissue substitutes presented in this section were formulated so that, whenever possible, they have exactly the same elemental composition and mass density as the corresponding real tissue. In most of the solid substitutes where epoxy resin

^aSee Ref. 31

systems, acrylics, or polyethylene were used as major components, a partial replacement of oxygen by carbon and vice versa had to be accepted. For this reason, an effort was made to determine which of the elements present in various tissues play a critical role in the energy deposition process when interacting with various radiation modalities. During this evaluation, basic interaction data have been calculated for photons and electrons from 10 keV up to 100 MeV, protons from 1 up to 1000 MeV, and neutrons from 100 eV up to 30 MeV. Detailed accounts of the computations are given in the literature (13,14,32) and only a summary is given here.

When a photon beam interacts with a tissue, photon energy absorption scattering depends primarily on the atomic number Z of the constituents and the electrons/kilogram of the tissue. Since hydrogen has double the electron density of other elements, hydrogen and the high Z constituents of a tissue are the critical elements. Consequently, their percentage by mass in the substitute must match that of a real tissue as accurately as possible. In order to evaluate the accuracy with which a substitute material simulated the corresponding real tissue, the mass attenuation coefficients (μ/ρ) and energy absorption coefficients (μ_{en}/ρ) were calculated at 33 energy points between 10 keV and 100 MeV, using the mixture rule:

$$\mu/\rho = \sum_i w_i(\mu/\rho)_i$$

where w_i is the proportion by mass of the i th element having a coefficient $(\mu/\rho)_i$.

The irradiation of tissues with beams of charged particles, such as electrons and protons, leads to energy deposition through collisional and radiative processes. Collisional interactions of incident particles with the electrons of the target material are the major cause of energy loss for electrons < 500 keV and protons < 1000 MeV. Radiative (bremsstrahlung) losses become important for higher energies. In order to evaluate the new tissue substitutes for electron and proton interactions, the collision stopping powers $(s/\rho)_{\text{coll}}$ and the radiative stopping powers $(s/\rho)_{\text{rad}}$ were calculated for both substitutes and the corresponding real tissues, and comparison was made between the total stopping powers $(s/\rho)_{\text{tot}}$ of the substitutes and those of the corresponding real tissues. A phantom material was accepted as a useful substitute only if its radiation characteristics were within $\pm 5\%$ of those of the real tissue that it was designed to simulate.

In the case of tissues being irradiated with neutrons (10 eV–50 MeV), hydrogen was found to be the most critical element for all energies. Nitrogen was found to be the second most important element of neutron energies < 5 MeV. This is due to the significance of the elastic scattering of neutrons with hydrogen nuclei at higher neutron energies $^1\text{H}(n, n)^1\text{H}$ and the contribution of the capture process $^1\text{H}(n, \gamma)^2\text{H}$ and $^{14}\text{N}(n, p)^{14}\text{O}$ at the low and thermal neutron energies. Oxygen and carbon play a great role than nitrogen above 10 MeV. For neutron energies up to 14 MeV, the interactions with hydrogen account for 70–90% of the total dose in soft tissue (33,34). In view of

the above finding, efforts were made to match the hydrogen, oxygen, carbon, and nitrogen contents of all the substitutes to those of the real tissues as accurately as possible.

The relative proportion of carbon and oxygen in tissue was found to be less critical in the attenuation and energy absorption from neutrons and high energy protons. Trace elements, with concentrations of < 0.5% by mass, were found to play no significant role in the absorption of energy from fast neutrons, high energy protons, and X rays > 100 keV. Detailed calculation and tabulation of the above-mentioned radiation interaction quantities for all the real tissues and their substitute material are available in the literature (13,14,30,35).

FORMULATION PROCEDURES

Three main methods were applied in the formulation of the tissue substitutes described in this article, namely, the elemental equivalence method, the basic data method, and the effective atomic number method. The following criteria formed the basis of the tissue simulation studies.

Criteria for Tissue Equivalence

Two materials will absorb and scatter any type of radiation in the same way, only if the following quantities are identical between them: (1) photon mass attenuation and mass absorption coefficients, (2) electron mass stopping powers and mass angular scattering powers, (3) mass stopping powers for heavy charged particles and heavy ions, (4) neutron interaction cross-sections and kerma factors, and (5) the mass densities of the two materials must be the same. A brief description of the formulation methods is now presented.

Method of Elemental Equivalence

Based on the above criteria, it is obvious that only material with the same elemental constituents and in the same proportion by mass as the corresponding real tissue can be termed tissue equivalent for all radiation modalities. A number of such materials were formulated, particularly in the liquid and gel phase (14,15,30,36). If a substitute is elementally correct and has the correct bulk density, the only source of error in the absorbed dose calculations from measurements in the phantom material will be phase differences due to differences in chemical binding. Such errors are difficult to evaluate because of lack of extensive data, but they have been found small and rather insignificant in conventional radiation dosimetry.

The method of elemental equivalence was first applied by Rossi and Failla (8) who tried to reproduce an approximate formula for soft tissue $(\text{C}_5\text{H}_{40}\text{O}_{16}\text{N})_n$. They formulated a mixture of water–glycerol–urea and sucrose, which had the formula $\text{C}_5\text{H}_{37.6}\text{O}_{18}\text{N}_{0.97}$, but their publication did not explain how they arrived at their formulation. Frigerio et al. (37) used water as base material and then selected compound that could be dissolved in it in such proportions as to satisfy the CHNO molar ratio. They considered each compound as the sum of two components one of which

was water; for example, glycerol $C_3H_2(H_2O)_3$ can be written as $C_3H_8O_3$. Using this approach, they produced a liquid system with elemental composition almost identical to that of muscle tissue.

The method of elemental equivalence was applied later with minor modifications (14,30), and as a result > 35 tissue equivalent liquids and gels were formulated. The following constraints were used during this work.

1. Once a base material was selected, the additives should be chosen from a library of compounds that are neither toxic nor corrosive, explosive, volatile, or carcinogenic.
2. The number of components should be kept to a minimum.
3. The proportion by mass of each constituents of a tissue substitute should be within 0.5% of that of the real tissue, except for hydrogen for which the agreement should be within 0.1%.

The basic steps followed in the formulation of elementally correct tissue substitutes have been reported in the references cited.

Basic Data Method

The second most accurate method of formulating tissue substitutes is the basic data method, which matches basic interaction data, for example, mass attenuation coefficients for photoelectric and Compton scattering, and mass stopping powers of the tissue substitutes to those for the body tissue over the required energy interval. This method was used by White (13,38) to formulate a large group of solid and liquid tissue substitutes for use with photons and electrons. The mathematical procedures developed enable two-component tissue substitutes (base material + filter) to be formulated for a given base material, with the most appropriate filler being selected from a library of compounds. Any degree of matching accuracy (e.g., 1% between μ/ρ values) can be specified. Recently, Homolka et al. (21) developed a computer program, which minimizes the difference between the linear attenuation coefficients of a phantom material and a tissue by considering the energy dependence of the attenuation coefficient. The program optimizes the components of base materials, such as polystyrene, polypropylene, and high density polyethylene together with admixtures of TiO_2 , MgO , $CaCO_2$, and graphite. They showed that the measured Hounsfield number of the water equivalent phantom material agrees with those of water within eight Hounsfield units for X ray energy from 80 to 140 kV.

Effective Atomic Number Method

An indirect method of simulation is based on effective atomic number, Z_e , which may be used to characterize a partial mass attenuation coefficient (τ/ρ , σ_e/ρ , κ/ρ , etc.) for a given group of elements and specified photon energy. The fundamental assumption for this method is that materials with the same value of the product of electron density and Z_e^x , where x is the Z exponent derived for a given partial interaction process, as a reference material shows the same

photon and electron interaction characteristics as the reference material. A formulation technique similar to the basic data method can be derived, that is, the selection of an appropriate filler for a specific base material and the establishment of the relative proportions to achieve a specified degree of matching accuracy of the electron density and the effective atomic number between two materials. Accounts of this method were given by White et al. (39) and Geske (40).

MATERIALS AND METHOD OF MANUFACTURE OF THE NEW TISSUE SUBSTITUTES

Phantom materials currently in use can be grouped in-to four types depending on the base material. White et al. mainly developed epoxy-resin-based material (13,14,16, 38,41,42). Hermann et al. used polyethylene-based technique. ¹⁷Homolka's group made phantoms based on fine-polymer powders, such as polyethylene, polypropylene, polystyrene or polyurethane (20). Suess, Iwashita and others used polyurethane resin (23,24). Since one of the current authors is very familiar with the epoxy-resin-based method and other methods use similar manufacturing techniques except the base material, more space is devoted to discussing the epoxy-resin-based phantom in this section than other methods.

Epoxy Resin-Based Method

Materials. The base materials used by White and Constantinou for the manufacturing of solid-phantom materials included four epoxy resin systems designated CB1, CB2, CB3, and CB4, respectively. The epoxy resin systems consist of a viscous resin and a lower viscosity liquid hardener (Diluents). The two are mixed in such proportions by mass as determined by the chemical reaction occurring during the curing process. The constituents and elemental compositions of the epoxy-resin systems used in the manufacture of the new tissue substitutes were described in detail (14,38). These resin systems are rich in hydrogen (7.9–11.3% by mass) and nitrogen (1.60–65.62% by mass), but they are rather low in oxygen (13.15–20.57% by mass), compared to what is needed to match the oxygen content of the real tissue. As a result, in most solid substitutes, part of the oxygen needed was replaced by carbon, but an effort was made to have the sum of (C+O) in the substitute equal to that in the real tissue. Following the addition of the necessary powdered filler, low density ($\sim 200 \text{ kg}\cdot\text{m}^{-3}$) phenolic microspheres (PMS) are also added in small precalculated quantities to make the bulk density of the mixture match that of real tissues. In the case of lung substitutes, the addition of a foaming agent (DC1107) in quantities of 1% by mass or less leads to sample with bulk densities as low as $200 \text{ kg}\cdot\text{m}^{-3}$ (43).

In the case of liquid substitutes, water was selected as the base material because it is an important component of real tissues and it is readily available. Various organic and inorganic compounds can be dissolved in it, in proportions necessary to satisfy the requirements for both the main elements C, H, N, O and the trace elements, such as Na, Mg, P, S, Co, K, and Ca.

The use of gelatin facilitated the formulation of many gel substitutes useful for short-term applications. For the production of elementally equivalent material, gelatin is preferred to other gelling agents such as agar (37) and Laponite used in the production of thyrotrophic gels (44), because it has an elemental composition very close to that of protein. Since real tissues are composed of varying proportions of water, carbohydrates, protein, and fat, it is easier to formulate elementally correct gel substitutes with it. By adding trace quantities of bacteriostatic agent (e.g., sodium azide) and sealing them into polyethylene base, gels can be preserved for longer periods.

Mixing Procedures. The manufacture of a solid substitute starts by adding first the appropriate quantity of the resin into a Pyrex reaction vessel followed by the lower viscosity hardener-diluent. The powder fillers are then added in order of decreasing mass density. Following a short manual mix, a ground glass lid is attached to the reaction vessel. This lid has one central and two peripheral glands (openings). A twin-bladed rotor is passed through the central gland and connected to an electric stirrer. One of the peripheral gland openings is connected to a vacuum pump while the third is used to control the air pressure inside the mixing vessel. During mixing, the system is evacuated to approximately 1.3 Pa (10^{-2} mmHg). The trapped air escapes as the rotor blades break the resulting foam. After ~ 20 min of stirring under reduced pressure, a homogeneous, air-free mix is obtained. The vacuum is then released and the mix is carefully poured into waxed metal, silicon, rubber, or Teflon molds. A more detailed description is found in the references listed above.

When mixing lung substitutes, no vacuum is applied. The components are mixed thoroughly under atmospheric pressure and then a liquid foaming agent is added (activator DC1107) and quickly stirred into the mix. The foaming action starts in ~ 30 s and the mixture must be poured in the mold to foam to the required mass density. The resulting bulk density depends on the volume of the activator added. For example, 170 kg mass of foaming agent will result in a lung substitute with a density of $\sim 250 \text{ kg}\cdot\text{m}^{-3}$.

The manufacture of water-based liquid and gel substitutes is relatively easy. The required quantity of distilled water is used and the inorganic compound necessary for the introduction of trace elements are stirred into solution one by one, ensuring that each is completely dissolved, before adding the next, thus avoiding the formation of intermediate precipitates. Urea, commonly used to satisfy the nitrogen requirements, is dissolved next, followed by any other organic liquid components. If a gel substitute is required, the water with the dissolved trace elements is heated up to ~ 80 °C before adding and dissolving the necessary quantity of gelatin. Once a clear uniform solution is obtained, it is left to cool to almost room temperature before the remaining components and the bacteriostatic agent are added. The mixture is usually added into polyethylene bags, heat sealed to inhibit water loss, and left to gel before use.

Polyethylene-Based Method

This method uses polyethylene powder and inorganic admixtures, CaCO_3 and MgO , in powdered form (17,18). The polyethylene powder has a melting point of 105 °C and density of $0.917 \text{ g}\cdot\text{cm}^{-3}$. A processing temperature is 200–240 °C. Dry mixing of the polyethylene powder and inorganic powder is performed in a long Plexiglas drum rotated on a lath, with internal Plexiglas shelves providing mixing. The mixture was then poured on iron plates that carried quadratic iron frames. Plastic plates are formed during melting at 180 °C. Homogeneous and smooth plastics are obtained with inorganic admixtures of up to 10 % of the total mass. Machining is easy to make different thickness of plates. For making thinner foils, a milling machine was provided with a vacuum fixing device.

Polymer Powder-Based Method

Homolka and Nowotny discusses the manufacturing technique of polymer powder-based phantom in a publication (20). The base materials for this method are polymer powders made of polyethylene (PE), polypropylene (PP), polystyrene (PS), and polyurethane (PU). All powders are particles of sizes much $< 100 \mu\text{m}$. Typical additives were CaCO_3 , MgO , TiO_2 , calcium hydroxyapatite (bone mineral), and high purity graphite. These additives are available in a suitable grain size $< 100 \mu\text{m}$. A base material is mixed with additives using a ball mill. The material then is sintered in an evacuated vessel at temperature above the melting point of the polymers. The melting temperature (softening temperature) of PE, PP, and PS are 107, 165, and 88 °C, respectively. To remove any air or other gases, a pressure of ~ 1 Pa was applied during the sintering process.

Polyurethane-Based Method

Polyurethane consists of a chain of organic units joined by urethane links. It can be made in a variety of textures and hardness by varying the particular monomers and adding other substances. It is most commonly used to produce foam rubber. Suess and Kalendar manufactured tissue equivalent phantom materials using low density polyurethane-resin (23). The resin has a high viscosity, leading to a homogeneous mixing of fillers. The stirring of the resin, hardening, and additives are done under vacuum conditions. Air bubbles are removed at pressures < 100 Pa. The ingredients are dehumidified since different degrees of humidity interfere with the polymerization and causes variations in the cured resin density. The temperature of the base materials are maintained at 20 °C before mixing and at 40 °C during curing. The density of the material is modified by adding small amounts of low density phenolic microspheres and high density poly(tetrafluorethylene) powder.

Quality Control

Quality control is necessary in order to maintain the quality of the manufactured substitutes. Two simple and effective types of investigations are usually performed, namely, mass density measurements and radiographic imaging. Casing or machining rigid solids into cubes or cylinders and measuring their mass and volume directly

provides mass density data with an error of $\pm 0.5\%$. Density bottles are useful for mass density determinations of liquids and gels.

The use of X rays in the 20–50 keV energy range and computed tomography scans are simple and sensitive methods for homogeneity test on the tissue substitutes. With radiographic techniques, the smallest detectable size of high atomic number particulate fillers or trapped air pockets are $\sim 100 \mu\text{m}$. The high contrast resolution of CT scanners is limited to $\sim 0.6 \text{ mm}$, but the ability of the scanners to show low contrast differences can help in detecting unacceptably nonuniform macroscopic areas in the samples. Optical transmission microscopy of thin sample scan offers more sophisticated uniformity testing if a high degree of homogeneity is required.

The uniformity of the manufactured solid substitutes may be tested by mass density determinations, multiple slice CT scanning, and conventional radiographic techniques as discussed above. The mass densities at different point in a well made sample were found to be within $\pm 0.5\%$ of the average value, except for lung substitutes, which show a density variation of up to $\pm 3\%$ of the average value.

CLASSIFICATION AND TESTING OF THE NEW TISSUE SUBSTITUTES

The available tissue substitutes were classified according to the magnitude of the discrepancy between their radiation characteristics and the radiation characteristics of the corresponding real tissues. A muscle substitute, for example, with mass attenuation and mass energy absorption coefficients within 5% of the same coefficient for real muscle, is considered as Class A substitute for photon interactions. If the discrepancy is between 5 and 20%, the substitute is called Class B material and if the error exceeds 20%, the substitute is termed Class C. In addition, material with discrepancy within 1% are called tissue equivalent and classified as A*. A tissue substitute that is not elementally correct could be Class A for one radiation modality, but may be Class B or even Class C for another. Table 2 shows some of the recommended tissue substitutes and their components by mass, while Table 3 shows their classification for photon, electron, proton, and neutron interactions. The best results are obtained with Class A* materials, which are elementally correct and have mass densities within $\pm 1\%$ of the real tissue densities. The

Table 2. Tissue Substitutes

Tissue Substitutes	Description	Kg·m ⁻³	References
	Adipose Tissue		
AP/SF1	Flexible solid based on Epoxy CB3 with fillers of glucose, polyethylene, and phenolic microspheres; a four-component formula is available for trace elements	920	14
AP6	Rigid solid using low exotherm Epoxy CB4; fillers are Teflon, polyethylene, and phenolic microspheres	920	40
AP/LS	Water-based substitutes containing urea, propanol, and phosphoric acid; a four-component formula is available for trace elements	920	14
RF1	Polyethylene-based solid, fat equivalent	930	18
	Blood		
BL/L2	Water-based substitutes containing urea, ethylene glycol, and acetic acid; trace elements are available (five components)	1060	14
	Muscle		
A150	Polymer-based (electrically conducting) substitute comprising polyethylene, nylon, carbon, and calcium fluoride	1120	9, 47
Griffith urethane	Polyurethane-based material having calcium carbonate as filler	1120	10
MS/SR4	Rigid solid using Epoxy CB4 and fillers urea, polyethylene, and phenolic microspheres; five-component formula for trace elements are available	1060	14
MS20	Rigid end-product made up of Epoxy CB2 and fillers magnesium oxide, polyethylene, and phenolic microspheres	1000	40
Figerio liquid	Water-based substitute containing urea, ethylene glycol, and glycerol; a six-component formula for trace elements is available	1080	12
MS/L1	Water-based substitute containing urea, ethylene glycol, urea, and acetic acid; a six-component formula for trace elements is available	1070	14, 30
Water	H ₂ O	1000	2
MS/G1	A water–gelatin gel containing ethanol and, if required, a six-component formulation for trace elements	1060	14,30
MS/G2	As MS/G1, but urea and propanol replace ethanol.	1050	14,30
RM1	Polyethylene-based solid.	1030	18
	Cortical bone		
B110	A polymer-based electrically conducting, material made up of nylon, polyethylene, carbon, and calcium fluoride	1790	48
HB/SR4	Rigid end-product comprising Epoxy CB2, urea, calcium oxide, calcium hydrogen orthophosphate, magnesium sulfate, and sodium sulfate	1670	14
SB3	Rigid end-product comprising Epoxy CB2 and calcium carbonate	1790	42
Witt liquid	Saturated solution of dipotassium hydrogen orthophosphate in water	1720	49
BTES	Polymer-based material made up of Araldite GY6010, Jeffamine T403, silicon dioxide, and calcium carbonate	1400	22

Tissue Substitutes	Description	Kg·m ⁻³	References
IB/SR1	Inner bone Epoxy resin-based (CB2) solid having fillers of calcium orthophosphate, polyethylene, and sodium nitrate	1150	14
IB7	Rigid solid based on Epoxy CB4; fillers are calcium carbonate polyethylene, and phenolic microspheres	1120	40
IB/L1	Water-based substitute comprising dipotassium hydrogen orthophosphate, sodium nitrate, phosphoric acid, urea, and ethylene glycol	1140	14
RM/SR4	Red marrow Rigid solid using Epoxy CB4 and fillers of ammonium nitrate, polyethylene, and phenolic microspheres; a five-component formula for trace elements is available	1030	14
RM/L3	Water-based substitute containing urea and glycerol; a five-component formula for trace elements is available	1040	14
RM/G1	A water-gelatin gel containing glucose; trace elements may be added using a four-component formulation	1070	14
BRN/SR2	Brain Epoxy resin-based (CB2) solid using fillers of acrylics and polyethylene; formula (five-components) for trace element is available	1040	14
BRN/L6	Water-based substitute containing urea, ethanol, and glycerol; a four-component formula for trace elements is available	1040	14, 30
A181	Polyethylene-based solid		25
KD/L1	Kidney Water-based substitute containing sodium chloride, dipotassium hydrogen orthophosphate, urea, and ethylene glycol	1050	14, 30
LV/L1	Liver Water-based substitute containing sodium chloride, dipotassium hydrogen sulfate, sodium chloride, urea, ethanol, and glycol	1060	14, 30
LN/SB4	Lung Foamed rigid epoxy (CB4) system; fillers include urea, polyethylene and the foaming agent DC1107; a five-component formula is available for trace elements	300	14
LN10/75	Foamed rigid epoxy (CV2) system; fillers include polyethylene, magnesium oxide, phenolic, microspheres, surfactant DC200/50, and the foaming agent DC1107	310	42
LTES	Epoxy resin-based system; fillers include phenolic microspheres, surfactant, and foaming agent DC1107,	300	22
TH/L2	Thyroid Water-based substitute containing urea, ethylene glycol, and acetic acid; a three-component formula for trace elements is available	1080	14, 30
BR12	Average breast Rigid solid using low exotherm Epoxy CB4; fillers are calcium carbonate, polyethylene, and phenolic microspheres	970	40
AV.BR/L2	Water-based substitute containing ethanol and pentanediol	960	14
TST/L3	Total soft tissue Water-based substitute containing urea, ethanol, and ethylene glycol; a five-component formula is available for trace elements	1040	14
TSK/SF3	Total skeleton Flexible solid-based on Epoxy CB3; fillers include calcium hydrogen orthophosphate, calcium orthophosphate, and acrylics; a three-component formula is available for trace elements	1360	14
TSK/L1	Water-based substitute containing diammonium hydrogen orthophosphate, dipotassium hydrogen orthophosphate, and glucose	1360	14

two-part code used indicates the type of tissue being simulated; for example, MS is muscle and BRN is brain, and whether the end product is solid flexible (SF), solid rigid (SR), liquid (L), and so on. Table 4 shows the elemental composition of the recommended substitutes.

As an example for agreement of photon interaction parameters between real tissue and a tissue mimicking material, the mass absorption coefficients for adult adipose tissue and AP6 for photon energies ranging from 10 keV to 10 MeV were calculated. The adult adipose tissue data

were obtained from an ICRU report (31). The book compiles photon, electron, proton, and neutron data for body tissues. The AP6 data were calculated using the atomic composition given in Table 3 and the photon interaction data compiled in a NIST report (45). Figure 1 shows an excellent agreement of the interaction parameter between two materials. Table 3 indicates that AP6 is Class A material of the adipose tissue for the entire photon energy range.

Several experiments were carried out to verify the accuracy with which the various substitutes simulate

the corresponding real tissues. In one such series of experiments, thin-walled cells with $10 \times 10 \text{ cm}^2$ cross section were filled with real tissues and immersed in to appropriate tissue equivalent liquid to displace equal volume of that liquid. Central axis depth doses and beam profiles were then measured in the liquid behind the cells and the results compared with those obtained in the liquid alone. The material used or the construction of the cells was solid muscle substitute for the comparison with human muscle, beef stake, and pork, Brain substitute was used for the comparison with human brain. Co-60 γ source was used for the irradiation experiments. In no case did the readings at

the depth differ by $> 1\%$ in each comparison. Similar tests were made with a 160 MeV synchrocyclotron proton beam and a neutron beam with average energy of 7.5 MeV (14,46). The results with the substitutes in place were generally within 0.5% of the readings for real tissues. In another series of tests, the relationship between the attenuation coefficients and the Hounsfield units measured with a computed tomography (CT) scanner was established first using 120 kVp X rays, and then the CT numbers were measured for a range of the new tissue substitutes. The attenuation coefficients derived from the measured CT number of each material was compared

to the calculated μ value of each material. The measured μ values were generally within 2% of the computed ones (14).

APPLICATIONS: RADIATION DOSIMETRY

Radiation exposure is equal to the number of electric charges liberated by interaction of photons with air. The gold standard for exposure measurement is a free-air chamber. The chamber size must be large enough to stop photons and associated secondary electrons. Since the size could be very large for practical uses, physicists developed small cylindrical chambers called thimble chambers by making the chamber wall with air-equivalent material (47–49). Graphite, Bakelite ($C_{43}H_{38}O_7$), or mixture of those is commonly used as the wall material. These have a smaller effective atomic number than that of air; but, it is accepted because the central electrode of the ionization chamber is usually made of aluminum, whose atomic number, 13, is much larger than air (or 7.67).

Radiation dose absorbed in tissue is the most important physical parameter for therapeutic applications of radiation. It can cause fatal effects on a person or may fail to kill the malignant cells of a patient unless the delivered dose is carefully monitored. The main instrument for dose measurement is the ionization chamber. The most common ionization chambers for dose measurement are cylindrical with an outer diameter of ~ 1 cm and a length of air cavity of ~ 2 cm. When the ionization chamber is used in a solid phantom or water, some corrections are needed to estimate the dose in the medium because of differences in materials of air, the chamber wall, and the phantom material (50).

Absorbed dose in real patients can be measured by placing radiation detectors on or inside the patient during treatment. Thermoluminescent detector (TLD), a solid-state detector, is a well-established instrument for the *in*

vivo dose measurements. The TLD is made of thermoluminescent material, which absorbs radiation energy. The electric charges created in the material can be measured by heating the chip after irradiation and used to estimate the absorbed dose. In addition to the thermoluminescent characteristics, TLD should be radiologically equivalent to tissue. The common TLD material is lithium fluoride (LiF) with some impurities such as Magnesium (Mg) or Titanium (Ti) to improve the property. The effective atomic number is kept close to the tissue, or 8.2, for LiF TLD to minimize the fluence disturbance due to a foreign material placed in tissue. Since the TLD material is not identical to tissue, the response to radiation is different from that of tissue. A great concern exists when absorbed dose for low energy photons, or energies < 100 keV, must be measured because the radiation response is very different from the tissue in this energy range (47).

APPLICATIONS: RADIATION THERAPY

Accurate prediction of radiation dose delivered to patients is the most important step to generate effective radiotherapy treatment strategies. Medical physicists, who are responsible for physical aspects of the treatment planning, have to establish the physical data necessary for radiotherapy before anyone can be treated and even during actual treatment. For given radiation sources, medical physicists have to know how much radiation energy or dose is absorbed at any point in the patient's body. Generally, computers are used to predict the dose distribution. The computer can calculate doses using radiation source specific physical data incorporated in the software. The necessary data vary according to the calculation model used by the computer program. In general the absolute dose at any point or at any depth in the human body and the relative dose in the entire body are needed.

Medical physicists have developed many physics concepts since radiation sources were introduced into the clinic. For radiotherapy using electron accelerators, medical physicists introduced three important concepts: output factor, depth dose, and beam profile (48,49). The output factor is the radiation dose at a specific depth along the central beam axis or at a reference point for a given standard field size, (e.g., 10×10 cm). The depth dose gives the dose to a point at a given depth as a fraction of the dose at the reference point along the central beam axis. The beam profile shows the variation of dose along a line on a plane perpendicular to the central beam axis.

Physical models of the radiation source and human body are not perfect. Dose calculations in a real human body are difficult because of the variation in shape and tissue densities. Consequently, necessary data must be measured. The measurements are generally performed in a uniform and large medium, such as a water phantom.

Tissue Equivalent Phantom

Water. Water is a favorite medium for dose measurements for several reasons. Water is nearly tissue equivalent and inexpensive (or readily available). Furthermore, a radiation detector can be scanned through in water for dose

Figure 2. The ratio of mass attenuation coefficients between water and muscle or adipose tissue versus photon energy.

measurements at points spaced very closely. One should remember, however, that the equivalence of water to tissue depends on the photon energy and the tissue to which water is compared. Mass attenuation coefficients of water, muscle, and adipose tissue were evaluated for photons in the energy range between 1 keV and 20 MeV. The ratios of water to muscle and water to adipose tissue are plotted in Fig. 2. The mass attenuation coefficients of water are 1 % larger than those of muscle and adipose tissue for energies > 0.1 MeV. However, in the energy range between 0.01 and 0.1 MeV the mass attenuation coefficients of water are smaller as much as 1.5% with those of muscle and adipose tissue.

Solid Phantom. Liquid water is cumbersome to use in a high electric voltage environment such as in an accelerator room. Hence, medical physicists manufactured water-equivalent solid phantoms. There are a few solid phantom materials currently available commercially. The list of products is given in Table 5. Poly (methyl methacrylate)

or acrylic is sold under names of Lucite, Plexiglas, or Perspex. Polystyrene has usually clear color and it is common phantom material for physics quality assurance programs because of relatively low price. Physicists discovered that PMMA and polystyrene leads to as much as 5% error when those are used for the absolute dose measurements of electron beams. Hence, an epoxy resin-based solid water material was developed as a substitute for water (16). It was made to simulate radiological characteristics of water more accurately than PMMA and polystyrene. Both mass attenuation coefficients and electron stopping powers of the solid water agree with those of water within 1% for the energy range between 10 keV and 100 MeV (51).

The new generation of solid water is being manufactured by Gammex-RMI (Middleton, WI). The phantoms are available in slabs of various sizes and thickness as seen in Fig. 3. Plastic Water was developed by CIRS (Computerized Imaging Reference Systems Inc., Norfolk, VA). It is a variation of the solid water. It is flexible. It was shown that measured outputs of electron beams in the Plastic Water agree with water within 0.5% for energy ranging from 4 to 20 MeV (52). Med-Tec, Inc. (Orange City, IA) is manufacturing what they call Virtual Water, which has the same chemical composition and density as solid water, but the manufacturing process is different. Hermann et al. developed polyethylene-based water-equivalent solid material (17). The material is manufactured by PTW (Freiburg, Germany) and it is sold as White Water or RW3. It contains titanium oxide as additive.

The dose at a depth (5 or 7 cm for photon beams and the depth of dose maximum for electron beams) in solid phantoms was measured with ionization chambers for various photon and electron energies. The results were compared with the dose measured in water. Figure 4 shows the ratio of measured doses in a solid phantom and water for plastic water (PW), white water (RW-3), solid water (SW-451 and SW-457), and virtual water (VW) (52,53). The horizontal axis of the figure indicates the photon energy. The larger the ionization ratio, the higher the photon energy. The beam energy ranges from Co-60 γ ray (1.25 MeV) to 24 MV. The solid water and virtual water show the best agreement

Table 5. Elemental Compositions of Common Water-Equivalent Phantom Materials

Tissue		Elemental Composition (percentage by mass)										Other Elements	Mass Density, $\text{kg}\cdot\text{m}^{-3}$	Z_{eff}	N, $\text{e}\cdot\text{kg}^{-1} \times 10^{26}$

among the evaluated materials. The results for electron beams are given in Fig. 5, where the horizontal axis indicates the effective energy, which is an approximation of the beam energy. The solid water and virtual water also show a good agreement for the entire electron energy.

Gel Phantom. A relatively new development is taking place on a tissue-equivalent material in gel form. The new material can record the radiation dose without additional instrument inserted in the phantom. The phantom can be made large enough to simulate the human body. Among many variations of gel phantoms, the most promising is polymer gel manufactured by MGS Research Inc. (Guilford, CT) (54). Originally it was made of acrylamide, *N, N'*-methylenebisacrylamide (bis), agarose, and water. The chemical composition was optimized over years. Currently,

Figure 4. The ratio of measured output in solid phantom and water for photon beams.

Figure 5. The ratio of measured output in solid phantom and water for electron beams.

the polymer gel is sold as BANG3 with 80% water, 14% of gelatin, and 6% of methacrylic acid by mass. A typical atomic composition of the polymer gel as well as the mass density, the effective atomic number, and the electron density are given in Table 5. The effective atomic number and the electron density of the polymer gel agree with those of water very well. The polymer gel produces highly linked polymers when it is irradiated. The structural change causes a change in color and mass density. The recorded dose distribution can be indirectly read by measuring the photon attenuation of both visible light and X ray. The polymerization also causes a change in the magnetic property of the gel. The most popular method is currently to scan the irradiated phantom with a magnetic resonance imaging (MRI) scanner. It takes advantage of the change in the spin-spin relaxation rate, which increases with increasing absorbed dose.

Differing from more traditional dose measurement tools, polymer gel dosimeter enables medical physicists to obtain full three-dimensional (3D) dose distributions in a geometrically consistent way. Polymer gel phantom was used to measure 3D dose distributions of advanced radiotherapy treatment such as those for intensity modulated radiation therapy (IMRT) (55) and Gamma Knife stereotactic radiosurgery (56). Figure 6 shows an MRI image taken after the polymer gel was irradiated with a Gamma Knife system (Elekta AB, Stockholm, Sweden). The blighter color indicates higher dose.

Geometric Phantom

With the advent of rapid development of highly conformal radiation therapy, modern radiation therapy requires high geometrical precision of radiation delivery. At the same time, the complexity of treatment planning software has substantially increased. This has urged medical physicists to test the geometrical precision of the treatment planning software (57). Special phantoms are being manufactured to assure the quality of geometry created by the software.

Figure 6. Dose distribution images obtained by polymer gel dosimeter for Gamma Knife irradiation.

Here we discuss two of those phantoms currently on market.

Lucy 3D Precision Phantom. Lucy phantom was developed by Toronto Sunny Brook Regional Cancer Center and Sandstrom Trade and Technology, Inc. (Ontario, Canada) (58). The acrylic phantom of a shape of head (Fig. 7) is used to test the image quality of CT, MRI, and X ray imaging modalities, which are used for stereotactic radiation therapy. It can verify imaging errors, image distortions, and the geometrical accuracy of treatment planning system. It serves also as routine machine QA equipment.

Figure 7. Lucy 3D precision phantom from the Sandstrom Trade and Technology Inc. (Ontario, Canada).

Figure 8. Quasar beam geometry MLC phantom from Modus Medical Devices, Inc. (Ontario, Canada).

Quasar Phantom. Another Canadian company, Modus Medical Device, Inc. (Ontario, Canada), developed phantoms to verify geometrical accuracy generated by radiation therapy treatment planning software (59). The phantoms are made of Lucite, cedar, and polystyrene. One of those, Quasar body phantom, can be used to test the accuracy of the digitally reconstructed radiography (DRR) images. DRR images are generated from a number of axial images taken by a CT scanner and the DRR images are compared with the images taken with an electronic portal imaging system or with radiographic port films before treatment to verify the patient position accuracy. Quasar beam geometry MLC phantom shown in Fig. 8 can verify the geometrical display accuracy of leaf position and the size of the multileaf collimator, which have replaced traditional blocks to define radiation fields.

Humanoid Phantom

Complex high precision radiation delivery techniques, such as IMRT and stereotactic radiation therapy, demand ever increasing accuracy of dose delivery in geometry close to the human body. Body phantoms such as Rando and Alderson were introduced many years ago. Those were used to predict to radiation exposure to humans during radiation therapy and diagnostic radiology procedures. The Rando phantom manufactured by the Phantom Laboratory (Salem, NY) is shown in Fig. 9. The body phantom is sliced into many 5 cm thick slabs. Radiographic films can be inserted between the slabs for dose measurements. The slabs can also hold TLD chips for absolute dose measurements. The phantom is made of soft-tissue equivalent material, which is manufactured with proprietary urethane formulation. The phantom uses natural human skeletons. Lungs and breast closely mimic the real tissues.

Recently, many phantoms which simulate a part of body were developed, for example, Gammex-RMI, Phantom

Figure 9. Rando phantom manufactured by the Phantom Laboratory (Salem, NY).

Laboratory, CIRS (60), and so on. Many of those phantoms are made to measure dose inside the phantom for verification of radiation therapy treatment. There are phantoms in various shapes for IMRT QA. Those phantoms can accommodate ionization chambers, radiographic films, and TLDs for dose measurements. Those may have special inserts for nonsoft tissue materials, such as lung and bone. The shapes of the phantoms are torso, head, thorax, pelvis, and neck.

DIAGNOSTIC IMAGING

X Rays

X rays are used to take images of parts of the body for diagnostic purposes (61). The oldest and most commonly used X ray imaging modality is X ray radiography. Images can be recorded on radiographic films. Recently, digital recording has become more common since the digital technique requires no wet-film processing and allows radiologists to manipulate and store the images more easily than hard-copy films.

Medical physicists use phantoms to test the quality of images. Some of common phantoms are dual-energy X ray absorptiometry phantom, anatomical phantoms (62), digital subtraction angiography (DSA) phantom, contrast detail phantom, and dental image QA phantoms.

Fluoroscopy

A regular X ray device can take static images of patients. A fluoroscopic unit, consisting of an X-ray tube, a camera, an image intensifier, and a TV monitor, can record images of moving parts of the body and of objects placed inside the body. This method of recording images is called fluoroscopy. Interventional radiologists use fluoroscopy to monitor the location of very thin wires and catheters going through blood vessels as those are being inserted during a procedure. Phantoms are an important instrument to assure the quality of fluoroscopy images. There are fluoro-

scopic phantoms, such as cardiovascular fluoroscopic benchmark phantom, fluoroscopy accreditation phantom, and test phantom.

Mammography

Mammography is a major diagnostic modality to detect breast cancer. The tumor size is often very small, that is, submillimeter diameter. Though small, early discovery of such small tumors is very important and can lead to better therapy outcomes, that is, higher cure rates and longer survival. Hence, the quality of X ray equipment used for mammography is a key for the success of this imaging modality and its performance is tightly controlled by federal and local governments. Consequently, medical physicists developed many phantoms to evaluate the imaging quality of mammography devices accurately and efficiently. Several phantoms are used, known as QA phantom, accreditation phantom, high contrast resolution phantom, contrast detail phantom, digital stereotactic breast biopsy accreditation phantom, phototimer consistency test tool, and collimator assessment test tool. A tissue-equivalent phantom manufactured by CIRS (Norfolk, VA) is shown in Fig. 10. The phantom is 4.5 cm thick and simulates the shape of a breast during the imaging. It is made of CIRS resin material mimicking the breast tissue. Objects with varying size within the phantom simulate calcifications, fibrous tissue in ducts, and tumor masses.

Computed Tomography

Computed tomography scanning systems were developed in the 1970s and rapidly deployed into clinics into the 1980s. Currently, this imaging modality is commonly used for diagnosis and radiation therapy in clinic and hospitals. Compute tomography provides patient's anatomy on planes transverse to body axis (from head to toe). The plane images called axial slices are taken every 0.05–1 cm. Depending on the axial length of the scan, the number of slices can vary from 20 to 200. Computed tomography

Model 011A

Figure 10. Tissue-equivalent mammography phantom from CIRS (Norfolk, VA).

enables radiologists to visualize the location of disease in 3D, leading to potentially more accurate diagnosis. Medical physicists use phantoms to estimate dose to patients during CT scan, to test the precision of scanning geometry, and verify the quality of CT images. Such phantoms are the bone mineral analysis phantom, spiral/helical CT phantom, CT dose phantom, orthopedic calibration phantom, spine phantom, electron density phantom, and CT performance phantom.

Each picture element (pixel) of a CT image is represented by a CT number (or Hounsfield units). The CT number for water is 0, while the CT numbers in the lung are below -200 and those in the bones are ~ 200 . Since the CT number is found to depend on the electron density, among other parameters, it can be used to identify the material type and the distribution of the tissue inhomogeneities, which is very useful in radiation therapy treatment planning. One electron density phantom, developed in order to establish the relationship of CT number and tissue electron densities, is made of solid water and has cylindrical shape with a radial size of pelvis and 6 cm thickness. Small cylindrical inserts mimicking different tissues are plugged into the phantom. When it is CT scanned, the measured CT numbers of those materials can be plotted against the predetermined electron densities and the resulting data are used in treatment planning computer. This electron density CT phantom, which is now commercially available, shown in Fig. 11, was designed by Constantinou (63) and manufactured by GAMMEX-RMI (Middleton, WI). Available insert materials are lung (LN-300 and LN-450), adipose (AP6), breast, CT solid water, CB3 resin, brain, liver (LV1), inner bone, bone (B200, CB2-30% mineral, CB2-50% mineral), cortical bone (SB3), Titanium simulating Titanium implants for hip replacements, and true water.

Tissue Characterization Phantom

Figure 11. Electron density phantom RMI 467 from GAMMEX-RMI (Middleton, WI).

NUCLEAR MEDICINE

For nuclear medicine procedures, radioactive compound composed from Technetium, Iodine, Fluorine, etc. is injected into blood stream (64). The material is carried to a potential disease site by blood and stays there. Radioactive material emits photons or positively charged electrons called positrons. Since photons can easily escape the patient body, the photons can be detected by a photon detecting device. The photons are used to form images. Positron emission tomography (PET) uses positron emitting radioactive material. When a positron interacts with an electron in the body, both particles are converted into photons. The PET is more advanced nuclear medicine procedure and can generate 3D distributions of radioactive material. Phantoms are used for quality assurance of nuclear medicine systems. A NEMA (National Electrical Manufacturers Association) scatter phantom manufactured by CIRS Inc. (Norfolk, VA) is a circular polystyrene cylinder. Radioactive material with known activity is delivered to line source insert tubes. The image of the phantom is taken to test scatter fraction and count losses.

FUTURE

Tissue-equivalent materials for solid phantoms are well developed. There may be a need of incremental improvement in phantom materials possibly for lower price and more accurate representation of tissue types. Furthermore, phantom materials are needed for newer radiation types such as heavy ions. As new therapy and imaging modalities will be put into practice, new phantoms will be developed for efficient and accurate testing of those new tools. Modern radiology utilizes not only ionizing radiation such as photons, electrons, and heavy particles, but also electromagnetic radiation (or EM-waves) and ultrasound. Phantom materials exist for testing ultrasound devices and MRI scanners. This is an active area for development. For example, D'Souza recently developed a phantom used for quality testing of ultrasound, MRI, and CT (65). Readers interested in those phantoms should consult with the phantom manufactures, such as GAMMEX-RMI (Middleton, WI), CIRS, Inc. (Norfolk, VA) and Fluke/Cardinal Health (Cleveland, OH).

Here, the focus is on two aspects of interest for future development. It may be necessary to develop more biologically tissue equivalent phantom materials. Such materials simulate not only the radiological characteristics of radiation modalities, but also it can closely simulate the radiation effects on the tissues in realistic geometry. Biomedical engineers and scientists are vigorously working on artificial tissue, potentially replacing the real tissue. Such material could be also used as phantom material. Readers should refer to a comprehensive review on the current state of art in tissue engineering authored by Lanza et al. (66).

Computer modeling of human body is an active field of research and development. Noticeable example is the Visual Human Project sponsored by National Library of Medicine, NLM (67). Whole bodies of male and female cadavers were scanned with CT and MRI. The datasets

are available for anyone who is interested in the information through licensing with NLM and with minimal cost. The datasets for the male consist of 12 bits axial MRI images of the head and neck and up to 1871 axial CT slices of the whole body. The female data set is 5000 axial CT images, with which one can reconstruct 3D images with $0.33 \times 0.33 \times 0.33$ mm cubic voxels. The data can be used to construct human body model for quality assurance of radiological systems, in particular, for testing the radiation therapy treatment planning system. In addition to real geometry, the data contain the detailed information of tissue heterogeneities in human body. Such data are indispensable for accurate assessment of new radiological technologies.

PHARMACOKINETICS AND PHARMACODYNAMICS

PAOLO VICINI
University of Washington
Seattle, Washington

INTRODUCTION

Drug discovery and development is among the most resource intensive private or public ventures. The Pharmaceutical Research and Manufacturers Association (PhRMA) reported that in 2001, pharmaceutical companies spent ~ \$30.5 billion in R&D, 36% of which was allocated to preclinical functions (1). Given the expense and risk associated with clinical trials, it makes eminent sense to exploit the power of computer models to explore possible scenario of, say, a given dosing regimen or inclusion–exclusion criteria before the trial is actually run. If anything, this goes along the lines of what is already commonly done in the aerospace industry, for example. Thus, computer simulation is a relatively inexpensive way to run plausible scenarios *in silico* and try and select the best course of action before investing time and resources in a (sequence of) clinical trial(s). Ideally, this approach would integrate information from multiple sources, such as *in vitro* experiments and preclinical databases, and that is where the difficulties specific to this field start.

System analysis (in the engineering sense) is at the foundation of computer simulation. A rigorous quantification of the phenomena being simulated is necessary for this technology to be applicable. Against this background, the quantitative study of drugs and their behavior in humans and animals has been characterized as pharmacometrics, the unambiguous quantitation (via data analysis or modeling) of pharmacology (drug action and biodistribution). In a very concrete sense, pharmacometrics is the quantitative study of exposure-response (2), or the systematic relationship between drug dosage (or exposure to an agent) and drug effect (or the consequences of agent exposure on the organism). Historically, there have been two main areas of focus of pharmacometrics (3). Pharmacokinetics (PK) is the study of drug biodistribution, or more specifically of absorption, distribution, metabolism, and elimination of xenobiotics; it is often characterized as “what the body does to the drug”. Pharmacodynamics (PD) is concerned with the effect of drugs, which can be construed both in terms of efficacy and toxicity. This aspect is often characterized as “what the drug does to the body”.

It has to be kept in mind that both pharmacokinetic and pharmacodynamic systems are “dynamic” systems, in the sense that they can be modeled using differential equations (thus, to an engineer, this distinction may seem

a bit unusual). In addition, a third aspect of drug action will be discussed, disease progression, in the rest of this article.

The joint study of the biodistribution and the efficacy of a compound, or a class of compounds, is termed PK-PD, to signify the inclusion of both aspects. While the PK subsystem is a map from the dosing regimen to the subsequent time course of drug concentration in plasma, the PD subsystem is a map from the concentration magnitudes attained in plasma to the drug effect. This paradigm naturally postulates that the time course in plasma is a mediator for the ultimate drug effect, that is, that there is a causal relationship between the plasma time course and the effect time course. As seen later, this causal relationship does not exclude the presence of intermediate steps between the plasma and effect time courses (e.g., receptor binding and delayed signaling pathways).

Both PK and PD are amenable to quantitative modeling (Fig. 1). In fact, there is a growing realization that the engineering principles of system analysis, convolution, and identification have always been (sometimes implicitly) an integral part of the study of new drugs, and that realization is now giving rise to strategies that aim at accelerating drug development through computer simulation of expected drug biodistribution and efficacy time courses. Interestingly, the intrinsic complexity of PK-PD systems has sometimes motivated the applications of generalizations of standard technology, (e.g., the convolution integral) (4),

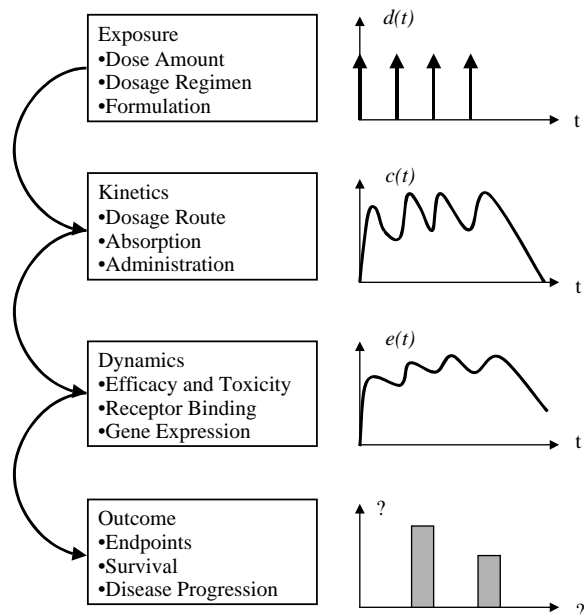

Figure 1. This figure briefly summarizes the functional pathways that exist from dosing (exposure) to outcome through drug biodistribution (pharmacokinetics) and drug effect (pharmacodynamics). It is not unusual to find a disconnect between the resolution available in the dynamic measurements and the actual clinical outcome. Also, while the convolution operator can be used to map the dosing regimen $d(t)$ to the concentration-time profile $c(t)$ and then to the effect $e(t)$, this is not necessarily true when going from the dynamic behavior to clinical measurements, which are often lower resolution and/or discrete.

through sophisticated methodological contributions that have yet to impact the engineering mainstream. Lastly, the PK-PD model is currently viewed as a perfectly adequate approach not only to process, but to extract new, quantitative information from noisy measurements. As such, the model can be construed as a probe, or a measurement tool or medical instrument in its own right, with its own built-in confidence limits and design limitations (5).

Pharmacokinetics: What Shapes the Concentration–Time Curve?

The first application of mathematical models to biology is usually attributed to Teorell (6) and led to the development of the class of compartmental models whose usage is now so widespread. Teorell's work was conducted on exogenous substances, xenobiotics (e.g., drugs). Model-based analysis of exogenous substances is somewhat simpler than endogenous compounds (e.g., glucose, insulin and other hormones, where autoregulation is crucial to understanding), since endogenous fluxes that may be exquisitely sensitive to changes in circulating concentrations are absent.

Teorell's original motivation survives in modern PK-PD modeling. The PK model is typically a useful mathematical simplification of the underlying physicochemical and physiological processes. It is usually a lumped parameter, compartmental model, and describes the absorption, distribution, metabolism, and elimination (ADME) of a drug from the body (7). A practical review of simple PK models can be found, for example, in Ref. 8. As an example, the distribution of a drug in the plasma space following an intravenous injection may be well described by a monoexponential decay:

$$c(t) = C_0 e^{-\alpha t} \quad (1)$$

where $c(t)$ is the drug concentration at time t , C_0 is the concentration at time 0 and α is the decay rate. As it is straightforward to verify, this functional form of $c(t)$ is the solution to a first-order ordinary linear differential equation, or a single compartment model:

$$\begin{aligned} \dot{q}(t) &= -k_{el}q(t) + D\delta(t) \\ q(0) &= 0 \\ c(t) &= \frac{q(t)}{V} \end{aligned} \quad (2)$$

where $q(t)$ is the amount of drug in the plasma space, D is the injected dose, $\delta(t)$ is the Dirac delta, and V is the drug's volume of distribution. It can be easily verified that

$$\begin{aligned} C_0 &= \frac{D}{V} \\ \alpha &= k_{el} \end{aligned}$$

so that the elimination rate of the drug is equal to the decay rate of the concentration–time curve. An important pharmacokinetic parameter is the drug's clearance, or the volume cleared per unit time, which for the model above can be expressed as:

$$CL = k_{el}V$$

Another common pharmacokinetic parameter is the area under the concentration curve:

$$\text{AUC} = \int_0^{\infty} c(t) dt = \frac{D}{\text{CL}}$$

The AUC is probably the most common measure of exposure in pharmacokinetics, since it summarizes dosing and systematic information. The model in equation 2 could be extended to accommodate first-order absorption, for example, to model the plasma appearance of an oral or intramuscular dose as opposed to an intravenous dose:

$$\begin{aligned} \dot{q}_1(t) &= -k_a q_1(t) + D\delta(t) \\ \dot{q}_2(t) &= +k_a q_1(t) - k_{el} q_2(t) \\ q_1(0) &= q_2(0) = 0 \\ c(t) &= \frac{q_2(t)}{V} \end{aligned} \quad (3)$$

where k_a is the absorption rate constant (again in units of inverse time), and $q_1(t)$ and $q_2(t)$ are the amounts in the absorption compartment and in the plasma compartment, respectively. It can be easily verified that this model also describes the convolution of a single-exponential absorption forcing function with the single exponential impulse response of the plasma space.

For the simple single compartmental model (eq. 2), the pharmacokinetic parameters can be readily estimated from the data (9), and the assumption of a mechanistic model does not affect their values. In other words, both compartmental (model-dependent) and noncompartmental (data-dependent) analyses provide the same result. However, this relatively straightforward interpretation of the eigenvalues of the system matrix in relation to the observed rate of decay is correct only for single-compartment systems such as this one. In the case when the drug diffuses in two compartments (e.g., a plasma and extravascular compartment), then its time course is described by a sum of two exponential functions:

$$c(t) = A_1 e^{-\alpha t} + A_2 e^{-\beta t} \quad (4)$$

but the corresponding ordinary linear differential equation is

$$\begin{aligned} \dot{q}_1(t) &= -(k_{10} + k_{12})q_1(t) + k_{21}q_2(t) + D\delta(t) \\ \dot{q}_2(t) &= +k_{12}q_1(t) - k_{21}q_2(t) \\ q_1(0) &= q_2(0) = 0 \\ c(t) &= \frac{q_1(t)}{V} \end{aligned} \quad (5)$$

where the parameters are the same as before, except that now $q_1(t)$ and $q_2(t)$ are the amount of drug in the plasma and extraplasmal compartments, respectively, k_{10} is the rate constant (in units of inverse time) at which the drug leaves the system, and k_{12} and k_{21} are the rate constants at which the drug is transported out of the plasma and extraplasmal compartments, respectively. One can relatively easily estimate the α and β parameters describing the observed rates of decay (one slow and the other fast) of concentration; however, the algebraic relationship

between those and the fractional rate constants that mechanistically describe plasma-extraplasmal exchange is not trivial. The complexity of these expressions increases with increasing number of compartments (10) and rapidly grows to be daunting. The limitations of noncompartmental and compartmental analysis of pharmacokinetic data have been discussed elsewhere, so we will not cover them here (20). There are other sources of complexity in pharmacokinetics and drug metabolism, which turn into more complex expressions for the model equations required to describe the drug's fate. For example, the underlying compartmental model may be not linear in the kinetics. This could happen, for example, when the fractional rate of disappearance changes with the drug level and goes from zero order at high concentrations to first order at low concentrations, as it happens for phenytoin (11) or ethanol (12):

$$\begin{aligned} \dot{q}(t) &= -\frac{V_m}{K_m + q(t)} q(t) + D\delta(t) \\ q(0) &= 0 \\ c(t) &= \frac{q(t)}{V} \end{aligned} \quad (6)$$

where the elimination rate is not constant, rather it exhibits a saturative behavior that resembles the classic Michaelis-Menten expression from enzyme kinetics. In this case, the principle of superposition does not hold and the concentration-time curve cannot be expressed in algebraic (closed) form, and the time course is not exponential, except at values of $q(t)$ that are much smaller than K_m . There are many other types of pharmacokinetic nonlinearities, of which this is just an example. This is why most modern PK analyses directly use the differential equations when building a PK model.

Excellent historical reviews of the properties of compartmental models, especially with reference to tracer kinetics, can be found in Refs. 13-16. More modern viewpoints are available in Refs. 17,18. Perspectives from drug development are available in Refs. 7,19. A succinct and practical review of compartmental and noncompartmental methods can be found in Ref. 8. Lastly, as we mentioned, a comparison of the strengths and weaknesses of compartmental and noncompartmental approaches has been carried out in Ref. 20.

A PK model can be used to make informed predictions about localized drug distribution and dose availability to the target organ, especially with physiologically based pharmacokinetic (PBPK) and toxicokinetic (PBTK) models. An important application has always been to individualize dosing (21,22) and improve therapeutic drug monitoring (23,24), often by borrowing approaches from process engineering and automatic control theory (25,26). Physiologically based models of pharmacokinetics are becoming an integral part of many drug development programs (27), mainly because they provide a mechanistic way to scale dosing regimens between species and between protocols. This affords (at least in theory) a seamless integration between the preclinical (*in vitro* and *in vivo*, animal studies) and clinical (*in vivo*, human studies) aspects of a drug development program. Animal to human scaling is of

increasing importance in several areas of pharmacotherapy (28) and has a long and illustrious history, from the early work by Dedrick and co-workers on methotrexate (29) to a more general application (30,31) to modern experiences (32) motivated by first time in man (FTIM) dose finding (33,34). The approach is, however, not without its critics (35), mainly due to the lack of statistical evaluation that often accompanies the scaling. It is noteworthy that between-species scaling of body mass (36,37) and metabolic rate (38) has been and is currently an object of investigation outside drug development, and mechanistic findings about the origin of allometric scaling (39) have lent scientific support to the empiricism of techniques used in drug development (40,41).

Now is a good time to note that, most often, these projections are accompanied by some statistical evaluation. From the very beginnings of PK-PD, the realization that one needed to account both for variation between subjects (due to underlying biological reasons, e.g., genetic polymorphisms and environmental factors) and variation within subject (due, e.g., to intrinsic measurement error associated with the quantification of concentration time courses and efficacy levels) was particularly acute. Statistical considerations have thus always been a part of PK-PD. The role of *population analysis*, or the explicit modeling of variability sources, in the analysis of clinical trial data is discussed in more detail later. As far as other examples, statistical applications to PK-PD have proven useful in aiding the estimation of rates of disease progression (42,43), determining individually tailored dosing schemes (23,44) and resolving models too complex to identify without prior information (45). As mentioned later, a common framework often exploited in PK-PD has to do with the incorporation of population-level information (e.g., statistical distributions of model parameters) together with individual-specific information (limited concentration–time samples, e.g.).

Pharmacodynamics: The Mechanistic Link Between Drug Exposure and Effect

The PD models (46–49) can link drug effect (characterized by clinical outcomes or intermediate pharmacological response markers) with a PK model (50), through biophase distribution, biosensor process and biosignal flux (51). Formally, the simplest PD model is the so-called E_{\max} model, where effect plateaus at high concentrations:

$$e(t) = \frac{E_{\max}c(t)}{EC_{50} + c(t)} \quad (7)$$

where E_{\max} is maximal effect, and EC_{50} is the effective plasma concentration at which effect $e(t)$ is half-maximal. This model is sometimes modified to account for sigmoidal effect shapes by adding an exponent that varies from ~ 1 to around 2:

$$e(t) = \frac{E_{\max}c^H(t)}{EC_{50}^H + c^H(t)} \quad (8)$$

Often, the driver of pharmacological effect is not plasma concentration $c(t)$, but some concentration remote from plasma and delayed with respect to plasma. This repre-

sentation is similar to the one used to represent delayed effect of glucose regulatory hormones such as insulin (52). The delayed effect site concentration is then modeled using the differential equation:

$$c_e(t) = k_{eo}[c(t) - c_e(t)] \quad (9)$$

whereas the PD model now contains effect site concentration, not plasma concentration:

$$e(t) = \frac{E_{\max}c_e(t)}{EC_{50} + c_e(t)} \quad (10)$$

and the interpretation of the parameters is the same as before except that they are defined with reference to effect site concentration as opposed to plasma concentration. Other classes of models are the so-called indirect response models, where the drug modulates either production or degradation of the effect (response) variable. These models are particularly appealing due to their mechanistic interpretation, and have been proposed in Refs. (53) and (54), reviewed in Ref. (55), and applied in many settings, including pharmacogenomics (56).

In many ways, the PD aspect of drug development is more challenging than the PK aspects, for many different reasons. First of all, the process of gathering data to inform about the PD of a drug is more challenging. Moreover, PD measurements may be less sensitive than it would be desirable (pain levels, which are both categorical and subjective, are a good example). Lastly, the mechanism of action of the drug may not be entirely known, and thus the best choice of measurements for the PD time course may be open to debate. How should the effect of a certain drug be quantified? If the drug is a painkiller, are pain levels sufficient, or would the levels of certain chemical(s) in the brain provide a more sensitive and specific correlate of efficacy? These and other questions become very relevant, for example, when drugs are studied that exert their effect in traditionally inaccessible locations (e.g., the brain) (57).

This is the “best biomarker question”, as it relates to the now classical classification of biomarkers, surrogate endpoints and clinical endpoints (58). Basically, while a biomarker is any quantitative measure of a biological process (concentration levels, pain scores, test results and the like), a surrogate endpoint is a biomarker that substitutes for a clinical endpoint (e.g., survival or remission). In other words, surrogate endpoints, when unambiguously defined, are predictive of clinical endpoints, with the added advantage of being easier to measure and usually being characterized by a more favorable time frame (59). In the United States, the Food and Drug Administration (FDA) now allows the possibility of accelerated approval based on surrogate endpoints, provided certain conditions are met (60). Against this framework, it makes eminent sense for the PK-PD model to be focused on a relevant biomarker (or surrogate endpoint) as soon as possible in the drug development process. Often, the earlier in the process, the less influence the choice of biomarker will have. In other words, when the selection of lead compounds is just starting, proof of concept may be all that is needed, but the closer one gets to the clinical trial stage, the more crucial an appropriate

choice of surrogate endpoint will be. Another way to think about this is the establishment of a causal link between therapeutic regimen and outcome. Where these concepts come together is in the (relatively novel) idea of disease progression, and how it can be monitored.

Disease Progression: How to Know Whether the Drug is Working

Recently, the contention has been made that an integral part of the understanding of PK and PD cannot prescind from, say, the background signal that is present when the drug is administered. In other words, not all patients will be subjected to therapy at the same point in time, or at the same stage in their individual progression from early to late disease stages. There is thus a growing realization that the therapeutic intervention is made against a constantly changing background of disease state, and that the outcome of the therapy may depend on the particular disease state at a given moment in time. Disease progression modeling (61) is thus the point of contact between PK and PD and the mechanistic modeling of physiology and pathophysiology that is advocated, e.g., by the Physiome Project (62,63), recently taken over by the International Union of Physiological Sciences' Physiome and Bioengineering Committee (64).

Interesting applications are starting to emerge. For example, Ref. 65 has shown that the rate of increase of bloodstream glucose concentration in Type 2 diabetic patients is $\sim 0.84 \text{ mmol}\cdot\text{L}^{-1}\cdot\text{year}^{-1}$ (with a sizable variation between patients of 143%), thus providing a quantitative handle on the expected deteriorating trend of overall glycemic levels in this population of patients (together with a measure of its expected patient-to-patient variability). In Alzheimer's disease, another study (66) has demonstrated a natural rate of disease progression of $6.17 \text{ ADASC units}\cdot\text{year}^{-1}$ (where ADASC is the cognitive component of the Alzheimer disease assessment scale). A word of caution: As often done in this area of application, the models are informed on available data. In other words, the model parameters are quantified (estimated) based on available measurements for the drug PK and PD. This poses the challenge of developing models that are not too detailed nor too simplistic, but that can be reasonably well informed by the data at hand. Clearly, a detailed mechanistic model of the disease system requires substantial detail, but a balance needs to be struck between detail and availability of independently gathered data. Visualization approaches are a recent addition to the arsenal of the drug development expert (67). This kind of mechanistic pharmacodynamics is being applied more and more often to a variety of areas: A good example of rapid development comes from anticancer agents (68), where applications of integrated, mechanistic PK-PD models that take into account the drug mechanism of action are starting to become more and more frequent (69).

Population Variation: Adding Statistical Variation to PK, PD and Disease Models

In drug development, it is of utmost interest to determine the extent of variation of PK-PD and disease progression

among members of a population. Basically, this implies determining the statistics of the biomarkers of interest in a population of patients, not just in an individual, and provide these measures together with some degree of confidence. This requirement connects well with analogous epidemiological population studies (often not model-based). The estimation of variability coupled with the evaluation of the relative role of its sources (covariates), for example, demographics, anthropometric variables or genetic polymorphisms, is tackled by the discipline of population kinetics, mainly due to the pioneering work of Lewis Sheiner and Stuart Beal at UCSF (70,71). Often called also population PK-PD, it makes use of two-level hierarchical models characterized by nested variability sources, where the models' individual parameter values are not deterministic, but unknown: They instead arise from population statistical distributions (biological variation, or BSV, between subject variability). On top of this source of variability, measurement noise and other uncertainty sources are added (RUV, residual unknown variation) to the concentration or effect signals (Fig. 2). The pharmaco-statistical models that integrate BSV and RUV are often described in statistical journals as nonlinear mixed effects models.

An example that builds on those we have already presented earlier may suffice here to clarify the fundamental concept of mixed effects models. Let us extend the model just described for intravenous injection (eq. 2) to the situation when the concentration measurements are affected by noise:

$$\begin{aligned} \dot{q}(t) &= -k_{el}q(t) + D\delta(t) \\ q(0) &= 0 \\ c(t) &= \frac{q(t)}{V} + \varepsilon(t) \end{aligned} \quad (11)$$

where the parameters are the same as in equation 2, except that now $\varepsilon(t)$ is a normally distributed measurement error with mean zero and variance σ^2 , that is $\varepsilon(t) \in N[0, \sigma^2]$. If data about $c(t)$ are available and have been gathered in a single individual, the model parameters k_{el} and V (assuming D is known) can then be fitted to the data using weighted (9) or extended (72) least squares or some other variation of maximum likelihood, and thus individualized estimates (with confidence intervals) can be obtained (often the measurement error variance σ^2 is not known but it can also be estimated). This can be done even if only a single subject data are available, provided that the sampling is performed (at an absolute minimum) at three or more time points (since the model has two unknown structural parameters, k_{el} and V , plus σ^2).

The nonlinear mixed-effects modeling approach is an extension of what we have just seen. It takes the viewpoint that the single subject estimates are realizations of an underlying population density for the model parameters. As such, the individual values of k_{el} and V simply become realizations (samples) of this underlying density. For example, the assumption could be made that they are both distributed lognormally: in which case, $\log(k_{el}) \in N(\mu_{kel}, \omega_{kel}^2)$ and $\log(V) \in N(\mu_v, \omega_v^2)$, where the μ denote expected logarithmic values and the ω^2 denote population variances.

Figure 2. Nested uncertainty in pharmacokinetics. Panel A shows the true, but unknown, time course over 24 time units of a hypothetical drug administered orally to a single experimental subject. The true, but unknown, time course is a smooth function of time. Panel B shows the same smooth function sampled at discrete time points, which in practice may correspond to as many blood draws. Measurement uncertainty (currently termed RUV, residual unknown variability) is now superimposed to the true, but unknown time course in Panel A. Panel C shows the true, but unknown, time course over 24 time units of a hypothetical drug administered orally to several experimental subjects. Clearly, no time course is the same, since each subject will have a different absorption and elimination rate, together with a different volume of distribution. The time courses in Panel C are the result of BSV (between subject variability). Lastly, Panel D shows the same smooth functions in Panel c sampled at discrete time points. The RUV is again superimposed to the true, but unknown time courses, but this time the data spread is due to both BSV and RUV, and distinguishing between BSV and RUV requires a model of the system. See text for details.

The assumption is implicitly made here that k_{el} and V are uncorrelated (which may or may not be the case). In the nonlinear mixed-effects model procedure, the moments of the statistical distributions of model parameters become the new unknowns, and thus μ_{k01} , ω_{k01}^2 and μ_v , ω_v^2 are estimated by optimizing approximations of the maximum likelihood objective function expressed for the whole population of data. The value of σ^2 in the population (a composite value of the measurement error variance across subjects) can also be estimated, as before. The five distribution parameters are the fixed effects of the population (since they do not change between subject), while the individual values attained by the parameters k_{el} and V in separate individuals are random effects, since every subject has a different value (hence, the mixed-effects parlance). The approach requires data on more than one subject, ideally on many more subjects than there are fixed effects (the caveat is that it is easier to estimate expected values than it is to estimate variances or covariances, and the data needs consequently grow). Note also

that, if k_{el} and V are both lognormal, clearance CL is *not* lognormal: which statistical model to choose for which parameter will depend on the available information. The main advantage of population kinetics is that, since it is estimating distributional parameters (moments), it can use relatively sparse and/or noisy data at the individual level, provided that there is a large number of population data (in other words, there can be few data for each subject, as long as there are many subjects).

This framework is quite general and powerful, and allows for modeling of complex events (e.g., adherence, or patient compliance to dosing recommendations) (73). Tutorials on this modeling approach can be found in papers (74–76), review articles (70,61,77,78), and textbooks (79). Software is also available, both for population (Aarons, 1999) and individual (Charles and Duffull, 2001) PK-PD analysis.

Mixed-effects models are used both to solve the forward problem (simulation of putative drug dosing scenarios) and the inverse problem (estimation of BSV and RUV statistics conditional on PK-PD models and clinical

measurements). Which one is of interest depends on what is available and what the intent of the study is. If the intent is to analyze data and determine the underlying distribution of PK-PD and disease parameters, then one has an inverse, or estimation, problem (80). If the intent, on the other hand, is to explore possible dosing or recruitment scenarios, then this is a direct, or simulation, problem (81). As mentioned, mixed-effects models can be applied to sparse and noisy data, as often happens in therapeutic monitoring in the clinical setting (a situation that occurs both in drug development and in applied clinical research). Their use is so widespread that the FDA recently issued one of its guidances for industry to deal with their use for population pharmacokinetic analysis (82). Interestingly, a very similar framework is also applied to evolutionary genetics, in the study of “function-valued traits” (also called “infinite-dimensional characters”). The idea is to use mixed models to link genetic information to traits that are not constant, rather are functions of time (83–85). It is important to model population genetics both for polymorphisms of drug-metabolizing enzymes affecting ADME and for polymorphisms affecting the dynamics of response.

A Role for Modeling and Simulation

In summary, the overall goal of integrated PK-PD mathematical models is a better understanding of therapeutic intervention: Their contribution are often reflected in improved clinical trials designs. While evidence of the impact of modeling and simulation of PK-PD on the drug development process is often anecdotal, many reviews of PK-PD in drug development have recently appeared (86–89), together with compelling examples of subsequent drug development acceleration (90,91).

While the fundamental algorithmic steps of computer simulation, especially Monte Carlo simulation, are well known, they require some adaptation to be used within the field of pharmacokinetics and pharmacodynamics and in the context of drug development (Fig. 3) A good practices document was issued in 1999 following a workshop held by the Center for Drug Development Science (92). The crafting of this document has contributed to clarifying the steps and tools necessary for carrying out a simulation experiment within the context of drug development. In particular, the report clarifies that simulation in drug development has an untapped potential which extends well beyond the pharmacokinetic aspect and into the pharmacodynamic and clinical domains (92).

Nowadays, pharmacometric technology (93) is used in industry and academia as a way to support and strengthen R&D. As an example, low signal/noise ratio routine clinical data obtained with sparse sampling may often be analyzed with pharmacometric techniques to determine whether a compound is metabolized differently because of phenotypic differences arising from genetic makeup, ethnicity, gender, age group (young, elderly), or concomitant medications causing drug–drug interactions (94). The role of this technology can only increase. A recently issued FDA report that focuses on the recent decrease in applications for novel therapies submitted to the agency is clear in this regard: “The concept of model-based drug development, in which

Figure 3. Information flow in a clinical trial simulation or data analysis. The doses, the measured concentration and drug effect are situated at the beginning or the end of the process (Data level). At the core of the simulation (Model level) lie models of PK, PD and disease processes. Trial designs are possible conditional on these other elements, or features like model parameters can be estimated from the trial data and measured doses and PK and PD data (Findings level). The picture is oversimplified and does not include, for example, adherence to dosing recommendations and protocol dropouts, which may be important to ensure realistic trial designs.

pharmaco-statistical models of drug efficacy and safety are developed from preclinical and available clinical data, offers an important approach to improving drug development knowledge management and development decision making. Model-based drug development involves building mathematical and statistical characterizations of the time course of the disease and drug using available clinical data to design and validate the model. The relationship between drug dose, plasma concentration, biophase concentration (pharmacokinetics), and drug effect or side-effects (pharmacodynamics) is characterized, and relevant patient covariates are included in the model. Systematic application of this concept to drug development has the potential to significantly improve it” (95).

In summary, modern-day drug development displays a need for information integration at the whole-system, cellular, and genomic level (96) similar to that found in integrative physiology (97) and comparative biology (98,99). As mentioned earlier, simulation of clinical trials is a burgeoning discipline well-founded upon engineering and statistics (81): examples have appeared in clinical pharmacology (100,101) and pharmacoeconomics (102). Drug candidate selection is another application, possibly through PK models of varying complexity (103) and high throughput screening coupled with PK (104). Next, integrated models allow to link genomic information with disease biomarkers and phenotypes, such as in the Luo-Rudy model of cardiac excitation (105).

As a concluding remark, progress in the development of plausible, successful, and powerful data analysis methods has already had a substantial payoff, and can be substantially accelerated by encouraging multidisciplinary, multi-institutional collaboration bringing together investigators at multiple facilities and providing the infrastructure to support their research, thus allowing the timely and cost-effective expansion of new technologies. The need is more

and more often voiced for increased training of quantitative scientists in biologic research as well as in statistical methods and modeling to ensure that there will be an adequate workforce to meet future research needs (106).

INTRODUCTION

Mechanical heart action is accompanied by audible noise phenomena, which are easy to perceive when the ear is placed next to a person's chest wall. These cardiovascular sounds can be designated as being weak in comparison with other physiological sounds, such as speech, stomach and intestine rumbling, and even respiration noises. In fact, the latter can be heard at a certain distance from the subject, which is not true for heart noises (provided one overlooks cases of artificial heart valves). The frequency content of heart sounds is situated between 20 and 1000 Hz, the lower limit being set by the ability of human hearing; Mechanical valve prostheses may largely exceed the upper limit. Examination of cardiovascular sounds for diagnostic purposes through the human hearing sense, that is, auscultation, has been commonly practiced for a long time (1–5). The only technology involved is the stethoscope, establishing a closed air compartment between a part of the person's chest surface and the physician's ear orifice. This investigation method, however, being completely psychophysical and thus subjective, has proved its benefit and continues to be an important tool in cardiovascular diagnosis.

Phonocardiography (PCG) may simply be defined as the method for obtaining recordings of cardiovascular sound, that is, the phenomena perceivable by auscultation. The origins of the method are strongly anchored in auscultation. The recordings of sounds are evaluated, on paper

or computer screen, possibly in the presence of other synchronous signals (e.g., the electrocardiogram) (ECG), partly psychophysically with another human sense, the eye, in examining waveform patterns and their relation with the other signals. Phonocardiographic signals are examined with respect to the occurrence of pathological patterns, relative intensities and intensity variations, timing and duration of events. Evidently more objective evaluation can be performed ranging from simple accurate timing of phenomena to advanced waveform analysis and comparing recorded results with waveforms from data banks. The importance of auscultation can be explained by the simplicity of the technique and by the strong abilities of the ear with respect to pattern recognition in acoustic phenomena. For obtaining equivalent information with phonocardiography, a single recording fails to be sufficient: A set of frequency filtered signals, each of them emphasizing gradually higher frequency components (by using high pass or band-pass filters), is needed. In this way, visual inspection of sound phenomena in different frequency ranges, adapted by a compensating amplification for the intensity falloff of heart sounds toward higher frequencies, is made possible, thus rendering the method equivalent with hearing performance: pattern recognition abilities and increasing sensitivity toward higher frequencies (within the above mentioned frequency range).

Laennec (1781–1826) was the first to listen to the sounds of the heart, not only directly with his ear to the chest, he also invented the stethoscope and provided the basis of contemporary auscultation. As physiological knowledge increased through the following decades, faulty interpretations of heart sounds were progressively eliminated. The first transduction of heart sounds was made by Hürthle (1895), who connected a microphone to a frog nerve-muscle preparation. Einthoven (1907) was the first to record phonocardiograms with the aid of a carbon microphone and a string galvanometer (6). Different investigators were involved in the development of filters to achieve a separation of frequency phenomena, as the vacuum tube, and thus electronic amplification became available. The evolution of PCG is strongly coupled with auscultatory findings and the development was predominantly driven by clinicians. A result of this situation is that a large variety of apparatus has been designed, mostly according to the specific needs of a clinic or the scientific interests of a medical researcher. During the 1960s, the necessity for standardization was strongly felt. Standardization committees made valuable proposals (7–9) but the impact on clinical phonocardiographic apparatus design was limited.

During the 1970s and the beginning of the 1980s, fundamental research on physical aspects of recording, genesis, and transmission of heart sound was performed (10–12) which, together with clinical investigations, improved the understanding of the heart sound phenomena. At the same time, ultrasonic methods for heart investigation became available and gradually improved. Doppler and echocardiography provided information closer related to heart action in terms of heart valve and wall movement, and blood velocity. Moreover, obtaining high quality recordings of heart sound with a high signal-to-noise ratio is difficult. Hampering elements are the inevitable pre-

sence of noise (background noise, respiration noise, muscle tremors, stomach rumbling), nonoptimal recording sites, weak sounds (obese patients), and so on. Thus interest in PCG gradually decreased.

In describing the state of the art, PCG is usually compared with ECG, the electrical counterpart, also a noninvasive method. The ECG, being a simple recording of electrical potential differences, was easily standardized, thus independent of apparatus design and completely quantitative with the millivolt scale on its ordinate axis. Phonocardiography has not reached the same level of standardization, remains apparatus dependent, and thus semiquantitative. Nowadays Doppler echocardiography and cardiac imaging techniques largely exceed the possibilities of PCG and make it redundant for clinical diagnosis. Whereas auscultation of cardiac sounds continues to be of use in clinical diagnosis, PCG is now primarily used for teaching and training purposes and for research. As a diagnostic method, conventional PCG has historical value. Nevertheless, the electronic stethoscope (combined with PC and software), as a modern concept for PCG, may gain importance for clinical purposes.

The generation of sounds is one of the many observable mechanical effects caused by heart action: contraction and relaxation of cardiac muscle, pressure rising and falling in the heart cavities, valve opening and closure, blood flowing and discontinuation of flow. Figure 1 shows a schematic representation of typical cardiac variables: the ECG, the logic states of the heart valves, low and high frequency phonocardiograms, a recording of a vessel pulse (carotid artery), and of the heart apex pulse (apexcardiogram). The heart cycle is divided into specific intervals according to the valve states of the left heart. The left ventricular systole is composed of the isovolumic contraction and the ejection period; The left ventricular diastole covers the isovolumic relaxation and the left ventricular filling (successively, the rapid filling, the slow filling, and the atrial contraction). A similar figure could be given for the right heart; Valve phenomena are approximately synchronous with those of the left heart. Small time shifts are typical: Mitral valve closure precedes tricuspid closure and aortic valve closure precedes pulmonary closure. The low frequency PCG shows the four normal heart sounds (I, II, III, and IV); In the high frequency, trace III and IV have disappeared and splitting is visible in I and in II. In the next sections details are given on the physiological significance, the physical aspects and recording methods, processing and physical modeling of heart sounds. Special attention is given to the electronic stethoscope.

HEART SOUNDS AND MURMURS

The sounds of the normal heart can be represented by a simple onomatopoeic simulation: "...lubb-dup..." (1–5). Two sounds can clearly be identified, the first being more dull than the second. A heart sound or a heart sound component is defined as a single audible event preceded and followed by a pause. As such, "splitting of a sound" occurs as one can clearly distinguish two components separated by a small pause. The closest splitting that

Figure 1. The ECG, PCG (low and high filtered), carotid pulse, apexcardiogram, and logic states (high = open) of left heart valves, mitral and aortic valve, and right heart valves, tricuspid and pulmonary valve. Left heart mechanical intervals are indicated by vertical lines: isovolumic contraction (1), ejection (2), isovolumic relaxation (3), and filling (4) (rapid filling, slow filling, atrial contraction). The low frequency PCG shows the four normal heart sounds (I, II, III, and IV); In the high frequency trace III and IV have disappeared and splitting is visible in I [Ia and Ib (and even a small Ic due to ejection)] and in II [IIA (aortic valve) and IIP (pulmonary valve)]. Systolic intervals LVEP (on carotid curve) and Q-IIA (on ECG and PCG) are indicated.

can be appreciated is ~20–30 ms. Similar guidelines are followed for the identification of phonocardiographic recordings: A sound is a complex of succeeding positive and negative deflections alternating with respect to the baseline, preceded and followed by a pause. A sound is said to be split if a small pause between the components can be perceived. At this point, the effect of frequency filtering may be important: Splitting, being invisible on a low frequency recording, may become recognizable on a high frequency recording (Fig. 1). Summarizing, we can state

that in clinical PCG primarily the envelope of the recorded signal is regarded, not the actual waveform as, for example, in ECG, blood pressure, and velocity recordings. As spectral performance of phonocardiography may exceed the possibilities of human hearing inaudible low frequency phenomena can be recorded; They are also indicated as “(inaudible) sounds”.

Acoustic phenomena originated by the heart are classified into two categories: heart sounds and heart murmurs (1–5,10–12). Although the distinction between them is not strict, one can state that heart sounds have a more transient, musical character (cf. the touching of a string) and a short duration (Fig. 1), whereas most murmurs have a predominantly noisy character and generally (but not always) a longer duration (e.g., a “blowing” murmur, a “rumbling” murmur) (Fig. 2). It is also believed that the genesis of both types is different: Heart sounds are indicated as types of resonant phenomena of cardiac structures and blood as a consequence of one or more sudden events in the cardiohemic system (such as valve closure), and most heart murmurs are said to be originated by blood flow turbulence. Many aspects of the problem of the genesis of these phenomena are still being discussed, including the relative importance of the valves and of the cardiohemic system in the generation of heart sounds (valvular theory versus cardiohemic theory).

Four normal heart sounds can be described (Fig. 1): I, II, III, and IV (also indicated as S1, S2, S3, S4). The two having the largest intensity, that is, the first (I, S1) and the second (II, S2) sound, are initially related to valve closure. The third (III, S3) and the fourth (IV, S4) sound, appearing extremely weak and dull and observable only in a restricted group of people, are not related to valve effects. The so-called closing sounds (I and II) are not originated by the coaptation of the valve leaflets (as the slamming of a door). On the contrary, it is most probably a matter of resonant-like interaction between two cardiohemic compartments suddenly separated by an elastic interface (the closed valve leaflets) interrupting blood flow: Vibration is generated at the site of the valve with a main direction perpendicular to the valve orifice plane and dependent on the rapid development of a pressure difference over the closed valve. In the case of the first sound, this phenomenon is combined with the effect of a sudden contraction of cardiac ventricular muscle. Pathologies of the cardiohemic system can affect the normal sounds with respect to intensity, frequency content, timing of components (splitting) (1).

The first heart sound (I) occurs following the closing of the mitral valve and of the tricuspid valve, during the isovolumic contraction period, and, furthermore, during the opening of the aortic valve and the beginning of ejection. In a medium or high frequency recording, a splitting of the first sound may be observed. Components related to the closing of the mitral valve (Ia, M1), the closing of the tricuspid valve (Ib, T1) and the opening of the aortic valve may be observed. There is a direct relation between the intensity of I and the heart contractility, expressed in the slope of ventricular pressure rising; with high cardiac output (exercise, emotional stress, etc.) sound I is enhanced. The duration of the PR-interval (electrical conduction time from the physiological pacemaker in the right

Figure 2. Examples of pathological sounds and murmurs. (1). A systolic murmur (ejection murmur, crescendo, decrescendo) as a consequence of aortic valve stenosis preceded by a clear aortic ejection click (EC). (2). Mid-systolic click (C) as a consequence of mitral valve prolapse followed by a systolic murmur due to mitral valve regurgitation.

atrium to the ventricles) is a determining factor: The shorter the time between the atrial and ventricular contraction and, consequently, the larger the distance between the mitral valve leaflets, the larger the intensity of the first sound appears. With a long PR-interval mitral valve leaflets have evolved from wide open during atrial contraction to a state of partially open to almost closed when ventricular contraction starts; the result is a weak first sound. Cardiovascular pathologies can have an effect on timing and intensities of the first heart sound components. Wide splitting is observed in right bundle branch block, tricuspid stenosis, and atrial septal defect due to a delayed tricuspid component (Ib). In left bundle branch block Ia and Ib can coincide resulting in a single sound I. A diminished sound I is found in cases of diminished contractility (myocardial infarction, cardiomyopathy, heart failure), in left bundle branch block, mitral regurgitation and aortic stenosis; An intensified sound I is found in mitral stenosis with mobile valve leaflets and in atrial septal defect.

The second sound (II) is associated with the closure of the aortic valve and, following, the closure of the pulmonary valve. Splitting of the sound in an aortic (IIA, A2) and a pulmonary (IIP, P2) component is often observed. Splitting increases during inspiration as a consequence of increased difference in duration of left and right ventricular systole caused by increased right and decreased left ventricular filling; both components may fuse together at the end of expiration. Paradoxical splitting (the pulmonary component preceding the aortic one) is pathological. The pulmonary component normally has a lower intensity; an increased intensity with respect to the aortic component is generally abnormal. There is a direct relation between the intensity and the frequency of II and the slope of ventricular pressure falling during isovolumic relaxation. Stiffening of the valve leaflets results in a reduction of II. A higher valve radius or a lowered blood viscosity gives rise to an increased second sound. Cardiovascular pathologies can have an effect on timing and intensities of the second heart

sound components. Wide splitting of sound II can be due to delayed pulmonary valve closure or advanced aortic valve closure. Delayed pulmonary valve closure can be caused by right bundle branch block, pulmonary stenosis, pulmonary hypertension, atrial septal defect; advanced aortic valve closure can result from mitral regurgitation and ventricular septal defect. Paradoxical splitting of sound II can be due to delayed aortic valve closure or advanced pulmonary valve closure. Delayed aortic valve closure can be caused by left bundle branch block, aortic stenosis and arteriosclerotic heart disease. Advanced pulmonary valve closure can be caused by tricuspid regurgitation and advanced right ventricular activation. IIA, respectively, IIP, can be absent in severe aortic, respectively, pulmonary, valve stenosis. IIA is decreased in aortic regurgitation and in pathologically diminished left ventricular performance.

The third sound (III) occurs during the rapid passive filling period of the ventricle. It is believed that III is initiated by the sudden deceleration of blood flow when the ventricle reaches its limit of distensibility, causing vibrations of the ventricular wall. It can often be heard in normal children and adolescents, but can also be registered in adults (although not heard) in the low frequency channel. It is a weak and low pitched (low frequency) sound. Disappearance of III is a result of aging as a consequence of increasing myocardial mass having a damping effect on vibrations. High filling rate or altered physical properties of the ventricle may cause an increased third sound. If III reappears with aging (beyond the age of 40 years) it is pathological in most cases. A pathological sound III is found in mitral regurgitation, aortic stenosis, ischemic heart disease.

The fourth sound (IV) coincides with the atrial contraction and thus the originated increased blood flow through the mitral valve with consequences as mentioned for the third sound. It is seldom heard in normal cases, sometimes in older people, but is registered more often in the low frequency channel. The sound is increased in cases of

augmented ventricular filling or reduced ventricular distensibility. A pathological sound IV is found in mitral regurgitation, aortic stenosis, hypertensive cardiovascular disease, and ischemic heart disease.

Besides these four sounds, some pathological heart sounds may be present (Fig. 2). Among the systolic sounds there is the ejection sound and the nonejection systolic click. The ejection sound can be found in different pathological conditions such as congenital aortic or pulmonary valvular stenosis where opening of the cusps is restricted. A nonejection systolic click may be associated with a sudden mitral valve prolapse into the left atrium. An opening snap, a diastolic sound, may occur at the time of the opening of the mitral valve, for example, in cases with valve stenosis.

Heart murmurs are assumed to be caused by different mechanisms as compared to heart sounds. In fact, most murmurs result from turbulence in blood flow and occur as random signals. In normal blood vessels at normal velocity values blood flow is laminar, that is, in layers, and no turbulence is observed. In a normal resting human, there may be turbulent flow only in the vicinity of the aortic and pulmonary valves. As flow turbulence, a phenomenon that is generally irregular and random, is associated with pressure turbulence and, consequently, vessel wall vibration, acoustic phenomena may be observed. For flow in a smooth straight tube, the value of the Reynolds number, a dimensionless hydrodynamic parameter, determines the occurrence of turbulence. This number is proportional to the flow velocity and the tube diameter, and inversely proportional to the viscosity of the fluid. If this number exceeds a threshold value, laminar flow becomes turbulent. According to this theory, so-called innocent murmurs can be explained: They are produced if cardiac output is raised or when blood viscosity is lowered; they are generally early or midsystolic, have a short duration, and coincide with maximum ventricular outflow. Turbulence and thus intensity of the murmur increase with flow velocity. Pathological murmurs may be originated at normal flow rate through a restricted or irregular valve opening (e.g., in cases of valve stenosis) or by an abnormal flow direction caused by an insufficient (leaking) valve or a communication between the left and the right heart. As such systolic, diastolic, or even continuous murmurs may be observed. Systolic ejection murmurs occur in aortic and in pulmonary stenosis (valvular or non-valvular), diastolic filling murmurs in mitral and tricuspid stenosis. Aortic and pulmonary regurgitation cause diastolic murmurs; mitral and tricuspid regurgitation cause systolic murmurs. A systolic murmur and a diastolic murmur can be observed in ventricular septal defect. Continuous murmurs occur in patent ductus arteriosus (a connection between pulmonary artery and aorta). Musical murmurs occur as deterministic signals and are caused by harmonic vibration of structures (such as a valve leaflet, ruptured chordae tendinae, malfunctioning prosthetic valve) in the absence of flow turbulence; these are seldom observed.

The location of the chest wall where a specific sound or murmur is best observed (in comparison with the other phenomena) may help in discriminating the source of the sound or the murmur (1). These locations are dependent, not only on the distance to the source, but also on the

vibration direction. Sounds or murmurs with an aortic valve origin are preferably investigated at the second intercostal space right of the sternum and those of pulmonary origin left of the sternum. The right ventricular area corresponds with the lower part of the sternum at the fourth intercostal space level, the left ventricular area between the sternum and the apex point of the heart (at the fifth intercostal space level). Furthermore, specific physiological maneuvers influencing cardiac hemodynamics may be used for obtaining better evaluation of heart sounds and murmurs.

In conclusion, the existence, timing, location at the chest wall, duration, relative intensity and intensity pattern, and frequency content of murmurs and/or pathological sound complexes form the basis of auscultatory, and/or phonocardiographic diagnosis of cardiac disease.

FUNDAMENTAL ASPECTS OF HEART VIBRATIONS

Mechanical heart action can be indicated by a set of time signals, which can be measured by invasive means: Most important variables are blood pressure in heart cavities and in blood vessels, myocardial and vessel wall tension, ventricular volume, blood flow velocity, heart wall deformation, and movement. At the chest surface only kinematic information is available: the movement of the chest surface as a result of mechanical heart action. As, in general, the movement of a material point can be indicated by a vector and as this vector appears to differ at various chest wall sites, one can state that mechanical information available at the chest wall is described by a spatiotemporal vector function. As far as the effect of the heart is concerned the movement is defined with respect to an equilibrium position; thus one can speak of a vibratory phenomenon. This movement of the chest surface, surrounded with air, gives rise to acoustic pressure in air; the latter is generally so weak that nothing can be perceived by hearing at a distance from the chest wall (except for artificial valve cases). Only if closed air cavities are used is a sound effect observable by the ear: The closed cavity (such as the stethoscope) prevents dispersion of acoustic energy and thus attenuation of acoustic pressure. It is out of the spatiotemporal kinematic vector function that phonocardiography takes a sample in order to evaluate cardiac activity.

As there is a vector function involved, three components should be taken into account. In practice, only the component perpendicular to the chest surface is measured and the two tangential components are disregarded. A kinematic function may be represented by different time representations, for example, displacement (m), velocity (m/s), acceleration (m/s^2), or even higher time derivatives (m/s^n , n representing the order of time derivative). Fundamentally, each representation contains identical information as they are all connected by a simple mathematical operation, that is, time derivation, but for visual inspection or time signal processing they reveal different vibratory patterns. Speaking in terms of the frequency domain, time derivation implies multiplication of the amplitude of an harmonic with its frequency: Time derivation is thus an operation of emphasizing higher frequencies in the signal with respect

to the lower ones. According to linear system theory, a similar effect is obtained with high pass filtering, the effect of filtering being described by the N th time derivative of the signal in the attenuation band (i.e., for frequencies well below the cutoff frequency). The number N represents the order of the filter and determines the slope in the attenuation band of the amplitude characteristic ($N \times 20$ dB/decade). High pass filtering, order N , is theoretically identical with the corresponding low pass filtering of the N th time derivative of the signal.

In biomedical signal processing, it is relatively uncommon to consider different time representations. From auscultation, we learned that in case of PCG it is rather beneficial. In a chest wall displacement curve, no sounds can be perceived, for example, at the site of the apex of the heart one can measure the apexcardiogram (Fig. 1), which is essentially a recording of the displacement of the skin surface and the ordinate axis could have a millimeter scale. Nevertheless, at the site of the apex sounds can be recorded if time derivation or high pass filtering is applied. In practice, transients corresponding to heart sounds become clearly visible in the acceleration recording. The ear cannot sense displacements such as the apexcardiogram; this can simply be explained if one regards the ear's sensitivity curve. In the range below < 1000 Hz, the sensitivity increases with increasing frequency, equivalent with the effect of high pass filtering.

The kinematic effect of heart action at the chest surface is not completely covered by phonocardiography. Historically, the frequency spectrum is divided into two parts: the low frequency part (up to 20 Hz) is handled under the title mechanocardiography and the second part beyond 20 Hz under PCG. The reason of separation lies in the nature of auscultation (frequencies beyond 20 Hz, according to hearing performance) and, additionally, palpation (frequencies < 20 Hz, according to tactile sensitivity). According to this, displacement recording belong to the domain of mechanocardiography, which studies arterial and venous pulse tracings, and the apexcardiogram. The carotid pulse (Fig. 1) is a recording of skin surface displacement at the site of the neck where the carotid artery pulsation is best palpated. The curve reflects local volume changes, and consequently pressure changes in the artery at the measurement site. It thus reflects changes in aortic pressure after a time delay determined by the propagation time of the blood pressure wave (10–50 ms). The beginning of the upstroke of the graph corresponds to the opening of the aortic valve and the dicrotic notch corresponds to its closing. As such, the left ventricular ejection period (LVEP) can be derived. The apexcardiogram (Fig. 1) is a recording of skin surface displacement of the chest wall at the site of the heart apex; in this case there is no propagation delay. The abrupt rise of the graph corresponds to the isovolumic contraction, the fall with the isovolumic relaxation. The minimum point occurs at the time of opening of the mitral valve. These displacement curves have been used for identifying heart sounds.

Chest wall kinematics are not exclusively caused by heart action. The most important movement in a resting human is originated by the respiration act. Two phenomena should be mentioned: a low frequency event corresponding

with the breathing movement itself, and having its fundamental frequency at the breathing rhythm (~ 0.2 – 0.4 Hz), and a high frequency phenomenon corresponding to breathing noises, "lung sounds", due to the turbulent air stream in airways and lungs. The latter may cause great disturbances in high frequency heart sound recording. To these effects one can add the result of stomach and intestine motility and, moreover, environment noise picked up by the chest wall. From the standpoint of PCG, these effects are merely disturbing and thus to be minimized.

In PCG, one discriminates between heart sounds and murmurs (based on auscultation). It has already been indicated that the source types are different as well as the acoustic impressions they provoke. From the standpoint of signal analysis heart sounds correspond better with transients originated by a sudden impact, whereas murmurs, except for the musical types, have a random character. In fact, if one considers a set of subsequent heart cycles, one may find that heart sounds are more coherent compared to murmurs. For example, averaging of sounds of subsequent heart cycles with respect to an appropriate time reference gives a meaningful result, but the same fails for murmurs as a consequence of their random character.

Conventional heart sound recording is executed at the chest wall. Some exceptions are worth mentioning. Intracardiac phono signals are obtained from cardiac blood pressure curves during catheterization. If a catheter-tip pressure transducer with sufficient bandwidth is used, intracardiac sound recordings can be obtained by submitting the pressure signal to high pass filtering or time derivation. It is also possible to get closer to the heart in a noninvasive way by measuring pressure or kinematics in the esophagus. In this way, the posterior part of the heart, lying close to the esophagus, is better investigated.

RECORDING OF HEART SOUNDS

In auscultation, the physician uses a stethoscope as a more practical alternative for putting the ear in close contact to the chest wall. Recording of heart sounds is a problem of vibration measurement (13), more specifically on soft tissue. It implies the need of a sensor, appropriate amplification and filtering, storage and visualization on paper (14,15), or by using information technology. The useful bandwidth is ~ 20 – 1000 Hz. The sensor needs to be a vibration transducer (vibration pickup), in this case also called a heart sound microphone; an alternative is a stethoscope provided with a microphone: the electronic stethoscope. Except for the sensor, virtual instrumentation technology can be used in the measuring chain: This implies a PC with a data acquisition card and signal processing software (such as Labview).

The Transducer

In a normal situation the chest wall vibrates only surrounded with air, which exerts an extremely low loading effect. Consequently, force at the surface may be neglected and only the kinematic variable is important. This ceases to be true when a transducer is connected to the chest wall,

exerting a significant loading effect. This loading influence is described by the mechanical impedance of the pickup (force/velocity) or by the dynamic mass (force/acceleration). The loading effect is also dependent on the chest wall tissue properties; chest wall mechanical impedance is determined by tissue elasticity, damping, and mass. In general, heart sound microphones provoke a large and difficult to quantify loading effect on the chest wall, so that in no case the standard unloaded vibration is recorded. The same is not true in electrocardiography, for example, where the apparatus is designed with a sufficiently high input impedance to record the unaffected electrical potential at the electrode site. The latter is hard to achieve in phonocardiography (16).

Heart sound transducers can be divided into two types: the absolute pickup and the relative pickup. The absolute pickup measures the vibration at the site of application, averaged over the area of application. In general, these are contact pickups that are rigidly connected to the chest wall; the measuring area is thus identical to the contact area. These types are similar to the ones used for industrial measurements on mechanical structures or in seismography. The relative pickup measures the vibration averaged over a certain area with respect to a reference area; it is thus a kind of differential pickup. Air-coupled pickups are differential pickups. Essentially they consist of an air-filled cavity, generally with a circular shape, the edge of the cavity rigidly and air-tight-connected to the chest wall. It is thus the difference of the displacement under the cavity (the measuring area) and the displacement under the edge of the cavity (the reference area) giving rise to an acoustic air pressure within the cavity that is measured. The electronic stethoscope can be considered as a relative pickup. Figure 3 shows the principles.

With the contact vibration pickup the average kinematics of the measuring area in the loaded situation is recorded. The most generally applied transducing principle is the seismic type: A seismic mass is connected via a

Figure 3. A schematical representation of heart vibration pickups: left, the relative type; right, the absolute type; above, the pickup positioned at the vibrating chest wall; below, the corresponding areas relating the pickup with the chest wall. The absolute pickup measures the kinematics x_t at its contact area A_t . The relative pickup, presented as an air cavity with a pressure-sensing device at the top of the cavity (black part), measures the difference between the kinematics under the cavity x_{tM} , that is, of the measuring area A_{tM} , and the one under the edge of the cavity x_{tR} , that is, the reference area A_{tR} .

Figure 4. The seismic system, the mechanical model for a contact pickup (i.e., an accelerometer). The system is attached to the vibrating surface (F, x) with its contact mass M_2 ; The seismic mass M_1 is coupled to the contact mass via a stiffness S and a damping D . The displacement y between the contact and the seismic mass represents the measuring value.

spring-damping system to the contact mass coupled with the vibrating surface (Fig. 4). The relative displacement between the seismic mass and the contact mass is measured with the aid of a mechanoelectric transducing device. The latter can be a piezoelectric crystal that generates an electrical charge proportional to its deformation (Fig. 5); The complete device behaves as an accelerometer for frequencies (f) below its acceleration resonance frequency (f_1); it measures displacement above f_1 . Measuring acceleration is generally the normal function. The acceleration charge sensitivity s_Q (charge per acceleration unit, $\text{pC}/\text{m}\cdot\text{s}^{-2}$) is thus

$$s_Q = B/(2\pi f_1)^2 \tag{1}$$

for $f < f_1$. The parameter B stands for a mechanoelectric transducing efficiency and depends on the crystal type and

Figure 5. A schematic representation of two types of phonocardiographic contact pickups: at left, the heavy, and at right, the low weight type. The mechanoelectric transducing device (here presented as a bilaminar bending crystal) is built in to measure the displacement between the seismic mass and the material in contact with the vibrating surface. The black parts indicate elastic material. The heavy type (possibly held by hand at the massive case, representing the seismic mass) makes contact with the chest wall via a coin-shaped disk connected to the crystal by an extension rod. For the low weight type, the case makes contact with the vibrating surface and all remaining parts (including the seismic mass attached to the crystal) are at the inside. *Note:* The heavy type is mentioned because of its historical value.

Figure 6. The acceleration amplitude frequency characteristic of a seismic pickup (double logarithmic scale). Curves presented can be obtained using the same mechanoelectric transducing device, but with a different mechanical layout of the seismic system. The oblique broken line represents a sensitivity limit for the specific mechanoelectric transducing device. The characteristic of a seismic system corresponds with a second-order low pass filter. The resonant frequency f_1 determines the bandwidth (flat part), but also the sensitivity (Eq. 1). Two different types are shown; the low resonant frequency f_{11} can be found in heavy phonocardiographic pickups; the high one, f_{12} , in low weight types. For the latter, the effect of damping is shown: Curve 2b corresponds to a higher damping in the system, as can be seen by the decreased height of the resonance peak.

on its mounting; f_1 is a construction parameter determined by the seismic mass and the stiffness incorporated between the seismic and the contact mass. The complete amplitude frequency characteristic corresponds with a low pass second-order filter, with f_1 also representing the cutoff frequency (Fig. 6), thus determining the measuring bandwidth and the sensitivity. Evidently other than piezoelectric elements can be used for measuring displacement: piezoresistance, variable capacitance (both of them needing a polarization voltage), electret elements, and so on.

The loading influence of the pickup can be presented by its dynamic mass. In comparing contact pickups with different masses with an ultralow weight type (Fig. 7) it was found that distortion and attenuation is caused by the mass (16): Beyond 100 Hz, the amplitude ratio (loaded compared to unloaded) approximates a value (A_L):

$$A_L = M_t / (M_t + M_1) \tag{2}$$

Figure 7. Amplitude frequency characteristic of the loading effect caused by the coupling of a rigid element to the soft tissue of the chest wall (as e.g., a contact pickup) (drawing for a 10 g, 20 mm diameter element). Attenuation is about constant beyond 100 Hz (Eq. 2).

with $M_t = a d_t^3$, $a = 280 \text{ kg/m}^3$ (typical); M_1 is the loading mass (of the pickup), M_t is the thorax wall output mass, and d_t is the contact diameter. According to this formula, a 10-g pickup with a 20 mm diameter would result in an attenuation to 18% of the original unloaded amplitude. For quantitative purposes, ultralow weight pickups can thus be recommended. It must also be emphasized that not the weight per se, but the weight divided by the third power of the contact diameter is the parameter to be minimized (according to Eq. 2).

In the case of the air-coupled vibration pickup (17), the average kinematics of the measuring area (under the cavity) with respect to the reference area (under the edge of the cavity) in the loaded situation is recorded (Fig. 3). Air pressure in the cavity as a result of the relative displacement of the chest wall is registered with a built-in sensor measuring acoustic pressure (a microphone). The movement of the membrane of this microphone is transformed into an electrical signal, for example, by the moving coil principle (dynamic type) and variable capacitance (condenser type with a polarizing voltage, electret type). As such, the measuring characteristics of the air-coupled pickup are determined by the dimensions of the air cavity and by the features of the included microphone. If the microphone membrane is rather stiff as compared with air and the height (l) of the cavity small as compared with the wavelength of heart vibrations in air, the pressure (p) generated at the site of the membrane is simply proportional to the relative displacement of the chest wall ($x_{tMR} = x_{tM} - x_{tR}$):

$$p = (c^2/l) x_{tMR} \tag{3}$$

Figure 8. Calibration of heart vibration pickups. The pickup to be tested is compared with a reference accelerometer (RA): left, the contact pickup; right, the relative pickup. The contact pickup is rigidly connected with the reference accelerometer, mounted on a vibrator (left). For the relative pickup two measurements can be performed (right, vibrator not displayed). In a first test, the differential characteristic is determined (right, above): With the housing fixed, a movement is generated at the orifice of the cavity, which is closed airtight with (e.g., an elastic membrane). In a second test the common mode sensitivity is determined, the pickup fixed at a stiff plate. An ideal relative pickup features zero common mode sensitivity.

where ρ is the air density (kg/m^3) and c is the wave propagation velocity in air (m/s). The loading effect under the cavity is given by a stiffness term (S_{LM} , N/m) and

$$S_{LM} = d_{LM}^2 \rho c^2 / (4l) \quad (4)$$

where d_{LM} is the diameter of the measuring area. At the reference area, the pickup exerts a mass loading; the combined loading effect is hard to describe.

For calibration of a phonocardiographic pickup one can use a vibrator, a reference accelerometer having an ideal frequency response, and two amplifiers (Fig. 8). The contact pickup to be tested should be rigidly attached to the reference pickup. In case of an air-coupled pickup, one has to investigate the differential and the common mode characteristics, the first one with the housing fixed, a displacement being generated at the input of the cavity (e.g., airtight sealed with an elastic membrane), and the second one with the complete microphone fixed at the rigid vibration table (the relative displacement between inner and edge of the cavity being zero). For an ideal relative pickup, the common mode term should be zero; In practice, it is to be small with respect to the differential sensitivity. Mechanical impedance of a pickup can similarly be measured by applying a force transducer combined with the reference accelerometer (an impedance head). It should be emphasized that in this way only the properties of the pickup can be obtained, but no information is acquired on the ultimate distortion effect due to the loading of the chest wall, as this is also dependent on the tissue parameters. This effect can only be measured *in situ*, that is, on the patient himself; the procedure is rather complicated.

In conclusion, accurate quantitative recording of the unloaded chest wall vibration is extremely difficult. Industrial accelerometers (equivalent to the described contact types) show the same disadvantages with respect to loading on the soft tissue of the chest wall. Moreover, as a rule they are less sensitive and have an unnecessary broad bandwidth. Some noncontact methods have been reported, but only for infraphonocardiographic frequencies.

Preamplification and Signal Preprocessing

Without going into details regarding electronics, we must emphasize the importance of the preamplifier, as this part of the recording unit, in combination with the pickup, determines the electronic noise level of the apparatus. It is adequate to resume possible disturbing influences at this point. First, there are the physiological vibrations generated by organs other than the heart. Respiration sounds may be the most inconvenient disturbances, especially with patients suffering from lung disease. Recording in an expired resting state can thus be advised. Furthermore there are environmental vibrations; Air-transmitted noises, especially the higher frequencies at which cardiac vibration intensity is weak, can be very inconvenient. Therefore, the air-coupled pickup should be attached in an airtight manner to the chest wall. This does not solve the problem completely, as environmental noises seem to be picked up by the chest wall and, in this way, transmitted to the pickup (air-coupled as well as contact type). Theoretically, these disturbing vibrations can be minimized, but for a given apparatus electronic noise cannot be affected and thus sets a limit to noise diminishing and determines a threshold under which no heart sound or murmur can be recognized.

Besides the noise level, the frequency characteristic of the preamplifier connected to the pickup should be regarded. For example, in the case of a piezoelectric pickup, its electrical output property is capacitive and one must bear in mind that the combination of this capacitance with the input resistance of a voltage preamplifier gives rise to a first-order high pass effect. To avoid this problem, charge or current amplifiers can be used. Whereas the charge amplifier measures acceleration, the current amplifier measures its time derivative.

Whether or not signals are digitized after preamplification, a high pass filtering (or band-pass filtering) process is necessary (18,19). High pass filtering and appropriate amplification (analogue or digital) of the filter channels compensate for the fact that visual inspection of a single recorded phonocardiogram (even when optimally chosen) does not reveal the same amount of information as gained from the acoustical impression during auscultation. Furthermore, the amplification has to compensate for the decreasing amplitude of heart vibrations at increasing frequencies. Conventionally, a set of about four high pass filters are used, each characterized by a gradually increasing cutoff frequency and/or increasing slope in the attenuation band. For example, Maass Weber high pass filters are used with a common cutoff frequency of 1 kHz and slopes of 20, 30, 40, and 60 dB/octave (EEC, see the section Hardware and Software). Generally, filter sets have been

determined qualitatively by applying a range of subsequent filters and recording a set of normal subjects and patients with different heart diseases: A filter providing information also perceivable in another one was eliminated from the set. Furthermore, filtering must permit discrimination between phenomena having a different physiological or pathological origin. Clear splitting between slightly asynchronous phenomena (or minimal overlapping) is thus desired for vibrations having similar frequency content. Now discrimination between phenomena having a different frequency content in adjacent filter channels is expected. The chosen set is not uniquely optimal: It depends on the preceding elements in the measuring chain (the vibration pickup, including its loading effect, and the preamplifier). As such, a filter set chosen for a contact pickup is not evidently optimal for an air-coupled type.

Different transducers, the mostly unknown distortion effect due to loading and different filter sets, might seem remarkable to physicists and engineers from the viewpoint of measuring quality. Nevertheless, for (semiquantitative) phonocardiography the use of filtering with adaptable amplification compensates in some degree for microphone, loading, and preamplification characteristics. For example, attenuation due to loading in a specific frequency band may be partly compensated by increased amplification of the corresponding channel.

Storage and Visualization

In older apparatus intended for recording of ECG, PCG, and pulses, a paper recorder (strip chart recorder) was included. The first was an analog type [as the galvanometric pen writer, having a limited bandwidth (~ 100 Hz), but equipped with special techniques for recording high frequency sounds], and later it was a digital type as the thermal array recorder. The latter, also available as a general purpose paper recorder, functions completely digitally: It sets a dot at the point corresponding to the instantaneous value of the signal to be recorded: No moving mechanical parts are present except for the paper drive. The recording technique is characterized by a sampling and a writing frequency. The latter may be lower than the first: During the writing interval all points between the maximum and the minimum value of the signal samples are dotted. As such, the recording is a subsequence of vertical lines: For visual inspection of the overall vibration pattern no information is lost.

Furthermore, data can be handled by common information technology: a (portable) personal computer with appropriate data-acquisition possibilities, virtual instrument software for signal conditioning and processing, visualization, archiving, and hard copy generation.

PROCESSING OF HEART SOUNDS AND PHYSICAL MODELING

Physical modeling aims at the localization of a specific sound source in the heart and, by analyzing the externally recorded vibration signals, at the quantification of the constitutive properties of the cardiac structures involved (e.g., stiffness of a valve leaflet, myocardial contractility)

and of the driving forces, which set these structures into vibration. The physical situation is extremely complicated. The vibration source is situated within the cardiac structures (having viscoelastic properties) containing and driving blood (a viscous fluid). The transmission medium, the tissues between the heart and the chest wall, is viscoelastic and inhomogeneous.

Transmission in such a viscoelastic medium implies compression and shear waves, which both contribute to the vibrations at the chest wall (20). It is not simply a problem of acoustic pressure as in a perfect fluid. Distortion due to transmission seems obvious. In order to study transmission and to relate chest wall vibrations to properties of cardiac structures and hemodynamic variables, advanced signal processing techniques are used. A broad review is given by Durand et al. (21).

As the chest wall vibratory phenomenon is represented by a spatiotemporal kinematic function, it can principally be approached in two ways: by sampling in time, as a set of images of chest wall movement, or by sampling in space by a set of time signals obtained with multisite recording. Multisite heart sound recording implies a large set of pickups (preferably light weight, thus inducing minimal loading). In this way, spatial distribution of vibration waveforms on the chest wall can be derived. Based on the results of such a method a physical model for heart sound genesis has been presented that can analytically be solved in a viscoelastic medium: a sphere vibrating along the axis of the valve orifice (20). This mechanical dipole model agrees to the idea of sound generation as a resonant-like vibration of the closed elastic valve leaflets and the surrounding blood mass. With this model a typical inversion of vibration waveforms on the chest wall could be explained: The phase reversal is expressed most for the second sound, according to the anatomical position and direction of the aortic orifice. The model has been used to calculate source functions (the inverse problem). Spatial parameters on vibration waveforms have been formulated (22–25).

Physical modeling aims at the quantification of the constitutive properties of cardiac structures (e.g., of the valve leaflets) and the driving forces (e.g., blood pressure). For example, with respect to the second sound, the aortic valve was modeled as a circular elastic membrane, it was allowed to vibrate in interaction with the surrounding blood mass, with as a driving force the slope of the development of the transvalvular pressure difference during isovolumic relaxation (11,26). Typical characteristics of IIA and IIP could thus be explained. For example, the reduction of amplitude and frequency shift (toward higher frequencies) as a consequence of valve stiffening, the diminishing of amplitude in patients with poor ventricular performance (characterized by a slow pressure drop in the ventricle during the isovolumic relaxation), and the augmentation of amplitude in cases of anemia (implying reduced blood viscosity and thus reduced damping in the resonant system). In another model, the ventricle is modeled as a finite thick-walled cylinder and the amplitude spectra of computed vibration waveforms contain information concerning the active elastic state of muscular fibers that is dependent on cardiac contractility (27).

Transmission of vibrations by comparing vibrations at the epicardial surface and at the chest wall has been studied (21). Esophageal PCG proved to be beneficial for recording vibrations originated at the mitral valve (28). The disappearance of the third sound with aging was explained with the ventricle modeled as a viscoelastic oscillating system with increasing mass during growth (29). Spectral analysis of the pulmonary component of the second sound reveals information on the pressure in the pulmonary artery (30).

Frequency content and timing of heart vibrations is of major importance; Time–frequency analysis of signals is thus performed. Classical Fourier analysis uses harmonic signals (sine and cosine waves) as basic signals. The frequencies of the harmonics are multiples of the fundamental frequency and the signal can be composed by summing the sine and cosine waves multiplied with the Fourier coefficients. Sine waves have an infinite duration and the method is thus beneficial for periodic functions. A phonocardiogram can be considered as a periodic function, but it is composed of a number of phenomena shifted in time with specific frequency content (heart sound components and murmurs). When applying classical Fourier analysis, information on timing is lost. Thus Fourier analysis has to be performed on shorter time intervals (by dividing the heart cycle into subsequent small intervals) resulting in time and frequency information. To minimize errors resulting from calculating in these small intervals, mathematical techniques have to be applied. Wavelet analysis calculates wavelet coefficients based on transient-like irregular signals with limited duration, called wavelets. Wavelets are derived from a mother wavelet and obtained by scaling in time (subsequently with a factor 2) and by shifting in time. As in Fourier analysis, the signal can be composed by summing shifted and scaled wavelets multiplied with their wavelet coefficients. The waveform of the mother wavelet can be chosen. As scaling in time corresponds to frequency, this method also gives time and frequency information, but it performs better for analyzing signals of a nonstationary nature, such as heart sounds and murmurs. Sudden changes or discontinuities in the signal can better be identified and located in time. A large number of studies has been executed with respect to time–frequency analysis of heart sounds and murmurs and different calculation methods have been compared (21). Spectral analysis of heart murmurs appeared to be useful to estimate transvalvular pressure difference in patients with aortic valve stenosis (31,32). Spectral analysis was used to monitor the condition of bioprosthetic valves and mechanical valve prostheses (33,34). Wavelet transform (35) and a nonlinear transient chirp signal modeling approach (36) were used to detect the aortic and the pulmonary component of the second sound. The matching pursuit method was used to identify the mitral and the tricuspid component in the first sound (37). A tailored wavelet analysis has been used to automatically detect the third heart sound (38). Time–frequency analysis was applied for classification of heart murmurs produced by bioprosthetic valves (39), for studying the first heart sound (40), and for automated detection of heart sounds (41).

THE ELECTRONIC STETHOSCOPE

Clinical interest in PCG in its classical form has been decreasing during the last decade, but there seems to be an increasing interest in heart sound recording with the aid of electronic stethoscopes (1), combined with information technology allowing easy data-acquisition, visualization, data handling and parameter extraction, playback, telemedicine applications, waveform recognition, and diagnosis with the aid of databanks. Also, virtual instrumentation technology (such as Labview) is used for heart sound acquisition and processing.

The modern acoustic stethoscope comprises a binaural headset and a chest piece connected by elastic tubing (1). The headset is composed of ear tubes and ear tips; the chest piece can consist of a bell and a diaphragm part. The ear tips should fit in the ear orifice, preventing air leakage, with the tube properly aligned to the hearing canal, that is slightly directed forward. The tube connecting the headset and the chest piece should not be too long to restrict attenuation of acoustic pressure, especially of higher frequencies, generated at the chest piece. With the diaphragm part provided with a stiff membrane (diameter ~ 4 cm), applied firmly to the skin, the high frequency sounds are better observed. With the bell part of the chest piece, applied with low pressure to the skin (enough to prevent air leaks between skin and bell edge) low frequency vibrations are best picked up. The bell diameter should be large enough to span an intercostal space (~ 2.5 cm for adults). Firm application of the bell makes the skin act as a membrane thus diminishing its low frequency performance. Some stethoscopes have only one part with a specially mounted membrane, which can function in the “bell mode” or in the “membrane mode” by altering applied pressure for the purposes cited above. As such, in the application of the stethoscope, frequency filtering (as in phonocardiography) is performed by using a specific shape and mechanical coupling to the chest wall.

The electronic stethoscope (e-stethoscope) combines the simplicity of the acoustic stethoscope with the benefits of electronics and information technology. Essentially, the e-stethoscope is an acoustical type provided with a built-in microphone; as such, it can be indicated as an air coupled vibration pick-up. In its simplest form, sounds are transmitted to the ears by tubing as in the acoustical one. The more advanced type has the microphone built within the chest piece, with adjustable amplification and filtering, mode control with easy switching between bell and diaphragm modes, generation of processed sound by miniature speakers to the air tips, cable or wireless connection to a personal computer for further processing. Adjustment of stethoscope performance can be executed during auscultation. Most stethoscopes are intended for observation (and recording) of heart sounds and murmurs, and for lung and airway sounds as well. A special type, the esophageal stethoscope, can be used for monitoring heart and lung sounds during anesthesia (42).

User-friendly software is available for diagnostic and for training purposes. Recorded signals can be printed, visualized, adapted by digital filtering and scaling, improved by elimination of artifacts and disturbances, and combined

with synchronously recorded ECG. Processed sounds can be reproduced and played back with speakers with a sufficient bandwidth (in the low frequency range down to 20 Hz). Spectral analysis is also possible: Frequency content as a function of time can be displayed. Automated cardiac auscultation and interpretation can be useful in supporting diagnosis (43–45). Sounds recorded by a local general physician can be sent via internet to the cardiologist for accurate diagnosis (46).

Educational benefits are obvious. Heart sounds recorded with the e-stethoscope or obtained from a data-bank can be visually observed and listened to. CD-ROMs with a collection of typical heart sounds and murmurs are available for training purposes. Multimedia tools were found to contribute to the improvement of quality of physical examination skills (47,48).

HARDWARE AND SOFTWARE

In this paragraph, some practical details are given with respect to available hard and software. A conventional form of a phonocardiograph (heart sound transducer, amplifier and filters, audio, output connectable to recorder, also fit for lung sound recording) can be obtained from EEC (<http://www.eeconnet.com>). ADInstruments provides a heart sound pickup (<http://www.adinstruments.com>). Colin (<http://www.colin-mt.jp/eng>) provides a phonocardiograph together with ECG and noninvasive blood pressure measurement for noninvasive assessment of arteriosclerosis. Electronic stethoscopes can be purchased at Cardionics (<http://www.cardionics.com>), 3M (Littmann) (<http://www.3m.com/product/index.jhtml>), Meditron (<http://www.meditron.no/products/stethoscope>), Philips (<http://www.medical.philips.com/main/products/>), EEC (<http://www.eeconnet.com>). Software supporting the physician in the evaluation of heart sounds recorded with an electronic stethoscope is provided by Zargis (<http://www.zargis.com>), Stethographics (<http://www.stethographics.com/index.html>). Software intended for training in heart sound auscultation (heart sounds recorded with an electronic stethoscope or from data banks) can be obtained from Biosignetics (<http://www.bsignetics.com>), Zargis (<http://www.zargis.com>), Cardionics (<http://www.cardionics.com>).

EVALUATION

Evaluation of heart sounds and murmurs remains an important method in the diagnosis of abnormalities of cardiac structures. Conventional PCG, however, essentially the graphic recording of sounds for visual inspection, has lost interest as a result of a number of reasons. First, the vibration signals are complex and thus difficult to interpret; they are characterized by a broad frequency range and, as such, different time representations present specific information (low and high frequencies). Obtaining high quality recordings having a high signal-to-noise ratio is difficult. Genesis and transmission of vibrations is difficult to describe and insufficiently known. A variety of waveforms are observable at the chest surface; Multisite recording and mapping are useful with respect to the solving of the genesis and transmission

problem but are difficult to execute and result in a large amount of data to be analyzed. The recording technique is not standardized; The ordinate axis of a phonocardiographic waveform does not have a physical unit as, for example, the millivolt in electrocardiography. The latter is due to the different transducer types, unquantified loading effect of the transducer on the chest wall, different frequency filter concepts. Thus, the method remains bound to a specific recording method and is semiquantitative. No guidelines for universal use have been developed and proposed to the clinical users. The most important reason evidently is found in the availability of technologies like echocardiography, Doppler, and cardiac imaging techniques, which provide more direct and accurate information concerning heart functioning. The latter, however, have the disadvantages of being costly and restricted to hospitals. Nevertheless, knowledge of heart sounds and murmurs has been greatly increased with the PCG technique and research is still going on. Signal analysis, more specifically time–frequency analysis, has proven to be very useful in the identification and classification of heart sound components and murmurs and their relation to cardiac structures and hemodynamic variables.

Conventional PCG has lost interest. Nevertheless, the historical value of the method has to be stressed. Auscultation, being simple, cheap, and not restricted to the hospital environment, held its position as a diagnostic tool for the general physician and for the cardiologist as well. However, this technique requires adequate training. Recording and processing of heart sounds remain beneficial for training and for supporting diagnosis. Electronic stethoscopes coupled to a laptop with suitable software and connected to the internet for automated or remote diagnosis by a specialist may grow in importance in the coming years.

New York

INTRODUCTION

Photography is widely used in many areas of medicine for the documentation and treatment of diseases. Photography involves making pictures by capturing light reflected from objects onto a sensitive medium (e.g., film or the more recent technique of light-sensitive chips from a digital camera). In ophthalmology, the transparency of the living eye allows photographs to image diseases as far back as the retina. In dermatology, traditional methods of photography are used to document and track skin lesions. Every type of medical imaging comes with its own technical challenges. The medical photographer plays a vital part in promoting and supporting quality healthcare by providing services in photography. Furthermore, imaging has served as an important research tool. Photomicrography involves taking images in the laboratory of tissue or culture specimens in both the gross and cell level. The goals of photography, in general, may include characterizing the basic anatomy and physiology of the body, understanding changes caused by aging or disease, and discovering disease mechanisms.

OPHTHALMIC PHOTOGRAPHY

Photographing the living eye poses some challenging issues despite its transparency. The eye is sensitive to light and can easily be bleached after a certain number of flashes and intensity. The human retina is also designed for capturing light rather than reflecting it. Images may result in poor contrast and may affect the performance of diagnostic procedures. The main absorbing pigments in the eye are blood, hemoglobin, photo pigments, macular pigments, and water. Moreover, research has shown that many sight-threatening diseases are embedded deep in the retina, where conventional tools of photography cannot be used (1,2). Fortunately, specialized instruments and image enhancement processes have been developed to obtain better images (Fig. 1).

The Fundus Camera

The instrument widely used by ophthalmologists to view the posterior segment of the eye is the fundus camera. The fundus is photographed using a white light source to provide high resolution images at the micron range. Fundus photography can also create stereographic images that provide depth. These qualities make fundus photography the established standard for clinical studies of

macular diseases. Newer models now take digital images and can be directly stored to a computer database.

Many fundus camera models are currently available in the United States: the German Zeiss, the Topcon fundus camera, the Olympus fundus camera, and the Nikon fundus camera. In choosing an instrument, one should compare the engineering and more importantly, the photo quality. Some instruments will be more expensive than its competitors, but takes excellent photographs while others have a wider view and good quality images (3) (Fig. 2).

General Methodology

A full-time photographer is specialized to operate the equipment in a clinic. While gaining technical skills, the photographer is often familiar with the clinical pathology of the fundus. This is advantageous to the ophthalmologist in situations where photos need to be interpreted. In operating a fundus camera, there are some general guidelines to follow (3):

1. The pupil of the patient must be dilated. Dilation of the pupil may take 20–30 min. An 8 mm diameter pupil is ideal, but even a pupil much smaller may be acceptable.
2. The eyepiece must be carefully focused to avoid getting out-of-focus photographs. Young children will have accommodation problems and may pose extra attention. The settings should be checked before each set of photographs on the patient is taken.
3. Check the shutter speed for the proper electronic flash synchronization. Shutter speeds in the range of 1/30 to 1/60 of a second can be used.
4. Take an identification photograph of the patient's name, date photographed, and other pertinent information. Properly labeling photos will avoid confusion later.

Figure 1. Cross-section of the eye. The transparency of the eye permits the ability to receive light from the external world. Light enters the cornea and goes through the iris and the lens until it reaches the retina. The macula contains many rods and cones and is the area of greatest visual acuity.

Figure 2. The optical pathway of the fundus camera. Light generated from either the viewing lamp (V) or the electronic flash (F) (A) is projected through a set of filters and onto a round mirror (B). This mirror reflects the light up into a series of lenses that focus the light. A mask on the uppermost lens shapes the light into a doughnut. The doughnut shaped light is reflected onto a round mirror with a central aperture (C), exits the camera through the objective lens, and proceeds into the eye through the cornea. When the illuminating light is seen from the side, one can appreciate the complexity and precision of the optical scheme (D). Assuming that both the illumination system and the image are properly aligned and focused, the retinal image exits the cornea through the central, unilluminated portion of the doughnut (E). The light continues through the central aperture of the previously described mirror, through the astigmatic correction device and the diopter compensation lenses, and then back to the single lens reflex camera system. (From Saine PJ, Taylor ME, *Ophthalmic Photography* (2nd ed.), Butterworth-Heinemann, 2002 with permission.)

5. When the patient is comfortably seated at the instrument with their chin on the chin rest and their forehead against the headrest, instruct the patient to look at the fixation device.
6. After properly focusing the filament of the viewing lamp, look through the eyepiece and bring the retinal vessels into focus. Release the shutter.

Stereo Fundus Photos

Fundus photos in stereo pair give a perception of depth that greatly improves reading performance. For example, a stereo photo can document blurred disk margins, optic nervehead cupping, and the degree of retinal elevation from conditions (e.g., serous or solid detachments). When evaluating patients with age-related macular degeneration (AMD), graders can view the elevation of drusen under the retina much more effectively.

The most popular method of taking stereo photographs was the cornea-induced parallax method, advocated by Bedell (4). To take the stereo pair, the first photograph is taken through the temporal side of the pupil and the second through the nasal side. A lateral shift of 3.5 mm is recommended for optimum stereopsis, but any lateral shift will create a stereo photograph. The photographer aligns and focuses the camera through the center of the pupil, then uses the joystick to move the camera slightly to the right, takes an image, and then slightly to the left, and takes the second image. The translation of the camera sideways changes the angle of view. The amount of camera shift can vary from image pair to image pair, making apparent depth a variable. Attachments are available for some cameras that allow the photographer to shift the camera through a consistent distance. Specialized cameras are commercially available to take stereo-pair fundus photos simultaneously, though the resolution is reduced.

Digital Imaging

Until recently, fundus photos were developed in film and the photographer had to wait hours or even days to see the results. The resolution was limited by the grain size of the film. Today, fundus cameras take digital photos that can be evaluated instantaneously and stored digitally. A typical image is in 24-bit, red, green, and blue (RGB), true color with a resolution size of 2000 × 2000 pixels. A digital imaging system ensures that the original quality of the image is preserved and will produce flawless duplication.

Images can be stored in a number of different formats, but with digital files comes the requirement for an efficient digital storage system. Tagged image file format (TIFF) images are not compressed, and therefore require large storage spaces. Recent advances in computer engineering have provided large storage in affordable costs. Nevertheless, it has been shown by Lee (5) that joint photographic experts group (JPEG) formats allow for varying degrees of image compression without compromising the resolution of fundus photos necessary for image analysis. In image compression, images are applied to a lossy algorithm, which permit the image to be reconstructed based on partial data. The result is not an exact restoration of the image, but is sufficient for diagnostic purposes.

In the evaluation of clinical AMD, Lee reported that TIFF images and low compression (30:1) JPEG images were virtually indistinguishable (5). Digital images of AMD patients were analyzed in software for drusen identification and quantification. Drusen detection in the conventional stereo fundus slides using a manual protocol was highly comparable to the digital format (Figure 3).

Figure 3. Fundus image of an AMD patient. The fundus camera is used to photograph the retina. The macula corresponds to an area of the retina 5–6 mm in diameter, centered on the fovea. Drusen are the white deposits surrounding the fovea that are characteristic of AMD, a sight-threatening disease. The retina has many layers, including the retinal pigment epithelium (RPE) and the choroid. Drusen are usually found embedded below the RPE layer.

Clinical Evaluation of AMD in Fundus Photos

The fundus camera has been routinely employed for diagnostic purposes (e.g., the clinical study of patients with AMD) (6,7), which is the leading cause of blindness in the developed world (8). The natural history of AMD is hallmarked by a subretinal pathology known as drusen (9–17). The identification and measurement of drusen are central to clinical studies of early AMD. The current standard of grading AMD is through manual viewing of stereographic fundus slides on a light box. However, this method involves time-consuming analysis of drusen size, number, area, and morphology in several subcategories (18).

Despite the movement to digital fundus imaging, a digital and automated method of quantification of macular pathology in AMD has yet to gain widespread use. Computer-assisted image analysis offers the potential for greater accuracy, objectivity, and reproducibility, but designing algorithms for that purpose is nontrivial. Many methods have been attempted in the last two decades with unsatisfactory results (19–25).

One major obstacle stems from the clinical appearance of the normal macula, which is a composite of complex light reflections from and absorption by multiple layers of the retina and associated structures. The application of segmenting any pathology superimposed on the macula in an automated fashion is a difficult task by the nonuniform reflectance of the normal macular background. For example, absorption by luteal pigment in the central macula

(fovea and parafovea) contributes to the darker central appearance. The nerve fiber layer, conversely, is highly reflectant. It is thickest in the arcuate bundles along the arcades and thinnest at the central fovea. This makes the arcade regions relatively brighter, hence also contributes to the macula appearing darker centrally (26). Therefore, simply choosing a global threshold would not be equally effective in segmenting or identifying drusen in the darker central regions as it would in the relatively brighter regions in the periphery, and vice versa.

Shin et al. (19) used adaptive thresholding techniques to handle the nonuniform macular background reflectance. They divided the image into separate windows of variable sizes. Within each window, a local histogram was applied to check for skewness, and to determine if drusen was present. However, the method was often misleading if either a large area of background or a large drusen dominated the region, which resulted in an incorrect threshold. Moreover, windows containing vessels would sometimes be incorrectly interpreted in the bimodal distribution. Thus, operator supervision and some postprocessing steps were added.

Shin's method was improved by Rapantzikos et al. (20), which used morphological operators (e.g., kurtosis and skewness) to predict whether drusen was present in the local window. Their idea gave better results, but was not infallible as a completely automated system of drusen segmentation. For example, many different combinations of image features (drusen and background) can yield the same histogram.

An alternative method was presented by Smith et al. (27,28) that aims to level the macular background reflectance, which can change significantly over distances of 50–100 μm . In previous methods, inadequate segmentation centrally and overinclusive segmentation in the peripheral macula was an indication that the background variability of the macula had not been resolved.

Smith found that the background reflectance of a normal fundus image could be modeled geometrically (29–31). It has been shown that a partial normal background containing drusen provided enough information to model the entire background by an elliptical contour graph (27,32). After leveling the nonhomogeneity of the background reflectance, they overcame the challenges posed in purely histogram-based methods of other researchers. A combined automated histogram technique and the analytic model for macular background presented a completely automatic method of drusen measurement.

Their algorithm is briefly explained. First, an initial correction of the large-scale variation in brightness found in most fundus photographs was applied. This is achieved by calculating a Gaussian blur of the image and subtracting it from the original image in each of the three RGB color channels. Further processing was carried out in this preprocessed image. The main idea was to level the background such that the reflectance was uniform over the entire macula. They proposed a multizone math model to reconstruct the macula. Each zone divided the macula into different annular and grid-like regions. The pixel gray levels were used as input for fitting into the custom software employing least-squares methods. After the geo-

metric model of the macula was created, it was subtracted from the original image to obtain a leveled image. The process was automatically iterated until a sufficient leveling has been achieved. In other words, the range of gray levels in the image is minimized to an acceptable level.

The drusen, which is superimposed on the image, appears brighter than the regular intensity of the background. The final threshold was obtained by applying a histogram analysis approach to the final leveled image (33). An optimal threshold defined the separation of background areas from drusen areas.

Smith's technique has been validated successfully with the current standard of fundus photo grading by stereo pair viewing in the central 1000 and middle 3000 μm diameter subfields (28). One advantage of automation is portability of the software to use at other institutions. The work to create an automated algorithm will provide a useful, cost-effective tool in clinical trials of AMD.

Despite the advances in automated quantification of drusen, some obstacles still remain. Drusen identification may be confounded by other objects present in the image. A computer ultimately must be taught how to differentiate drusen from other lesions (e.g., as retinal pigment epithelial hypopigmentation, exudates, and scars). Implementation with neural networks or morphological criteria may prove effective in eliciting unique features in the lesions. For now, some cases may still require supervision in digital automated segmentation (Fig. 4).

SCANNING LASER OPHTHALMOSCOPE

Photography is often associated with taking a white light source to obtain an image. However, monochromatic sources of light at a specific wavelength are available with the scanning laser ophthalmoscope (SLO). Originally used as a research tool, it is increasingly favored with other clinical imaging standards now. Moreover, pupil dilation is unnecessary, and light levels are dim during acquisition (34). The reflectance and absorbance spectra of the structures of interest can be seen. For example, the SLO provides better penetration and give views of the choroids layer. By the same token, things of less interest on the retina (e.g., drusen) will not be seen (26).

In autofluorescence (AF) imaging, a 488 nm laser source with a 500 nm barrier filter is used (26). This light source reveals structures that intrinsically fluoresce, primarily due to lipofuscin and its main fluorophore, A_2E (35,36). Focal changes in AF or the changes in their spatial distribution are means of studying the health of the RPE. Previous studies have been made on correlations of change in AF distribution with pathological features (35,37–41). Focally increased AF (FIAF) refers to increased fluorescence in an area with respect to the rest of the background. This is abnormally high in patients with Stargardt disease and may be a marker for RPE disease in ARMD. In actual RPE death, as in geographic atrophy, there is focally decreased AF (FDAF), seen as a blackened area in the AF image (26).

Figure 4. Automated digital photo grading. Color fundus photo with circular grading template overlaid on top (a). Green channel (grayscale) of fundus photo (b). Using an algorithm that finds the lower and upper thresholds, the macula is divided into three sections: vessels and darker perivasculature, normal background, and bright drusen. The normal background was used to calculate the mathematical model, displayed as a contour graph (c). The model was subtracted from the original image to yield a background leveled image of uniform intensity in (d). Contrast-enhanced image of a to show the boundaries of drusen (e). The algorithm then uses the leveled image (d) to calculate a threshold that determines the drusen areas (segmented in green) and overlaid on top of the contrast enhanced layer (f).

TELEMEDICINE

As the average age of populations in developed countries continue to rise, the number of elderly people needing an eye exam will boom. In less populated areas, an ophthalmologist may not be readily accessible. In the United States, less than one-half of the diabetic population received an annual eye examination (42). One of the goals of telemedicine is to bridge the gap between places where patients can be evaluated and where service is rendered. An examination usually involves taking the patient's fundus photos. With the advent of telemedicine and digital photography, the patient and doctor do not even have to be in the same room. Data can be efficiently and securely transferred across different institutions.

Telemedicine Framework

The goal of telemedicine is to establish a screening system with the ability to reach out to millions of unexamined patients for primary prevention. The following guidelines can be used to set up a generalized framework for telemedicine. We will use an ophthalmology setting as an example:

First, a patient will come into a primary care office to have their retina imaged. The camera itself should be operator-friendly, one that is easy to use by either a doctor's assistant or a technician. The disease to be screened should have identifiable pathology on the image. Examples would

be diabetic retinopathy or AMD. The fundus photograph is then sent electronically to a reading center, which can be established at a far away university or hospital. Photos should be in a compressed digital format (e.g., JPEG).

In a paper by Sivagnanavel et al. (43), it was suggested that custom software for detecting AMD could be used at two different institutions. A grader at each institution independently ran the software and performed drusen quantification successfully, thus demonstrating portability and potential for automated software examinations. The results of the grading with software are comparable to grading manually by stereo-viewing. The only drawback is that the software may not be suitable in $\sim 20\%$ of the images taken. For the percentage of cases that need supervision, a trained reader can manually examine the images. Images that were disqualified had poorly identified areas or multiple types of lesions that were difficult to distinguish.

At the reading center, a patient report is generated and sent electronically back to the primary care physician (PCP). Finally, a good network referral base must be established such that the PCP can refer an ophthalmologist if the patient screening comes up positive.

Screening Instrument

Built differently from the classic fundus camera, a telemedicine instrument is meant for screening more than

Figure 5. Layout of the DigiScope. The imaging head (1) is mounted on an XYZ motorized and computer-controlled stage. The X, Y, and Z components (2, 3, and 4, respectively) allow movements in the superior-inferior direction, to and from the eye, and in the nasal-temporal direction, respectively. The operator interfaces with the camera by a touch screen (5). The subject leans the head and places it against the nosepad (6) to view the imaging system inside. The electronics and computer (7) that control the system and store the images are embedded in the machine and hidden from view. (used with permission for R. Zeimer, IOVS 43:5,2002.)

careful clinical diagnosis. In a telemedicine fundus camera (e.g., the DigiScope) (44), the goal was to create a good model for providing ophthalmic screening to the primary care office.

Keeping the instrument at low cost for production greatly increased its attractiveness for the primary doctor's office. Therefore, a video camera with a resolution of 50 pixels per degree provided enough detail comparable to a fundus photograph. Such cameras typically yield images with 930 pixels diagonally, or a field of 19° .

Figure 5 shows a simplified diagram of the DigiScope. The eye to be imaged is oriented by an internal light-emitting diode. Fixation and imaging covers the entire posterior pole and takes about eight images. The illumination is generated by a halogen bulb. Infrared light is eliminated by the first filter and the visible spectrum is limited to green by the second filter, which passes light between 510 and 570 nm. The beam then expands and illuminates the fundus.

There are two modes of imaging with the DigiScope. The first mode takes four frames per shutter, with the shutter lasting 130 ms. The four frames differ by the fine focus, such that the sharpest image can be chosen out of each set. The second mode is meant for stereoscopic effect. Four frames are acquired while the optical head moves horizontally along the x axis. A pair of images can be selected to generate a stereo effect.

The operator interfaces with the machine by a simple touch-screen. The duties of the operator are limited to basic

tasks (e.g., explaining the procedure, encouraging the patient to fixate at the blinking light, and checking the quality of the image).

A non-mydratic camera is in consideration to provide greater patient comfort. Poor imaging quality and lack of stereo may cause a tendency to include RPE atrophy as drusen. However, newer generation cameras taking higher resolution images, coupled with the ability for digital stereo, may eliminate such drawbacks in the future.

PHOTOMICROGRAPHY

Photomicrography in biomedicine is the creation of images of biomaterial at magnification. Tissue or culture samples can be photographically recorded at both the gross level and at the level of cells. Images can be used for archival purposes or for analysis. Photomicrography replaced earlier camera lucida apparatus that projected microscope images through a beam splitter onto a plane for manual tracing.

Still photographs of biological specimen have traditionally been captured on 35 mm film. The development and popularization of digital camera technology, however, has had a drastic impact on the field of photomicrography. The relative ease of use has spurred the application of photomicrography in many areas, especially pathology and basic research.

Digital Cameras

Digital cameras offer several advantages over their film variants for most uses. Most digital cameras include some type of LCD (liquid-crystal display) screen. This screen can be used to display a photograph right after it is taken, allowing the user to evaluate the result of different camera settings and adjust as needed. This is a great convenience given the unusual light conditions under which photomicrographs are generally taken and the fact that most scientific users will probably not have professional photography training. On consumer models, the LCD can also display a real-time image of the scene to be photographed. Furthermore, digital cameras store images in a digital format, usually on a removable memory card. Images can be directly transferred to a personal computer for analysis or processing without having to use a scanner to digitize as with 35 mm film. The formats come in JPEG or TIFF. Still others cameras have the option of outputting in the RAW format. This is the raw data from the CCD (charge-coupled device) array that forms the core of the camera. The CCD cameras have also proven particularly useful in extremely low light microscopy, such as in certain fluorescence microscopy situations. Quantum efficiency, a measure of light sensitivity, can reach 90% in a back illuminated electron multiplying CCD, compared to $\sim 20\%$ for a conventional video camera (45,46) (Fig. 6).

Photomicroscope Description

The attachment of the camera to the microscope is essentially the same for both digital and film cameras though different adapters may be used. A camera can simply be held with the lens pressed flush against the eyepiece of a microscope or mounted with a special adapter for the

Figure 6. Retrofitted computerized microscope system with motorized stage and CCD digital imager directly connected to computer by Firewire cable. (used with permission from the laboratories of Victoria Arango, Ph.D., J. John Mann, M.D., and Mark Underwood, Ph.D. at NYSPI and Columbia University.)

eyepiece (46,47). This method can be used for many consumer digital cameras. Alternatively, a camera can be attached to the phototube or trinocular port of a microscope or through a special beam splitting adapter (47,48). Typically, SLRs (single lens reflex) and cameras specifically designed for photomicrography are attached in this way by their lens mounts. The tube thread standards commonly used in professional cameras to attach the lens are C-, T-, and F-mounts. Relay lens adapters may be necessary to correctly focus the image onto the film or CCD array in the camera as the normal lens is removed to use the C-, T-, or F-mount. Many of the major camera brands as well as third-party manufacturers produce these adapter kits. The primary concerns when attaching a camera are ensuring correct focus and avoiding vignetting. Vignetting refers to the darkening of the edges of an image (47). Proper Koehler's illumination of the microscope, as well as focusing and zooming should correct this effect.

The CCD technology has also been applied successfully to real-time imaging through the microscope. Dedicated computer microscopy systems with CCD cameras have been made available by the major microscope manufacturers (e.g., Leica and Zeiss). The CCD video cameras can also be attached to existing microscope setups through the phototube as with still cameras. Traditional CCTV cameras can usually output in NTSC (National Television System Committee) or PAL (Phase Alternating Line), the common video standards in the United States and Europe, respectively. An image capture board is necessary to convert the TV signal for use with a computer. The CCD digital imagers specifically designed for scientific or microscopic use often can be connected by means of more conventional computer ports [e.g., Firewire (IEEE 1394) and USB (universal serial bus)]. These are preferred due to their resistance to radio frequency (RF) interference and higher resolutions (49). In both cases, specialized software is needed to manipulate and display the video image. Some of these imagers can be used to capture high resolution still images as well.

Figure 7. Montage of photomicrographs taken with 40 \times objective and stitched together with NeuroLucida software (MicroBrightfield, Inc., Williston, VT). Brodmann area 24 of the prefrontal cortex is depicted. (used with permission from the laboratories of Victoria Arango, Ph.D., J. John Mann, M.D., and Mark Underwood, Ph.D. at NYSPI and Columbia University.)

For video applications, a more expensive three-chip, one-shot CCD system is preferred (46). These cameras use an array of photodetectors to record an image. One such array is referred to as a chip. Currently, cameras are available in one-chip and three-chip designs. A one-chip design produces color images by switching three colored filters over the array. This arrangement is referred to as one-chip, three-shot. Due to the switching of RGB (red, green, blue) filters, the framerate is necessarily reduced. A three-chip, one-shot camera splits the individual color channels and directs each to its own CCD array, imaging them simultaneously. Thus a higher framerate is maintained.

Camera computer systems integrated with a motorized microscope stage make possible more complicated photomicrograph sets. A computer controlled stage and camera can be programmed to take many overlapping digital images. With special software, these can be stitched together to form high magnification photomicrographs of large tissue sections (50). This represents an interesting alternative to low magnification macroscopic photography of tissue specimen. Systems have also been developed for 3D reconstruction using stacks of properly registered two-dimensional (2D) photomicrographs (Fig. 7).

PHYSIOLOGICAL SYSTEMS MODELING

N. TY SMITH
University of California,
San Diego, California
KENTON R. STARKO
Point Roberts
Washington

INTRODUCTION

First, physiological systems need to be characterized. The word “system” means an interconnected set of elements that function in some coordinated fashion. Thus, the heart, with its muscles, nerves, blood, and so on, may be regarded as a physiological system. The heart, however, is a subsystem of the circulatory system, which is in turn a subsystem of the body. Dynamic systems are time-varying systems, and most physiological systems fall into this category. This article deals with classical, or macro, physiological systems, usually ignoring genetic, cellular and chemical systems, for example.

It should come as no surprise that the term super system has been used to describe the brain and the immune system (1). The cardiovascular system (CVS) and central nervous system (CNS) are closer to being super systems, however.

Correct terminology is vital. To paraphrase George Bernard Shaw, engineering and medicine are two disciplines separated by the same language. The same word may have two different meanings (system) or two different words may have the same meaning (parameter and variable; model and analogue). The latter is particularly pertinent. Medical researchers working with animals because of their resemblance to humans use the term “animal model”, while engineers would use the more descriptive “animal analog”.

Unless otherwise stated, model, We means mathematical model. Thus, these models are generally ignore: animal, *In vitro*, chemical, structural (Harvey’s observations on the circulation), and qualitative (Starling’s law of the heart).

What is a mathematical model? A mathematical model consists of elements each describing in mathematical terms

the relation between two or more quantities. If all the descriptions are correct, the model will simulate the behavior of real-life processes. Especially when many different subprocesses are involved, the models are useful in helping understand all the complex interactions of these subsystems. A useful characteristic of a mathematical model is that predictions of the outcome of a process are quantitative. As Bassingthwaight et al. (2) point out, these models are therefore refutable, thereby facilitating the entire process of science.

The difference between modeling and simulation is important. Modeling attempts to identify the mechanisms responsible for experimental or clinical observations, while with simulation, anything that reproduces experimental clinical, or educational data is acceptable. For this article, when you run a model, you are performing a simulation. Thus, simulation is not necessarily an overworked word. Most of the models described here are not simulators, however. That word should be reserved for those models that allow a nontechnologically oriented user to interact with the model and run a simulation. The words simulation or simulator are used when appropriate.

Having said that, the backgrounds and connotations of simulate and model are strikingly different. Reading the etymology of simulate and simulation is a chastening process, emphasizing as it does the unsavory past of the terms. In contrast, model has a more virtuous past. The Latin *simulare* can mean to do as if, to cheat, to feign or to counterfeit. Hence, a set of its meanings, from the OED, includes To assume falsely the appearance or signs of (anything); to feign, pretend, counterfeit, imitate; to profess or suggest (anything) falsely. The action or practice of simulating, with intent to deceive; false pretence, deceitful profession.

The Middle French *modelle*, on the other hand, implies perfect example worthy of imitation. Thus, one definition, again from the OED, is Something which accurately resembles or represents something else, esp. on a small scale; a person or thing that is the likeness of another. Freq. in the (very) model of. . . . Another definition is “A simplified or idealized description or conception of a particular system, situation, or process, often in mathematical terms, that is put forward as a basis for theoretical or empirical understanding, or for calculations, predictions, etc.; a conceptual or mental representation of something.” Our final definition is “A person or thing eminently worthy of imitation; a perfect exemplar of some excellence. Also: a representative specimen of some quality.”

This remarkable difference between the two terms can be transmuted to our basic philosophy: A simulation is no better than the model that drives it. Put another way, the model is arguably the most important part of the simulation. It helps prevent the simulation from being something that feigns.

Model Reduction versus Model Simplification

We were asked to consider the introduction of reduction, to distinguish from simplification, of the size of available models by weeding out minor effects. These concepts are indeed essential for the physiome project (at end of this

article). Unfortunately, the literature that we have found usually fails to distinguish between the two terms, and too often uses them interchangeably. The following fragment of a definition was particularly discouraging: “Model reduction is the simplification or reduction of a mathematical model. . .” Not only is it a partial circular definition, but it also uses the term simplification as a way of achieving reduction of a model.

Dr. George Hutchinson, of GE Healthcare, has provided considerable help, and the remainder of this section comes from his ideas, as well as from the literature. He suggests that the difference between the two terms is in the purpose and the effect rather than in the action. Simplification of a model will eliminate elements, knowing that accuracy or validity may be significantly compromised. This simplification may be necessary because of (1) limitations in the platform running the model, (2) a decision to delay the work to model this portion of the system, or (3) this part of the model’s not being germane to the focus of the model’s intent. BODY Simulation does not model a real electrocardiogram (it is constructed from a look-up table) and that is a simplification of the model. This does compromise the overall validity of the model, but it was a simplification needed to make the rest of the model available to the public; this currently unnecessary submodel would have overwhelmed the rest of the model.

On the other hand, reduction is the elimination of some elements of a model in a way that should not significantly affect the accuracy or validity of the overall model. This could be done to streamline the code, to improve the faster-than-real-time performance, or to allow the model to run on a lesser platform. Again, with BODY Simulation as an example, deciding to limit the modeling of the arterial tree to large peripheral arteries, but not to extend it to the digits or the capillaries, is a reduction of the overall model, but it does not affect the intended use of BODY. The arterial waveforms are still good enough and the action of the MAP is unaffected.

This suggests that reduction and simplification are relative. Relative morality may be unacceptable, but relative definitions are reasonable. In a model built for one purpose, elimination of elements is reduction. In the same model built for a different purpose, such elimination is simplification. The problem of model reduction is to find a smaller system such that the number of components is much smaller than the original and the transfer function of the new system is close to the original transfer function.

Models, almost by definition, are necessarily simplifications and abstractions, to some degree, of the reality of the system. The modeler attempts to extract the important elements of the system (not all the variables, as that is not possible) and represent them so that they are simple enough to be understood and manipulated, yet realistic enough to portray the essential constructs and parameters of the situation. If either simplification or reduction is used, the techniques must be identified and justified, and the magnitude of their effect quantified.

Uncertainty analysis and sensitivity analysis are prerequisites for model building. The former allows quantifying the precision associated with the model response as a result of problems in the model input. Sensitivity analysis

is aimed at establishing how the variation in the model output can be apportioned to different sources of variation, so that the modeler can establish how the given model depends on the information fed into it. Both are essential to assess the impact of simplification or reduction.

Here are some of the techniques that have been proposed for simplification and for reduction. Although these methods do overlap in their intended use, we have chosen to include them only with one or the other term. Also, lack of space precludes our going into detail about any of them.

Simplification

- Eliminate short-term changes, when long-term ones only are important.
- Make sure that the parameters and variables are important to the model.
- Use a coarser (simpler) finite-element model.
- Use intermediate variables, that is, reduce the number of input and output variables.
- Use the reduced basis technique.
- Simplify equations.
- Simplify assumptions.
- Use algebraic equations, instead of differential equations.

Reduction

- Reduce the number of dimensions in a model.
- Narrow down the search space among the input parameters.
- Considers only significant inputs, as opposed to all inputs, of the full model.
- Eliminate redundant information.
- Use a numerical model reduction technique that assumes no knowledge of the system involved.

With such a large topic, one must draw the line somewhere, and the line used is rather large. For example, CNS is an enormous topic, and we have to be content with a small subset: cerebral circulation. In general, pathology, diseases, or their effects are rarely addressed, although normal aging is discussed. Also usually avoided are the following systems and topics: GI, immune, CNS, peripheral nervous, hepatic, enzyme, cellular physiology, receptors and coagulation, as well as the effects of altitude, temperature changes, diving, microgravity, exercise, conditioning, hypertension, or pregnancy, for example. There will be little discussion of pediatrics, obstetric and other specialties. The ANS and acid–base regulation will be included with some extensive models, but not discussed as a separate topic. However, physiological PKPD models, which have been influential in the development of whole-body physiological models are included.

Since many physiological models involve control systems, this feature will be emphasized, including a special kind of control system known as autoregulation. Much of physiological systems modeling involves control systems. The body has many control systems, and only a few of them

can be addressed here. Those discussed will be embedded in larger models, of the CVS, for example.

This is not intended to be a critical review, but rather a review resource for those wishing to use models. A few of the uses for a few of the models are mentioned briefly, in addition to that of incorporating them into one's own model or simulation. An attempt is made to differentiate between where a model is described and where the author presents material, especially equations, that could be used in a model.

Data to construct a model can come from many sources, including the literature and an author's own ad hoc experiments. Unless otherwise stated, assume that data generated from the usually performed validating experiments fit a given model reasonably well. Weinstein (3) contends, however, that this form of validation may not be enough. Arguably, one may endorse a standard of model presentation in which the model builder shows not only what works, but also where the model fails, or where it makes novel predictions that have yet to be tested. While Weinstein suggests a good paradigm, published models are offered to the world to test out. Models are hypotheses, and no one expects final proof of an hypothesis in a paper: or series of papers. Some hypotheses, like some of Einstein's, seem to be eternally hypotheses. Modeling is a perpetual process.

The following lists a few uses of models:

1. Education is certainly the primary one.
2. Compression of enormous amounts of data.
3. An hypothesis.
4. Simulation and simulators.
 - (a) Manikin-based simulators, such as an operating-room simulator.
 - (b) Part-task trainer. The trainer could include a model and a ventilator, to teach students how to use the ventilator.
 - (c) Screen-based simulator
5. Construct pharmacological models.
6. Simplify concepts to the user, especially in a simulation or simulator. The user of a model does not need to understand the mathematics or software, no more than one must understand how a car works before one drives it.
7. Suggest counterintuitive concepts for further exploration.
8. Suggest experiments to perform.
 - (a) Fill missing gaps of knowledge.
 - (b) Answer a posited question.
 - (c) Try to explain ostensible modeling anomalies.
 - (d) Provide more data for the model.
 - (e) Any combination.
9. Substitute for animals or people in experiments.
10. Control part or all of an experiment.
11. Serve as an important component in adaptive control systems. A generic patient model learns about the patient and thereby helps improve the closed-loop control of an infused agent.

The most practical use to the reader, researcher, or educator is to operate a model, that is, run one's own simulation with it. Although most published models can not do that without considerable effort on the user's part, several models or sets of models make the process much easier. Werner et al. (4) state that their excellent model is "available for everybody". Levitt, Don Stanski, and Stephen Shafer all have large amounts of freely available software and data. The physiome project has more resources available than most of us can handle. The BODY Simulation model (see PBPM) is available as a simulator or as a dynamic linked library (dll). Because of the structure of this model, the latter means that the model can be connected to other software, such as simulation interfaces, or to a piece of electronically driven equipment, such as a ventilator, a patient monitor or an anesthesia machine. All of these are described in further detail, below.

RESOURCES

Several books stand out as resources for the reader. The classic is the late Vince Rideout's scholarly monograph *Mathematical and Computer Modeling of Physiological Systems* (5). It covers modeling for the CV, respiratory, and thermal regulatory systems, as well as transport and multiple modeling and parameter estimation. Baan, Noordergraaf, and Raines edited the proceedings of a symposium on cardiovascular system dynamics (6). The participants represented the international leaders in their fields: cardiology, physiology, engineering and physics. The postpresentation discussions alone are worth finding the book. The book comprises 62 papers, and it is difficult to choose which to emphasize. Some of them, however, will be discussed in the appropriate section. Most articles are detailed and worth exploring, for many reasons. A book edited by Papper and Kitz (7), again the result of a symposium, is described below.

TYPES OF MODELS

Mathematical models in our area fall into various categories, including mechanistic, black box; physiological, pharmacological, pharmacokinetic, pharmacodynamic; multiple, transport; analogue, hybrid and digital. Each one except physiological, is briefly described.

Mechanistic models can be understood in contrast to black box models in which only the input-output relations are important and not how these are realized. Though sometimes very useful, black box models have the limitation that they can only be used for descriptive purposes. Mechanistic models, for example, the prediction of flow through a vessel on the basis of diameter and length and pressure fall over it, allow the test of hypotheses. In case of the vessel example, one can test whether the viscosity assumed is the right one. Mechanistic models are important in testing hypotheses and formulating new ones.

Pharmacological is divided into two parts. Pharmacokinetic refers to the uptake, distribution and elimination of an agent, while pharmacodynamic refers to the action of the agent on the body. This is best remembered by the

Table 1. What, where, and how can be transported^a

What	What (cont.)	Where	Route
Mass	Toxins	Atmosphere	Blood
Momentum	Chemical warfare agents	Anesthesia machine/ventilator	Lungs
Energy	Bacteria	Organs	Nerves
Gases	Viruses	Tissues	Membranes
Drugs	Genes	Blood	
Electrolytes	Molecules	Cells	
Proteins	Atoms	Receptors	
Hormones			
Endocrines			
Heat			
Information			

^aThere is no connection among the terms in each row.

following: pharmacokinetic is what the body does to the agent, while pharmacodynamic refers to what the agent does to the body.

Most of the complex models that are described are modular. Each of these modules can be a model, and the entire model is called a multiple model. A model with two or more modules is called a multiple model. If a model has CVS and respiratory components, each of those is a model. Essentially, anything that can be transported (see Table 1 and the next paragraph) can be a submodel in a multiple model. This includes anything from O₂ to a bacterial species, to a specific atom. In addition, the physiological systems themselves are submodels, for example CV, respiratory, and liver. Thus, the model for BODY Simulation (see PBPM) has almost 100 modules, or submodels. Ideally, each model can be sufficient unto itself, and can therefore be tested before it is incorporated into the main model.

Transport models are accurately named. Essentially, they transport something from one place to another. That something, we call an agent. In the case of the circulation, they, of course, transport agents around and around. The concept of transport modeling was developed by chemical engineers (8), whose models transported mass, momentum, and energy. Transport modeling is incredibly powerful. One has to be optimistic and creative about transport modeling. Assume, until proven otherwise, that a model can transport anything, anywhere and by any route. Table 1 lists a few of the agents that have been or could be transported in a model.

The following describes the various types of transport.

Momentum transport. In the wave equations describing blood flow, the concern is with momentum, blood viscosity, and the elasticity of the vessel walls in determining pressures and flows of the system.

Mass transport. Blood and lungs carry many important substances, such as O₂, CO₂, and pharmacological agents. The diffusion of these substances into or out of tissue is often essential to a model.

Energy transport. The blood in vessels, as well as the air we breathe, carries heat energy. This heat may diffuse through tissues, although in a way different from the mass diffusion mentioned above. Also,

energy transformation, as well as transport, occurs in some tissues, including muscle, heart, brain, kidney, and liver.

Information transport. Information is carried throughout the body via nerve fibers, much as messages are transmitted in a communication system. Hormones also carry information, moving mostly with the aid of the bloodstream.

Models can also be categorized by the type of computer that implements them: analogue, hybrid or digital. This is not trivial, because even the most powerful digital computer cannot approach the speed and power of an analogue or hybrid computer, and we have yet to implement the entire original Fukui hybrid model (9) on a digital computer.

Whole-Body Models

A whole-body model is arbitrarily defined as one that includes the circulatory and respiratory systems, plus at least two other major systems. There is no model that includes all the major systems, much less any one system in detail. The good whole-body models have not been used extensively in education, while most simulators have used adhoc models assembled to meet the perceived needs.

The earliest and still archetypal whole-body model is that developed by Guyton and co-workers (4,10–13). To understand Guyton's contributions is to understand his model, and vice versa. One of his most important legacies was his application of principles of engineering and systems analysis to CV regulation. He used mathematical and graphical methods to quantify various aspects of circulatory function before computers were widely available. He built analogue computers and pioneered the application of large-scale systems analysis to modeling the CVS before the advent of digital computers. As digital computers became available, his CV models expanded dramatically in size to include many aspects of cardiac and circulatory functions. His unique approach to physiological research preceded the emergence of biomedical engineering, a field that he helped establish and promote in physiology, leading the discipline into a much more quantitative science.

The Guyton model has five main empirically derived physiological function blocks, with many subcomponents. The model has nearly 400 parameters and is remarkable in

its scope. It comprises the following physiological subsystems, or modules:

- Circulatory dynamics.
- Nonmuscle oxygen delivery.
- Muscle blood control and PO_2 .
- Vascular stress relaxation.
- Kidney dynamics and excretion.
- Thirst and drinking.
- Antidiuretic hormone control.
- Angiotensin control.
- Aldosterone control.
- Electrolytes and cell water.
- Tissue fluids, pressures and gel.
- Heart hypertrophy or deterioration.
- Red cells and viscosity.
- Pulmonary dynamics and fluids.
- Heart rate and stroke volume.
- Autonomic control.
- Nonmuscle local blood flow control.

The Guyton model is alive and healthy. Werner et al. (4) coupled the Guyton model, which does not have a beating heart, to a pulsatile model. The new model comprises the hemodynamics of the four cardiac chambers, including valvular effects, as well as the Hill, Frank-Starling, Laplace, and ANS laws. They combined the two models because, with few exceptions, the extant published models were optimized for either studying short-term mechanics of blood circulation and myocardial performance—pulsatile models, for example—or mid- and long-term regulatory effects, such as exercise, homeostasis, and metabolism. In a gesture of intellectual philanthropy, the authors state that the program is written in the “C” language and is available to everybody (14). Fukui’s model (9), actually, could do both short- and long-term studies. This was possible because it was implemented on a hybrid computer, and neither speed nor power was a consideration.

Another whole-body model, the Nottingham Physiology Simulator, uses a combination of CV, acid–base, respiratory, cerebrovascular, and renal models. Hardman et al. (15) partially validated this model for examining pulmonary denitrogenation, followed by apnea, by reproducing the methods and results of four previous clinical studies. They then used the model to simulate the onset and course of hypoxemia during apnea after pulmonary denitrogenation (replacing the nitrogen in the lung with O_2) (16). Several parameters were varied to examine their effects: functional residual capacity, O_2 consumption, respiratory quotient, hemoglobin concentration, ventilatory minute volume, duration of denitrogenation, pulmonary venous admixture, and state of the airway (closed versus open) The Nottingham group used their simulator for two other purposes. First, they assessed the accuracy of the simulator in predicting the effects of a change in mechanical ventilation on patient arterial blood–gas tensions. Second, they compared two methods of venous admixture estimation: one using the simulator and data commonly available in the intensive

care unit, and the other using an isoshunt style calculation that incorporated assumed values for the physiological variables (17,18).

To read about the fascinating quest for a true whole-body model, (see Physiome), at the end of this article, plus (<http://nsr.bioeng.washington/PLN>) Other whole-body models will be discussed in the next section (physiologically based pharmacokinetic/pharmacodynamic models). Also, there are several whole-body models in the section on models of systems.

PHYSIOLOGICALLY BASED PHARMACOLOGICAL MODELS

It would seem outside the remit of this article to discuss pharmacological models, but some of them represent a source of detailed whole-body models. Many whole-body models were developed primarily as pharmacological models, and these models help flesh out what would otherwise be a scanty topic. Whole-body pharmacological models were originally called uptake-and-distribution models, but are now called a more respectable sounding physiological PKPD models. The term is broad, and very few physiological PKPD models are whole-body models, however.

It also turns out that pharmacology can be useful in physiological models, helping create realism. For example, by using epinephrine and norepinephrine, BODY Simulation simulates the CV response to pain or to hypercapnia simply by internally injecting one or both of these agents. Part of the realism relates to the fact that it takes time for circulating epinephrine, and its effects, to fade away: after the stimulus has vanished. The agent must be metabolized and redistributed, as in real life.

The history of these models is briefly explored. The senior author’s interest in uptake and distribution was stimulated in the mid-1950s during Avram Goldstein’s course on pharmacology, which highlighted the subject in a lucid, prescient way.

The desire for more accurate pharmacological modeling has had a significant impact on the development of better physiological models, especially whole-body models. Part of this improvement came from the need for more compartments, which were often physiological systems. The history of whole-body physiological PKPD models is embedded in the history of uptake and distribution, which goes back to the mid nineteenth century, when John Snow, the first epidemiologist and the first scientific anesthesiologist, made observations on the uptake and elimination of several agents that he was testing in patients, including chloroform (19,20). In the late nineteenth and early twentieth centuries, Frantz (21) and Nicloux (22) observed that among all the tissues, the brain had the highest tissue concentration of diethyl ether after inhalation of that agent. In 1924, Haggard (23) correctly surmised that this phenomenon was related to the brain’s small size and relatively large blood flow, as well as ether’s brain–blood partitioning coefficient, which he uncannily estimated to be 1.11, compared with the currently accepted 1.14.

Less than four decades after Haggard’s papers, whole-body anesthetic models were appearing in the literature

(7,24–26). Because of the therapeutic and physical-chemical characteristics of anesthetic agents, especially inhaled, the early models usually contained fat, muscle and brain, plus low and high perfused compartments. The seminal book in the area was *Uptake and Distribution of Anesthetic Agents*, edited by Papper and Kitz (7). This multiauthored book summarized the extant modeling knowledge in clear detail. Most of the literature, and the book, were based on the uptake and distribution of inhaled anesthetic agents, with the notable exception of Henry Price (26), whose model on thiopental was apparently the first uptake and distribution model. Modeling pioneers featured in the book include Eger and Severinghaus.

As exciting and useful as the early models were, they suffered from at least four problems. (1) They were not pulsatile, that is, the heart did not beat and the lungs did not breathe. Incorporating pulsatility can solve many physiological and pharmacological problems. (2) They were linear. Neither CO_2 , along with its regional distribution, nor ventilation, for example, changed as a function of the concentration of the agent—or vice versa. (3) They usually only dealt with one agent at a time. Thus, for example, one could not determine the interactions among two or more agents. [A brave exception was Rackow et al. (27).] (4) They were not true physiological models, partly because of concern No. 1 and partly because none of the physiology of the organs was incorporated: they simply acted as agent capacitors.

Little changed from the 1960s until the early 1970s, when Ashman et al. (28), plus Zwart, Smith and Beneken. (29–31), published the first nonlinear models in this area. In our model, cardiac output, regional circulation, and ventilation changed as a function of agent concentration. These changes, in turn, affected the uptake of the agent. Our model used both mass transport and multiple modeling and was implemented on an analog–hybrid computer.

Another breakthrough also occurred in the 1970s: the incorporation of our uptake and distribution model into the Fukui hybrid-computer pulsatile model (9,32–35). Physiological and pharmacological modeling were united. Among other things, venous return, the effects of arrhythmias, and some drug interactions were now possible. Our original model (29–31) used the inhaled anesthetic halothane for the agent; Fukui's (9) used CO_2 and O_2 . The second Fukui-Smith model (35) incorporated halothane, plus CO_2 . All of these models were multiple, transport models, implemented on analog–hybrid or hybrid computers.

One major problem remained. Only about half a dozen computers, and people, in the world could run these models, and the wide spread use of simulation was not possible. In 1983 our laboratory translated the hybrid code into digital, on a VAX, in FORTRAN. In 1985, Charles Wakefield, from Rediffusion Simulation Corporation, transferred the code into C on a Sigmagraphics Iris 2300. Two processors were used, one for running the model and one for the graphics display. Finally, there was a portable simulator, portable if one were strong. More importantly, Sleeper could be used for teaching (36).

The next goal was to incorporate the model and simulator into a PC. This was accomplished in 1989 and was a major step. Now it was possible to bring simulation to a

larger audience. Unfortunately, the PCs available then were not quite ready. In 1992, Starko completely revised the code, in DOS assembly language, making a simulator available on a laptop. Starko achieved an amazing fourfold increase in efficiency. He used many of the techniques used in flight simulation, his main work, to create stunning graphics and interfaces. In 1998, the code was converted to Windows in C++. The conversion allowed many new features that were not possible in DOS, however, DOS was much faster, and running the simulation in Windows slowed it down noticeably.

The model currently has 37 compartments, >90 agents, >80 parameters to set for each patient, and 45 parameters to set for each agent. The parameters are user settable. The latest additions to the agents have included cyanide and sarin (37,38), the latter a nerve gas. We were able to model cyanide toxicity because each organ and tissue has a changeable O_2 consumption. The nerve gases are actually physiological, involving as they do cholinergic and muscarinic effects. We could implement both agents because BODY Simulation has receptors, with agent concentration-effect curves that have user adjustable slopes (γ) and amplitudes (IC_{50}). All of the agents involved in the therapy for both toxins have also been incorporated, including the therapeutic byproducts methemoglobin, cyanmethemoglobin, and thiocyanate. Five equations relating to cyanide therapy have been incorporated. In keeping with our definition of a simulator (interactivity) the user can change the rate and, when appropriate, the equilibrium constants of the equations.

Because of the detail in BODY Simulation, it has been possible to incorporate the normal aging process (39). Over 60 user-changeable patient parameters are changed, directly or indirectly, to implement each elderly patient. Four patients were constructed, aged 65, 75, 85, and 95, although patients of any age can be implemented. To assess these patients, three scenarios were run: (1) administration of an anesthetic agent (thiopental) with CV and respiratory depressant properties, (2) hemorrhage of 1000 mL in 10 min, and (3) nonfatal apnea. The results confirm that the elderly generally have a decreased physiological reserve: the older the patient, the less the reserve.

More details on BODY Simulation can be found online (40).

Oliver et al. (41) used a whole-body physiologically based PK model that incorporated dispersion concepts. In whole-body PBPK models, each tissue or organ is often portrayed as a single well-mixed compartment with limited distribution and perfusion rate. However, single-pass profiles from isolated organ studies are more adequately described by models that display an intermediate degree of mixing. One such model is the dispersion model. A salient parameter of this model is the dispersion number, a dimensionless term that characterizes the relative axial spreading of a compound on transit through the organ. The authors described such a model, which has closed boundary conditions.

PKQuest (42–44), as the abbreviation implies, is also a pharmacokinetic model only, with no pharmacodynamics. Thus, the nonlinearities that some PKPD models possess

are lost. Levitt's whole-body models have 12 compartments, including the essential brain and heart. The models, as well as files of tissue and agent parameters, are easily and freely accessible online (45) or from links in the papers, which are published on BioMed Central. The other models described above, including BODY Simulation, use only intravenous or pulmonary administration of an agent, while PKQuest explores the gastrointestinal, intramuscular, and subcutaneous routes. These models have been used to explore many areas that not only elucidate the PK of agents, but also give insight into body compartments, thus enhancing our knowledge of the compartments and suggesting further areas to explore physiologically. These compartments include the interstitial space.

The Stanford group, led by Donald Stanski and Steven Shafer have developed an extensive array of PKPD models, some of them incorporating whole-body models. Details and considerable software, much of it public domain, can be found online (46). These models usually do not incorporate the nonlinearities associated with agent-induced or physiologically induced changes in patient physiology.

Many anesthesia simulators incorporate whole-body models, although the completeness of the model varies considerably. Sometimes, little detail is available to the public concerning these models. A description of some of these models can be found in the section Uses of Models.

Even with the computational resources now available, most PK and many PKPD models contain only two to four compartments. Compare BODY Simulation's 37 compartments. Whole-body models are complex and difficult. Pharmacologists have seriously asked, Why do we need all those compartments? Can't I achieve the same results from an uncluttered three-compartment model? Aside from losing the physiological essence of any simulation that is run, one also loses nonlinearity, the impact of physiology on drug kinetics, the important feature of drug interactions, the influence of patient condition, such as aging, and the effect of stresses, such as hemorrhage or apnea. As just one example, any agent that decreases hepatic blood flow will affect the concentration, and therefore the action, of any agent that is metabolized by the liver.

REGIONAL CIRCULATION AND AUTOREGULATION

Regional Circulation

Only whole-body models can have regional circulation, of course. In fact, regional circulation is crucial in this type of model, to connect the various physiological modules. Many factors control regional circulation, as well as the relation among the circulations, but only some of them are discussed, briefly, primarily because few models take these factors into account. The BODY Simulation model (see PBPM) is one of the few exceptions.

One of the interesting factors controlling regional circulation is the importance to the body of a given organ or tissue. How well is an organ's circulation maintained in the face of an acute stress, rapid hemorrhage, for example? Organs and tissues can be divided, simplistically, into four types/classes.

1. Essential in the short term (a few minutes) (brain and heart).
2. Essential in the medium term (a few hours) (hepatic, renal and splanchnic).
3. Essential in the longer term (several hours) (skeletal muscle).
4. Essentially nonessential (skin, cartilage, bone).

The overall regulation of regional circulation reflects this hierarchy. In addition, some agents can influence it. Few models, except for Guyton's model (see Whole-body Models) and some of the whole-body models described above, incorporate detailed regional circulation. BODY Simulation (see PBPM) and one of Ursino's many models (47) take this hierarchy into account. In BODY Simulation (see PBPM), regional circulation is impacted by several factors, including O_2 , CO_2 , the baroreceptors, strength of the heart, blood volume, hemorrhage, extracellular fluid, pharmacological agents, the presence of circulating epinephrine (pain or hypercapnia), and so on.

The regional-circulation hierarchy impacts the various regional circulation control mechanisms, and autoregulation is often subservient to this pecking order (except for cerebral). If severe shock occurs, the hypoxic muscle will not get its allotted supply for example. The cerebral and coronary circulations come first. In some ways, this is a form of regional steal, a term often used in physiology, but not in this context.

General Autoregulation

When sudden alterations in perfusion pressure are imposed in most types of arterial beds, the resulting abrupt changes in blood flow are only transitory, with flow returning quickly to the previous steady-state level. The exception is, of course, a sudden arterial occlusion. The ability to maintain perfusion at constant levels in the face of changing driving pressure is termed autoregulation. Autoregulation only occurs between certain pressure limits (if the pressure drops too low or soars too high, autoregulation fails, and organ perfusion is compromised) at low pressures, perfusion decreases, and at high pressures, excessive flow occurs. Autoregulation keeps tissue or organ flow essentially constant between an MAP of 60–180 mmHg (7.9–23.9 kPa), the limits varying with the tissue or organ.

Much of autoregulation may occur in the microcirculation. Groebe (48) outlined gaps in the understanding of how the microvasculature maintains tissue homeostasis, as of the mid-1990s: (1) integration of the potentially conflicting needs for capillary perfusion and hydrostatic pressure regulation, (2) an understanding of signal transmission pathways for conveying information about tissue energetic status from undersupplied tissue sites to the arterioles, (3) accounting for the interrelations between precapillary and postcapillary resistances, and (4) an explanation of how the body achieves local adjustment of perfusion to metabolic demands. Using mathematical modeling, Groebe argued that precapillary pressure regulation combined with postcapillary adjustment of perfusion to tissue metabolic status helped clarify the understanding of microvascular control.

Mechanisms of autoregulation vary substantially between organs. Coronary autoregulation is, for example, quite different from brain autoregulation. During hemorrhagic shock in pigs, microcirculatory blood flows in the stomach, colon, liver, and kidney decrease in concert with decreasing systemic blood flow; flow in the jejunal mucosa is preserved, and pancreatic blood flow is selectively impaired (49). Differential autoregulation has also been shown in response to increases in blood pressure. For example, in response to infusion of pressor agents, renal autoregulation is almost unimpaired, while regulation in the mesenteric vascular bed is less adequate, and differs with different pressor agents. Muscle autoregulation is mediated partly by the metabolic byproducts of exercise. The main site of autoregulation in the kidney is, however, the afferent glomerular arteriole. There are two main factors that affect vascular tone in the afferent arteriole: stretch-activated constriction of vessels (as for the brain) and tubulo-glomerular feedback. The autoregulatory response and the factors causing it can also vary in the same organ. For example, in exercising dogs, increased O_2 demand of the LV is met primarily by increasing coronary flow, while increased O_2 extraction makes a greater contribution to RV O_2 supply (50).

Needless to say, autoregulation is complex, and difficult to model. The following section gives some examples, in different circulatory beds.

Cerebral Autoregulation

Because the brain resides in a rigid box, very small changes in CBF can lead to catastrophic changes in intracranial pressure (ICP). Rapid CBF autoregulation is therefore vital, and cerebral flow normally remains constant within MAP ranges of 50–150 mmHg (6.6–19.9 kPa). Any sudden changes in MAP are transmitted to the cerebral circulation, inducing similar changes in CBF, but fortunately, under normal conditions the CBF tends to return to its original value within a few seconds. The main regulator of brain blood flow is pressure-dependent activation of smooth muscle in the arterioles of the brain. The more the arteriole is stretched, the more it contracts, and this lasts as long as the stretch occurs.

Paneraiy (51) critically reviewed the concepts of cerebral autoregulation, including the role of mathematical models. The most common approach to evaluating cerebral autoregulation tests the effects of changes in MAP on CBF, and is known as pressure autoregulation. A gold standard for this purpose is not available and the literature shows considerable disparity of methods and criteria. This is understandable because cerebral autoregulation is more a concept than a physically measurable entity. Static methods use steady-state values to test for changes in CBF (or velocity) when MAP is changed significantly. This is usually achieved with the use of drugs, or from shifts in blood volume, or by observing spontaneous changes. The long time interval between measurements is a particular concern. Concomitant changes in other critical variables, such as PCO_2 , hematocrit, brain activation, and sympathetic tone, are rarely controlled for. Proposed indices of static autoregulation are based on changes in cerebrovas-

cular resistance, on parameters of the linear regression of flow–velocity versus pressure changes, or only on the absolute changes in flow. Methods of dynamic assessment are based on transient changes in CBF (or velocity) induced by the deflation of thigh cuffs, Valsalva maneuvers (a bearing down, that induces an increase in airway pressure with resultant complex, but easily understood, hemodynamic changes), tilting, and induced or spontaneous oscillations in MAP. Classification of autoregulation performance using dynamic methods has been based on mathematical modeling, coherent averaging, transfer function analysis, cross-correlation function, or impulse response analysis.

Cerebral autoregulation has been modeled independently and in concert with other factors. The most nearly complete model of the combination of factors is by Lu et al. (52). The goal of their work was to study cerebral autoregulation, brain gas exchange, and their interaction. Their large model comprised a model of the human cardiopulmonary system, which included a whole-body circulatory system, lung, and peripheral tissue gas exchange, and the CNS control of arterial pressure and ventilation, and central chemoreceptor control of ventilation, as well as a detailed description of cerebral circulation, CSF dynamics, brain gas exchange, and CBF autoregulation. Two CBF regulatory mechanisms were included: autoregulation and CO_2 reactivity.

Three groups have mathematically examined cerebral autoregulation by itself (53–56). This allows insight into the process, as well as the ability to incorporate the concepts into one's own model. In addition, Czosnyka et al. (57) constructed a model that helps the clinician interpret bedside tests of cerebrovascular autoregulation.

A simple model (authors' term) was described by Ursino and Lodi (58). The model includes the hemodynamics of the arterial–arteriolar cerebrovascular bed, CSF production and reabsorption processes, the nonlinear pressure–volume relationship of the craniospinal compartment, and a Starling resistor mechanism for the cerebral veins. Moreover, arterioles are controlled by cerebral autoregulation mechanisms, which are simulated by a time constant and a sigmoidal static characteristic. The model is used to simulate interactions between ICP, cerebral blood volume, and autoregulation.

Hyder et al. (59) have developed a model that describes the autoregulation of cerebral O_2 delivery *In vivo*. According to the model, the O_2 diffusivity properties of the capillary bed, which can be modified in relation to perfusion, play an important role in regulating cerebral O_2 delivery *In vivo*. Diffusivity of the capillary bed, in turn, may be altered by changes in capillary PO_2 , hematocrit, and/or blood volume.

Kirkham et al. (60) presented a mathematical model representing dynamic cerebral autoregulation as a flow-dependent feedback mechanism. They introduced two modeling parameters: the rate of restoration, and a time delay. Velocity profiles were determined for a general MAP, allowing the model to be applied to any experiment that uses changes in MAP to assess dynamic cerebral autoregulation. The comparisons yielded similar estimates for the rate of restoration and the time delay, suggesting

that these parameters are independent of the pressure change stimulus and depend only on the main features of the dynamic cerebral autoregulation process. The modeling also indicated that a small phase difference between pressure and velocity waveforms does not necessarily imply impaired autoregulation. In addition, the ratio between the variation in maximum velocity and pressure variation can be used, along with the phase difference, to characterize the nature of the autoregulatory response.

Coronary Autoregulation

The range of coronary autoregulation is 60–130 mmHg (7.9–17.3 kPa). Demonstration of autoregulation in the coronary bed is difficult in intact animals because modification of coronary perfusion pressure also changes myocardial oxygen demand and the extrinsic compression of the coronary vessels. However, when perfusion pressure is altered, but ventricular pressure, cardiac contractility, and heart rate (the principal determinants of myocardial oxygen demand) are maintained constant, autoregulation is clearly evident.

The coronary circulation has a different set of problems from other systems, as well as many paradoxes. These problems include the following: (1) It is caught in a unique situation: it must feed and cleanse the very organ that generates it. (2) The heart is a high oxidative organ with a high demand for O_2 and a very high O_2 consumption. (3) The $av O_2$ difference is much wider in the coronary circulation, implying that less reserve is available. (4) As myocardial function increases (increased HR or contractility, e.g.), the demand for O_2 increases dramatically. (5) Intramyocardial flow actually decreases as contractility increases, however, because of compression and shearing effects; in other words, the more the heart works, the more it impedes the flow that it needs. (6) Because of the impairment of myocardial blood flow during systole, nearly 80% of coronary flow occurs during diastole. (7) Although most arterial flow occurs during diastole, most venous flow occurs during systole, both phenomena because of the compression effects. (8) Even though increased HR places an increased energy demand on the myocardium, there is less coronary flow as HR increases, since the valuable diastolic time decreases out of proportion to systolic time during tachycardia.

As in any vascular bed, blood flow in the coronary bed depends on the driving pressure and the resistance offered by this bed. Coronary vascular resistance, in turn, is regulated by several control mechanisms: myocardial metabolism (metabolic control), endothelial (and other humoral) control, autoregulation, myogenic control, extravascular compressive forces, and neural control. Each control mechanism may be impaired in a variety of conditions and each can contribute to the development of myocardial ischemia.

Control of coronary blood flow also differs depending on the type of vessel being considered: arteries, large arterioles, or smaller arterioles. Coronary capillaries also appear to make a significant contribution to coronary vascular resistance!

Several factors play a role in coronary autoregulation itself, including myogenic responses, resistance distribu-

tion in various size vessels, O_2 consumption, capillaries, flow-dependent dilation, and direct metabolic control. Regarding the last, for a substance to be considered a mediator of local metabolic control of coronary flow it should (1) be vasoactive, (2) found, in appropriate concentrations, to affect vascular tone, and (3) be of variable concentration in response to changes in metabolism. Myocardial O_2 , along with CO_2 and other waste products are likely mediators of local metabolic control. Several models have examined one or more of these factors, although we could find no model that put everything together (61–68). One can, however, begin to separate out the contribution of each factor. For example, the synergistic interaction between PO_2 and PCO_2 accounts for about one-fourth of the change in coronary vascular conductance during autoregulation (62).

Cardiac Autoregulation

Cardiac autoregulation is briefly mentioned, although it is not circulatory autoregulation. The topic was one of the first to be studied, namely, the Frank–Starling mechanism, the dependence of individual stroke volume on end-diastolic volume. This mechanism helps ensure that what comes into the heart goes out, so that the heart does not blow up like a balloon. The functional importance of the Frank–Starling mechanism lies mainly in adapting left to right ventricular output. Just as with vascular autoregulation, many other factors can override the Frank–Starling mechanism, but it can become particularly important in CV disease.

In the past, the study of mechanical and electrical properties of the heart has been disjointed, with minimal overlap and unification. These features, however, are tightly coupled and central to the functioning heart. The maintenance of adequate cardiac output relies upon the highly integrated autoregulatory mechanisms and modulation of cardiac myocyte function. Regional ventricular mechanics and energetics are dependent on muscle fiber stress–strain rate, the passive properties of myocardial collagen matrix, adequate vascular perfusion, transcapillary transport and electrical activation pattern. Intramural hydraulic “loading” is regulated by coronary arterial and venous dynamics. All of these components are under the constant influence of intrinsic cardiac and extracardiac autonomic neurons, as well as circulating hormones.

MODELS OF SYSTEMS

Cardiovascular–Circulation

The CVS is essential to the body as the means for carrying substances, such as O_2 , nutrients, and hormones to the tissues where they are needed and for bringing xenobiotics or waste products, such as CO_2 and acids, to the lungs, kidneys, or liver to be eliminated.

A pioneer in CV models was Bram Noordergraaf and his group, starting in the 1950s. His model began with the systemic circulation and later expanded to the pulmonary circulation. Over the period of 15 years, they evolved into

models of great size, complexity, and sophistication. The model has a heart, and the systemic circulation has >115 segments. It included adjustable peripheral resistances, plus viscoelasticity, stiffness, radius and wall thickness of each segment, viscous properties of the blood, tapering in radius and elasticity, and frictional losses. Abnormalities, such as aortic stenosis, aortic insufficiency, idiopathic hypertrophic subaortic stenosis, and atrial septal defect have been simulated. We give two later, easily accessible references (69,70).

Another pioneer, in the Dutch school of modeling, was Jan Beneken. His models have also been sophisticated and rigorous (71,72). His models and the impressive ones of Karel Wesseling will be discussed later.

Two CV models are available for those who want to run one. The first is an interactive tutorial and mathematical model described by Rothe and Gersting (73). In addition, one can play with the 52-compartment CV model of Wesseling, as implemented by Starko, Haddock, and Smith (unpublished data). The inclusion of the two atria has made this model an especially unique and useful tool. Eventually, this model will be incorporated into BODY Simulation (see PBPM). Currently, however, it has no transport model(s), nor any control system, for example, an autonomic nervous system or baroreceptors. In essence, it is a heart–lung preparation, without the lungs, but with pulmonary circulation. By itself, however, it is very useful in the study of the basics of the heart and circulation, allowing one to examine in great detail the subtle and not so subtle interactions of the CVS. This is made possible by the detail involved, as well as the ability to change any of hundreds of parameters and to study the time plots of any of hundreds of variables. The model allows the user to adjust the contractility and stiffness of the four chambers, as well as the pressure, volume, compliance and, when appropriate, resistance of each of the 52 compartments. In addition, heart rate, SVR, and total blood volume can be adjusted. Some of these changes involve changes in preload and afterload. Pressure, volume, and flow waveforms can be displayed for each compartment, and pressure–volume plots are available for the four chambers. Thirteen values, such as HR, MAP, and end-diastolic ventricular volumes, are numerically displayed. A small manual describes the model and how to use it.

Most cardiac models incorporate only a freestanding chamber, or chambers. The two ventricles, however, affect each other's dynamics. In addition, the pericardium, the stiff membrane that surrounds almost the entire heart, affects each chamber. The model of Chung et al. (74) describes the dynamic interaction between the LV and the RV over the complete cardiac cycle. The pericardium-bound ventricles are represented as two coupled chambers consisting of the left and right free walls and the interventricular septum. Timevarying pressure–volume relationships characterize the component compliances, and the interaction of these components produces the globally observed ventricular pump properties (total chamber pressure and volume). The model (1) permits the simulation of passive (diastolic) and active (systolic) ventricular interaction, (2) provides temporal profiles of hemodynamic variables (e.g., ventricular pressures, volumes

and flows), and (3) can be used to examine the effect of the pericardium on ventricular interaction and ventricular mechanics. The model also yields qualitative predictions of septal and free wall displacements.

Similarly, few models have addressed the mechanical interaction between the CV and pulmonary systems, for example, how the combined cardiopulmonary system responds to large amplitude forcing (change in an important variable). To address this issue, Lu et al. (75), developed a human cardiopulmonary system model that incorporates important components of the cardiopulmonary system and their coupled interaction. Included in the model are descriptions of atrial and ventricular mechanics; hemodynamics of the systemic and pulmonary circulations; baroreflex control of arterial pressure; airway and lung mechanics; and gas transport at the alveolar–capillary membrane. They applied this model to the analysis of the Valsalva maneuver. The model could predict the hemodynamic responses to markedly increased intrathoracic (pleural) pressures during a Valsalva maneuver. In short, this model can help explain how the heart, lung, and autonomic tone interact during the Valsalva maneuver.

BODY Simulation (see PBPM) also incorporates an interaction between intrapleural pressure (as reflected by airway pressure) and venous return. Problems with a patient ventilator, for example, can create disastrous depression of the CVS (76). Combining computational blood flow modeling with 3D medical imaging provides a new approach for studying links between hemodynamic factors and arterial disease. Although this provides patient-specific hemodynamic information, it is subject to several potential errors. A different approach, developed by Moore et al. (77) can quantify some of these errors and identify optimal reconstruction methodologies.

For several reasons, modeling the pulmonary circulation presents challenges. Huang et al. (78) described a mathematical analogue–circuit model of pulsatile flow in cat lung based on existing morphometric and elastic data. In the model, the pulmonary arteries and veins were treated as elastic tubes, whereas the pulmonary capillaries were treated as two-dimensional (2D) sheets. Input impedances of the pulmonary blood vessels of every order were calculated under normal physiological conditions. The pressure–flow relation of the whole lung was predicted theoretically. Comparison of the theoretically predicted input impedance spectra with their experimental results showed that the modulus spectra were well predicted, but significant differences existed in the phase angle spectra between the theoretical predictions and the experimental results. The authors state that the current model cannot explain this latter discrepancy.

Occlusion experiments yield time–pressure and time–flow curves that are related to the longitudinal distribution of compliances and resistances in the pulmonary circulation. The standard approach to the analysis of these curves involves the observation of relevant features of their graphs, which may directly reflect model parameter values. De Gaetano and Cremona (79) considered five possible models of pulmonary vascular pressure dynamics and the relative (nonlinear) least-squares parameter estimation from experimental data, making simultaneous use

of all available information. The five models included two linear models without inductance units, one linear model with inductance units, one nonlinear model with variable resistance, and one nonlinear model with variable compliance. In all cases, parameter estimation for the numerically integrated model was performed by unweighted least squares, using a variable-metric minimization technique.

Potentially, the more detailed the model, the more accurate it is. Karamanoglu et al. (80) simulated the effects of wave travel and wave reflection with a mathematical model of the whole arterial tree, which comprised 142 uniform transmission-line segments. The arterial model was partitioned into three separate segments: upper limbs, trunk, and lower limbs. Aging was simulated by increasing average pulse wave velocities of these segments. Reflection coefficients at the terminal elements were altered to simulate vasodilation and vasoconstriction.

Karamanoglu and Feneley (81) also used a linear mathematical model of the entire human arterial tree to derive realistic impedance patterns by altering (1) Young's modulus of the arterial wall of the individual branches, (2) peripheral reflection coefficients, and (3) distal compliances at the terminations. These calculated impedance patterns were then coupled to realistic LV outflow patterns determined by unique (1) end-diastolic and endsystolic pressure-volume relationships, (2) preload-recrutable stroke work relationships, and (3) shortening paths simulated by altered aortic flow contours. Left ventricular outflow patterns were as important as impedance parameters in determining late systolic pressure augmentation, at least in this model.

Cardiac valvular modeling and simulation are important, especially given the common use of echocardiography. Sun et al. (82) examined this area. The transmitral and pulmonary venous flow velocity patterns were related to the physiological state of the left heart with an electrical analogue model. Filling of the LV through the mitral valve was characterized by a quadratic Bernoulli's resistance in series with an inertance. Filling of the LA through the pulmonary veins was represented by a lumped network of linear resistance, capacitance, and inertance. The LV and LA were each represented by a time-varying elastance. A volume dependency was incorporated into the LV model to produce physiological PV loops and Starling curves. The model accurately reflected the expected effects of aging and decreasing LV compliance, and could serve as a useful theoretical basis for echocardiographic evaluation of LV and LA function.

Yellin et al. (83) examined the mechanisms of mitral valve motion in mid-diastole, diastole and at closure by simultaneously measuring mitral flow (electromagnetic), valve motion (echo), and AV pressures. Large variations in peak flow were accompanied by small variations in valve excursion. They concluded that the valve overshoots its equilibrium position and that the chordae produce tension on the valve during diastole. Their model offered a valve-closure theory unifying chordal tension, flow deceleration, and vortices, with chordal tension as a necessary condition for the proper functioning of the other two.

The Doppler transmitral velocity curve is commonly used to assess LV diastolic function. Thomas et al. (84)

developed a mathematical formulation to study the physical and physiological determinants of the transmitral velocity pattern for exponential chamber PV relationships with active ventricular relaxation (2187 combinations investigated). They showed that transmitral velocity is fundamentally affected by three principal physical determinants: the transmitral pressure difference, the net AV compliance, and the impedance characteristics of the mitral valve. These physical determinants in turn are specified by certain compliance and relaxation parameters. They found that the peak mitral velocity is most strongly related to initial LA pressure but decreased by prolonged relaxation, low atrial and ventricular compliance, and systolic dysfunction. Peak acceleration varies directly with atrial pressure and inversely with the time constant of isovolumic relaxation, with little influence of compliance, whereas the mitral deceleration rate is approximately valve area divided by AV compliance.

A moderate reduction in coronary blood flow results in decreased myocardial O₂ consumption, accelerated glycolysis, decreased pyruvate oxidation, and lactate accumulation. To quantitatively understand cardiac metabolism during ischemia, Salem et al. (85) demonstrated a mechanistic, mathematical model based on biochemical mass balances and reaction kinetics in cardiac cells. Computer simulations showed the dynamic responses in glucose, fatty acid, glucose-6-phosphate, glycogen, triglyceride, pyruvate, lactate, acetyl-CoA, and free-CoA, as well as CO₂, O₂, phosphocreatine/creatine, nicotinamide adenine dinucleotide (reduced form)/nicotinamide adenine dinucleotide (oxidized form) (NADH/NAD⁺), and adenosine diphosphate/adenosine triphosphate (ADP/ATP). When myocardial ischemia was simulated by a 60% reduction in coronary blood flow, the model generated myocardial concentrations, uptakes, and fluxes that were consistent with experimental data from *in vivo* pig studies. With the onset of ischemia, myocardial lactate concentration increased and the myocardium switched from a net consumer to a net producer of lactate.

Olufsen et al. (86) modeled blood flow in large systemic arteries by using one-dimensional (1D) equations derived from the axisymmetric Navier-Stokes equations for flow in compliant and tapering vessels. The arterial tree is truncated after the first few generations of large arteries with the remaining small arteries and arterioles providing outflow boundary conditions for the large arteries. By modeling the small arteries and arterioles as a structured tree, a semianalytical approach based on a linearized version of the governing equations can be used to derive an expression for the root impedance of the structured tree in the frequency domain. In the time domain, this provides the proper outflow boundary condition. The structured tree is a binary asymmetric tree in which the radii of the daughter vessels are scaled linearly with the radius of the parent vessel. Blood flow and pressure in the large vessels are computed as functions of time and axial distance within each of the arteries.

The CVS is an internal flow loop with multiple branches circulating a complex liquid. The hallmarks of blood flow in arteries are pulsatility and branches, which cause wall stresses to be cyclical and nonuniform. Normal arterial

flow is laminar, with secondary flows generated at curves and branches. Arteries can adapt to and modify hemodynamic conditions, and unusual hemodynamic conditions may cause an abnormal biological response. Velocity profile skewing can create pockets in which the wall shear stress is low and oscillates in one direction. Atherosclerosis tends to localize to these sites and creates a narrowing of the artery lumen: a stenosis. Plaque rupture or endothelial injury can stimulate thrombosis, which can block blood flow to heart or brain tissues. The small lumen and elevated shear rate in a stenosis create conditions that accelerate platelet accumulation and occlusion. The relationship between thrombosis and fluid mechanics is complex, especially in the poststenotic flow field. New convection models have been developed to predict clinical occlusion from platelet thrombosis in diseased arteries (87).

Cardiovascular Regulation

Vasquez et al. (88) presented a lucid review of the overall coordination of three of the major mechanisms involved in CVS control: the baroreceptors, chemoreceptors, and cardiopulmonary reflexes. The central chemoreceptors are the main body CO_2 (actually, pH acts as a surrogate for CO_2) sensors, the main sensors in the feedback loop. They are located in the medulla, near the ventricle and bathed in brain extracellular fluid, which is close to the composition of CSF. The normal pH of the fluid is 7.32 and is poorly buffered. Thus, CSF pH is regulated more rapidly than in the rest of the body. Although CO_2 diffuses rapidly into all tissues, H^+ does not penetrate into CSF. However, if PCO_2 increases in the blood, it diffuses into CSF and lowers the pH. Ventilation responds to changes in CSF pH.

Peripheral chemoreceptors are located in the carotid and aortic bodies and in clumps along the route of the abdominal vagus. Their role in the regulation of the CVS cannot be understood without knowing the various factors that can change chemoreceptor afferent activity. Furthermore, changes in chemoreceptor activity not only exert primary reflex effects on the CVS, but they evoke changes in the central drive for ventilation that secondarily affect the CVS. For an excellent, comprehensive review of this subject, see Marshall (89).

The arterial baroreflex contributes significantly to the short-term regulation of blood pressure and CV variability. Several factors, including reflex, humoral, behavioral, environmental and age, may influence gain and effectiveness of the baroreflex, as well as CV variability. Many central neural structures are also involved in the regulation of the CVS and contribute to the integrity of the baroreflex. For those who wish a good summary of the subject, read the review by Lanfranchi and Somers (90).

Continuous blood pressure recordings usually show a surprising variability in MAP. Short-term variability includes components with periods of a few seconds to many hours, and can be spontaneous or in response to a maneuver or activity. Blood pressure can increase 50 mmHg (6.6 kPa) during painful stimuli in a matter of a minute, or decrease 20–30% in a few seconds during an orthostatic maneuver. Often, blood pressure shows oscillatory fluctuations in an ~ 10 s rhythm. All this variability has been

demonstrated in normal subjects, especially by Wesseling and co-workers (91–93). This short-term blood pressure variability challenges the concept of an effective, stabilizing baroreflex. Wesseling has called this phenomenon the baroreflex paradox and has proposed a baromodulation hypothesis (91–93). The baromodulation hypothesis states that the baroreflex gain can be modulated to have high gain in some situations, low gain in others. A decrease in baroreflex gain by itself causes blood pressure to increase, while an increase in gain causes it to fall (91). A gain change does not change baroreceptor function itself. No changing baroreceptor sensitivity is postulated, and no baroreceptor resetting need occur. Theoretically, the physiological location where modulation occurs could be anywhere in the reflex loop, even in the individual efferent-pathways, separately. However, the logical site would be the vasomotor center in the medulla.

We should point out that this insight was made possible by using a noninvasive monitoring device that is enhanced by several models (see Finapres, under uses for Models), and that yet another model was used to test the hypothesis. Several investigators have based their work on this remarkable insight (references on request).

When blood volume is expanded, CVP increases, stimulating cardiopulmonary receptors in the atria and ventricles and perhaps arterial baroreceptors in the aortic arch and carotid sinus. Volume expansion or stimulation of atrial receptors can inhibit vasopressin release, decrease sympathetic nerve activity, and attenuate drinking. Atrial distension stimulates secretion of atrial natriuretic peptide (ANP) from the atria leading to natriuresis. Thus it is possible that ANP may inhibit vasopressin release, reduce blood pressure, decrease drinking, and lead to natriuresis and diuresis via central pathways.

Rose and Schwaber (94) described a model that included only HR in the baroreceptor modulation of arterial pressure, since the vagus HR response is the most rapid responder to changes in arterial pressure. They observed that vagal induced changes in HR do not influence arterial pressure, except when certain initial conditions of the CVS are met. It may be that vagally mediated alterations in an inotropic and dromotropic state, which are not included in this model, play important roles in the fast reflex control of blood pressure or that the vagal limb of the baroreflex is of rather limited effectiveness. Had the authors decreased heart rate $>50\%$, they may have observed profound CV changes arising from a heart rate change.

Ursino and Magosso (95) detailed a mathematical model of the acute CV response to isocapnic hypoxia. The model includes a pulsating heart, the systemic and pulmonary circulation, a separate description of the vascular bed in organs with higher metabolic need, and the local effect of O_2 on these organs. The model also includes the action of several reflex regulatory mechanisms: the peripheral chemoreceptors, the lung stretch receptors, the arterial baroreceptors, and the hypoxic response of the CNS. The early phase of the biphasic response (8–10 s), caused by activation of peripheral chemoreceptors, exhibits a moderate increase in MAP, a decrease in HR, a relatively constant CO, and a redistribution of blood flow to the organs with higher metabolic need, at the expense of other organs (see

the hierarchy scheme, in Regional Circulation and Auto-regulation). The later phase (20 s) is characterized by the activation of lung stretch receptors and by the CNS hypoxic response. During this phase, CO_2 and HR increase, and blood flow is restored to normal levels, in organs with lower metabolic need.

These authors performed an extensive validation of this model (96). The role of the different mechanisms involved in the CV response to hypoxia (chemoreceptors, baroreceptors, lung stretch receptors, and CNS hypoxic response) was analyzed in different physiological conditions. The simulation results revealed the following: (1) the model can reproduce the CV response to hypoxia very well between 100 and 28 mmHg (13.3 and 3.7 kPa) PO_2 . (2) Sensitivity analysis of the impact of each individual mechanism underlines the role of the baroreflex in avoiding excessive derangement of systemic arterial pressure and CO_2 during severe hypoxia and suggests the existence of significant redundancy among the other regulatory factors. (3) With chronic sinoaortic denervation (i.e., simultaneous exclusion of baroreceptors, chemoreceptors, and lung stretch receptors), the CNS hypoxic response alone is able to maintain reasonably normal CV adjustments to hypoxia, although suppression of the CNS hypoxic response, as might occur during anesthesia, led to a significant arterial hypotension. (4) With controlled ventilation, a significant decrease in HR that can only partly be ascribed to inactivation of lung stretch receptors. (5) When maintaining a constant CO_2 during severe hypoxia, the chemoreflex can produce a significant decrease in systemic blood volume.

As an extension of the group's isocapnic hypoxia model, Magosso and Ursino (97) studied the effect of CO_2 on the CVS. The previous model (95) had already incorporated the main reflex and local mechanisms triggered by O_2 changes. The new features covered by the model were the O_2 - CO_2 interaction with the peripheral chemoreceptors, the effect of local CO_2 changes on peripheral resistances, the direct CNS response to CO_2 , and the control of central chemoreceptors on minute ventilation and tidal volume. The model could simulate the acute CV response to changes in blood gas content in a variety of conditions (normoxic hypercapnia, hypercapnia during artificial ventilation, hypocapnic hypoxia, and hypercapnic hypoxia). The model ascribes the observed responses to the complex superimposition of many mechanisms simultaneously working (baroreflex, peripheral chemoreflex, CNS response, lung-stretch receptors, local gas tension effect), which may be variably activated depending, on the specific stimulus under study. However, although some experiments can be reproduced using a single basal set of parameters, reproduction of other experiments requires a different combination of the mechanism strengths (particularly, a different strength of the local CO_2 mechanism on peripheral resistances and of the CNS response to CO_2).

Melchior et al. (98) used as an example the short-term response of the human CVS to orthostatic stresses to develop a mathematical model. They reviewed the physiological issues involved and how these issues have been handled in previous CV models for simulation of the orthostatic response. Most extant models were stimulus specific

with no apparent ability to simulate the responses to orthostatic stimuli of different types. They suggest that a comprehensive model incorporating all known phenomena related to CV regulation is needed. The paper represents a good start in providing a framework for future efforts in mathematical modeling of the entire CVS, and the review of issues is outstanding.

Lerma et al. (99) combined parts of two systems: the baroreceptor reflex in the CVS and the renal system in chronic renal failure (CRF). They developed a model of baroreflex control of MAP, in terms of a delay differential equation, and used it to predict the adaptation of short-term CV control in CRF patients. The model predicts stable and unstable equilibria close to steady-state MAP. Their results suggest that the cardiac pump has a more restricted response in CRF patients. The model quantifies the CV adaptations to CRF, including increased SVR and baroreflex delay, as well as decreased arterial compliance, cardiac period, and stroke volume.

In yet another paper, Ursino and Magosso (100) examined the response to O_2 and CO_2 changes mediated by one CV regulator mechanism, the carotid body chemoreceptor. The model assumes that the static chemoreceptor characteristic depends on O_2 saturation in the arterial blood and on CO_2 arterial concentration. The values of O_2 saturation and of CO_2 concentration are computed, from pressure, using blood dissociation curves, which include both the Bohr and Haldane effects. The dynamic response includes a term depending on the time derivative of CO_2 concentration and a low pass filter, which accounts for the time required to reach the steady-state level. With a suitable choice of parameters, the model reproduced the carotid chemoreceptor response under a variety of combined O_2 and CO_2 stimuli, both in steady-state conditions and in the transient period following acute CO_2 or O_2 pressure changes. During transient conditions, the effect of CO_2 pressure changes prevail over the effect of O_2 changes, due to the intrinsic derivative component of the response to CO_2 .

Ursino et al. (101) explored one of the most important regulator effectors of the CVS: venous capacitance. To elucidate the role of venous capacity active changes in short-term CV homeostasis, they developed a mathematical model of the carotid-sinus baroreflex system. In the model, the CVS was represented as a series arrangement of six lumped compartments, which synthesized the fundamental hemodynamic properties of the systemic arterial, systemic venous, pulmonary arterial, and pulmonary venous circulations as well as of the left and right cardiac volumes. Cardiac outputs from the left and right ventricles were computed as a function of both downstream (afterload) and upstream atrial pressure (preload). Four distinct feedback regulatory mechanisms, working on SVR, HR, systemic venous unstressed volume, and systemic venous compliance, were assumed to operate on the CVS in response to carotid sinus pressure changes. The model was used to simulate the pattern of the main hemodynamic quantities in the short time period (1–2 min) after acute carotid sinus activation in vagotomized subjects. Simulations indicated that the model can reproduce experimental data quite well, with reference both to open-loop

experiments and to acute hemorrhage performed in closed-loop conditions. Computer simulations also indicated that active changes in venous unstressed volume are very important in regulating CO_2 and MAP during activation of the carotid sinus baroreflex.

Modeling HR and blood pressure spontaneous variability can contribute to the understanding of both normal and pathologic CVS physiology. The observed fluctuations in HR and blood pressure are meaningful rhythmical fluctuations that reflect useful information about autonomic regulation. These rhythmical fluctuations, known as heart rate variability and blood pressure variation, are normally grouped into three major components: (1) the high frequency component, ~ 0.25 Hz, in synchrony with respiratory rate; (2) the low frequency component, generally centered ~ 0.1 Hz, which is attributed to the sympathetic activity and the closed-loop controlling action of cardiovascular regulation; and (3) The very low frequency component, ~ 0.04 Hz, which is probably due to the vasorhythmicity thermoregulatory system or to humoral regulations. Cohen and Taylor (102) nicely reviewed the subject and constructed their own model. Seydnejad and Kitney (103), as well as Cavalcanti and Belardinelli (104) have also modeled these areas. Of particular interest are the studies of Magosso et al. (105). Their findings include the following: (1) A significant increase in the gains and time delays (>9 s) of all the arterial baroreflex sympathetic mechanisms is required to induce instability (see Baromodulation and Wesseling, below). In this condition, systemic arterial pressure exhibits spontaneous oscillations with a period of ~ 20 s, similar to Mayer waves. The control of peripheral resistance seems more important than the venous volume control in the genesis of these oscillations. (2) An increase in the gain and time delay (~ 3 s) of the arterial baroreflex vagal mechanism causes the appearance of unpredictable fluctuations in heart period, with spectral components in the range 0.08–0.12 Hz (3) The cardiopulmonary baroreflex plays a less important role than does the arterial baroreflex in the genesis of these instability phenomena.

Aljuri and Cohen (106) took yet another approach to the problem. They emphasized the analytic algebraic analysis of the systemic circulation composed of arteries, veins, and its underlying physiological regulatory mechanisms of baroreflex and autoregulatory modulation of SVR, where the behavior of the system can be analytically synthesized from an understanding of its minimal elements. As a result of their analysis, they presented a mathematical method to determine short-term SVR fluctuations, which account for observed MAP fluctuations, and proposed a new CVS identification method to delineate the actions of the physiological mechanisms responsible for the dynamic couplings between CO_2 , MAP, RA pressure, and SVR.

Ben-Haim et al. (107), using a finite-difference equation to model cardiac mechanics, simulated the stable action of the LV. Their model described the LV end-diastolic volume as a function of the previous end-diastolic volume and several physiological parameters describing the mechanical properties and hemodynamic loading conditions of the heart. Their simulations demonstrated that transitions (bifurcations) can occur between different modes of dynamic

organization of the isolated working heart as parameters are changed. Different regions in the parameter space are characterized by different stable limit cycle periodicities. They proposed that mechanical periodicities of the heart action are an inherent part of its nonlinear nature. Although their model predictions and experimental results were compatible with previous experimental data, they may contradict several hypotheses suggested to explain the phenomenon of cardiac periodicities.

Ursino (108) made some interesting observations with his model on short-term carotid baroregulation and the pulsating heart. The model includes an elastance variable description of the left and right heart, the systemic (splanchnic and extrasplanchnic) and pulmonary circulations, the afferent carotid baroreceptor pathway, the sympathetic and vagal efferent activities, and the action of several effector mechanisms. The latter mechanisms work, in response to sympathetic and vagal action, by modifying systemic peripheral resistances, systemic venous unstressed volumes, heart period, and endsystolic elastances. The model is used to simulate the interaction among the carotid baroreflex, the pulsating heart, and the effector responses. Experimental data on HR control can be explained fairly well by assuming that the sympathetic-parasympathetic systems interact linearly on the heart period. The carotid baroreflex can significantly modulate the cardiac function curve. This effect, however, is masked *In vivo* by changes in arterial and atrial pressures. During heart pacing, CO_2 increases with frequency at moderate levels of heart rate and then fails to increase further because of a reduction in stroke volume. Shifting from nonpulsatile to pulsatile perfusion of the carotid sinuses decreases the overall baroreflex gain and significantly modifies operation of the carotid baroreflex. Finally, sensitivity analysis suggests that venous unstressed volume control plays the major role in the early hemodynamic response to acute hemorrhage, whereas systemic resistance and heart rate controls are slightly less important.

Short-term regulation of arterial blood pressure is accomplished by complex interactions between feedback and feed-forward information from the arterial and cardiopulmonary baroreceptors that combine with other local and neural factors to modulate CO_2 (HR and stroke volume) and SVR. Hughson et al. (109) used transfer function analysis and autoregressive moving average analysis to explore the interrelationships between CVP as an input to the cardiopulmonary baroreflex and MAP as an input to the arterial baroreflex in the regulation of SVR.

O'Leary et al. (110) used transfer function analysis to study the HR and vascular response to spontaneous changes in blood pressure from the relationships of systolic blood pressure to heart rate, MAP to SVR, and cerebrovascular resistance index, as well as stroke volume to SVR in healthy subjects in supine and 45° head-up tilt positions. Their data, which showed changes in MAP preceded changes in SVR as well as a possible link between stroke volume and SVR are consistent with complex interactions between the vascular component of the arterial and cardiopulmonary baroreflexes and intrinsic properties such as the myogenic response of the resistance arteries.

Toska et al. (111) used their mathematical model of baroreflexes and a simple circulation to analyze data from a previous study on humans (112). They modeled the heart, vascular bed, baroreceptor reflexes and the ANS.

Microcirculation

Ostensibly, the microcirculation is the ultimate mediator of the major purposes of the circulation: delivering O_2 and cleansing the body of waste products, including CO_2 . In addition to the mission of mass transport, the microcirculation and its endothelial cells have the role of regulation, signal transduction, proliferation, and repair. Lee (113) suggests, in addition, that the microcirculation is distensible and contains 40–50% of the total blood volume. In his Distinguished Lecture, he emphasized the integrative role of the microcirculation on circulatory control and its therapeutic role on blood volume compensation. He discussed shifts of volume from the microcirculation to the macrocirculation. It is possible that the microcirculation can play a more important role as a reservoir to compensate for blood volume loss than the venous system, and models are needed to investigate this intriguing concept.

Almost as an anomaly, it appears that hematocrit and nodal pressures can oscillate spontaneously in large microvascular networks in the absence of biological control. Carr and Lacoïn (114) developed a model that not only explains the phenomenon, but also demonstrates how well-known phenomena explain it.

Schmidt-Schönbein (115) reviewed the mathematics of the microcirculation, including microvascular network topology, growth, and fluid mechanics; viscoelasticity and shape of microvessels; myogenic response; microvascular pressure–flow relationships; microvascular flow during pulsatile pressures; and non-Newtonian properties of blood in the microcirculation.

Pries and Secomb (116), in a paper that is part of the physiome project (see below), suggest a paradigm for attacking the complexity of the microcirculation. Terminal vascular beds exhibit a high degree of heterogeneity. Pertinent parameters are nonlinearly related, and their distributions are not independent. The classical typical vessel approach using averaged values for different vessel classes may not lead to a correct understanding of the physiology and pathophysiology of terminal vascular beds. Such problems can be avoided by studying microcirculatory functions at the network level using a combination of experiments and theoretical models. In this approach, distributions and relationships of pertinent parameters are measured *In vivo*, leading to the development of comprehensive databases. Such databases can be analyzed and complemented by suitable mathematical models, permitting estimation of parameters that are difficult to measure, and critical assessment of quantitative theories and hypotheses for microvascular function. This collaborative process between experimentally and theoretically oriented investigators may be facilitated in the future by the development of Web-based repositories of experimental data and theoretical models.

Beard and Bassingthwaight (117) used a realistic geometric model for the 3D capillary network geometry as a

framework for studying the transport and consumption of oxygen in cardiac tissue. The nontree-like capillary network conforms to the available morphometric statistics and is supplied by a single arterial source and drains into a pair of venular sinks. They explored steady-state O_2 transport and consumption in the tissue using a mathematical model that accounts for advection in the vascular network, nonlinear binding of dissolved oxygen to hemoglobin and myoglobin, passive diffusion of freely dissolved and protein-bound oxygen, and Michaelis–Menten consumption in the parenchymal tissue. The advection velocity field is determined by solving the hemodynamic problem for flow throughout the network. The resulting system is described by a set of coupled nonlinear elliptic equations, which are solved using a finite-difference numerical approximation. They found that coupled advection and diffusion in the 3D system enhance the dispersion of O_2 in the tissue compared with the predictions of simplified axially distributed models, and that no lethal corner, or oxygen-deprived region occurs for physiologically reasonable values for flow and consumption.

Cerebral

Considerable space has been devoted to this physiologically and personally important subject.

Clark and Kufahl (118) described a rigid-vessel model of the Circle of Willis, the complex circulatory system at the base of the brain. The circle is essential for redistributing blood flow after the sudden occlusion of a major cerebral vessel.

Lakin et al. (119) described a whole-body mathematical model for intracranial pressure dynamics. The model does not satisfy our definition of whole-body model, however, and we are including it in this section. Having said that, the model does avoid not simply presenting an isolated model of cerebral circulation. The model incorporates the dynamics of intracranial pressures, volumes, and flows. In addition to vascular connections with the rest of the body, the model incorporates a spinal-subarachnoid CSF compartment that bridges intracranial and extracranial physiology, allowing explicit buffering of ICP fluctuations by the spinal theca. The model contains cerebrovascular autoregulation, regulation of systemic vascular pressures by the sympathetic nervous system, regulation of CSF production in the choroid plexus, a lymphatic system, colloid osmotic pressure effects, and descriptions of CO_2 .

Olufsen et al. (120) used a similar approach to study CBF during posture change from sitting to standing. Their model described pulsatile blood flow velocity and pressure in several compartments representing the systemic circulation. The model included compartments representing the trunk and upper extremities, the lower extremities, the brain, and the heart. They used physiologically based control mechanisms to describe the regulation of CBF velocity and arterial pressure in response to orthostatic hypotension resulting from postural change.

Sato et al. (121) first studied dynamic cerebrovascular responses in healthy humans during repetitive stepwise upward tilt (SUT) and stepwise downward tilt (SDT) maneuvers. The tilt maneuvers produced stepwise changes in

both cerebral perfusion pressure and mean CBF velocity. The latter's response to SUT was well characterized by a linear second-order model. However, that to SDT demonstrated a biphasic behavior that was described significantly better by the addition of a slowly responding component to the second-order model. This difference may reflect both different CV responses to SUT or SDT and different cerebrovascular autoregulatory behaviors in response to decreases or increases in cerebral perfusion pressure.

The brain not only needs flow and O₂ regulation, it also needs temperature regulation, because of so many critical chemical and physical-chemical reactions. To study this phenomenon, Zhu (122) modeled selective brain cooling during hyperthermia. They developed a theoretical model to describe the effects of blood flow rate and vascular geometry on the thermal equilibration in the carotid artery based on the blood flow and the anatomical vascular geometry in the human neck. The potential for cooling of blood in the carotid artery on its way to the brain by heat exchange with the jugular vein and by radial heat conduction loss to the cool neck surface was evaluated. They showed that the temperature of the arterial blood can be as much as 1.1 °C lower than the body core temperature, an observation in agreement with the difference between tympanic and body core temperatures. The model also evaluates the relative contributions of countercurrent heat exchange and radial heat conduction to selective brain cooling.

Does O₂ directly regulate CBF, or are there mediators? Ursino et al. (123,124) modeled the production and diffusion of vasoactive chemical factors involved in CBF regulation. Their model comprises two submodels. In the first, transport from capillary blood to cerebral tissue was analyzed to link changes in mean tissue PO₂ with CBF and arterial O₂ concentration changes. The second submodel described the production of vasoactive metabolites by cerebral parenchyma, arising from a lack of O₂, and their diffusion toward pial perivascular space. They simulated the time dynamics of mean tissue PO₂, perivascular adenosine concentration and perivascular pH with changes in CBF. With their model, they concluded that the time delay introduced by diffusion processes is negligible compared with the other time constants in their system.

A second model (124) incorporated more submodels, each closely related to a physiological event. Thus, they could simulate the role played by the chemical factors described in the paragraph above, in the control of CBF during several different physiological and pathological conditions associated with the O₂ supply to cerebral tissue. These conditions included changes in autoregulation to changes in arterial and venous pressure, reactive hyperemia following cerebral ischemia and hypoxia. Their results suggest that adenosine and pH play a significant, but not exclusive, role in the regulation of the cerebrovascular bed.

Ursino and Magosso (125) presented a mathematical model of cerebrovascular regulation, in which emphasis was given to the role of tissue hypoxia on CBF. In the model, three different mechanisms are assumed to work on smooth muscle tension at the level of large and small pial

arteries: CO₂ reactivity, tissue hypoxia, and a third mechanism necessary to provide good reproduction of autoregulation to cerebral perfusion pressure changes. The model is able to reproduce the pattern of pial artery caliber and CBF under a large variety of physiological stimuli, either acting separately (hypoxia, cerebral perfusion pressure changes, CO₂ pressure changes) or in combination (hypercapnia + hypoxia; hypercapnia + hypotension-hypotension). Furthermore, the model can explain the increase in CBF and the vasoconstriction of small pial arteries observed experimentally during hemodilution, ascribing it to the decrease in blood viscosity and to the antagonistic action of the flow-dependent mechanism (responsible for vasoconstriction) and of hypoxia (responsible for vasodilation). The interaction between hypoxia and ICP turns out to be quite complex, leading to different ICP time patterns, depending on the status of the CSF outflow pathways and of intracranial compliance.

Wakeland et al. (126) described a computer model of ICP dynamics that evaluated clinical treatment options for elevated ICP during traumatic brain injury. The model used fluid volumes as primary state variables and explicitly modeled fluid flows as well as the resistance, compliance, and pressure associated with each intra- and extracranial compartment (arteries and arterioles, capillary bed, veins, venous sinus, ventricles, and brain parenchyma). The model evaluated clinical events and therapies, such as intra- and extraparenchymal hemorrhage, cerebral edema, CSF drainage, mannitol administration, head elevation, and mild hyperventilation. The model was able to replicate observed clinical behavior in many cases, including elevated ICP associated with severe cerebral edema following subdural, epidural, or intraparenchymal hematoma. The model also mimics cerebrovascular regulatory mechanisms that are activated during traumatic brain injury.

Lodi and Ursino (127) demonstrated a mathematical model of cerebral hemodynamics during vasospasm. The model divided arterial hemodynamics into two cerebral territories: with and without vasospasm. It also included collateral circulation between the two territories, cerebral venous hemodynamics, CSF circulation, ICP, and craniospinal storage capacity. Moreover, the pial artery circulation in both territories was affected by CBF autoregulation mechanisms. First, the model was used to simulate some clinical results reported in the literature, concerning the patterns of middle cerebral artery flow velocity, CBF and pressure losses during vasospasm. Second, they performed a sensitivity analysis on certain model parameters (severity of caliber reduction, longitudinal extension of the spasm, autoregulation gain, ICP, resistance of the collateral circulation, and MAP) to clarify their influence on hemodynamics in the spastic area. The results suggested that the clinical impact of vasospasm depends on several concomitant factors, which should be simultaneously taken into account to reach a proper diagnosis.

Pasley et al. (128) used a mathematical model to test two hypotheses: (1) cyclic extravascular compressional modulation of the terminal venous bed occurs with positive pressure inhalation; and (2) the degree of modulation is diminished with increasing vascular dilation induced by

increasing the level of $PaCO_2$. They made two modifications of Ursino's model of CSF dynamics (129–131): (1) terminal venous bed resistance was synchronously modulated with the ventilation cycle; and (2) both the depth of modulation and cerebrovascular resistance were progressively reduced with increasing levels of $PaCO_2$. Simulated and experimental correlation values progressively increased monotonically as the level of PCO_2 increased. Their results suggested that dilation of the cerebral vasculature reduces the influence of positive pressure ventilation on ICP by increasing venous pressure and thus diminishing the likelihood of vascular compression.

Increased ICP, which can result from etiologies ranging from tumors to trauma, can produce devastating results, of which death may be one of the more merciful. Modeling the phenomenon is critically important. Ursino and Lodi (132) used a mathematical model to characterize the relationships among CBF, cerebral blood volume, ICP, and the action of cerebrovascular regulatory mechanisms (autoregulation and CO_2 reactivity). The model incorporated CSF circulation, the ICP–volume relationship, and cerebral hemodynamics. The latter is based on three assumptions. (1) The middle cerebral arteries behave passively following transmural pressure changes. (2) The pial arterial circulation includes two segments (large and small pial arteries) subject to different autoregulation mechanisms. (3) The venous cerebrovascular bed behaves as a Starling resistor. A new aspect of this model relates to the description of CO_2 reactivity in the pial arterial circulation and in the analysis of its nonlinear interaction with autoregulation. Simulations obtained at constant ICP using various combinations of MAP and CO_2 support data on CBF and velocity concerning both the separate effects of CO_2 and autoregulation and their nonlinear interaction. Simulations performed in dynamic conditions with varying ICP suggest a significant correlation between ICP dynamics and cerebral hemodynamics in response to CO_2 changes. The authors believe that the model can be used to study ICP and blood velocity time patterns in neurosurgical patients, so that one can gain a deeper insight into the pathophysiological mechanisms leading to intracranial hypertension and resultant brain damage.

Loewe et al. (133) used a mathematical model to simulate the time pattern of ICP and of blood velocity in the middle cerebral artery in response to maneuvers simultaneously affecting MAP and end-tidal CO_2 . First, they performed a sensitivity analysis, to clarify the role of some important model parameters (CSF outflow resistance, intracranial elastance coefficient, autoregulation gain, and the position of the regulation curve) during CO_2 alteration maneuvers performed at different MAP levels. Next, the model was applied to the reproduction of real ICP and velocity tracings in neurosurgical patients. They concluded that the model could be used to give reliable estimates of the main factors affecting intracranial dynamics in individual patients, starting from routine measurements performed in neurosurgical intensive care units.

Ursino et al. (134) analyzed changes in cerebral hemodynamics and ICP evoked by MAP and $PaCO_2$ challenges in patients with acute brain damage. The study was performed using a simple mathematical model of intracranial

hemodynamics, particularly aimed at routine clinical investigation. The parameters chosen for the identification summarize the main aspects of intracranial dynamics, namely, CSF circulation, intracranial elastance, and cerebrovascular control.

By using a mathematical model, Ursino et al. (135) also studied the time pattern of ICP in response to typical clinical tests, namely, a bolus injection or withdrawal of small amounts of saline in the craniospinal space in patients with acute brain damage. The model included the main biomechanical factors assumed to affect ICP, CSF dynamics, intracranial compliance, and cerebrovascular dynamics. The simulation results demonstrated that the ICP time pattern cannot be explained simply on the basis of CSF dynamics, but also requires consideration of the contribution of cerebral hemodynamics and blood-volume alterations.

Sharan et al. (136) explored an interesting O_2 -related phenomenon with a mathematical model. CBF increases as arterial O_2 content falls with hypoxic (low PO_2), anemic (low hemoglobin), and carbon monoxide (CO) (high carboxyhemoglobin) hypoxia. Despite a higher arterial PO_2 , CO hypoxia provokes a greater increase in CBF than hypoxic hypoxia. They analyzed published data using a compartmental mathematical model to test the hypothesis that differences in PO_2 in tissue, or a closely related vascular compartment, account for the greater response to CO hypoxia. Calculations showed that tissue, but not arteriolar, PO_2 was lower in CO hypoxia because of the increased oxyhemoglobin affinity with CO hypoxia. Analysis of studies in which oxyhemoglobin affinity was changed independently of CO supports the conclusion that changes in tissue PO_2 (or closely related capillary or venular PO_2) predict alterations in CBF. They then sought to determine the role of tissue PO_2 in anemic hypoxia, with no change in arterial and little, if any, change in venous PO_2 . Calculations predicted a small fall in tissue PO_2 as hematocrit decreases from 55 to 20%. However, calculations showed that changes in blood viscosity can account for the increase in CBF in anemic hypoxia over this range of hematocrits. It would have been interesting if the authors had tested hypoxia from cyanide poisoning, which blocks the utilization of O_2 at the enzyme cytochrome oxidase; blood and tissue actually increases.

Exploring well-defined physical phenomena is one thing; exploring fuzzy, undefined concepts, like consciousness, is quite another. Cammarota and Onaral (137) realized that complex physiological systems in which the emergent global (observable) behavior results from the interplay among local processes cannot be studied effectively by conventional mathematical models. In contrast to traditional computational methods, which provide linear or nonlinear input–output data mapping without regard to the internal workings of the system, complexity theory offers scientifically and computationally tractable models that take into account microscopic mechanisms and interactions responsible for the overall input–output behavior. The authors offered a brief introduction to some of the tenets of complexity theory and outlined the process involved in the development and testing of a model that duplicates the global dynamics of the induction of loss of

consciousness in humans due to cerebral ischemia. Under the broad definition of complexity, they viewed the brain of humans as a complex system. Successful development of a model for this complex system requires careful combination of basic knowledge of the physiological system both at the local (microscopic) and global (macroscopic) levels with experimental data and the appropriate mathematical tools. It represents an attempt to develop a model that can both replicate human data and provide insights about possible underlying mechanisms. They presented a model for complex physiological systems that undergo state (phase) transitions. The physiological system modeled is the CNS, and the global behavior captured by the model is the state transition from consciousness to unconsciousness. Loss of consciousness can result from many conditions such as ischemia (low blood flow), hypoxia (low oxygen), hypoglycemia, seizure, anesthesia, or a blow to the head, among others. Successful development of a model for this complex system requires careful combination of basic knowledge of the physiological system both at the local (microscopic) and global (macroscopic) levels with experimental data and the appropriate mathematical tools. Due to the wealth of human research and data available, the specific focus of the model is unconsciousness that results from the cerebral ischemia experienced by aircrew during aggressive maneuvering in high-performance aircraft.

Coronary

In the section Coronary Autoregulation, the problems and paradoxes of the coronary circulation are described. One of them was that myocardial perfusion was decreased in some areas by mechanical and shearing effects, and the harder the contraction, the greater the impairment. Smith (138) used an anatomically based computational model of coronary blood flow, coupled to cardiac mechanics to investigate the mechanisms by which myocardial contraction inhibits coronary blood flow. From finite deformation mechanics solutions the model calculates the regional variation in intramyocardial pressure (IMP) exerted on coronary vessels embedded in the ventricular wall. This pressure is then coupled to a hemodynamic model of vascular blood flow to predict the spatial-temporal characteristics of perfusion throughout the myocardium. The calculated IMP was shown to vary approximately linearly between ventricular pressure at the endocardium and atmospheric pressure at the epicardium through the diastolic loading and isovolumic contraction phases. During the ejection and isovolumic relaxation phases, IMP values increased slightly above ventricular pressure. The average radius of small arterial vessels embedded in the myocardium decreased during isovolumic contraction (18% in LV endocardium) before increasing during ejection (10% in LV endocardium) due to a rise in inflow pressure. Embedded venous vessels show a reduction in radius through both phases of contraction (35% at left ventricular endocardium). Calculated blood flows in both the large epicardial and small myocardial vessels show a 180° phase difference between arterial and venous velocity patterns with arterial flow occurring predominantly during diastole and venous flow occurring predominantly during systole. Their results

confirm that the transmission of ventricular cavity pressure through the myocardium is the dominant mechanism by which coronary blood flow is reduced during the isovolumic phase of contraction. In the ejection phase of contraction, myocardial stiffening plays a more significant role in inhibiting blood flow.

Also illustrating this problem of impaired coronary flow during systole is a mathematical model that was based on an *In vitro* mechanical model consisting mainly of collapsible tubes (67). The pressure and flow signals obtained from both models were similar to physiological human coronary pressure and flow, both for baseline and hyperemic conditions.

Smith et al. (139) developed a discrete anatomically accurate finite element model of the largest six generations of the coronary arterial network. Using a previously developed anatomically accurate model of ventricular geometry, they defined the boundaries of the coronary mesh from measured epicardial coronaries. Network topology was then generated stochastically from published anatomical data. Spatial information was added to the topological data using an avoidance algorithm accounting for global network geometry and optimal local branch-angle properties. The generated vessel lengths, radii and connectivity were consistent with published data, and a relatively even spatial distribution of vessels within the ventricular mesh was achieved.

Pulmonary-Respiratory

The respiratory system is important as a means of O₂ uptake and CO₂ elimination. It may be compared with the CVS because gases are carried in it by pulsatile fluid flow, somewhat as gases and many other substances are carried by pulsatile blood flow in the CVS. The respiratory system is anatomically simpler, since it has but one branching out of the airflow passages, whereas the CVS fans out to the many body capillaries from the aorta, then fans in to the vena cavae, and repeats this pattern in the pulmonary circulation. However, analysis and modeling are far more complex in the respiratory system because air is a compressible fluid and because flow of air in the lungs is a tidal, or back-and-forth, flow, in contrast to the one-way flow with superimposed pulsatility in the CVS. Also, although the respiratory system does not have valves as the CVS does, there are some important and rather difficult nonlinearities.

Good reviews are worth their weight in gold. Grotberg (140) reviewed respiratory fluid mechanics and transport processes. This field has experienced significant research activity for decades. Important contributions to the knowledge base come from pulmonary and critical care medicine, anesthesia, surgery, physiology, environmental health sciences, biophysics, and engineering. Several disciplines within engineering have strong and historical ties to respiration, including mechanical, chemical, civil-environmental, aerospace and, of course, biomedical engineering. Grotberg's review draws from the wide variety of scientific literature that reflects the diverse constituency and audience that respiratory science has developed. The subject areas covered include nasal flow and transport, airway gas

flow, alternative modes of ventilation, nonrespiratory gas transport, aerosol transport, airway stability, mucus transport, pulmonary acoustics, surfactant dynamics and delivery, and pleural liquid flow. Within each area are several subtopics whose exploration can provide the opportunity of both depth and breadth for the interested reader.

The pioneer of computer modeling of respiratory control was Jim Defares (141,142). The one with the most impact, however, has been Fred Grodins (143), and several of the papers in this section acknowledge his significant contributions.

Chiari et al. (144) presented a comprehensive model of O_2 and CO_2 exchange, transport, and storage. The model comprises three compartments (lung, body tissue, and brain tissue) and incorporates a controller that adjusts alveolar ventilation and CO_2 by dynamically integrating stimuli coming from peripheral and central chemoreceptors. A realistic CO_2 dissociation curve based on a two-buffer model of acid-base chemical regulation is included. In addition, the model considers buffer base, the nonlinear interaction between the O_2 and CO_2 chemoreceptor responses, pulmonary shunt, dead space, variable time delays, and Bohr and Haldane effects. Their model fit the experimental data of ventilation and gas partial pressures in a very large range of gas intake fractions. It also provided values of blood concentrations of CO_2 , HCO_3^- , and hydrogen ions in good agreement with more complex models characterized by an implicit formulation of the CO_2 dissociation curve.

Good sensitivity analysis can be difficult, at best. The tools in the paper by Hyuan et al. (145) are general and can be applied to a wide class of nonlinear models. The model incorporates a combined theoretical and numerical procedure for sensitivity analyses of lung mechanics models that are nonlinear in both state variables and parameters. They applied the analyses to their own nonlinear lung model, which incorporates a wide range of potential nonlinear identification conditions including nonlinear viscoelastic tissues, airway inhomogeneities via a parallel airway resistance distribution function, and a nonlinear block-structure paradigm. Model nonlinearities motivate sensitivity analyses involving numerical approximation of sensitivity coefficients. Examination of the normalized sensitivity coefficients provides insight into the relative importance of each model parameter, and hence the respective mechanism. More formal quantification of parameter uniqueness requires approximation of the paired and multidimensional parameter confidence regions. Combined with parameter estimation, they used the sensitivity analyses to justify tissue nonlinearities in modeling of lung mechanics for healthy and constricted airway conditions, and to justify both airway inhomogeneities and tissue nonlinearities during bronchoconstriction. Some of the variables, parameters and domains included pressures, flows, volumes, resistances, compliances, impedances, pressure-volume and frequency.

A model of breathing mechanics (146) was used to interpret and explain the time course of input respiratory resistance during the breathing cycle, observed in ventilated patients. The authors assumed a flow-dependent resistance for the upper extrathoracic airways and

volume-dependent resistance and elastance for the intermediate airways. A volume-dependent resistance described the dissipative pressure loss in the lower airways, while two constant elastances represented lung and chest wall elasticity. Simulated mouth flow and pressure signals obtained in a variety of well-controlled conditions were used to analyze total respiratory resistance and elastance estimated by an on-line algorithm based on a time-varying parameter model. These estimates were compared with those provided by classical estimation algorithms based on time-invariant models with two, three, and four parameters. The results confirmed that the difference between the end-expiration and end-inspiration resistance increases when obstructions shift from the upper to the lower airways.

Ursino et al. (147) presented a mathematical model of the human respiratory control system. It includes three compartments for gas storage and exchange (lungs, brain, tissue, and other body tissues), and various types of feedback mechanisms. These comprise peripheral chemoreceptors in the carotid body, central chemoreceptors in the medulla and a central ventilatory depression. The last acts by reducing the response of the central neural system to the afferent peripheral chemoreceptor activity during prolonged hypoxia of the brain tissue. The model also considers local blood flow adjustments in response to O_2 and CO_2 arterial pressure changes. Sensitivity analysis suggests that the ventilatory response to CO_2 challenges during hyperoxia can be almost completely ascribed to the central chemoreflex, while, during normoxia, the peripheral chemoreceptors also provide a modest contribution. By contrast, the response to hypercapnic stimuli during hypoxia involves a complex superimposition among different factors with disparate dynamics. Results suggest that the ventilatory response to hypercapnia during hypoxia is more complex than that provided by simple empirical models, and that discrimination between the central and peripheral components based on time constants may be misleading.

The phenomena collectively referred to as periodic breathing (including Cheyne Stokes respiration and apneustic breathing) have important medical implications. The hypothesis that periodic breathing is the result of delays in the feedback signals to the respiratory control system has been studied since the work of Grodins et al. (148) in the early 1950s. Batzel's dissertation (149) extended a model developed by Khoo et al. (150), to include variable delay in the feedback control loop and to study the phenomena of periodic breathing and apnea as they occur during quiet sleep in infants. The nonlinear mathematical model consists of a feedback control system of five differential equations with multiple delays. Numerical simulations were performed to study instabilities in the control system, especially the occurrence of periodic breathing and apnea in infants ~ 4 months of age. This time frame is important, since during it there is a high incidence of Sudden Infant Death Syndrome. Numerical simulations indicate that a shift in the controller ventilatory drive set point during sleep transition is an important factor for instability. Analytical studies show that delay-dependent stability is affected by controller gain, compartment

volumes and the manner in which changes in minute ventilation are produced (i.e., by deeper breathing or faster breathing). Parenthetically, the increased delay resulting from congestive heart failure can induce instability at certain control gain levels.

The dimensions, composition, and stiffness of the airway wall are important determinants of airway cross-sectional area during dynamic collapse in a forced expiration or when airway smooth muscle is constricted. This can occur with asthma or COPD (emphysema). Under these circumstances, airway caliber is determined by an interaction between the forces acting to open the airway (parenchymal tension and wall stiffness) and those acting to close it (smooth-muscle force and surface tension at the inner gasliquid interface). Theoretical models of the airway tube law (relationship between cross-sectional area and transmural pressure) allow simulations of airway constriction in normal and asthmatic airways (151).

An excellent mathematical model of neonatal respiratory control (152) consists of a continuous plant and a discrete controller. Included in the plant are lungs, body tissue, brain tissue, a CSF compartment, and central and peripheral receptors. The effect of shunt is incorporated in the model, and lung volume and dead space are time varying. The controller uses outputs from peripheral and central receptors to adjust the depth and rate of breathing, and the effects of prematurity of peripheral receptors are included in the system. Hering–Breuer-type reflexes are embodied in the controller to accomplish respiratory synchronization. See also the Nottingham Physiology Simulator for a similar approach (Whole-body models).

Lung gas composition affects the development of anesthesia-related atelectasis, by way of differential gas absorption. A mathematical model (153) examines this phenomenon by combining models of gas exchange from an ideal lung compartment, peripheral gas exchange, and gas uptake from a closed collapsible cavity. The rate of absorption is greatest with O_2 , less with NO_2 and minimal with N_2 . BODY Simulation (see PBPM) achieves the same results.

Most respiratory models are limited to short-term (minutes) control. Those wishing to model longer term (days) control and adjustments should start with the detailed review by Dempsey and Forster (154). They discuss several important areas, including central chemoreception, cerebral fluids and chemoreceptor environment, physiologically important stimuli to medullary chemoreception, medullary chemoreceptor contributions to ventilatory drive, metabolic acid–base derangements, ventilatory response, mediation of ventilatory adaptation, ventilatory acclimatization to chronic hypoxia, ventilation during acute hypoxia, acclimatization during short-term hypoxia, acclimatization during long-term hypoxia, physiological significance of short- and long-term ventilatory acclimatization, ventilatory acclimatization to chronic CO_2 exposure, ventilation during chronic CO_2 inhalation, and whole-body CO_2 and H^+ during CO_2 exposure.

Renal

The kidneys have important physiological functions including maintenance of water and electrolyte balance;

synthesis, metabolism and secretion of hormones; and excretion of the waste products from metabolism. In addition, the kidneys play a major role in the excretion of hormones, as well as drugs and other xenobiotics. The story of fluids and solutes is the story of the kidney, and vice versa.

The understanding of renal function has profited greatly from quantitative and modeling approaches for a century (155). One of the most salient examples is the concentration and dilution of the urine: a fundamental characteristic of the mammalian kidney. Only in the last three decades have the necessary components of this and other renal mechanisms been confirmed at the molecular level, but there have also been surprises. In addition, the critical role played by the fine regulation of Na^+ reabsorption in the collecting duct for the maintenance of normal blood pressure presents challenges to our understanding of the integrated interaction among systems. As a first step in placing the kidney in the physiome paradigm (see below), Schafer suggests (1) integrating currently restricted mathematical models, (2) developing accessible databases of critical parameter values together with indices of their degrees of reliability and variability, and (3) describing regulatory mechanisms and their interactions from the molecular to the interorgan level.

By now, you will have guessed our enthusiasm for good reviews. An excellent one to start with in this area is by Russell (156), on Na-K chloride cotransport. Obligatory, coupled cotransport of Na^+ , K^+ , and Cl^- by cell membranes has been reported in nearly every animal cell type. Russell's review examines the status of the knowledge about this ion transport mechanism.

In another review (the Starling Lecture, actually), DiBona (157) describes the neural control of the kidney. The sympathetic nervous system provides differentiated regulation of the functions of various organs. This differentiated regulation occurs via mechanisms that operate at multiple sites within the classic reflex arc: peripherally at the level of afferent input stimuli to various reflex pathways, centrally at the level of interconnections between various central neuron pools, and peripherally at the level of efferent fibers targeted to various effectors within the organ. In the kidney, increased renal sympathetic nerve activity regulates the functions of the intrarenal effectors: the tubules, the blood vessels, and the juxtaglomerular granular cells. This enables a physiologically appropriate coordination between the circulatory, filtration, reabsorptive, excretory, and renin secretory contributions to overall renal function. Anatomically, each of these effectors has a dual pattern of innervation consisting of a specific and selective innervation, in addition to an innervation that is shared among all the effectors. This arrangement permits maximum flexibility in the coordination of physiologically appropriate responses of the tubules, the blood vessels, and the juxtaglomerular granular cells to a variety of homeostatic requirements.

Physiologists have developed many models for interpreting water and solute exchange data in whole organs, but the models have often neglected key aspects of the underlying physiology to present the simplest possible model for a given experimental situation. Kellen and

Bassingthwaite (158) developed a model of microcirculatory water and solute exchange and applied it to diverse observations of water and solute exchange in the heart. The key model features that permit this diversity are the use of an axially distributed blood-tissue exchange region, inclusion of a lymphatic drain in the interstitium, and the independent computation of transcapillary solute and solvent fluxes through three different pathways.

Endocrine

The insulin–glucose subsystem will be used as a paradigm of the endocrine system. Because diabetes is such a clinically complex and disabling disease, as well as a major and increasing personal and public health problem, many attempts at modeling have been made. Most of these models have examined various parts of the overall process, and one or two have tried to put it all together.

The normal blood glucose concentration in humans lies in the range of 70–110 mg·dL⁻¹. Exogenous factors that affect this concentration include food intake, rate of digestion, exercise, and reproductive state. The pancreatic hormones insulin and glucagon are responsible for keeping glucose concentration within bounds. Insulin and glucagon are secreted from beta-cells and alpha-cells respectively, which are contained in the islets of Langerhans, which are scattered in the pancreas. When blood glucose concentration is high, the beta-cells release insulin, resulting in lowering blood glucose concentration by inducing the uptake of the excess glucose by the liver and other cells (e.g., muscles) and by inhibiting hepatic glucose production. When blood glucose concentration is low, the alpha-cells release glucagon, resulting in increasing blood glucose concentration by acting on liver cells and causing them to release glucose into the blood.

Glucose concentrations outside the range 70–110 m·dL⁻¹ are called hyperglycemia or hypoglycemia. Diabetes mellitus is a disease of the glucose–insulin regulatory system that is characterized by hyperglycemia. Diabetes is classified into two main categories: type 1 diabetes, juvenile onset and insulin dependent; and type 2 diabetes, adult onset and insulin independent.

Makroglu et al. (159) presented an extensive overview of some of the available mathematical models on the glucose–insulin regulatory system in relation to diabetes. The review is enhanced with a survey of available software. The models are in the form of ordinary differential, partial differential, delay differential and integrodifferential equations.

Tibell et al. (160) used models to estimate insulin secretion rates in patients who had undergone pancreas-renal transplant procedures.

When the complex physiology goes awry, manmade control systems can be used to understand and perhaps deal with the problem. These control systems require models. Ibbini et al. (161) have recently developed one such system. Parker et al. (162) set up a model-based algorithm for controlling blood glucose concentrations in type I diabetic patients.

Bequette (163) examined the development of an artificial pancreas in the context of the history of the field of

feedback control systems, beginning with the water clock of ancient Greece, and including a discussion of current efforts in the control of complex systems. The first generation of artificial pancreas devices included two manipulated variables (insulin and glucose infusion) and nonlinear functions of the error (difference between desired and measured glucose concentration) to minimize hyperglycemia while avoiding hypoglycemia. Dynamic lags between insulin infusion and glucose measurement were relatively small for these intravenous-based systems. Advances in continuous glucose sensing, fast-acting insulin analogues, and a mature insulin-pump market bring closer the commercial realization of a closed-loop artificial pancreas. Model predictive control is discussed in-depth as an approach that is well suited for a closed-loop artificial pancreas. A major remaining challenge is handling an unknown glucose disturbance (meal), and an approach is proposed to base a current insulin infusion action on the predicted effect of a meal on future glucose values. Better meal models are needed, as a limited knowledge of the effect of a meal on the future glucose values limits the performance of any control algorithm.

One of the fascinating features of the insulin–glucose subsystem, and with other endocrine subsystems, is that it either oscillates or releases its hormones in an intermittent fashion. The terms oscillations, rhythms, ultradian, (relating to biologic variations or rhythms occurring in cycles more frequent than every 24 h [cf. circadian, about every 24 h]) pulses, biphasic and bursting appear frequently in regards to insulin secretion. The following describes some of the models that study these phenomena.

Insulin is secreted in a sustained oscillatory fashion from isolated islets of Langerhans, and Berman et al. (164) modeled this phenomenon. Straub and Sharp (165) reviewed some models that have tried to explain the well-documented biphasic secretory response of pancreatic beta-cells to abrupt and sustained exposure to glucose.

Lenbury et al. (166) modeled the kinetics of insulin, using a nonlinear mathematical model of the glucose–insulin feedback system. The model has been extended to incorporate the beta-cells' function in maintaining and regulating plasma insulin concentration in humans. Initially, a gastrointestinal absorption term for glucose is used to effect the glucose absorption by the intestine and the subsequent release of glucose into the bloodstream, taking place at a given initial rate and falling off exponentially with time. An analysis of the model was carried out by the singular-perturbation technique to derive boundary conditions on the system parameters that identify, in particular, the existence of limit cycles in the model system consistent with the oscillatory patterns often observed in clinical data. They then used a sinusoidal term to incorporate the temporal absorption of glucose to study the responses in patients during ambulatory-fed conditions. They identified the ranges of parametric values for which chaotic behavior can be expected, leading to interesting biological interpretations.

An interesting electrophysiological phenomenon occurs in the islets of Langerhans: The release of insulin is controlled in these islets by trains of action potentials occurring in rapid bursts followed by periods of quiescence. This

bursting behavior occurs only in intact islets: single cells do not display such bursting activity. Chay and Keizer (167) were the first attempt to model this phenomenon quantitatively. Sherman et al. (168) sought to explain the absence of bursting in single beta-cells using the idea of channel sharing. Keizer (169) modified this model by substituting an ATP- and ADP-dependent K channel instead of the Ca-dependent K channel. This model was then further improved by Keizer and Magnus (170). Sherman et al. (171) constructed a domain model to examine the effect of Ca on Ca-channel inactivation. Further refinements have been made by Keizer and Young (172).

Sherman (173) also reviewed mechanisms of ionic control of insulin secretion. He focused on aspects that have been treated by mathematical models, especially those related to bursting electrical activity. The study of these mechanisms is difficult because of the need to consider ionic fluxes, Ca handling, metabolism, and electrical coupling with other cells in an islet. The data come either from islets, where experimental maneuvers tend to have multiple effects, or from isolated cells, which exhibit degraded electrical activity and secretory sensitivity. Modeling aids in the process by integrating data on individual components such as channels and Ca handling and testing hypotheses for coherence and quantitative plausibility. The study of a variety of models has led to some general mathematical results that have yielded qualitative model-independent insights.

Endocrine systems often secrete hormones in pulses. Examples include the release of growth hormone and gonadotropins, as well as insulin. These hormones are secreted over intervals of 1–3 h and 80–150 min, respectively. It has been suggested that relative to constant or stochastic signals, oscillatory signals are more effective at producing a sustained response in the target cells. In addition to the slow insulin oscillations, there are more rapid pulses that occur every 8–15 min. The mechanisms underlying both types of oscillations are not fully understood, although it is thought that the more rapid oscillations may arise from an intrapancreatic pacemaker mechanism. One possible explanation of the slow insulin oscillations is an instability in the insulin-glucose feedback system. This hypothesis has been the subject many studies, including some that have developed a mathematical model of the insulin-glucose feedback system. Tolic (174) reviewed several models that investigated oscillations, with glucose and the pancreas. Tolic's model (175) and others are available on the CellML site (176).

Shannahoff-Khalsa et al. (177), in Gene Yates' group, have expanded the purview of these fascinating phenomena by comparing the rhythms of the CV, autonomic, and neuroendocrine systems. Their results, from a time-series analysis using a fast orthogonal search method, suggested that insulin secretion has a common pacemaker (the hypothalamus) or a mutually entrained pacemaker with these three systems.

Fortunately, there is an excellent glucose-insulin model that helps one understand some of these concepts. Erzen et al. (178) have posted GlucoSim, a web-based simulator that runs on almost all computer platforms. GlucoSim is a program for simulating glucose-insulin interaction in

a healthy person and in a type 1 diabetes patient. It has a flexible data output structure that can be used as an input into most postprocessing programs such as spreadsheet and graphics programs. Simulations can be performed by changing initial conditions or meal and insulin injection times. Simulation results can be plotted in 2D directly from the simulator by choosing appropriate buttons. The software is freely available to all users. This model is also on the CellML Site (176), but not the running model.

GlucoSim is one of the more nearly complete models that we have reviewed, and it satisfies our criteria for a whole-body model. It is a good example of the usefulness of a whole-body model with many compartments. This model is actually two whole-body models combined, with food ingestion in the glucose model and subcutaneous injection in the insulin model.

Action Potentials

In 1952, Hodgkin and Huxley published a paper showing how a nonlinear empirical model of the membrane processes could be constructed (179). In the five decades since their work, the Hodgkin-Huxley paradigm of modeling cell membranes has been enormously successful. While the concept of ion channels was not established when they performed their work, one of their main contributions was the concept that ion-selective processes existed in the membrane. It is now known that most of the passive transport of ions across cell membranes is accomplished by ion-selective channels. In addition to constructing a nonlinear model, they also established a method to incorporate experimental data into a nonlinear mathematical membrane model. Thus, models of action potentials comprise some of the oldest of nonlinear physiological models.

Action potential is a term used to denote a temporal phenomenon exhibited by every electrically excitable cell. The transmembrane potential difference of most excitable cells rests at some negative potential called the resting potential, appropriately enough. External current or voltage inputs can cause the potential of the cell to deviate in a positive direction, and if the input is large enough, the result is an action potential. An action potential is characterized by a depolarization that typically results in an overshoot >0 mV, followed by repolarization. Some cells may actually hyperpolarize before returning to the resting potential. After the membrane has been excited, it cannot be reexcited until a recovery period, called the refractory period, has passed.

When excitable cells are depolarized from their resting potential beyond a certain level (threshold), they respond with a relatively large, stereotyped potential change. It is the action potential's propagating away from the site of origin that constitutes impulse conduction in nerve, muscle and heart.

Action potentials are everywhere in life; if there's electricity, there are action potentials. This topic deserves an entire book, much less an encyclopedia entry. Accordingly, much of the information in this comes from articles in other books. Unless one defines electricity as a system, there seem to be no models that fit our definition of physiological systems models.

Having said that, electric phenomena are an integral part of every biological system, no matter what one's definition of the latter is. Action potentials keep our heart beating, our mind thinking—and make possible our seeing, hearing, smelling, feeling, tasting, digesting and moving. They are everywhere (plants and animals) and taking place all the time. We tried to estimate the number of action potentials occurring per second in one part of the human body (the brain) and may be underestimating by orders of magnitude. There are a trillion neurons in the human brain alone, and 10 quadrillion synapses, more than there are stars in the universe. The rate of action potentials can be from zero to >1000 action potentials per second. Let us estimate 10^{18} s^{-1} ($10^{16} \times 10^2$). We have not even started with muscles or sensory receptors, for example. We repeat, it's a large topic.

Varghese (180) tells us that the key concept in the modeling of excitable cells is that of ion channel selectivity. A particular type of ion channel will only allow certain ionic species to pass through; most types of ion channels are modeled as being permeant to a single ionic species. In excitable cells at rest, the membrane is most permeable to K. This is because only K channels (i.e., channels selective to K) are open at the resting potential. For a given stimulus to result in an action potential, the cell has to be brought to threshold, that is, the stimulus has to be larger than some critical size. Smaller, subthreshold, stimuli will result in an exponential decay back to the resting potential. The upstroke, or fast initial depolarization of the action potential, is caused by a large influx of Na ions as Na channels open (in some cells, entry of Ca ions though Ca channels is responsible for the upstroke) in response to a stimulus. This is followed by repolarization as K ions start flowing out of the cell in response to the new potential gradient. While responses of most cells to subthreshold inputs are usually linear and passive, the suprathreshold response (the action potential) is a nonlinear phenomenon. Unlike linear circuits where the principle of superposition holds, the nonlinear processes in cell membranes do not allow responses of two stimuli to be added. If an initial stimulus results in an action potential, a subsequent stimulus administered at the peak voltage will not produce an even larger action potential; indeed, it may have no effect at all. Following an action potential, most cells have a refractory period, during which they are unable to respond to stimuli. Nonlinear features, such as these make modeling of excitable cells a nontrivial task. In addition, the molecular behavior of channels is only partially known and, therefore, it is not possible to construct membrane models from first principles.

Most membrane models discussed in Varghese's excellent article (180) involve the time behavior of electrochemical activity in excitable cells. These models are systems of ordinary differential equations where the independent variable is time. While a good understanding of linear circuit theory helps understand these models, most of the phenomena of interest involve nonlinear circuits with time-varying components. Electrical activity in plant and animal cells is caused by two main factors: (1) differences in the concentrations of ions inside and outside the cell; and (2) molecules embedded in the cell membrane that allow

these ions to be transported across the membrane. The ion concentration differences and the presence of large membrane-impermeant anions inside the cell result in a polarity: the potential inside a cell is typically 50–100 mV lower than that in the external solution. Almost all of this potential difference occurs across the membrane itself; the bulk solutions both inside and outside the cell are usually at a uniform potential. This transmembrane potential difference is, in turn, sensed by molecules in the membrane, and these molecules control the flow of ions. The lipid bilayer, which constitutes the majority of the cell membrane, acts as a capacitor with a specific capacitance. Because the membrane is thin ($\sim 7.5 \text{ nm}$), it has a high capacitance, $\sim 1 \mu\text{F}\cdot\text{cm}^{-2}$. The rest of the membrane comprises large protein molecules that act as (1) ion channels, (2) ion pumps, or (3) ion exchangers. The flow of ions across the membrane causes changes in the transmembrane potential, which is typically the main observable quantity in experiments.

Barr (181), in another excellent article, expounds on bioelectricity, which has its origin in the voltage differences present between the inside and outside of cells. These potentials arise from the specialized properties of the cell membrane, which separates the intracellular from the extracellular volume. Much of the membrane surface is made of a phospholipid bilayer, an electrically inert material. Electrically active membranes also include many different kinds of *integral proteins*, which are compact, but complex structures extending across the membrane. Each integral protein comprises a large number of amino acids, often in a single long polypeptide chain, which folds into multiple domains. Each domain may span the membrane several times. The multiple crossings may build the functional structure, for example, a *channel*, through which electrically charged ions may flow. The structure of integral proteins is loosely analogous to that of a length of thread passing back and forth across a fabric to form a buttonhole. Just as a buttonhole allows movement of a button from one side of the fabric to the other, an integral protein may allow passage of ions from the exterior of a cell to the interior, or vice versa. In contrast to a buttonhole, an integral protein has active properties, for example, the ability to open or close. Cell membranes possess several active characteristics important to the cell's bioelectric behavior. (1) Some integral proteins function as *pumps*. These pumps use energy to transport ions across a membrane, working against a concentration gradient, a voltage gradient, or both. The most important pump moves Na ions out of the intracellular volume and K ions into that volume. (2) Other integral proteins function as channels, that is, openings through the membrane that open and close over time. These channels can function selectively so that, for a particular kind of channel, only Na ions may pass through, for example. Other kinds of channel may allow only K ions or Ca ions. (3) The activity of the membrane's integral proteins is modulated by signals specific to its particular function. For example, some channels open or close in response to photons or to odorants; thus they function as sensors for light or smell. Pumps respond to the concentrations of the ions they move. Rapid electrical impulse transmission in nerve and muscle is made possible by changes that respond to the transmembrane potential

itself, forming a feedback mechanism. These active mechanisms provide ion-selective means of current's crossing the membrane, both against the concentration or voltage gradients (pumps) or in response to them (channels). While the pumps build up the concentration differences (and thereby the potential energy) that allow events to occur, channels use this energy actively to create the fast changes in voltage and small intense current loops that constitute nerve signal transmission, initiate muscle contraction, and participate in other essential bioelectric phenomena.

Action potentials, of course, are responsible for the external voltages that are measured all over the body: the electrocardiograph, the electroencephalograph, and the electromyography, for example.

There are two excellent sources for action-potential models, one a book article and the other a Web site. Varghese (180), in his article *Membrane Models*, (see above) reviewed a large number of models relating to action potentials (we counted 110 models). A listing will give an idea of the magnitude of the scope of this topic. In addition, it points out the fragmentation of the research in this area. Varghese's article nicely demonstrates the disparateness of the topic, as well as the lack of putting the models together into subsystems, much less systems.

Nerve Cells
Sensory Neurons
Efferent Neurons
Skeletal Muscle Cells
Endocrine Cells
Cardiac Cells
Epithelial Cells
Smooth Muscle
Plant Cells
Simplified Models

Under the heading 'Sensory Neurons', for example, are described.

Rabbit Sciatic Nerve Axons
Myelinated Auditory-Nerve Neuron
Retinal Ganglion Cells
Retinal Horizontal Cells,
Rat Nodose Neurons
Muscle Spindle Primary Endings
Vertebrate Retinal Cone Photoreceptors
Primary and Secondary Sensory Neurons of the Enteric Nervous System
Invertebrate Photoreceptor Neurons
Fly Optic Lobe Tangential Cells
Rat Mesencephalic Trigeminal Neurons
Primary Afferents and Related Efferents
Myelinated I Primary Afferent Neurons

Lloyd and the CellML site (176) have assembled an online repository of physiological system models, many of them related to action potentials. The models all conform

with the CellML Specification (182). They are based on published mathematical models taken from peer-reviewed journals, from conference proceedings, and from textbook-defined metabolic pathways. The group has remained true to the original publications and has not assumed any reaction kinetics or initial values if they were not included in the original publication. All sources of information have been referenced in the model documentation.

These models represent several types of cellular processes, including models of electrophysiology, metabolism, signal transduction and mechanics. To facilitate the process of finding a particular model of interest, the models are grouped into broad subject categories.

The models on the site have been validated to a certain degree. Current validation processes include comparing the equations in the original paper with a PDF of the equations used in the CellML description. As tool development continues, both by the CellML team and by international collaborators, the groups expect to be able to carry a validation of the intent of the models by running simulations and comparing these results with those of the original publication. Presumably, validation of the model itself will ultimately take place.

With hundreds of models available on this site, it is impossible to go into detail. The topics include the following. Note that many of them deal with action potentials. GlucoSim (see above) is on this site, also: Signal Transduction Pathway Models, Metabolic Pathway Models, Cardiac Electrophysiological Models, Calcium Dynamics Models, Immunology Models, Cell Cycle Models, Simplified Electrophysiological Models, Other Cell Type Electrophysiological Models, Smooth and Skeletal Muscle Models, Mechanical Models and Constitutive Laws.

The following are examples of the formats in which a model may be obtained/downloaded.

1. The raw XML.
2. An HTML version for browsing online.
3. A PDF version suitable for printing.
4. A gzipped tarball with the XML and the documentation on the site.
5. A PDF of the equations described in the model generated directly from the CellML description using the MathML Renderer.

Thermal

Temperature control is one of the more impressive achievements in life. In higher forms of life, internal body temperature is maintained at a rather constant level, despite changes in the internal and external environment, to help provide conditions favorable to metabolism and other necessary processes within blood and tissue. Thus, in the human, an internal temperature close to 37 °C is normally maintained by a thermoregulatory feedback system despite large changes in ambient temperature and other environmental factors. It is also a daunting system to model, for many reasons.

Kuznetz (183) was one of the first to use more than 1D in thermal modeling. Previous models had failed to account for temperature distribution in any spatial direction other

than radially outward from the body centerline. The models therefore could not account for nonuniform environmental conditions or nonuniform heat generation from muscles or organs within the body. However, these nonuniform conditions are commonplace and can lead to disparate skin temperatures and heat loss rates on different sides of the same body compartment. Kuznetz' mathematical model of human thermoregulation could predict transient temperature variations in two spatial dimensions, both radially and angularly, as measured from the body centerline. The model thereby could account for nonuniform environments and internal heat generation rates.

Downey and Seagrave (184) developed a model of the human body that integrates the variables involved in temperature regulation and blood gas transport within the CV and respiratory systems. It describes the competition between skin and muscles when both require increased blood flows during exercise and/or heat stress. After a detailed study of the control relations used to predict skin blood flow, four other control relations used in the model were tweaked. Dehydration and complete water replacement were studied during similar environmental and exercise situations. Control relations for skin blood flow and evaporative heat loss were modified, and water balance was added to study how the loss of water through sweat can be limiting. Runoff from sweating as a function of relative humidity was introduced, along with evaporation.

In two papers, Fiala et al. (185,186) developed a dynamic model predicting human thermal responses in different environmental temperatures. The first paper was concerned with the passive system: (1) modeling the human body, (2) modeling heat-transport mechanisms within the body and at its periphery, and (3) the numerical procedure. Emphasis was given to a detailed modeling of heat exchange with the environment: local variations of surface convection, directional radiation exchange, evaporation and moisture collection at the skin, and the non-uniformity of clothing ensembles. Other thermal effects were also modeled: the impact of activity level on work efficacy and the change of the effective radiant body area with posture. From that passive model, they developed an active mathematical model for predicting human thermal and regulatory responses in cold, cool, neutral, warm, and hot environments (186). The active system simulates the regulatory responses of shivering, sweating, and peripheral vasomotion of unacclimatized subjects. The rate of change of the mean skin temperature, weighted by the skin temperature error signal, was identified as governing the dynamics of thermoregulatory processes in the cold. Good general agreement with measured data was obtained for regulatory responses, internal temperatures, and the mean and local skin temperatures of unacclimatized humans for a wide spectrum of climatic conditions and for different activity levels.

Boregawda (187) used a novel approach based on the second law of thermodynamics to investigate the psychophysiology of and to quantify human stress level. Two types of stresses (thermal and mental) were examined. Using his own thermal and psychological stress indices, he implemented a human thermal model based on a finite element

method. With this model, he examined thermal, mental and CV stress in the human body.

Gardner and Martin (188) developed a model of the human thermoregulatory system for normal subjects and burned patients. The human body was split into eleven segments (The Rule of Nines suggests that one can estimate surface areas in the cranial, abdominal, thoracic and extremity regions by multiplying the patient's body surface area by 9%, or a multiple thereof.), each having core, muscle, fat and skin layers. Heat transport through blood flow and conduction were simulated, and surface heat loss was separated into radiative, convective and evaporative components. The model was refined to fit the data through manipulation of heat flow commands and temperature set points controlling sweating and shivering. The model also described the responses of burn patients to skin layer destruction, increased body metabolism and fluid loss. The model shows that the ambient temperature at which sweating occurs increases with the area of burn injury. It has been used to predict optimum environmental temperatures for treatment of patients with burn wounds of varying extent, a critical need.

Aging of Physiological Systems

Geriatric medicine is becoming increasingly important, due to the aging of our population. Physiologists need to understand that physiological function continually changes with age, and that they need to take aging into account in their studies and in their models. Healthcare givers need methods that can teach efficiently and painlessly the complexities involved with aging. Modeling and simulation are ideal for this area. We implemented the anatomy and physiology of aging in BODY Simulation (see PBPM). In the BODY model, we changed >50 patient parameters. The categories changed included anatomical, cardiovascular, and respiratory, as well as hepatic and renal function. Four patients were created: normal, but elderly, patients, aged 65, 75, 85, and 95 years. To evaluate the new patients, we imposed three stresses in the elderly patients and in a young, healthy patient: anesthesia induction, hemorrhage, and apnea. We observed an age-related response to these stresses. In general, we saw a reduced physiological reserve. Again, this model is available as an interactive simulation, no knowledge of mathematics required.

USES FOR MODELS

Please see a list of uses, in the Introduction. One use for models is to substitute as an animal or person in experiments, with the goal of reducing the use of either type of subject in experiments. A control system was developed (189), using three models (190–192). When a control system had been developed with the models, we performed one animal experiment to test the control system. Noting any problems or discrepancies, we returned to the model, tuned up the control system, and repeated an experiment, reiterating between model and animal several times. We estimated that the decrease in animal experiments was 82.5%, from a projected 120–21. Furthermore, the dangerous

experiments were performed on the models, and no animal was sacrificed. Noninvasive methods are less painful and dangerous in patients, and methods that render more accurate the data obtained from these methods are clinically and experimentally valuable. Kjaergaard et al. (193) used a model of pulmonary shunt and ventilation-perfusion mismatch to help them quantify those two variables in patients, using noninvasive methods. The equations and diagrams can be found in the supplementary material to the paper, on the Web (click in the appropriate link, below the abstract).

Mesic et al. (194) used a mechanical lung simulator to simulate specific lung pathologies, to test lung-function equipment, and to instruct users about the equipment. A mathematical model of the respiratory system was interfaced with a model of physical equipment (the simulator, actuators, and the interface electronics) so that one can simulate the whole system. The control system, implemented on a personal computer, allows the user to set parameters.

Our noninvasive measurement theme continues, as we explore the work of Wesseling and his group. To the word noninvasive, we can add another important term, continuous, or continual. For areas where a patient's status can change in a matter of seconds (operating room, intensive care unit, and emergency room, e.g.), monitoring data should be available continuously or continually, and without delay. The work began with the Finapres, a device for noninvasively quantifying an arterial pressure waveform (195). They also developed a method for measuring continual cardiac output from an (invasive) aortic pressure waveform (196,197). Using a model, they could combine the two methods to achieve noninvasive, continual cardiac output from the radial artery (invasive) (198) or finger (noninvasive) (199). The pulse contour method has been extensively and carefully tested with aortic pressures, and it seemed prudent to use this pressure, if at all possible. To convert the less invasive radial pressure or the noninvasive finger pressure into an aortic pressure, Wesseling's group uses a three-element model of aortic input impedance that includes nonlinear aortic mechanical properties and a self-adapting systemic vascular resistance (200). Using the model enhances the accuracy of the less invasive methods (198,201). Another model increases the accuracy of the noninvasive technique even further (202). An inverse model of the averaged distortion models corrects for the pulse-wave distortion occurring between brachial and finger arteries.

Education should be one of the primary uses of physiological systems modeling. To adapt a complex whole-body model to a manikin-based simulator, however, requires considerable time and expense. As far as we can tell, two extant model- and manikin-based simulators exist. Another manikin-based simulator, which did not use a model, did not survive. Several disparate models have been published on the educational uses of one of the simulators (METI). The METI manikin-type simulator uses models based on the excellent models of Beneken, although how much, how detailed and to what extent is difficult to determine. The published models include some intracranial dynamics (203,204), pharmacokinetics and pharma-

codynamics (205) and obstetric cardiovascular physiology (206). The PK-PD model is not a whole-body model, however, and the obstetric model omits the fetal circulation and hence is not realistic. BODY Simulation (see PBPM) uses a very detailed model for education, both clinical and in the basic sciences, and is a screen-based simulator. The best simulator from a purely educational point of view is Gas-Man, another screen-based simulator, developed by Jim Philip (207). As the name implies, the simulation deals only with inhaled anesthetic agents, but the manual and the teaching exercises are superb. The simulation is available for a Macintosh or a PC.

THE PHYSIOME PROJECT

What's next in physiological systems modeling? Hundreds of physiological models have been developed, some very small, some surprisingly large and complex. No one, however, is anywhere near describing human physiology in any reasonable completeness and detail. The physiome project may point the way. Essentially, the physiome project is the successor to the genome project, albeit many times more difficult. The following description of the project is adapted from Bassingthwaighe (208); the original was written in 2000. For MUCH more information, go to (209).

The physiome is the quantitative description of the functioning organism in normal and pathophysiological states. The human physiome can be regarded as the virtual human. Think genome, or proteome. The physiome is built upon the morphome, the quantitative description of anatomical structure, chemical and biochemical composition, and material properties of an intact organism, including its genome, proteome, cell, tissue, and organ structures up to those of the whole intact being. (We understand that the morphome, except for gross anatomy, is still in an early stage.) The physiome project is a multicenter integrated program to design, develop, implement, test and document, archive and disseminate quantitative information, and integrative models of the functional behavior of molecules, organelles, cells, tissues, organs, and intact organisms from bacteria to humans. A fundamental and major feature of the project is the databasing of experimental observations for retrieval and evaluation. Technologies that allow many groups to work together are rapidly being developed. Given a project that is so huge and complex, a particular working group can be expert in only a small part of the overall project. The strategies to be worked out must therefore include how to bring models composed of many submodules together, even when the expertise in each is scattered among diverse institutions, departments, talents and constituencies. Developing and implementing code for large-scale systems has many problems. Most of the submodules are complex, requiring consideration of spatial and temporal events and processes. Submodules have to be linked to one another in a way that preserves mass balance and gives an accurate representation of variables in nonlinear complex biochemical networks with many signaling and controlling pathways. Microcompartmentalization

vitiates the use of simplified model structures. The stiffness of the systems of equations is computationally costly. Faster computation is needed when using models as thinking tools and for iterative data analysis. Perhaps the most serious problem is the current lack of definitive information on kinetics and dynamics of systems, due in part to the almost total lack of databased observations, but also because, although we are nearly drowning in new information being published each day, either the information required for the modeling cannot be found, has never been obtained or is totally irrelevant. Simple things like tissue composition, material properties, and mechanical behavior of cells and tissues are not generally available.

Currently, there are several subprojects, the magnitude of each of which boggles the mind. As the *Economist* put it, Computer organs are not for the technologically faint-hearted (210). The subprojects include the Cardiome Project (211), the Microcirculatory Project (212), the Pulmonary/Respiratory Project (213,214), The Kidney Project (215), and the Coagulation Project (210).

How rapidly and completely can all of this take place? This is an enormously ambitious project, many times more difficult than the genome project. The genome project succeeded relatively quickly for at least two reasons. First, to fill well-defined gaps in knowledge, a huge number of devices automatically churned out mountains of carefully and precisely specified data. Second, industry, sensing that there was gold in the genome, invested (and is still investing) enormous sums of money.

We have several questions and comments regarding the physiome project, questions that might apply to any very large project. The questions are restricted mainly to normal physiology. Disease and normal aging will add to the number and difficulty of the questions. These questions are intended to help sort out the potential problems, difficulties and considerations while the project is still at an early stage.

1. The questions in the physiome project are much more difficult to formulate than those of the Genome Project.
 - (a) Should these questions be formulated formally?
 - (b) If so, who will formulate them?
2. Can or should the physiome project control the data, including the content and structure, back to and including the planning of the experiment that generates the data?
3. Who is going to determine whether the whole-body model works? We worry that it may become like some software (no single person knows every detail about it) what it can do and what it cannot do.
4. How does one handle the flood of new information?
 - (a) How often will a large, multicenter submodel be updated: and who decides?
 - (b) Do new methods for handling the flood of information need to be developed?
 - (c) If so, what?

- (d) What are the methods for validating models and for sensitivity analysis?
 - (e) How will validation and sensitivity analysis proceed?
 - (f) At what stages should validation and sensitivity analysis proceed, for example, every time models are combined? Every 6 months?
5. There will be an enormous library of physiological normals: equations, parameters, and so on.
 - (a) How will one deal with variations from normal? Presumably this will be partly with sensitivity analysis.
 - (b) How much variation from normal will be allowed? In other words, what are the limits on normal: upper and lower?
 - (c) Does one anticipate large variations in normal, from parameter to parameter and from equation to equation?
 - (d) Will clinicians be in on this and other decision processes?
 6. How will one deal with the effects of aging and responses to the environment, including exercise, hypoxia, altitude, and temperature?
 7. The genome project is relatively simple, and mistakes can be relatively easily corrected.
 - (a) Is this the case with the physiome project?
 - (b) How will one deal with errors in the physiome project?
 - (c) If there is one error in one submodel, how will one find that error?
 - (d) How will one determine the effect of errors in a submodel that is a component of the overall model on that larger model: by sensitivity analysis?
 8. Can anyone input data, equations, formulae and models into the project database?
 - (a) If so, who "edits" the deposits into databases, or are they done just ad hoc?
 - (b) If not, is there a gatekeeper?
 - (c) Asked another way, what is the quality control and who is in charge of it?
 - (d) Who is going to determine what finally winds up in the library/database?
 - (e) Who will be in charge of the information/data?
 9. Several computer languages are currently mentioned. Will there ultimately be a single language?
 10. Is there a freely available Web journal for the project? (The Virtual Journal of the Virtual Human)
 - (a) Perhaps the VJVH could be the filter for the information and data, as well as a means for developing standards (see next question).
 11. Standards, if done properly, should help in several areas. Some standards are being developed (216).

- (a) We gather that part of the significant difference among models arises from their being published in different journals.
 - (b) Do common standards exist for the project?
 - (c) Who is responsible for implementing and coordinating generic and specific standards?
12. A very important set of questions involves intellectual philanthropy versus intellectual property.
- (a) Are there any tools, including developmental tools, that are freely available, that is, public domain?
 - (b) The NLM has made the Visible Human data public domain. How much of the physiome database will be public domain and how much private domain?
 - (c) Would dividing the database into multiple public and private sections inhibit the integrity, the wholeness and the usefulness of the database?
 - (d) How will one audit, in one huge model, the amalgamated data from government employees, universities, research institutes and industry?
 - (e) How will one determine credit, cash, brownie points, or whatever for data, equations, models, and so on?
 - (f) The same questions hold for developmental tools.
13. How will ongoing projects fit into the project? How will future projects fit in?
14. What data are required, for each step?
- (a) Who decides what data are required, or do data just appear in the database because they were there?

Excellent reviews on the Physiome Project include (216–219). In addition try an IUPS Web site (220).

EPILOGUE

Over one-half of a century ago, two papers were published in the same year, in the same country. These two papers point the way to the future in physiological systems modeling, given all the enormous amount of models and data pouring in. The authors of one paper went on to win the Nobel Prize. The author of the other committed suicide within two years. Neither knew of the other's existence, and one paper probably went unnoticed, and was certainly misunderstood.

If nothing else, our article has illustrated the need to integrate mathematical biology with experimental biology. To achieve this integration, experimentalists must learn the language of mathematics and dynamical modeling and theorists must learn the language of biology. Hodgkin and Huxley's quantitative model of the nerve action potential and Alan Turing's work on pattern formation in activator–inhibitor systems (221) represent those two languages. These classic studies illustrate two ends of the spectrum in mathematical biology: the detailed-model approach and the minimal-model approach. When combined, they are highly synergistic in analyzing the mechanisms underlying the behavior of complex biological systems. Their

effective integration will be essential for unraveling the physical basis of the mysteries of life. For more detail on this important concept, see the fascinating account by Weiss et al. (222).

ACKNOWLEDGMENTS

The authors are grateful to the American Physiological Society and to the American Society for Biological Chemistry and Molecular Biology for making available PDF files of all issues of their journals. The 1924 Haggard articles were required reading for the senior author, during his residency. Classic and macro physiology, much of which is to be found in the older literature have been emphasized.

The senior author is also grateful to all the mentors in his modeling life. There are so many that they can only be listed and thanked, in more or less chronological order. Avram Goldstein, Aldo Corbascio, Bram Noordergraaf, Isaac Starr, Bob Fleming, Jan Beneken, Karel Wesseling, The late Vince Rideout, Yas Fukui, James Martin, Ken Starke. The senior author is an anesthesiologist, and the bias occasionally shows.

GLOSSARY

CVS	Cardiovascular system
CNS	Central nervous system
ANS	Autonomic nervous system
MAP	Mean arterial pressure
CVP	Central venous pressure
CO	Cardiac output
CBF	Cerebral blood flow
CSF	Cerebrospinal fluid
ICP	Intracranial pressure
LV	Left ventricle
LA	Left atrium
RV	Right ventricle
PV	Pressure volume
SVR	Systemic vascular resistance
avu	Arteriovenous
AV	Atrioventricular
PO ₂	Partial pressure of oxygen
PKPD	Pharmacokinetic/pharmacodynamic
Physiological PKPD	physiologically based pharmacokinetic/pharmacodynamic (PBPKPD!)
PBPM	Physiologically based pharmacological models

Some systems are so familiar that an abbreviation suffices: CVS for cardiovascular system and CNS for central nervous system. A glossary of abbreviations follows for your reference.

PICTURE ARCHIVING AND COMMUNICATION SYSTEMS

KATHERINE ANDRIOLE P.
Harvard Medical School
Boston, Massachusetts

INTRODUCTION AND HISTORICAL OVERVIEW

A picture archiving and communication system (PACS) is a medical image management system, or a collection of electronic technologies that enable the digital or filmless imaging department. In a PACS, images are acquired, stored, and transmitted or distributed digitally, as well as interpreted digitally using what is known as soft copy display.

In the analog world, even images that were created by inherently digital modalities are printed to film for display on a light box or alternator, and for image archival as the legal record where films are stored in large rooms of filed film jackets. Imaging examinations on film must be transported from one location to another by foot for viewing by radiologists and referring clinicians. Films are retrieved and re-archived manually by film library personnel. Using a PACS, images are acquired as digital computer files, stored on computer disks or other digital media, transmitted across computer networks, and viewed and manipulated on computer workstations.

The benefits of PACS are numerous and include rapid and remote data distribution within and between health-care enterprises. Digital archival is more permanent than film with regard to media degradation as well as the problem of lost films. A PACS gives multiple users in distinct locations simultaneous access to the same imaging examinations. Also, the digital nature of the data allows for image manipulation and processing, which may lead to enhanced visualization of radiological features and improved interpretation of imaging studies. The potential impact of using a PACS can be more expedient care, more efficient workflow, and more cost-effective and higher quality care.

PACS and filmless radiology are a better way to practice imaging in medicine today. The number of images per study has grown beyond what is feasible for viewing on film. Still, today, only about 20% of health-care enterprises have implemented PACS.

Picture archiving and communication systems have come about via a convergence of technological and economic factors. The facilitating technologies responsible include a dramatic improvement in computing power, the advancement of network capabilities and storage devices, the development of imaging standards, and systems integration. In the 1990s, PACS applications challenged computer hardware. Today, PACS applications are only a subset of what computers can do.

Early PACS

In 1979, the earliest paper proposing the concept of a PACS was published by Heinz U. Lemke, Ph.D., entitled "Applications of Picture Processing, Image Analysis and Computer Graphics Techniques to Cranial CT Scans" (1). In the early 1970s, M. Paul Capp, M.D., Sol Nudelman, Ph.D., and colleagues at the University of Arizona Health Sciences Center organized a digital imaging group that developed the first digital subtraction angiography (DSA) device that was the precursor to clinical digital imaging. They introduced the notion of a "photoelectronic radiology department" and depicted a system block diagram of the demonstration facility they had built (2).

Samuel J. Dwyer, III, Ph.D. predicted the cost of managing digital diagnostic images in a radiology department (3) and, along with Andre Duerinckx, M.D., Ph.D., organized a landmark conference at which the acronym PACS was coined (4). This meeting, sponsored by the International Society for Photo-Optical Engineering (SPIE), titled "The First International Conference and Workshop on

Picture Archiving and Communications Systems (PACS) for Medical Applications," was held in Newport Beach, CA, January 18–21, 1982, and continues today as the Annual SPIE International Symposium on Medical Imaging. Two panel discussions "Equipment Manufacturers' View on PACS" and "The Medical Community's View on PACS" that took place at the first PACS conference were captured in the proceedings (4). Talk occurred of linking imaging modalities into a single digital imaging network and the recognition that, in order for this linking to be practical, standards would be required. Steven C. Horii, M.D., participated in those beginning discussions and has been instrumental in bringing about the creation and implementation of a standard for digital medical imaging, now known as the Digital Imaging and Communications in Medicine or DICOM Standard.

A number of PACS pioneers have contributed to the advancement of digital medical imaging to its current status through efforts in research and development, design, implementation, testing, analysis, standards creation, and education of the technical and medical communities. In 1982–1983, Dwyer oversaw the building of what is often considered the first PACS. In 1983, the first of numerous papers was presented by H. K. Bernie Huang, D.Sc., FRCR, detailing the PACS efforts at the University of California at Los Angeles, which culminated years later in a clinically operational filmless radiology department (5). G. James Blaine, D.Sc., and R. Gilbert Jost, M.D., at the Washington University School of Medicine, focused their efforts on the development of utilities enabling PACS research and development (6). In the mid- to late-1980s, several researchers described their prototype PACS hardware and software efforts (7–10).

Similar activities were taking place in Europe and Asia. Hruby opened a completely digital radiology department in the Danube Hospital in Vienna in 1990, setting the tone for the future (11). Several academic radiology departments in the United States began working with major vendor partners to further the technology and its clinical implementation. Such academic–industry collaborations continue the advancement of PACS today.

Standards

The development of standards in medical imaging is one of the facilitating factors that has enabled PACS to mature and become more widely used. DICOM (Digital Imaging and Communications in Medicine) (12) along with several other integration standards, has been one of the most important accomplishments for PACS. DICOM is a standard that was created to promote an open architecture for imaging systems, allowing interoperability between systems for the transfer of medical images and associated information. As an exchange protocol, it was designed to bridge differing hardware devices and software applications.

With the increasing use of computers in clinical applications, and with the introduction of digital subtraction angiography and computed tomography (CT) in the 1970s, followed by other digital diagnostic imaging modalities, the American College of Radiology (ACR) and the

National Electrical Manufacturers Association (NEMA) recognized the emerging need for a standard method for transferring images and associated information between devices manufactured by the various vendors (12). These devices produced a variety of digital image formats. The push by the radiological community for a standard format across imaging devices of different models and makes began in 1982. ACR and NEMA formed a joint committee in 1983 to develop a standard to promote communication of digital image information, regardless of device manufacturer. It was felt that this committee would facilitate the development and expansion of picture archiving and communication systems that could also interface with other hospital information systems and allow the creation of diagnostic information databases that could be interrogated by a wide variety of geographically distributed devices.

The ACR-NEMA Standard version 1.0 was published in 1985. Two revisions followed, one in October 1986 and the second in January 1988 as version 2.0. It included version 1.0, the published revisions, and additional revisions. ACR-NEMA 2.0 consisted of a file header followed by the image data. The file header contained information relevant to the image, such as matrix size or number of rows and columns, pixel size, gray-scale bit depth, and so on, as well as information about the imaging device and technique (i.e., Brand X CT scanner, acquired with contrast). Patient demographic data, such as name and date of birth, were also included in the image header. The ACR-NEMA 2.0 standard specified exactly where in the header each bit of information was to be stored, such that the standard required image information could be read by any device, simply by going to the designated location in the header. Version 2.0 also included new material to provide command support for display devices, to introduce a new hierarchy scheme to identify an image, and to add data elements for increased specificity when describing an image. These standards publications specified a hardware interface, a minimum set of software commands, and a consistent set of data formats. Data included patient demographic information as well as imaging parameters. This standard unified the format of imaging data but functioned only as a point-to-point procedure, not including a networking communications protocol until later versions.

In 1994, at the Radiological Society of North America (RSNA) Meeting, a variety of imaging vendors participated in an impressive demonstration of the new and evolving imaging standard (ACR-NEMA 3.0). Participants attached their devices to a common network and transmitted their images to one another. In addition to the standard image format of ACR-NEMA 2.0, the DICOM standard included a network communications protocol or a common language for sending and receiving images and relevant data over a network.

Today, this standard, which is currently designated Digital Imaging and Communications in Medicine (DICOM), embodies a number of major enhancements to previous versions of the ACR-NEMA Standard, the first that is applicable to a networked environment. The original ACR-NEMA Standard included a well-defined format for the image data but worked only in point-to-point config-

urations. In order to function in a networked environment, a Network Interface Unit (NIU) was required. Operation in a networked environment is supported today using the industry standard networking protocol TCP-IP (transfer communication protocol - Internet protocol). Thus, in addition to the format of the data being exchanged between medical imaging devices, the DICOM Standard also specifies how the devices themselves should communicate using simple commands such as Find, Get, Move, Send, and Store. These commands operate on objects such as images and text, which are formatted in terms of groups and elements. The hierarchy of data is of the form patient, study, series or sequence, and image.

DICOM specifies, through the concept of service classes, the semantics of commands and associated data, and it also specifies levels of conformance. The DICOM standard language structure is built on information objects (IO), application entities (AE), and service class users (SCU) and providers (SCP). Information objects include, for example, the image types, such as CT, MRI, and CR. The application entities include the devices, such as a scanner, workstation, or printer. The service classes (SC*) define an operation on the information object via service object pairs (SOP) of IO and SCU and SCP. The types of operations performed by an SCU-SCP on an IO include storage, query-retrieve, verification, print, study content notification, study content notification and patient, and study and results management. An example DICOM-formatted message is written in terms of a tag (consisting of a group and an element) followed by the length of the tag, followed by the value: 0008,0020-8-20050402 represents group 8, element 20, which corresponds to the study date given as an 8 character field. DICOM is a continuously evolving standard with significant updates yearly.

The information technologies most familiar to radiology departments are PACS and Radiology Information Systems (RIS). PACS or image management systems typically perform the functions of image acquisition, distribution, display, and archival. Often, separate systems exist for primary interpretation in the radiology department and for use enterprise-wide by nonradiologist clinicians. The RIS typically maintains radiology-specific data, such as imaging examination orders, reports, and billing information.

Although implementation of either one or both of these systems can improve workflow and reduce operating costs, the elimination of film and paper from the practice of radiology is not easily realized without integrating the functions performed by several other information technologies. These systems include hospital information systems (HIS), Computerized Physician Order-Entry (CPOE) Systems, Report Generation Systems, Decision Support Systems, and Case-Based Teaching Files. Together, these systems make up the electronic medical record (EMR).

Several of these systems are more widely known to the health-care enterprise outside of diagnostic imaging departments. They, none-the-less, contain data essential to high quality low cost radiological practice. The value these systems can bring to medical imaging in the clinical enterprise is high, but they must be seamlessly integrated. Including several features, such as single sign-on, electronic

master patient index, and context sensitivity, can help make these information systems tools and technologies most useful to radiology.

An effort known as Integrating the Healthcare Enterprise (IHE) provides a framework using existing standards, such as DICOM and Health Level 7 (HL7), to facilitate intercommunications among these disparate systems and to optimize information efficiency. The IHE is a joint effort of the Radiological Society of North America (RSNA) and the Healthcare Information and Management Systems Society (HIMSS) begun in 1998 to more clearly define how existing standards should be used to resolve common information system communication tasks in radiology.

The IHE technical framework defines a common information model and a common vocabulary for systems to use in communicating medical information. It specifies exactly how the DICOM and HL7 standards are to be used by the various information systems to perform a set of well-defined transactions that accomplish a particular task. The original seven tasks facilitated by the IHE include scheduled workflow, patient information reconciliation, consistent presentation of images, presentation of grouped procedures, access to radiology information, key image notes, and simple image and numeric reports. Profiles continue to be added yearly to the framework, enhancing its value in integrating information systems in a health-care environment.

Architectures

Two basic architectures are used in PACS today, distributed or cached and centralized or cacheless depicted in Figs. 1a and 1b, respectively. Data is acquired into the PACS in the same manner for both architectures, from the imaging modality via a DICOM sent to a network gateway. Demographic data is verified by interfacing to the radiology or hospital information system (RIS-HIS) through an IS gateway. Studies are permanently archived by a DICOM store to an electronic archive device.

In a distributed system, images and other relevant data are automatically routed to the workstation(s) where the studies are expected to be viewed and cached or stored on the local display station disk. The best-distributed PACS also prefetch relevant prior examinations from the long-term archive and automatically route them to the pertinent display for immediate access to comparison images. Studies not automatically routed to a workstation can be queried for and retrieved on request.

In a centralized system, images remain on a large central server and are only sent to the workstation when they are called up for display. In this query-on-demand architecture, data is retrieved instantaneously into memory for viewing and manipulation. Images are never stored on the local display station disk, thus centralized systems are also known as cacheless.

A centralized architecture is easier to implement and maintain and uses a simple on-demand data access model, but also has a single point-of-failure in the central server component. A cacheless system is also bandwidth-limited, requiring a fast network connection from display stations

Figure 1. (a) Distributed versus (b) centralized PACS architectures.

to the central server. The distributed architecture requires more complex workflow logic such as autorouting and prefetching of data to implement. However, distributed PACS may have more functionality and may be more easily scalable than centralized systems. Early PACS were predominately distributed systems. With the increasing availability of high bandwidth networks and large amounts of inexpensive storage media, most PACS today follow the centralized architecture. Web-based PACS typical of today's systems are a specialized subset of centralized architectures. Future PACS may evolve to be a combination of both distributed architectures and centralized architectures, encompassing the best of each design.

If a PACS operates with a cached architecture in which data is automatically distributed to and stored at the display station, then the online storage capabilities should include space for maintaining all the pertinent examinations for a given episode of current care, (i.e., three days for outpatients and six days for inpatients). Space for prefetched relevant historical examinations should also be included in the anticipated storage requirements.

If the PACS operates as a cacheless centralized system, then it is important to have adequate capacity to store a patient's clinical encounter on the server. In this case, it is important to have large amounts of online RAID (redundant array of independent disks—see section on RAID below) at the central server instead of large amounts of local storage at each display station. RAID capacity should also encompass relevant prior examinations prefetched to the server.

KEY COMPONENTS AND ESSENTIAL FEATURES

Image Acquisition

Digital acquisition of data from the various imaging modalities for input to a PACS is the first step to eliminating film in medical imaging. Essential features for successful clinical implementation include conformance with the DICOM standard, radiology information system – hospital information system (RIS-HIS) interfacing, and workflow integration Quality assurance (QA) and quality control (QC) and troubleshooting problems occurring specifically at image acquisition are also critical as these problems affect the integrity of data in the archive.

Integration with PACS. Image acquisition is the first point of data entry into a PACS system and, as such, errors generated here can propagate throughout the system, adversely affecting clinical operations. General predictors for successful incorporation of image acquisition devices into a digital imaging department include the following: ease of device integration into the established daily workflow routine of the clinical environment, high reliability and fault-tolerance of the device, simplicity and intuitiveness of the user interface, and device speed (13). The integration of modalities with PACS and information systems using the DICOM modality worklist feature (see below) can reduce the number of patient demographic errors and the number of cases that are inappropriately or unspecified and therefore not archiveable, which also ensures the correctness of permanently archived information.

DICOM. Imaging modality conformance with the DICOM standard is critical. DICOM consists of a standard image format as well as a network communications protocol. Compliance with this standard enables an open architecture for imaging systems, bridging hardware and software entities, allowing interoperability for the transfer of medical images and associated information between disparate systems.

The DICOM standard is used, for example, to negotiate a transaction between a compliant imaging modality and a compliant PACS workstation. The scanner notifies the workstation, in a language both understand, that it has an image study to send to it. The workstation replies to the modality when it is ready to receive the data. The data is sent in a format known to all, the workstation acknowledges receipt of the image, and then the devices end their negotiation. Data is formatted in terms of groups and elements. Group 8, for example, pertains to image identification parameters (such as study, series, and image number) and Group 10 includes patient demographics (such as patient name, medical record number, and date of birth).

Prior to DICOM, the acquisition of digital image data and relevant information was extremely difficult, often requiring separate hardware devices and software programs for different vendors' products, and even for different models of devices made by the same manufacturer because each vendor used their own proprietary data for-

mat and communication's protocol. Most of the major manufacturers of imaging devices currently comply with the DICOM standard, thus greatly facilitating an open systems architecture consisting of multivendor systems. For many legacy devices purchased prior to the establishment of DICOM, an upgrade path to compliance can be performed. For those few devices that do not yet meet the standard, interface boxes consisting of hardware equipment and software programs that convert the image data from the manufacturer's proprietary format to the standard form are available.

RIS-HIS Interfacing for Data Verification. Equally essential, particularly at acquisition, is integrating the radiology information system (RIS) or hospital information system (HIS) with the PACS, which greatly facilitates input of patient demographics (name, date, time, medical record number (MRN) to uniquely identify a patient, accession number (AccNum) to uniquely identify an imaging examination, exam type, imaging parameters, etc.) and enables automatic PACS data verification, correlation, and error correction with the data recorded in the RIS-HIS. Most imaging modalities are now tightly coupled with the RIS, providing automatic downloading of demographic information from the RIS via barcode readers or directly to the scanner console (via modality worklist capability) and, hence, to the DICOM header. This coupling eliminates the highly error-prone manual entry of data at acquisition.

HL7 is the RIS-HIS standard, and compliance with HL7 is desirable. RIS-HIS databases are typically patient-centric, enabling query and retrieval of information by the patient and study, series, or image data hierarchy. Integration of RIS-HIS data with the PACS adds intelligence to the system, helping to move data around the system based on "how, what data should be delivered where and when", automating the functions performed traditionally by the film librarian.

Modality Worklist. Many vendors now provide the capability to download RIS-HIS schedules and worklists directly to the imaging modality, such as most computed tomography (CT), magnetic resonance imaging (MRI), digital fluoroscopy (DF), and ultrasound (US) scanners. In these circumstances, the imaging technologist need only choose the appropriate patient's name from a list on the scanner console monitor (i.e., by pointing to it on a touch-screen pad), and the information contained within the RIS-HIS database will be downloaded into the PACS header and associated with the image data for that patient examination.

The general DICOM model for acquisition of image and relevant data from the imaging modality involves the modality device acting as a SCU, which provides the data, and storing it to a SCP, which provides the service: devices such as a PACS acquisition gateway or an image display workstation. In the modality worklist function, however, the image device receives the pertinent patient demographics and image study information from a worklist server, such as a PACS- RIS- or RIS-HIS-interfaced device.

Two modes exist for accomplishing the RIS-HIS data transfer to the imaging modality. The first involves data,

being transferred automatically to the modality based on the occurrence of an event trigger, such as an examination being scheduled or a patient having arrived. The second method involves a query from the modality to the RIS-HIS or some other information system that holds relevant data, such as an electronic order-entry system or even some PACS databases, which may be initiated by entry of some identifier at the modality, such as bar coding of the study accession number or the patient medical record number from the scheduling card. This method then initiates a request for the associated RIS-HIS information (patient name, date of birth) to be sent from the worklist server on demand.

The benefits of the DICOM modality worklist cannot be overstated. Incorrectly (manually) entered patient demographic data, such as all the permutations of patient name (i.e., James Jones, J Jones, Jones J) can result in mislabeled image files and incomplete study information and, as such, is crucial to maintaining the integrity of the PACS database. Furthermore, the improvements in departmental workflow efficiency and device usability are greatly facilitated by modality worklist capabilities. For those few vendors not offering DICOM modality worklist for their imaging devices, several interface or broker boxes are available that interconnect PACS to RIS-HIS databases translating DICOM to HL7 and vice versa. Figure 2 diagrams an example of how RIS, HIS, and PACS systems might interact upon scheduling an examination for image acquisition into a PACS (14).

Acquisition of the Native Digital Cross-Sectional Modalities. Image acquisition from the inherently digital modalities, such as CT, MRI, and US, should be a direct digital DICOM capture. Direct digital interfaces allow capture and transmission of image data from the modality at the full spatial resolution and full bit depth of gray scale inherent to the modality, whereas the currently outdated analog (video) frame grabbers digitize the video signal voltage output going to an image display, such as a scanner console monitor. In the frame-grabbing method, as in printing an image to film, the image quality is limited

Figure 2. Diagram of how RIS, HIS, and PACS systems might interact upon scheduling an examination for image acquisition into a PACS.

Table 1. The Commonly PACS-Interfaced Cross-Sectional Modalities and their Inherent File Sizes

Modality	Image Matrix Size	Grayscale Bit Depth
Computed Tomography (CT)	512 × 512 pixels	12 – 16 bits
Digital Angiography & (RA)	512 × 512 pixels or	8 – 12 bits
Digital Fluoroscopy (DF)	1024 × 1024 pixels or 2048 × 2048 pixels	
Magnetic Resonance Imaging (MRI)	256 × 256 pixels	12 – 16 bits
Nuclear Medicine Images (NUC)	64 × 64 pixels or 128 × 128 pixels or 256 × 256 pixels	8 – 32 bits
Ultrasound (US)	64 × 64 pixels or 128 × 128 pixels	16 – 32 bits

by the process to just 8 bits (or 256 gray values), whereas most modalities have the capability to acquire in 12, 16, or even 32 bits for color data. Capture of only 8 bits may not allow viewing in all the appropriate clinical windows and levels or contrast and brightness settings and is, therefore, not optimal.

For example, when viewing a CT of the chest, one may wish to view in lung window and level settings and in mediastinal and bone windows and levels. Direct capture of the digital data will allow the viewer to dynamically window and level through each of these settings on-the-fly (in real time) at the softcopy display station. However, to view all appropriate window and level settings on film, several copies of the study would have to be printed, one at each window and level setting. If one performs the analog acquisition or frame grabbing of the digital data, the viewer can only window and level through the 8 bits captured, which may not be sufficient. Thus, direct capture of digital data from the inherently digital modalities is the preferred method of acquisition. Table 1 lists the cross-sectional modalities commonly interfaced to PACS along with their inherent file sizes and bit depths.

Acquisition of Projection Radiography. Methods for digital image acquisition of the conventional projection X ray include computed radiography (CR) scanners or imaging with photostimulable or storage phosphors, digitization of existing analog film, and digital radiography (DR) devices. Digital acquisition of images already on film can be accomplished using a variety of image digitization devices or film scanners, including the no longer used analog video cameras with analog-to-digital converters (ADC), digital cameras, charge-coupled devices (CCD), and laser scanners. Both CR and DR are replacement methods for capturing conventional screen-film projection radiography.

Film Digitizers. Film digitizers will still be necessary even in the all digital or filmless imaging department, so that film images from outside referrals lacking digital capabilities can be acquired into the system and viewed digitally. Film digitizers convert the continuous optical

density values on film into a digital image by sampling at discrete evenly spaced locations and quantizing the transmitted light from a scan of the film into digital numbers. Several types of film digitizers exist today, with some used more frequently than others in PACS and teleradiology applications.

The analog video camera with ADC, or camera on a stick, was used in low cost, entry-level teleradiology applications but is no longer used in PACS applications today because of its manual operation. The analog video camera requires an illumination source and careful attention to lens settings, focus, f-stop, and so on. In addition, it has a maximum resolution of 1024 by 1024 by 8 bits (256 grays), thus limiting the range of window and level, or contrast and brightness values, the resulting digital image can be displayed in. Digital cameras produce a digital signal output directly from the camera at a maximum resolution of 2048 by 2048 by 12 bits (4096 grays) but are still infrequently used in PACS due to their high cost.

More commonly used are film scanners such as the CCD and laser scanners sometimes called flat-bed scanners. CCD scanners use a row of photocells and uniform bright light illumination to capture the image. A lens focuses the transmitted light from the collimated, diffuse light source onto a linear CCD detector, and the signal is collected and converted to a digital electronic signal via an ADC. CCD scanners have a maximum resolution of 4096 by 4096 by 8–12 bits, but they have a narrow film optical density range to which they can respond. CCD scanners have been used in high-end teleradiology or entry-level in-house film distribution systems, such as image transmission to the intensive care units (ICUs).

The laser scanner or laser film digitizer uses either a helium-neon (HeNe) gas laser or a solid-state diode laser source. The laser beam is focused by lenses and directed by mirror deflection components, and the light transmitted through the film is collected by a light guide, its intensity detected by a photomultiplier tube, converted to a proportional electronic signal, and digitized in an ADC. Laser scanners use a fine laser beam of generally variable or adjustable spot sizes down to 50 μm (producing an image sharpness of approximately 10 line pairs per millimeter). They have a maximum spatial resolution of 4096 by 5120 and a grayscale resolution of 12 bits, and can accommodate the full optical density range of film. They are semi- or fully-automatic in operation and are currently the scanner of choice for PACS applications even though they are often more expensive than CCD scanners.

Computed Radiography (CR). Computed Radiography (CR) refers to projection X-ray imaging using photostimulable or storage phosphors as the detector. In this modality, X rays incident upon a photostimulable phosphor-based image sensor or imaging plate produce a latent image that is stored in the imaging plate until stimulated to luminesce by laser light. This released light energy can be captured and converted to a digital electronic signal for transmission of images to display and archival devices. Unlike conventional screen-film radiography in which the film functions as the imaging sensor, or recording medium, as well as the display device and storage media, CR eliminates film from

the image recording step, resulting in a separation of image capture from image display and image storage. This separation of functions potentiates optimization of each of these steps individually. In addition, CR can capitalize on features common to all digital images, namely, electronic transmission, manipulation, display, and storage of radiographs (15).

Technological advances in CR over time have made this modality widely accepted in digital departments. Hardware and software improvements have occurred in the photostimulable phosphor plate, in image reading-scanning devices, and in image processing algorithms. Overall reduced cost of CR devices, as well as a reduction in the cost and increased utility of image display devices, have contributed to the increased acceptance of CR as a viable digital counterpart to conventional screen-film projection radiography.

Review of the Fundamentals

Process Description. ACR system consists of a screen or plate of a stimulable phosphor material that is usually contained in a cassette and is exposed in a manner similar to the traditional screen-film cassette. The photostimulable phosphor in the imaging plate (IP) absorbs X rays that have passed through the patient, "recording" the X-ray image. Like the conventional intensifying screen, CR plates produce light in response to an X ray, at the time of exposure. However, storage phosphor plates have the additional property of being capable of storing some of the absorbed X-ray energy as a latent image. Plates are typically made of an europium-doped barium-fluoro-halide-halide crystallized matrix. Electrons from the dopant ion become trapped just below the conduction band when exposed to X rays. Irradiating the imaging plate at some time after the X ray exposure with red or near-infrared laser light liberates the electrons into the conduction band, stimulating the phosphor to release some of its stored energy in the form of green, blue, or ultraviolet light—the phenomenon of photostimulable luminescence. The intensity of light emitted is proportional to the amount of X ray absorbed by the storage phosphor (16).

The readout process uses a precision laser spot-scanning mechanism in which the laser beam traverses the imaging plate surface in a raster pattern. The stimulated light emitted from the IP is collected and converted into an electrical signal, with optics coupled to a photomultiplier tube (PMT). The PMT converts the collected light from the IP into an electrical signal, which is then amplified, sampled to produce discrete pixels of the digital image, and sent through an ADC to quantize the value of each pixel (i.e., a value between 0 and 1023 for a 10 bit ADC or between 0 and 4095 for a 12 bit ADC).

Not all of the stored energy in the IP is released during the readout process. Thus, to prepare the imaging plate for a new exposure, the IP is briefly flooded with high intensity (typically fluorescent) light. This erasure step ensures removal of any residual latent image.

A diagram of the process steps involved in a CR system is shown in Fig. 3. In principle, CR inserts a digital computer between the imaging plate receptor (photostimulable phosphor screen) and the output film. This digital

Figure 3. The image production steps involved in CR. The imaging plate is exposed to X rays, read out by a laser scanning mechanism, and erased for reuse. A light guide collects the photostimulated luminescence and feeds it to a photomultiplier tube (PMT) that converts the light signal to an electrical signal. Amplification, logarithmic conversion, and analog-to-digital conversion produce the final digital signal that can be displayed on a cathode ray tube monitor or sent to a laser printer for image reproduction on film.

processor can perform a number of image processing tasks including compensating for exposure errors, applying appropriate contrast characteristics, enhancing image detail, and storing and distributing image information in digital form.

System Characteristics. One of the most important differences between CR and screen-film systems is in exposure latitude. The response of a digital imaging system relates the incident X ray exposure to the resulting pixel value output. System sensitivity is the lowest exposure that will produce a useful pixel value, and the dynamic range is the ratio of the exposures of the highest and lowest useful pixel values (17). Storage phosphor systems have extremely wide exposure latitude. The wide latitude of storage phosphor systems, and the effectively linear detector characteristic curve, allows for a wider range of exposure information to be captured in a single image than is possible with any screen-film system. In addition, the wide dynamic range of CR allows it to be used under a broad range of exposure conditions without the need for changing the basic detector, also making CR an ideal choice for applications in which exposures are highly variable or difficult to control, as in portable or bedside radiography. Through image processing, CR systems can usually create a diagnostic image out of under- or over-exposures via appropriate look-up table correction. In the screen-film environment, such under- or over-exposures might have necessitated retakes and additional exposure to the patient.

Dose requirements of a medical imaging system depend on the system's ability to detect and convert the incoming signal into a usable output signal. It is important to stress that CR systems are not inherently lower dose systems than screen-film. In fact, several studies have demonstrated a higher required exposure for CR to achieve equivalent optical density on screen-film (18,19). However, the wider latitude of storage phosphor systems makes

them much more forgiving of under- or over-exposure. As in any digital radiography system, when dose is decreased, the noise due to quantum mottle increases (20). Reader tolerance of this noise tends to be the limiting factor on the lowest acceptable dose.

In some clinical situations, the radiologist may feel comfortable in lowering the exposure technique factor to reduce dose to the patient, such as in pediatric extremity X-ray exams. In others, such as imaging the chest of the newborn, one may wish to increase exposure to reduce the more visible mottle (at lower doses) to avoid mistaking the noise over the lungs as an indication of pulmonary interstitial emphysema, for example. CR systems are signal-to-noise-limited (SNR-limited), whereas screen-film systems are contrast-limited.

Image Quality. DQE: Objective descriptors of digital image quality include detective quantum efficiency (DQE), which is a measure of the fidelity with which a resultant digital image represents the transmitted X-ray fluence pattern (i.e., how efficiently a system converts the X-ray input signal into a useful output image), and includes a measure of the noise added (17). Also taken into account are the input/output characteristics of the system and the resolution response of unsharpness or blur added during the image capture process. The linear, wide-latitude input/output characteristic of CR systems relative to screen-film leads to a wider DQE latitude for CR, which implies that CR has the ability to convert incoming X-ray quanta into "useful" output over a much wider range of exposures than can be accommodated with screen-film systems (20).

Spatial Resolution: The spatial resolution response or sharpness of an image capture process can be expressed in terms of its modulation transfer function (MTF), which, in practice, is determined by taking the Fourier Transform of the line spread function (LSF) and relates input subject contrast to imaged subject contrast as a function of spatial frequency (17). The ideal image receptor adds no blur or broadening to the input LSF, resulting in an MTF response of one at all spatial frequencies. A real image receptor adds blur, typically resulting in a loss of MTF at higher spatial frequencies.

The main factors limiting the spatial resolution in CR, similar to screen-film systems, is X-ray scattering within the phosphor layer. However, it is the scattering of the stimulating beam in CR, rather than the emitted light as in screen-film, that determines system sharpness (20,21). Broadening of the laser light spot within the IP phosphor layer spreads with the depth of the plate. Thus, the spatial resolution response of CR is largely dependent on the initial laser beam diameter and on the thickness of the IP detector. The reproducible spatial frequency of CR is also limited by the sampling used in the digital readout process. The spatial resolution of CR is less than that of screen-film, with CR ranging from 2.5 to 5 line pairs per millimeter (lp/mm) using a 200 μm laser spot size and a digital matrix size of approximately 2,000 by 2,500 pixels versus the 5–10 lp/mm or higher spatial resolution of screen-film.

Finer spatial resolution can technically be achieved today with the ability to tune laser spot sizes down to

50 μm or less. However, the image must be sampled more finely (approximately 4,000 by 5,000 pixels) to achieve 10 lp/mm. Thus, a tradeoff exists between the spatial resolution that can technically be achieved and the file size to practically transmit and store. Most general CR examinations are acquired using a 200 μm laser spot size and a sampling of 2 k by 2.5 k pixels. For examinations requiring very fine detail resolution, such as in mammography, images are acquired with a 50 μm laser spot size and sampled at 4 k by 5 k pixels.

Contrast Resolution: The contrast or gray-scale resolution for CR is much greater than that for screen-film. Note that because overall image quality resolution is a combination of spatial and gray-scale resolution, the superior contrast resolution of CR can often compensate for its lack of inherent spatial resolution. By manipulating the image contrast and brightness, or window and level values, respectively, small features often become more readily apparent in the image, which is analogous to “bright-lighting” or “hot-lighting” a bone film, for example, when looking for a small fracture. The overall impression is that the spatial resolution of the image has been improved when, in fact, it has not changed—only the contrast resolution has been manipulated. More work needs to be done to determine the most appropriate window and level settings with which to initially display a CR image. Lacking the optimum default settings, it is often useful to “dynamically” view CR softcopy images with a variety of window and level settings.

Noise: The types of noise affecting CR images include X-ray dose-dependent noise and fixed noise (independent of X-ray dose). The dose-dependent noise components can be classified into X-ray quantum noise, or mottle, and light photon noise (21). The quantum mottle inherent in the input X-ray beam is the limiting noise factor, and it develops in the process of absorption by the imaging plate, with noise being inversely proportional to the detector X-ray dose absorption. Light photon noise occurs in the process of photoelectric transmission of the photostimulable luminescence light at the surface of the PMT.

Fixed-noise sources in CR systems include IP structural noise (the predominant factor), noise in the electronics chain, laser power fluctuations, quantization noise in the analog-to-digital conversion process, and so on (20,21). IP structural noise develops from the nonuniformity of phosphor particle distribution, with finer particles providing noise improvement. Note that for CR systems, it is the noise sources that limit the DQE system latitude, whereas in conventional X-ray systems, the DQE latitude is limited by the narrower exposure response of screen-film.

Comparison with Screen-Film: The extremely large latitude of CR systems makes CR more forgiving in difficult imaging situations, such as portable examinations, and enables decreased retake rates for improper exposure technique, as compared with screen-film. The superior contrast resolution of CR can compensate in many cases for its lesser spatial resolution. Cost savings and improved radiology departmental workflow can be realized with CR and the elimination of film for projection radiographs.

Available CR Systems.

Historical Perspective. Most of the progress in storage phosphor imaging has been made since World War II (22). In 1975, Eastman Kodak Company (Rochester, NY) patented an apparatus using infrared-stimulable phosphors or thermoluminescent materials to store an image (23). In 1980, Fuji Photo Film (Tokyo, Japan) patented a process in which photostimulable phosphors were used to record and reproduce an image by absorbing radiation and then releasing the stored energy as light when stimulated by a helium-neon laser (24). The emitted phosphor luminescence was detected by a PMT, and the electronic signal produced reconstructed the image.

Fuji was the first to commercialize a storage phosphor-based CR system in 1983 (as the FCR 101) and published the first technical paper (in Radiology) describing CR for acquiring clinical digital X-ray images (25). The central processing type second-generation scanners (FCR 201) were marketed in 1985 (21). Third-generation Fuji systems marketed in 1989 included distributed processing (FCR 7000) and stand-alone (AC-1) types (21). Fuji systems in the FCR 9000 series are improved, higher speed, higher performance third-generation scanners. Current Fuji systems include upright chest units, CR detectors in wall and table buckeyes, multiplate autoloaders, and more compact stand-alone units.

In 1992, Kodak installed its first commercial storage phosphor reader (Model 3110) (16). Later models include autoloader devices. In 1994, Agfa-Gevaert N.V. (Belgium) debuted its own CR system design (the ADC 70) (26). In 1997, Agfa showed its ADC Compact with greatly reduced footprint. Agfa also introduced a low cost, entry-level single-plate reader (the ADC Solo) in 1998, appropriate for distributed CR environments such as clinics, trauma centers, and ICUs. In 1998, Lumisys presented its low cost, desktop CR unit (the ACR 2000) with manual-feed, single-plate reading. Numerous desktop units have been introduced including the Orex CR. Konica Corp. debuted its own device (XPress) in 2002 and, later, the Regius upright unit, both of which have relatively fast scan times (at 40 and 16 s cycle times, respectively).

Many companies have been involved in CR research and development, including N.A. Philips Corp.; E.I. DuPont de Nemours & Co.; 3M Co.; Hitachi, Ltd.; Siemens AG; Toshiba Corp.; General Electric Corp.; Kasei Optonix, Ltd.; Mitsubishi Chemical Industries, Ltd.; Nichia Corp.; GTE Products Co.; and DigiRad Corp. (20).

Technological Advances. Major improvements in the overall CR system design and performance characteristics include a reduction in the physical size of the reading/scanning units, increased plate-reading capacity per unit time, and better image quality. These advances have been achieved through a combination of changes in the imaging plates themselves, in the image reader or scanning devices, and in the application of image processing algorithms to affect image output.

The newer imaging plates developed for the latest CR devices have higher image quality (increased sharpness) and improved fading and residual image characteristics. Higher image quality has resulted from several modifications

in the imaging plate phosphor and layer thickness. Smaller phosphor grain size in the IP (down to approximately $4\ \mu\text{m}$) diminishes fixed noise of the imaging plate, whereas increased packing density of phosphor particles counteracts a concomitant decrease in photostimulable luminescence (21). A thinner protective layer is used in the plates tending to reduce X-ray quantum noise and, in and of itself, would improve the spatial resolution response characteristics of the plates as a result of diminished beam scattering. However, in the newest IPs, the quantity of phosphor coated onto the plate is increased for durability purposes, resulting in the same response characteristic of previous imaging plates (27).

An historical review of CR scanning units chronicles improved compactness and increased processing speed. The first Fuji unit (FCR 101) from 1983 required roughly $6\ \text{m}^2$ of floor space to house the reader and could only process about 45 plates per hour, whereas today's Fuji models as well as other vendor's devices occupy less than $1\ \text{m}^2$ and can process over 110 plates per hour, which represents a decrease in apparatus size by a factor of approximately one-sixth and an increase in processing capacity of roughly 2.5 times. Desktop models reduce the physical device footprint even further.

CR imaging plate sizes, pixel resolutions, and their associated digital file sizes are roughly the same across manufacturers for the various cassette sizes offered. For example, the 14" by 17" (or 35 cm by 43 cm metric equivalent) plates are read with a sampling rate of 5–5.81 pixels per mm, at a digital image matrix size of roughly 2 k by 2 k pixels (1760 by 2140 pixels for Fuji (21) and 2048 by 2508 pixels for Agfa and Kodak (16)). Images are typically quantized to 12 bits (for 4096 gray levels). Thus, total image file sizes range from roughly 8 megabytes (MB) to 11.5 MB. The smaller plates are scanned at the same laser spot size ($100\ \mu\text{m}$), and the digitization rate does not change; therefore, the pixel size is smaller (16). The 10" by 12" (24 cm by 30 cm) plates are typically read at a sampling rate of 6.7–9 pixels per millimeter (mm) and the 8" by 10" (18 cm by 24 cm) plates are read at 10 pixels per mm (16,21).

Cassetteless CR devices have been introduced in which the detector is incorporated into a chest unit, wall, or table buckey to speed throughput and facilitate workflow much like DR devices do. Dual-sided signal collection capability is available by Fuji, increasing overall signal-to-noise. Agfa has shown a product in development (ScanHead CR) that stimulates and reads out the imaging plate line-by-line, as opposed to the point-by-point scanning that occurs in most CR devices today. Increased speed (5 s scan time) and higher DQE have been demonstrated. In addition, needle phosphors have been explored as a possible replacement to powder phosphors, having shown improved spatial resolution and DQE.

Image Processing Algorithms. Image processing is performed to optimize the radiograph for output display. Each manufacturer has a set of proprietary algorithms that can be applied to the image for printing on laser film or display initially only on their own proprietary workstations. Prior to the DICOM standard, only the raw data

could be directly acquired digitally. Therefore, to attain the same image appearance on other display stations, the appropriate image processing algorithms (if known) had to be implemented somewhere along the chain from acquisition to display. Now image processing parameters can be passed in the DICOM header and algorithms applied to CR images displayed on generic workstations. Typically, however, advanced real-time manipulation of images can only be done on each manufacturer's specific processing station. In general, the digital image processing applied to CR consists of a recognition or analysis phase, followed by contrast enhancement or frequency processing. Note that the same general types of image processing applied to CR can also be applied to DR images.

Image Segmentation. In the image recognition stage, the region of exposure is detected (i.e., the collimation edges are detected), a histogram analysis of the pixel gray values in the image is performed to assess the actual exposure to the plate, and the appropriate look-up table specific to the region of anatomy imaged and chosen by the X-ray technologist at the time of patient demographic information input is selected. Proper recognition of the exposed region of interest is extremely important as it affects future processing applied to the image data. For example, if the bright-white area of the image caused by collimation at the time of exposure is not detected properly, its very high gray values will be taken into account during histogram analysis, increasing the "window" of values to be accommodated by a given display device (softcopy or hardcopy). The effect would be to decrease the overall contrast in the image.

Some segmentation algorithms, in addition to detection of collimation edges in the image, enable users to blacken the region outside these edges in the final image if so desired (16,28), which tends to improve image contrast appearance by removing this bright-white background in images of small body parts or pediatric patients. The photo in Fig. 4B demonstrates this feature of "blackened surround," as applied to the image in Fig. 4A.

Contrast Enhancement. Conventional contrast enhancement, also called gradation processing, tone scaling, and latitude reduction, is performed next. This processing amounts to choosing the best characteristic curve (usually a nonlinear transformation of X-ray exposure to image density) to apply to the image data. These algorithms are quite flexible and can be tuned to satisfy a particular user's preferences for a given "look" of the image (29). Look-up tables are specific to the region of anatomy imaged. Figure 5 shows an example of the default adult chest look-up table (Fig. 5a) applied to an image and the same image with high contrast processing (Fig. 5b). A reverse-contrast scale or "black bone" technique, in which what was originally black in the image becomes white and what was originally white in the image becomes black, is sometimes felt to be beneficial for identifying and locating tubes and lines. An example is shown in Fig. 6 where the contrast reversal algorithm has been applied to the image in Fig. 6a, resulting in the image in Fig. 6b.

Figure 4. Example image segmentation algorithm detection of (white) collimation edges of exposure region in image **A**, with “blackened surround” applied in image **B**. Note the improved overall contrast in the image in **B**.

Spatial Frequency Processing. The next type of image processing usually performed is spatial frequency processing, sometimes called edge enhancement. These algorithms adjust the frequency response characteristics of the CR systems essentially implementing a high- or band-pass filter operation to enhance the high spatial frequency content contained in edge information. Unfortunately, noise also contains high spatial frequency information and can be exacerbated by edge enhancement techniques. To lessen this problem, a nonlinear unsharp masking technique is typically implemented serving to suppress noise via a smoothing process. Unsharp masking

is an averaging technique that, via summation, tends to blur the image. When this result is subtracted from the original image data, the effect is one of noise suppression. Specific spatial frequencies can be preferentially selected and emphasized by changing the mask size and weighting parameters. For example, low spatial frequency information in the image can be augmented by using a relatively large mask, whereas high spatial frequency or edge information can be enhanced by using a small mask size (16).

Dynamic Range Control. An advanced algorithm by Fuji, for selective compression or emphasis of low density

Figure 5. Chest image processed with **A**. default mode and **B**. high contrast algorithm applied.

Figure 6. Chest image processed with **A.** default mode and **B.** backbone or contrast reversal algorithm applied.

regions in an image, independent of contrast and spatial frequency is known as dynamic range control (DRC) processing (30). The algorithm consists of performing an unsharp mask for suppression of high spatial frequency information, then application of a specific look-up table mapping to selected regions (i.e., low density areas). This mask is then added back to the original data with the overall result being improved contrast in poorly penetrated regions, without loss of high frequency and contrast emphasis. In a clinical evaluation of the algorithm for processing of adult portable chest exams, DRC was found to be preferred by five thoracic radiologists in a side-by-side comparison, providing improved visibility of mediastinal details and enhanced subdiaphragmatic regions (31).

Multiscale Image Contrast Amplification. Multiscale image contrast amplification (MUSICA) is a very flexible advanced image processing algorithm developed by Agfa (26,32). MUSICA is a local contrast enhancement technique based on the principle of detail amplitude or strength and the notion that image features can be striking or subtle, large in size or small. MUSICA processing is independent of the size or diameter of the object with the feature to be enhanced. The method is carried out by decomposing the original image into a set of detail images, where each detail image represents an image feature of a specific scale. This set of detail images or basis functions completely describes the original image. Each detail image representation and the image background are contrast equalized separately; some details can be enhanced and others attenuated as desired. All the separate detail images are recombined into a single image, and the result is diminished differences in contrast between features regardless of size, such that all image features become more visible.

Image Artifacts. The appearance and causes of image artifacts that can occur with CR systems should be recognized and corrected. Artifacts can develop from a variety of sources, including those related to the imaging plates themselves, to image readers, and to image processing.

Several types of artifacts potentially encountered with CR have been minimized with the latest technology improvements but may still be seen in older systems.

Lead backing added to the aluminum-framed, carbon-fiber cassettes has eliminated the so-called light-bulb effect, darkened outer portions of a film due to backscattered radiation (33). High sensitivity of the CR plates renders them extremely susceptible to scattered radiation or inadvertent exposure, thus routine erasure of all CR plates on the day of use is recommended as is the storing of imaging plates on end, rather than stacking of cassettes one on top of the other (34). The occurrence of persistent latent images after high exposures or after prolonged intervals between plate erasure and reuse (33,35) has been lessened by the improved efficiency of the two-stage erasure procedure used in the latest CR systems (34). Improved recognition of the collimation pattern employed for a given image allows varied (including off-angle) collimation fields and in turn, improves histogram analysis and subsequent processing of the imaged region (34), although these algorithms can fail in some instances. Plate cracking, from wear-and-tear, can create troublesome artifacts as depicted in Volpe (34).

Inadvertent double exposures can occur with the present CR systems, potentially masking low density findings, such as regions of parenchymal consolidation, or leading to errors in interpreting line positions. Such artifacts are more difficult to detect than with screen-film systems because of CR's linear frequency processing response, optimizing image intensity over a wide range of exposures (i.e., due to its wide dynamic range). Figure 7 shows an example double-exposure artifact, and additional examples are included in Volpe (34). Laser scanning artifacts can still occur with current CR readers and are seen as a linear artifact across the image, caused by dust on the light source (34). Proper and frequent cleaning of the laser and light guide apparatus as well as the imaging plates themselves can prevent such artifacts.

The ability of CR to produce clinically diagnostic images over a wide range of exposures is dependent on

Figure 7. Example inadvertent double exposure.

the effectiveness of the image analysis algorithms applied to each dataset. The specific processing parameters used are based on standards tuned to the anatomic region under examination. Incorrect selection of diagnostic specifier or inappropriate anatomic region can result in an image of unacceptable quality. Understanding the causes of some of these CR imaging artifacts described here, as well as maintaining formal, routine quality assurance procedures, can help to recognize, correct for, and avoid future difficulties.

Summary of CR. CR can be used for the digital image acquisition of projection radiography examinations into a PACS. As a result of its wide exposure latitude and relative forgiveness of exposure technique, CR can improve the quality of images in difficult imaging situations, such as in portable or bedside examinations of critically ill or hospitalized patients. As such, CR systems have been successfully used in the ICU setting, in the emergency room (ER) or trauma center, as well as in the operating room (OR). CR can also be cost-effective for a high volume clinic setting, or in a low volume site as input to a tele-radiology service, and have successfully reduced retake rates for portable and other examinations.

Technological advances in CR hardware and software have contributed to the increased acceptance of CR as a counterpart to conventional screen-film projection radiography, making the use of this modality for clinical purposes more widespread. CR is compatible with existing X-ray equipment, yet separates out the functions of image

acquisition or capture, image display, and image archival versus traditional screen-film, in which film serves as the image detector, display, and storage medium. This separation in image capture, display, and storage functions by CR enables optimization of each of these steps individually. Potential expected benefits are improved diagnostic capability (via the wide dynamic range of CR and the ability to manipulate the exam through image processing) and enhanced radiology department productivity (via networking capabilities for transmission of images to remotely located digital softcopy displays and for storage and retrieval of the digital data).

Digital Radiography (DR). In addition to CR devices for digital image acquisition of projection X rays are the maturing direct digital detectors falling under the general heading of digital radiography (DR). Note that digital mammography is typically done using DR devices, although CR acquired at much higher sampling matrices has also been tested.

Unlike conventional screen-film radiography in which the film functions as the imaging sensor or recording medium as well as the display and storage media, DR, like CR, eliminates film from the image recording step, resulting in a separation of image capture from image display and image storage. This separation of functions potentiates optimization of each of these steps individually. In addition, DR, like CR, can capitalize on features common to digital or filmless imaging, namely the ability to acquire, transmit, display, manipulate, and archive data electronically, overcoming some of the limitations of conventional screen-film radiography. Digital imaging benefits include remote access to images and clinical information by multiple users simultaneously, permanent storage and subsequent retrieval of image data, expedient information delivery to those who need it, and efficient cost-effective workflow with elimination of film from the equation.

Review of the Fundamentals.

Process Description. Indirect versus Direct Conversion: DR refers to devices for direct digital acquisition of projection radiographs in which the digitization of the X-ray signal takes place within the detector. Compare this method with CR, which uses a photostimulable phosphor imaging plate detector in a cassette design that must be processed in a CR reader following X-ray exposure, for conversion to a digital image. DR devices, also called flat-panel detectors, include two types, indirect conversion devices in which light is first generated using a scintillator or phosphor and then detected by a CCD or a thin-film-transistor (TFT) array in conjunction with photodiodes; and DDR devices, which consist of a top electrode, dielectric layer, selenium X-ray photoconductor, and thin-film pixel array (36). Figure 8 shows a comparison of the direct and indirect energy conversion steps in the production of a digital X-ray image. DDR devices offer direct energy conversion of X ray for immediate readout without the intermediate light-conversion step.

The basis of DR devices is the large area thin-film-transistor (TFT) active matrix array, or flat panel, in which each pixel consists of a signal collection area or charge

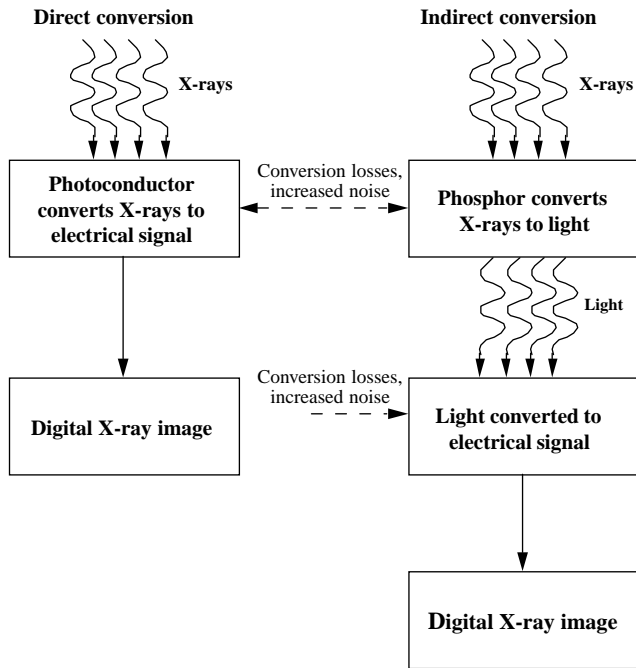

Figure 8. The image production steps involved in direct and indirect digital radiography detectors.

collection electrode, a storage capacitor, and an amorphous silicon field-effect transistor (FET) switch that allows the active readout of the charge stored in the capacitor (36). Arrays of individual detector areas are addressed by orthogonally arranged gate switches and data lines to read the signal generated by the absorption of X rays in the detector. The TFT arrays are used in conjunction with a direct X-ray photoconductor layer or an indirect X-ray-sensitive phosphor-coated light-sensitive detector or photodiode array.

An example DDR device, diagramed in cross section in Fig. 9 (36), uses a multilayer detector in a cassette design, in which the X-ray energy is converted directly to electron-hole pairs in an amorphous selenium (Se) photoconductive conversion layer. Charge pairs are separated in a bias field such that the holes are collected in the storage capacitors and the electrons drift toward the Se-dielectric interface. At the end of exposure, the image resides in the pixel matrix in the form of charges, with the charge proportional to the absorbed radiation. At the end of the readout, the charges are erased to prepare for another detection cycle.

An example indirect DR device uses an X-ray-sensitive phosphor coating on top of a light-sensitive flat-panel amorphous silicon (Am-Si) detector TFT array. The X rays are first converted to light and then to a proportional charge in the photodiode [typically a cesium iodide (CsI) scintillator], which is then stored in the TFT array where the image signal is recorded.

System Characteristics. DR detectors have high efficiency, low noise and good spatial resolution, wide latitude, and all the benefits of digital or filmless imaging. Similarly, DR has a very wide dynamic range of quantization to thousands of gray levels. These devices are becoming more

Figure 9. Cross-sectional view of an example direct digital radiography (DDR) detector panel.

widely used clinically and are available in table buckeyes as well as chest units. DR units have superior workflow and increased patient throughput due to the elimination of cassette handling (37).

The short imaging cycle time of DR may lend itself to combined static radiographic and dynamic fluoroscopic uses in future applications, which is true especially for the indirect devices. The direct Se detector, for example, has a ghosting problem due to charge trapping, which introduces a lag time at the end of each cycle, lengthening the time between readiness for the next exposure.

The cost of sensor production is still high such that the overall price of devices has not dropped appreciably. DR is sometimes referred to as a one-room-at-a-time technology because the detectors are built into the room and matched to the X-ray source. Detector fragility and poor portability makes DR difficult to use in the bedside X-ray environment, but some portable devices are now being introduced.

Image Quality. DR image quality is comparable with that of CR. However, DR devices have higher DQEs than CR, capturing roughly 80% absorption of the X-ray energy at optimum exposures. Thus, DR is a higher efficiency, low noise detector, converting much of the incoming X-ray signal into useful output. Several recent studies have demonstrated high image quality at lower radiation dose to the patient. The ability to lower exposure would be a significant advantage for DR. A factor limiting DR efficiency involves the packing fraction, or active detector area to dead space taken up by the data readout devices (transistors, data lines, capacitors, etc.). As the physical size of the data readout components is currently fixed, the smaller the pixel size, the smaller the packing fraction, with a larger proportion of dead area overwhelming the active area, in some cases reducing the active area to 30% or less (36). The overall effect is a reduction in geometric and quantum efficiency.

The spatial resolution of DR is comparable with CR, which is still less than that for analog X ray. Typical matrix sizes are on the order of 2000 to 2500 pixels by 2000 to 2500 pixels. The pixel size of the TFT array detector is the limiting factor for spatial resolution, with the direct Se detector yielding a better inherent spatial resolution than indirect detectors, which can lead to better signal modulation and superior contrast.

DR design presents a delicate tradeoff between detector efficiency, inversely proportional to pixel size, and spatial resolution, affected directly by pixel size. Typically, DR devices are specified for higher detection efficiency at a cost of less spatial resolution than screen-film, with compensation by a wide dynamic range or high contrast resolution. Design complexities requiring further development include wiring configurations to minimize dead space and maximize the detector packing fraction, fast and robust signal readout methods, and better error-correction matrices for more accurate signal readout.

Comparison of CR and DR. Table 2 lists the advantages of CR and DR, including all the benefits of digital images that can be electronically processed, manipulated, distributed, displayed, and archived. The superior contrast resolution of the digital modalities can compensate, in many cases, for the lesser spatial resolution as compared with screen-film. Both CR and DR can be used for the digital image acquisition of projection radiography examinations into a PACS.

As for any digital image acquisition device, CR or DR would be the first point of entry into a PACS. Errors may propagate from here, with the quality of the PACS output being directly dependent on the quality of the signal in. In addition to image quality, essential features for successful clinical implementation of CR or DR systems for a PACS include the following. DICOM conformance of the modality is essential and includes compliance with the image data and header format, as well as the DICOM communication protocol. Equally critical is interfacing to the RIS-HIS. Integration of the CR/DR system with the RIS-HIS can reduce human errors on patient demographic information input and improve efficiency. Ease of integration of the device into the daily workflow routine, and simplicity and robustness of the user interface are very important. Reliability, fault-tolerance, and capabilities for error tracking are also major issues to consider, as are device speed and performance.

As a result of CR's convenient workflow and portability, as well as its wide exposure latitude and relative forgive-

Table 2. Summary of Advantages of CR and DR Systems

- Produce digital images capable of being electronically processed, manipulated, distributed, displayed, and archived.
- Large latitude systems allowing excellent visualization of both soft tissue and bone in the same exposure image.
- Superior contrast resolution can compensate for lack of spatial resolution.
- Decreased retake rates.
- Potential cost savings if film is eliminated.
- Improved radiology department workflow with elimination of film handling routines.

% of Image Acquisition that is Digital (Elimination of Film)	↑↑

ness of exposure technique, CR can improve the quality of images in difficult imaging situations, such as in portable or bedside examinations of critically ill or hospitalized patients, and enable decreased retake rates for improper exposure technique. As such, CR systems have been successfully used in the ICU setting, in the ER or trauma center, as well as in the OR. CR can also be cost effective for a high volume clinic setting, or in a low volume site as input to a teleradiology service. Cost savings and improved radiology departmental workflow can be realized with CR and the elimination of film (37).

Technological advances in CR hardware and software have contributed to the increased acceptance of CR as the current counterpart to conventional screen-film projection radiography, making the use of this modality for clinical purposes more widespread. CR is compatible with existing X-ray equipment, yet separates out the functions of image acquisition or capture, image display, and image archival versus traditional screen-film, in which film serves as the image detector, display, and storage medium. This separation in image capture, display, and storage functions by CR enables optimization of each of these steps individually. Potential expected benefits are improved diagnostic capability (via the wide dynamic range of CR and the ability to manipulate the data through image processing) and enhanced radiology department productivity (via networking capabilities for transmission of images to remotely located digital softcopy displays and for storage and retrieval of the digital data).

DR devices have more efficient detectors, offering direct energy conversion of X ray for immediate readout. The higher DQE may enable DR to produce high quality images at a lower radiation dose to the patient. These detectors have low noise and good spatial resolution, wide latitude, and all the benefits of digital or filmless imaging. However, cost is still high because detector production is difficult and expensive, and DR is a one-room-at-a-time detector. DR may be cost-effective in high volume settings with constant high patient throughput (37).

However, meeting the cost competitiveness of screen-film systems is difficult unless film printing is eliminated from the cost equation. DR may be preferable for imaging examinations requiring very high quality, such as in mammography, upright chest exams and bone work. DR devices integrated into table and wall buckeyes are now making these devices highly efficient for emergency department trauma cases.

Future improvements in image processing algorithms, with a better understanding of optimum display settings for soft copy viewing, have the potential to greatly facilitate and standardize softcopy reading of digital projection radiographs, and further the acceptance of CR and DR in the clinical arena. It is likely that CR and DR devices will coexist for some time.

Future Trends in Image Acquisition. Although the types of imaging modalities will probably not change all that much in the next several years, the anticipated future trends in image acquisition for digital radiology and PACS include changes in the image dataset sizes, changes in the imaging devices themselves, and improvement in image processing for softcopy display of digital images.

Image Data Sets. No new types of imaging modalities are foreseen for the near future. However, it is anticipated, and has to a certain extent already begun, that the image datasets acquired from the existing modalities will increase in overall study file size, in some cases dramatically. For example, many radiology departments have begun installing multiple detector array or multislice CT scanners that tend to generate a greater number of individual images than do the single detector array scanners because the slice thickness in helical acquisition (~ 0.75 mm) versus the single detector arrays (~ 7 – 10 mm), and the clinical imaging protocols used, as well as the increasing clinical utility of 3D image display representations.

Image matrix sizes for the digital projection radiography devices (CR and DR) have gone up from roughly from one and two thousand square matrices to four by five thousand pixels squared for mammography applications. The increased sampling was done to improve the spatial resolution. Most laser film digitizers can now vary their spot sizes from $200\ \mu\text{m}$ down to $50\ \mu\text{m}$, greatly improving the inherent spatial resolution of the resulting images of the scanned analog film, with a concomitant increase in file size.

The bit depth representation of gray-scale pixel values has also increased from 8 bits to 10, 12, and 16 bits, and color images are stored as 32 bit or 4 byte per pixel data files. Further, the addition of post-processing results or slice reconstructions, and cinographic sequences to the image dataset, while improving the overall quality of the image, may greatly increase the amount of data to be acquired into a PACS.

Devices. While image datasets and file sizes are getting larger, the imaging devices themselves will continue to get smaller in physical footprint, which has been seen most dramatically with the CR devices, going from requiring roughly $36\ \text{m}^2$ of floor space and special electrical power and cooling, to desktop devices that can be placed in most any location. CT and MRI devices are also becoming smaller in size, more portable, and more robust. Hopefully, these devices will continue to become less expensive. Terahertz imaging currently used in aerospace applications may become developed for uses in imaging humans for medical purposes. These devices acquire images at 0.25

and 0.3 THz, creating a binary (two-color) picture to contrast between materials with different transmission and reflection properties. The main advantage of a terahertz imager is that it does not emit any radiation and it is a passive camera, capturing pictures of the natural terahertz rays emitted by almost all objects.

Image Processing. An important area of increased attention continues to be image processing capabilities for soft-copy image display. Future processing techniques will most likely go above and beyond the simple window and level (or contrast and brightness) manipulation techniques. These post-processing algorithms are currently available and tunable at the imaging modality, or accompanying modality acquisition workstation, but may, in time, be manipulable in real-time at the display station. Stand-alone 3D workstations are becoming more common. Efforts to embed advanced processing and visualization in the PACS workstation will ultimately allow real-time processing to be performed by the radiologist or even the referring clinician.

Image compression is currently being debated, but may, in time, be available at the modality to reduce image transmission time and archival space. Some techniques, such as the wavelet transform, may become more widely used not only as a compression technique, but also for image enhancement at the imaging devices.

In time, it is anticipated that the percentage of all imaging devices used by health-care enterprises that are digital in nature will increase greatly. Further, the percentage of digital image acquisition from the devices that are capable should increase, decreasing the amount of film used as an acquisition, display, and archival medium.

Medical Image Archival

Digital image archives were once thought of as costly inefficient impediments to moving toward PACS and digital imaging departments (38). However, current trends in archival technology have shown the cost of digital storage media decreasing steadily with capacity increasing, whereas analog devices such as paper and film continue to increase in overall cost (39). Improvements in storage devices along with the use of intelligent software have removed digital archives as a major stumbling block to implementing PACS. The following tutorial on electronic archival technologies for medical images includes a discussion of available digital media, PACS system architectures, and storage management strategies.

Digital image archival can be more efficient than the manual data storage of the traditional film file room. A study of image examination retrieval from a PACS versus a film-based system showed statistically significant reduction in times for the digital method, in many cases down from hours to minutes (40). The improved retrieval times with PACS were particularly striking for studies between six months and one year old, and for studies greater than one year (40).

An informal survey of 75 radiologists operating in a traditional film-based radiology department found that 70% experienced delayed access to films, which caused them and their staff money in terms of decreased efficiency

(41). Rarely did this delayed access to films result in repeated or unnecessary studies, or result in longer hospital stays. However, inaccessible or lost films did result in time spent, often by the radiologist or clinician, looking for films.

Digital archives are generally less people-intensive, eliminating the physical handling of films, and are, therefore, less expensive and less subject to the errors in filing and lost films that often plague film stores. Electronic archives can improve the security of stored image data and related records, assuring no loss of exam data while offering simultaneous case availability to many.

Digital archives must have an intelligent patient-centric system database interface to enable easy retrieval of imaging examinations. They should conform to the DICOM standard format and communications protocol by being able to accept and return DICOM format files. Many archive systems reformat the data once inside the storage device to a more efficient schema appropriate for the specific archive architecture.

Medical image data files are large compared with text-based clinical data, and are growing in size as new digital applications prove clinically useful. A single view chest X ray, for example, requires approximately 10 MB of storage space. With the expanding availability of multi-detector CT scanners and increasing use of magnetic resonance angiography examinations, thousand-slice studies are not uncommon. Imaging activity continues to increase significantly as it becomes a key diagnostic triage event, with most diagnostic imaging departments showing an increase in overall volume of cases. A typical 500 bed health-care enterprise performing approximately 200,000 examinations, for example, can generate on the order of 5–6 terabytes (TB) of data per year (42).

Compression can be used to reduce both image transmission time and storage requirements. Note that compression that can be achieved via hardware or software also occurs clinically (i.e., not all images of a study are filmed). Lossless (or bit-preserving) compression at 2:1 is done by most PACS archive systems already. Lossy or non-bit-preserving compression, by definition, does not provide an exact bit-for-bit replica of the original image data on decompression. However, studies have shown that numerically lossy compression can produce visually lossless images at compression ratios of 5:1 to 30:1 depending on modality (43–45). Compression at these levels can achieve much greater space savings and appear to be of adequate image quality for image comparison and review of prior studies. For perspective, without compression only 50 two-view digital projection X-ray examinations at approximately 10 MB per image can be stored on a 1 gigabyte (GB) disk. With compression at 25:1, approximately 1250 examinations can be stored on a 1 GB disk.

Digital Archival Media. The digital storage device media used in PACS today include computer hard drives or magnetic disks, RAID disks (redundant array of inexpensive disks), optical disks (OD), magneto-optical disks (MOD), and tape. Newer technologies such as digital video disks (DVD) and ultra-density optical (UDO) disks are being introduced. The properties and attributes of each

Figure 10. Graph of capacity versus performance characteristics of digital archive media.

storage device, including capacity, performance, and relative cost, are compared and summarized below. Figure 10 graphs the capacity versus performance characteristics of the various digital archive media widely used in PACS. Table 4 summarizes the relative cost of digital archive media per capacity or number of GB that can be stored per dollar, in addition to typical capacities and retrieval times.

Magnetic Disk (MD). The standard computer hard drive or magnetic disk (MD), also known as a direct access storage device (DASD), is the fastest medium from which to retrieve data. Retrieval times are on the order of 1 to 50 milliseconds (ms). However, MDs have the lowest capacity, typically hundreds of MB to hundreds of GB, and the highest cost per amount of data storage of all the archival media used in PACS today, although prices are continuing to decrease rapidly. As a result of the relative high cost in the past, MDs have historically been used for online local storage at the display workstation where fast access was required, yet large capacity was not cost-effective. Today, it is becoming cost-effective to use spinning media for all stages of storage – the trend toward everything-on-line.

Redundant Array of Inexpensive Disks (RAID). RAID devices consist of multiple MDs with high performance and larger capacity (now TB worth per device). These devices can offer redundancy, lessening the concerns with a single point of failure, and have hot-swappable components that can be replaced as needed without bringing the entire archive system down.

RAID has traditionally been used for “near line,” intermediate short-term storage, or clinical-operational storage cache to minimize the number of transactions hitting the deep or long-term archive. It is becoming cheap enough per

Table 4. Digital Archive Media Capacity, Retrieval Times, and Relative Costs per GB of Storage

Archive Media Type	Storage Capacity	Performance Retrieval Times	Cost per Capacity (in Order of \$ per GB)
Magnetic Disk	100s MB–10s GB	1 to 50 ms	\$1.00/GB
Optical Disk	1 – 10s GB for TB devices	s to min	\$0.40/GB
Tape	10s – 100s GB for 10s TB devices	10s s to min	\$0.25/GB
RAID	10s–100s GB for 10s TB devices	100–300 ms	\$10.00/GB
DVD	GB for TB devices	s	\$2.50/GB
UDO	30 GB for 10s – 100s TB devices	s to min	\$2.00/GB

capacity to consider using RAID in larger configurations for high performance longer-term storage. In these configurations, a higher percentage of studies, perhaps accounting for several years or more, can remain available online for immediate access.

Optical/Magneto-optical Disk (OD/MOD). Optical disks and magneto-optical disks are of the removable spinning storage media class typically stored in an automated media movement device or jukebox giving them total device storage amounts equal to hundreds of times the media capacity. ODs and MODs have higher capacity than MDs, typically GB to tens of GB yielding hundreds of GB to tens of TB total device storage. They are lower cost per capacity than RAID, on the order of a half dollar per GB of storage. Optical disks are a slower medium than RAID, on the order of seconds to minutes for data retrieval in batch and random seek modes.

ODs are also known as WORM or write once, read many disks with data permanently written onto the disks. MODs are erasable reusable platters and are able to hold more data per unit than ODs. As a result of the slower performance and lower cost per capacity, ODs and MODs have traditionally been used for long-term permanent PACS storage.

Tape. Tape is also a removable storage medium typically kept in a jukebox or tape library. The magnetic tape type most often used for PACS is digital linear tape (DLT). It has very high capacity, tens to hundreds of GB for many TB per tape library, and low cost on the order of a quarter dollar or less per GB of storage. It is, however, a slower medium than MOD, for example, in random retrieval times because of its sequential nature. Tape performance is competitive with MOD for retrievals of large files, however, using very high batch read-write rates. Even random retrievals of very large files (on the order of 50 MB) can be transferred faster with DLT than with MODs. Tape has historically and is currently being used for disaster backup as well as for long-term permanent storage.

Newer Technologies

Digital Video Disk (DVD). Newer technologies, such as DVDs, appear promising but have failed to move significantly into the medical arena due to their high cost and slow performance. DVDs use dual-sided storage, thus achieving greater amounts of storage (GB) than MODs fairly inexpensively. However, the cost of the drives still remain quite high and the lack of a universal standard

read-write format currently limits the use of DVDs for PACS, although the DICOM standard is currently addressing this issue.

Ultra-Density Optical (UDO). Recently released ultra-density optical (UDO) disks use a blue laser recording technology to achieve much greater data storage densities, on the order of 30 GB capacity per disk, predicted to double within six months. UDO is a WORM disk technology with a 50 year lifespan and a current cost of approximately \$2 per GB. Although just a first-generation device release in the medical arena (other fields including the defense industry have used UDOs), it may prove to be a useful technology for PACS.

A summary of capacity, performance, and relative cost of the types of digital archive media available today for PACS is given in Table 4. Figure 10 graphs the capacity versus performance characteristics of the MD, OD, and tape. Note that tape and OD are relatively similar in their tradeoff between capacity and performance.

Archival Strategies

Data Migration. Note that medical images have a life cycle in which, early on, quick access to the data is critical and is often needed by several people in many different locations simultaneously. After a patient has been treated and discharged, however, that same imaging study may rarely need to be accessed again, and if it is, taking minutes or even hours to retrieve it may be acceptable. This pattern of use suggests that hierarchical or staged archival strategies can be implemented for optimum cost-effective use of storage technologies, particularly for the older distributed PACS architectures.

The stages or terms of storage include online or local storage, short- or intermediate-term near-line storage, long-term or offline storage, and disaster recovery or backup storage. Online storage contains information that must be available to the user immediately at the display station and, therefore, requires high-speed access. As this performance is costly, online storage is usually reserved for clinically critical data needed during a single episode of current care (i.e., three days for outpatient clinical encounters and six days on average for a typical inpatient stay). The medium best meeting online local storage needs is the standard computer magnetic disk.

Short-term or near-line storage is used to provide relevant prior or historical imaging studies for comparison during a patient's return visit. This method does not require immediate access, particularly if the data can be

automatically prefetched with advanced notice of scheduled appointments. Note that most patients who do not return for continuing care within 18 months of the acute visit are unlikely to return at all. In other words, a large percentage of imaging examinations performed will never be re-reviewed after the original clinical episode, so slower access may be acceptable. As such, RAID devices work well as short-term or near-line storage, although RAID devices have nearly the high performance of a single magnetic disk but are more costly because of the controller and redundancy capabilities built in.

Long-term or permanent storage provides availability to data with advance notice for retrieval, especially when long-term storage is offline or on-the-shelf. Removable storage media devices such as OD, MOD, or tape jukeboxes are typically used for long-term storage due to their high capacity per cost characteristics. Long-term archives must cover an institution's entire medico-legal storage requirements, which vary from state to state (i.e., 5 years for general adult studies, 21 years for pediatric studies, and life for mammograms and images with orthopedic appliances for Massachusetts).

The requirements for fast retrieval of images initially followed by slower retrieval later, if at all, suggests that different types of storage devices could be used over time to archive images with cost savings. As fast retrieval times grow less important, images could be migrated to less costly, higher capacity, slower storage devices, as diagrammed in Fig. 11. Software is used to handle the movement of data from one medium to another, and the strategy makes the actual physical storage device transparent to the end user. Such a strategy is known as a hierarchical storage management (HSM) scheme.

Hierarchical Storage Management and Compression.

Note that data compression can be used to maximize the amount of online or near-line storage available to a PACS. Although the full resolution image data can be viewed originally for primary diagnosis, a losslessly compressed version can be sent off site to an inexpensive tape backup archive. The original data can also be wavelet lossy com-

Figure 11. Migration strategy and retrieval requirements versus cost over time.

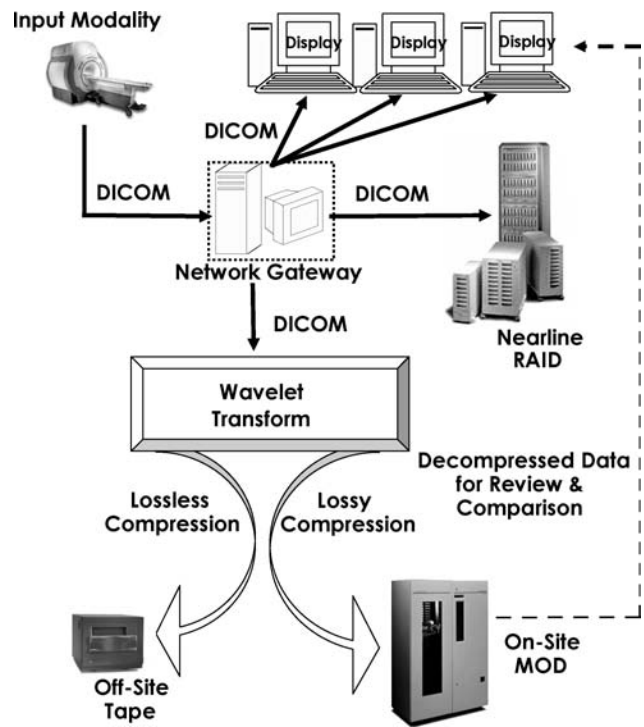

Figure 12. HSM scheme. Image data is viewed at its original content for primary diagnosis, losslessly compressed for the offsite legal record on tape, and wavelet lossy compressed for the onsite near-line storage on MOD for review and historic comparison.

pressed and stored on a large RAID device for maximum cost-effective online storage and retrieval of images for review and comparison (44). This scheme is depicted in Fig. 12.

An HSM scheme using short-term archival of uncompressed DICOM data for primary diagnosis, in an onsite RAID, coupled with a very deep long-term archive of diagnostic quality wavelet compressed data in an onsite optical jukebox, cost effectively maximizes online storage for immediate image retrieval. Diagnostically lossy compressed data (at ratios of 25:1 for CR, 10:1 for CT, and 5:1 for MCI) grows the onsite jukebox by 10 times row, depending on the mix of cases, making 20 or more years available online (44), which effectively maintains the entire legal record worth of original plus two relevant prior examinations all online. Note that no large-scale facility has implemented this schema, preferring to accommodate their needs by purchasing more hardware. Also it is unclear what the medico-legal ramifications would be in using lossy compressed images for historical comparison.

A hierarchical storage management scheme such as this provides a solution for maximum intermediate storage and retrieval through the use of onsite lossy compression and offsite tape backup of losslessly compressed data for the legal record and disaster recovery of data. The use of compression in this HSM scheme provides a cost-effective, high performance archive system. This HSM can be tailored to a given health-care enterprise's need to provide clinically and economically beneficial digital archival of medical images.

Other Scalable Solutions: EOL, NAS, SAN, CAS.

Everything-On-Line (EOL). With the dramatic decline in the cost and increase in capacity of RAID devices, it may become feasible to have all studies with their relevant prior examinations accessible online, which is particularly important for centralized or cacheless PACS architectures. On the other hand, imaging volume and study sizes continue to increase and may continue to overburden archive technologies. Thus, perhaps the intelligent use of the hardware and software technologies currently available through data migration schema is a sound strategy.

Networked-Attached Storage (NAS). Networked-Attached Storage (NAS) involves automated storage on a direct-access but separate local drive. NAS uses the existing local area network (LAN) to connect storage devices and the systems requiring data. A NAS server is optimized to perform file-sharing functions without the application processing overhead of typical network file servers, which enables files to be served rapidly to its clients. Performance is affected by the LAN capabilities and system configuration.

Storage Access Networks (SAN). Storage Access Networks (SAN) are dedicated networks that link storage devices and servers, creating an independent directly accessible pool of storage. SANs typically use fiber channel (FC) technology for high speed serial interconnections, usually over optical fiber. This network can provide simultaneous access from one or many servers to one or many storage devices and eliminates potential loading on the LAN.

Content-Addressed Storage (CAS). In Content-Addressed Storage (CAS) systems, data is stored and retrieved based on unique content ID keys. As medical image data is "fixed content" in that its information needs to be stored but cannot (typically) be altered in any way, CAS may prove useful. CAS associates a digital fingerprint, ID, or logical address to a stored element of data providing content security and integrity. The object-oriented nature of CAS could be exploited to improve database searchability.

Application Service Provider (ASP). An Application Service Provider (ASP) approach to medical data archival may be practical for some small entities. This strategy, in which an outside vendor provides services for storage using their hardware and software, has been around for several years. The advantages include less capital requirements for onsite hardware, technology obsolescence protection, maintenance and migration shifted to the ASP vendor, and offsite data backup. Disadvantages include potential vulnerability in performance and long-term viability of the ASP vendor, security issues, and potential high cost of service, particularly for large-volume sites.

Computer Networking

Computer networks enable communication of information between two or more physically distinct devices. They provide a path by which end user radiologists and clini-

cians sitting at one geographic location, for example, can access radiological images and diagnostic reports from a computer at another location. A private locally owned and controlled network (i.e., within a building or hospital) is called a LAN, whereas a network used outside of a local area is known as a wide area network or WAN. A WAN uses an external service provider and usually has lower bandwidth services than LANs. Intranet communication refers to communication across a private limited-access LAN. Internet communication is across public shared-access WANs.

Signals are transmitted via either bound media such as over cables or unbound broadcast media. Analog communications systems encode information into a continuous wave form of voltage signals, whereas digital systems encode the data into two discrete states or bits, either "0" or "1". The bits are packaged to form bytes, words, packets, blocks, and files based on a specified communication protocol. These communications standards give detailed specifications of the media, the physical connections between devices, the signal levels and timings, the packaging of the signals, and the software needed for the transport of data (46).

Serial data transmission sends digital signals one bit at a time over a single wire; the single bit stream is reassembled at the receiving end of transmission into meaningful byte-word-packet-block-file data (46). Parallel data transmission uses multiple wires to transmit bits simultaneously and, as such, provides increased transmission speeds. Synchronous communication is used in applications that require maximum speed and is carried out between two nodes that share a common clock. Asynchronous communication relies on start and stop signals to identify the beginning and end of data packets (46). An example of this technology is asynchronous transfer mode (ATM) technology.

Hardware. Important networking infrastructure considerations include bandwidth, or how much data can be transferred per period of time; latency, or how long the trip takes; topology or network segmentation, which describes the path data takes; and reliability and redundancy. Table 5 lists different types of network bandwidths or speeds available, in bits per second (bps), along with example transmission times for a single 10 MB CR digital projection radiograph. Note that over a telephone modem it would take approximately 24 minutes at best to transmit a single 10 MB image, whereas over Fast Ethernet it would

Table 5. Network Bandwidths and Example Image Transmission Times

	Maximum Bandwidth (bps)	Min Transmission Time for 10 MB CR
Modem	56 kbps	23.8 min
T1 Line	1.54 Mbps	52 s
Ethernet	10 Mbps	8 s
Fast Ethernet	100 Mbps	0.8 s
ATM	155 Mbps	0.52 s
Gigabit Net	1 Gbps	0.08 s

Figure 13. Network topologies typically used in PACS: bus, ring, and star.

be only a fraction of a second. LANs can consist of low speed Ethernet, medium speed Fast Ethernet, or fast speed Gigabit infrastructure. WANs can consist of a range of digital service speeds from slow telephone modem to medium speed T1 lines to fast ATM. Transmission speeds track with cost.

The most common network topologies used in PACS include bus, ring, and star configurations. These are diagrammed in Fig. 13. Bus topologies commonly use Ethernet and have the advantage of network simplicity, but the disadvantage of upper-level bottlenecking and difficult to identify channel failure. The ring topology uses fiber distributed data interface (FDDI) or high speed ATM SONET (synchronous optical NETWORK) ring technology. Ring topologies offer simplicity and no bottleneck, but, in a single ring, if the channel between two nodes fails, then the network is down. The star or hub topology uses high speed Ethernet or ATM switching and offers network simplicity but a bottleneck as well as a single point of failure at the hub or switch.

The physical media or cabling that makes up PACS networks varies from telephone wires to unshielded twisted pair (UTP) copper cabling, also referred to as CAT5 or CAT3, depending on the quality of the wiring, to coax cable (also known as thinnet or 10Base5), and fiber optic cabling. Fiber optic cabling can transmit more data over longer distances than conventional cabling by using light or lasers instead of electrical signals, but are of relatively high cost. The network interface card or NIC

connects a computer to the physical media or cabling of the network. A unique address, the Media Access Control or MAC address is derived from the NIC. This address is used to identify each individual computer on a network.

A hub or multiport repeater connects multiple computers on a network. A bridge isolates network traffic and connects two or more networks together. The bridge listens to all network traffic and keeps track of where individual computers are. A properly located bridge can take a large congested network segment and reduce the number of data collisions, improving performance.

A switch or router can scale a small-bandwidth network to a large bandwidth. Switches tend to be protocol-independent, whereas routers are protocol-dependent. Routers or relays are used in large networks because they can limit the broadcasts necessary to find devices and can more efficiently use the bandwidth. Routers, sometimes referred to as gateways, while beneficial in large complicated environments, can unfortunately slow traffic down because it has to examine data packets in order to make routing decisions. Bridges work much more quickly because they have fewer decisions to make. Switches have revolutionized the networking industry. They look at only as much of the data packet as bridges look at and are, in a sense, bridges with many interfaces. Switching incorporated with routing helps make network bottlenecks easier to remove. Some switches are used in the core of a network whereas others are used to replace hubs. Figure 14 shows example network switch and router devices.

Figure 15 diagrams an example PACS network, the one used at the University of California at San Francisco Medical Center for transmission of radiological images and related data around the hospital LAN and the health-care center WAN. The image acquisition devices, including the various modalities, such as CT and magnetic resonance scanners, are at the top of the diagram. As image acquisition devices are only capable of connecting to a network with Ethernet speeds, a switch or router is used to take scanner outputs over 10 Mbps in and transmit that data to the PACS servers using faster speeds of 100 Mbps. Images are sent to the display stations using the fastest network available. The circle in the upper-right corner of the diagram represents the UCSF Radiology WAN over which images and information are sent to other health-care facilities over 155 Mbps ATM.

Figure 14. Example network switches and routers.

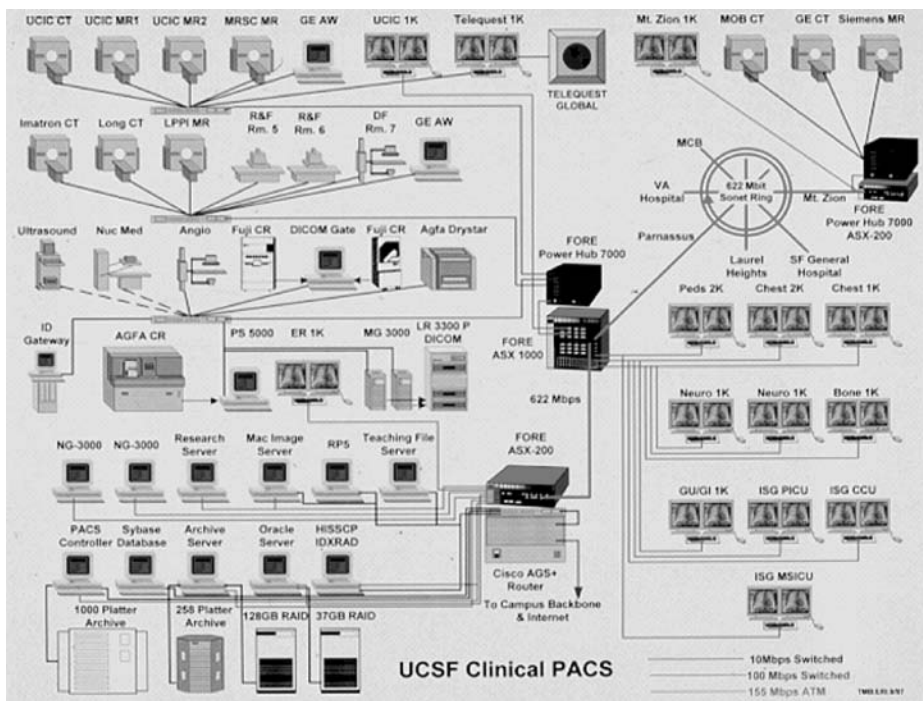

Figure 15. Example PACS network used at the University of California at San Francisco Medical Center for radiological images and related data.

Networking Software. The International Standards Organization (ISO) developed the Open Systems Interconnect (OSI) model as a framework to facilitate interoperation of computer networks from the application layer (i.e., the image viewer) all the way down to the physical layer (i.e., the wires). The ISO/OSI communication protocol stack is shown in Fig. 16. It consists of seven layers (46). Each layer in the stack is interested only in the exchange of information between the layer directly above or directly below, and each layer has different and well-defined tasks.

The top or seventh layer of the ISO/OSI stack is the Application Layer, which provides services to users. The Application Layer knows the data it wants to transmit and which machine it wants to communicate with. The sixth layer is the Presentation Layer, which takes care of data

transformation such as encryption, compression, or reformatting. Layer five is the Session Layer, which controls applications running on different workstations, which is followed in the stack by the fourth or Transport Layer, which transfers data between end points and is handled here with error recovery. Layer three is the Network Layer, which establishes, maintains and terminates network connections. The second layer is the Data Link Layer, which handles network access, collision detection, token passing, and so on, and network control of logical links such as sending and receiving data messages or packets. The bottom layer or layer one is the Physical Layer corresponding to the hardware layer or the cable itself.

Also diagramed in Fig. 16 are the stacks for TCP/IP (Transmission Control Protocol/Internet Protocol) widely

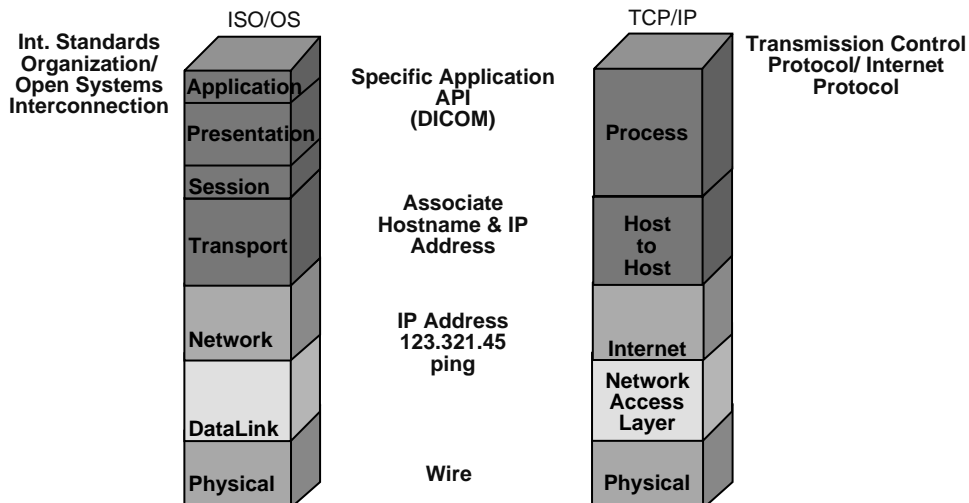

Figure 16. Communication protocol stacks for ISO/OSI and TCP/IP.

used in PACS applications. TCP/IP has four layers but is shown here as five layers, with the lowest level split out into two layers for the network access and physical layers. The top layer is called the Process Layer, and it corresponds to the Application and Presentation Layers in the ISO/OSI model. Such an application in the PACS world might be the DICOM communications protocol application. The layer below is the Host-to-Host or Transport Layer, followed by the Internet Layer and then the Network Access Layer, which encompasses Ethernet, token ring, for example, and the Physical or media Layer. To determine if two devices in a PACS network are communicating, the physical connection is tested. Using the unique IP address of the devices, a “ping” command will validate whether the one computer can reach the other over some network path. The TCP/IP hostname of the computer relates the unique IP address of the device to its DICOM AE (application entity) title so that computers can communicate using this protocol.

Figure 17 demonstrates the path messages take from one subnet, through a router, to another subnet. The process starts at the top of the stack in host A, where a DICOM port is opened. The information travels down the stack through the TCP Host-to-Host Layer to the Internet (IP) Layer and out the Network Access Layer across the Physical Layer. Messages then pass from the Physical Layer up the stack to the Network Access Layer, then the Internet Layer, to the Host-to-Host or Transport Layer, and, finally, a port is opened in the top Processor Application Layer.

Security and Redundancy. Advances in networking and communications devices have greatly facilitated the transfer of information between computers all over the world. For the secure transmission of private information such as clinical images and patient data, additional technologies are put into place to make the Internet a safe medium. The Health Insurance Portability and Accountability Act (HIPAA) of 1996 required the Department of Health and Human Services to establish national standards for electronic health-care transactions and national identifiers for providers, health plans, and employers. It also addresses

the security and privacy of health data, such that adopting these standards will improve the efficiency and effectiveness of the nation’s health-care system by encouraging the widespread use of electronic data interchange in health care.

Firewalls are protocol-dependent devices often used to secure a network by filtering traffic based on rules and policies. Intrusion detection systems (IDS) are another form of security device that uses policy-based monitoring, event logging, and alarms and alerting messaging to protect a network. Virtual Private Networks (VPNs) protect data by encrypting the information at the source device and decrypting it at the destination device. VPN clients are often used to securely access a hospital network for a location outside its LAN. A path can be created through the firewall or directly to a specific server enabling transmission of data.

PACS networks have become mission-critical devices in the transmission of digital medical images in and among health-care enterprises. As such, the networks must be highly available and have fault-tolerance mechanisms built in. Requirements for high availability networks include having redundant technology with automatic fail-over when devices are down. Redundant media and multiple paths should exist for the same information to get from one place to another. Redundant power for the devices involved is generally considered routine, as is proactive monitoring and problem mitigation with automated fault-detection processes in place.

Medical Image Display

Hardware – Monitors: CRT versus LCD. The choice of diagnostic display monitors was relatively straightforward for early adopters of PACS. Hardware was of a single type—cathode ray tube (CRT) technology—and was usually oriented in portrait mode emulating the shape of film. Monitors had high brightness, typically 200 to 300 candelas per square meter (cd/m²), relative to other computer and television monitors, and high refresh rates of greater than 72 Hz to reduce flicker visible to the human eye. The devices themselves were physically large, heavy, and expensive. They generated noticeable quantities of heat while consuming relatively high amounts of power, and their display quality degraded quickly in time, requiring frequent monitor replacement.

Early medical-grade monitors were available in two spatial resolutions (high and low) reflecting their pixel matrix sizes (2 k or 2048 columns by 2500 rows and 1 k or 1024 columns by 1280 columns, respectively). Medium resolution 1.5 k monitors of 1500 columns by 1500 rows were later added to the mix. As a result of the exponentially higher cost of 2 k monitors as compared with 1 k monitors, radiology departments typically had a combination of a few strategically placed high resolution displays and many low or medium resolution displays. The American College of Radiology (ACR) recommended that 2 k monitors be used for primary diagnosis of digital projection radiographs because a single image could be displayed per monitor in its full inherent acquired spatial resolution. The cross-sectional modalities with slice matrix sizes of 512 by 512

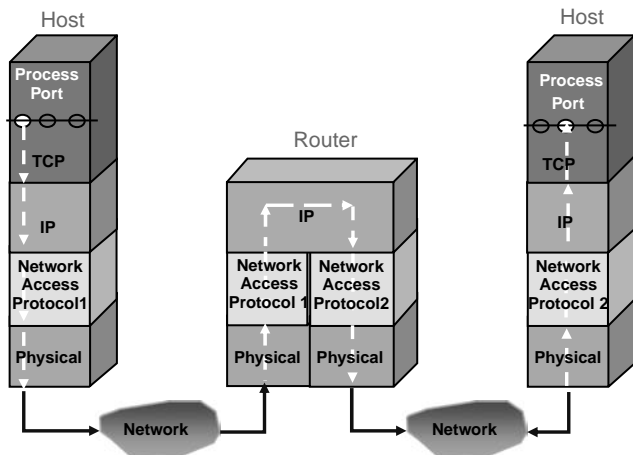

Figure 17. Connecting subnets via a router and DICOM.

for CT and 256 by 256 for MRI were considered adequately displayed on 1 k monitors. As display application software and graphical user interfaces (GUIs) improved, many radiologists became comfortable reading from 1 k monitors even for projection radiography, as long as the images were acquired at their full spatial and contrast resolutions and the GUIs allowed for easy manipulation, magnification, and comparison of images.

Today, a richer array of hardware technologies exist for the purposes of displaying digital medical images. Unfortunately, no formally defined standards or specification guidelines currently exist to clarify choices of monitors for users. The different display devices available today and the specifications to consider when purchasing monitors for use in radiological imaging are described. An explanation of the monitor types including CRTs, active-matrix liquid crystal displays (AM-LCDs), and plasma technologies is given along with a discussion of spatial resolution capabilities and requirements, contrast resolution and monitor luminance, the orientation or shape and number of displays necessary, and a comparison of color versus monochrome or gray-scale monitors. Device calibration and quality assurance practices are also addressed.

Two technology types of hardware displays are currently used in medical imaging, the half-century-old mature cathode ray tubes and what the popular literature refers to as flat-panel technology, of which several types exist (47). Of the two broad categories of flat-panel displays, one filters reflected light or light from a source behind the filter, whereas the second type creates light by exciting a phosphor. Note that the term flat panel is not meant to refer to the face of the monitor as some CRTs have a flat face (48). Rather, it refers to the thin-film transistor array panel that addresses each pixel.

CRTs produce light by exciting a phosphor-luminescent coating with a focused electron beam. Light is generated in an emissive structure, where it diffuses in a controlled manner forming the displayed image. The highest spatial resolution CRT monitors available have a display area of 2048 by 2560 or roughly 5 million (mega) pixels (Mpixels). They come in low- and high-bright versions of 50–60 FL and 100 FL or greater, respectively. High and low resolution (2 k and 1 k) monitors typically come in the portrait mode with a 9:16 or 3:4 aspect ratio emulating the shape of film. Most medium resolution CRTs (1.5 k) are square or in the landscape mode with an aspect ratio of 16:9 or 4:3. Choice of portrait versus landscape monitor shape is a function of personal user preference, with no technical issues bearing on the issue.

The flat-panel display type predominantly used in medical imaging is the active-matrix liquid crystal display (AM-LCD). LCDs use a transistor-driven matrix of organic liquid crystals that filter reflected light. LCDs use a light-modulating as opposed to a light-emitting mechanism for creating the display image. Polarization controls the light intensity such that the maximum intensity is perpendicular to the LCD panel. Consequently, this technology suffers from marked variations in luminance and contrast depending on viewing angle (47), which is the off-axis viewing or angle-of-regard problem in which images can appear quite different if viewed from different angles or heights above

and below the center axes of the screen. Newer LCD designs have a more uniform luminance and contrast profile within a larger viewing angle cone (some as high as 170°). Users should inquire about the horizontal and vertical viewing angle capabilities and, better yet, ask the vendor for a demonstration monitor for clinician testing. LCDs typically have the capability to display in portrait and landscape modes.

Plasma display panels (PDPs) are currently being developed largely for high definition television (HDTV) viewing with 37 inch or larger screens. A current passed through ionized gas (Ne-Xe) contained between a pair of glass layers causes emission of ultraviolet light that excites visible light-emitting phosphors to produce the display image. PDPs are very expensive and have roughly the same number of addressable pixels as 17 inch LCDs, can be hung on a wall, have a wide viewing angle with no loss of quality, and have high brightness but relatively slow response time (48). They are not used currently in medical imaging because of their high cost, slow refresh rates, ghosting artifacts, and contrast limitations. Other types of displays, such as field-emissive display (FEDs) and organic light-emitting diodes (OLEDs), are undergoing heavy developmental efforts but are not yet viable for medical imaging display purposes (48).

Although the spatial resolution terminology used for both CRTs and LCDs is based on the device pixel matrix dimensions — 1 k to 2 k for CRTs and 3, 5, and 9 Mpixels for LCDs — not all monitors are created equal. For example, 1 k and 2 k CRT monitors tend to have standard diagonals so that the larger pixel matrix size connotes smaller pixel size and, hence, better spatial resolution capabilities, and all 1 k monitors have had equivalent spatial resolution, as did all 2 k monitors, which is not the case for LCD displays. For example, 3 Mpixel monitors come with different sized diagonals, that is, different physical sizes such that the physically bigger monitor actually has larger pixel size and hence poorer spatial resolution. Users need to understand what the pixel or spot size is, because it directly reflects spatial resolution and perception of fine detail, and not necessarily choose the largest screen. Pixel size can be determined from the physical screen size, typically given as a display area diagonal in inches and total pixel count or horizontal and vertical matrix resolution. Often, vendors give the device pixel density or pixel pitch spacing and, to confuse the issue, it is often given in millimeters. As for comparison between CRT and LCD monitors, the 1 k CRTs at 1024 by 1280 correspond to 1 Mpixel monitors, 1500 by 1500 correspond to 2 Mpixel monitors, and 1760 by 1760 correspond to 3 Mpixel displays. The 2 k or 2048 by 2500 CRTs correspond to the 5 Mpixel LCD. The recently introduced 9 Mpixel LCD display has 200 pixels per inch on a 22 inch diagonal screen.

The brightness of a monitor or its luminance affects perceived contrast or the number of discernable gray levels. Studies have shown that diagnostic accuracy increases as monitor luminance increases. To gain a perspective on luminance values, the typical lightbox or alternator used to display film is on the order of 400 to 600 FL (1360 to 2040 cd/m^2), whereas the standard PC color

monitor is roughly 20 to 40 FL (68 to 136 cd/m^2). An LCD color monitor has 65 to 75 FL (221 to 255 cd/m^2) monitor luminance, whereas the low-bright medical-grade CRT monitors have 50 to 60 FL (170 to 204 cd/m^2) and the high-bright CRTs have 100 FL (340 cd/m^2) or greater monitor luminance. Among the device specifications reflecting monitor brightness and affecting contrast resolution are the monitor and display card bit depth (typically 8 bits for 256 potential gray values) and the monitor dynamic range or contrast ratio reflecting the maximum discernable luminance over the minimum, with typical values of 600:1 or greater.

In comparing CRT versus LCD display technologies, the advantages of LCD over CRT monitors include better stability for longer device lifetime. The change in brightness of standard LCD monitors has been measured at less than 0.5% per month (47). LCDs are not prone to the geometric distortion typical of CRTs, they tend to consume less power, and this has reduced sensitivity and reflection artifacts from ambient room lighting. Disadvantages of LCD monitors versus CRTs include the afore-mentioned off-axis viewing or angle-of-regard distortion of LCDs, backlight instabilities, liquid crystal fluctuations with temperature, and manufacturing defects creating dead or nonresponsive pixel areas.

Receiver Operating Characteristic (ROC) studies are currently the best methodology available to compare monitor quality and associate it with reader performance, that is diagnostic accuracy, sensitivity, and specificity. Numerous clinical studies have been performed, most showing no significant difference between diagnostic performance on CRTs and LCDs. Recent studies representative of CRT versus LCD comparison for radiological diagnosis include one that examined brain CTs for identifying early infarction (49) and the other looked at CRs of the chest for the evaluation of interstitial lung disease (50). The CT ROC study showed no statistically significant differences in diagnostic performance between a 21 inch monochrome CRT monitor with a pixel matrix of 1280 by 1600 and a brightness of 175 FL versus an 18 inch color LCD monitor with a pixel matrix of 1024 by 1280 and a luminance of 55 FL, when 10 radiologists were asked to rate the presence or absence of disease on a 5 point scale. Similarly, an ROC study comparing the efficacy of a 5 Mpixel CRT display versus a 3 Mpixel LCD for the evaluation of interstitial lung disease in digital chest radiography showed no statistically significant change in observer performance sensitivity between the two types of monitors.

Several studies have investigated the comparison of color versus monochrome (technically achromatic) or gray-scale monitors, and a clear consensus does not seem to exist, which is an important issue because color monitors tend to have decreased luminance, contrast, and spatial resolution capabilities than monochrome monitors, and the human visual system has decreased spatial resolution perception in the color channels, but greater dynamic range (500 just-noticeable-differences (JND) versus 60 to 90 JNDs in gray-scale). On the other hand, high performance monochrome monitors are expensive and have a relatively short lifetime of approximately 3 years, and color is becoming increasingly useful in diagnostic imaging with

the emergence of 3D display renderings. Although a study comparing monochromatic versus color CRT monitors found no statistically significant differences in display of CR chest images for the detection of subtle pulmonary disease, they did find higher sensitivity rates for specialty chest radiologists on the monochromatic monitor, perhaps due to the lower maximum luminance levels of the color displays (51). Another study comparing pulmonary nodule detection on P45 and P104 monochrome and color 1600 by 1200 pixel monitors found significantly greater false-positive and false-negative responses with the color monitors as well as longer search times (52). So, for primary diagnosis of projection radiographs in particular, monochrome monitors may still be the way to go. Note, however, that users prefer color LCDs when compared with color CRTs. This fact may be related to the Gaussian spot pixel and emissive structure of CRTs and the use of black matrix (shadow mask or aperture grille), which separates the red-green-blue phosphor dots that form an arrangement of color dots or stripes for luminance and chromatic contrast (47). Grille misalignment can degrade color purity and contrast.

Early PACS adopters equipped their radiology reading rooms with the highest quality display monitors, some 2 k, others 1 k, but all high brightness. The software applications were more complex than those targeted for the nonradiologist enterprise user. It was common to provide an intermediate application for use by image-intensive specialists such as orthopedists, neurosurgeons, and radiation oncologists as well as in image-intensive areas such as emergency departments and ICUs. Lesser quality monitors with stripped-down software capabilities were used by enterprise image users. It is interesting to note that as display hardware and software continue to evolve, display application software moves toward melding into one flexible easily configurable GUI, and one monitor type may, in time, meet most needs.

Monitor calibration and QA practices are important to maintaining high performing medical displays. The DICOM 14 Gray-scale Standard Display Function (GSDF) and the AAPM (American Association of Physicists in Medicine) Task Group 18 recommend that monitors be calibrated to a perceptually linearized display function as this is matched to the perceptual capabilities of the human visual system. Monitors forced to follow these standards produce more uniform images with optimum contrast. CRTs are less stable than LCD monitors requiring luminance calibration and matching to be conducted monthly, physically measuring light levels with a photometer. Many LCD displays have embedded luminance meters for automated QA measurements, Although some studies have also recommended doing external luminance measures but less frequently. LCDs must still be manually inspected for nonresponsive pixels. Routine manual viewing of test patterns, such as the SMPTE (Society of Motion Picture and Television Engineers) Test Pattern, are usually sufficient for evaluating overall monitor performance, low contrast, and fine detail detection.

Software Functionality. How many individual monitors does a user need per display workstation — 1, 2, 4, or 8?

Many feel that for primary diagnosis, dual-headed configurations are most efficient for comparison of current and prior relevant studies, particularly for projection radiographs. Note that a good GUI design can reduce the need for multiple monitors. The ability to page through and move images around the screen, the ability to instantaneously switch between tile and stack or cine modes of display, and the ability to view multiple studies on one monitor as well as side-by-side comparison of studies are critical to reducing the amount of hardware and physical display space required. In most cases, the two-monitor setup is sufficient for primary diagnosis and image intensive use with perhaps a third (color) monitor for worklist creation and access to other relevant medical data. The most common configuration for enterprise users is the single-headed or one-monitor display.

First and foremost, a software GUI must be intuitive and easy to use. The software application must be responsive, robust, and reliable. Most display workstations have GUIs to perform two basic functions. The first is to deliver a patient list or worklist of imaging examinations to be read, for example, "today's unread emergency department CTs." The worklist environment allows users to interrogate the entire PACS database for a subset of cases with which they wish to work. Typically, the database can be searched for by a specific patient name or other identifier, for individual imaging modalities, over specified time frames, by imaging or patient location within the hospital or health-care enterprise, and so on. The second basic function workstations perform is study display and image manipulation.

Automated hanging protocols based on examination type, the existence of prior historical examinations, and so on can greatly enhance radiology interpretation workflow. For example, if the current imaging study requiring interpretation is a two-view chest projection radiograph, then the default display might be to place the posterior-anterior (PA) view on the left display monitor and the lateral view on the right. If the patient has had a prior chest X ray, then the current PA should be placed on the left monitor with the lateral view behind and the prior PA on the right monitor with its corresponding lateral view waiting behind. If the current study is an MR of the brain, then automatically hang each sequence as a separate stack and place multiple (i.e., four-on-one) stacks per monitor so that they can be cined through simultaneously.

Basic display manipulation tools include the ability to dynamically change the window and level or contrast and brightness of the displayed image, the ability to magnify a portion of the image or zoom and pan through the entire image, and monitor configuration and image navigation tools such as paging, cine, and linked stack modes. Image mensuration capabilities, including linear, angle, and region-of-interest measurements, are also typical. Some advanced tools include the ability to track on a corresponding perpendicular slice, in MR studies, for example, where the cursor is on the perpendicular view for 3D referencing. Figure 18 depicts several example softcopy image displays on PACS workstations.

Well-designed PACS are tightly integrated with other information systems such as the hospital or radiology information system, enabling access to other relevant data

Figure 18. Example soft copy image display on PACS workstations.

about the patient or imaging examination from within the display application. Sometimes diagnostic radiology report generation systems, such as speech recognition, are embedded in the diagnostic workstation.

It is anticipated that the number of specialty display applications available on display stations will continue to increase as more features are added. Examples of the results of several advanced processing techniques are shown in Fig. 19. Some systems also provide algorithms for image processing such as image sharpening, or edge enhancement, and image smoothing. Maximum intensity projection (MIP) displays and multiplanar reformats (MPR) are also appearing on PACS workstations. Real-time 3D reconstruction of image data at the PACS display is beginning to be seen. Multimodality image data fusion such as CT and positron emission tomography (PET) images to depict the functional maps overlaid on the anatomical data maps will also likely be viewable.

Figure 19. Example advanced processing techniques: calculation of scoliosis Cobb angle, region-of-interest measurements, 3D magnetic resonance angiogram.

CURRENT TRENDS AND FUTURE PROSPECTS

Medical imaging is increasingly the key triage event in a patient's encounter with the health-care system. The ability to eliminate the use of film in radiological imaging is a reality today. In addition to the economic advantages of using PACS for digital medical imaging, rapid access to all clinical information on patients, including imaging studies, anytime and anywhere with security, enhances the quality of patient care.

Hurdles still exist today. PACS are not just a radiological tool. Images are required enterprise-wide by many different types of clinicians and other health-care providers. Images are required for viewing in emergency departments, ICUs, surgical ORs, outpatient clinics and referring physicians' offices as well as for teaching conferences, and at home for viewing by patients and clinical providers. Unless PACS can also deliver images to everyone in the health-care enterprise who requires them, film cannot be turned off, and facilities will have to operate in a painful mixed environment.

Web-based enterprise PACS applications do exist and continue to improve in their performance. Note that web-based PACS for within the radiology department are also becoming more common. Several requirements in the enterprise environment make transition to the all-digital, totally filmless medical imaging facility more difficult than just within the radiology department. The web-PACS enterprise application user interface or GUI must be very intuitive—like the rental car model. Most licensed drivers are able to get into a rental car, orient themselves to where the lights and windshield wipers are, and then go ahead and drive the car. They do not need to know how a car works in order to drive it, and the user interface is very standard across most all cars. The car works robustly and reliably and the user does not need to read a manual before they can drive the car. Unfortunately, the state-of-the-art in computer GUIs is not quite as intuitive, but much progress has been and continues to be made in this area, making GUIs self-training and bullet-proof. Human-computer interfacing and interaction along with GUI design are currently active areas of research and discovery.

Web-PACS applications are often required to operate in mixed-platform environments to accommodate PC, Macintosh, and Unix boxes, which is sometimes problematic. Applications must be improved to be able to handle bottlenecks in the system at both the input to the database and the output to multiple users accessing the system simultaneously. The best applications are purely web-based; that is, they are not dependent on having to download Active-X components to every physical machine that uses the system.

In summarizing the key components and essential features for clinical implementation of a PACS, at acquisition, all image acquisition devices or imaging modalities should be required to conform to the DICOM standard image format and communications protocol. Devices and PACS in general operate best when well interfaced to other clinical information systems such as the HIS-RIS, report generation systems such as speech recognition applications, computerized physician order-entry (CPOE), and

decision support systems. The inherently digital imaging modalities should be acquired into a PACS using direct DICOM capture. Film digitizers such as laser scanners can be used to acquire imaging examinations existing only on film into a PACS if required. Acquisition of digital projection radiographs, such as the conventional chest X ray, can be achieved using CR or photostimulable phosphor devices or digital radiography devices, which directly convert images to digital at the time of X ray exposure. CR and DR devices are likely to coexist for some time.

Archival media and devices will continue to advance, with databases becoming more patient-centric and seamlessly searchable. Computer networking will also improve in not only the hardware devices, but also the network management software strategies. Display GUIs must continue to become more intuitive and robust, and the monitors themselves will trend toward LCD devices as opposed to CRTs.

Predictors for success of the introduction of new technologies into the clinical arena include ease of integration into the existing workflow or change management activities to optimize new workflow with new devices. Systems must be reliable, simple to use, and have optimum performance so that processes can be completed more efficiently than in the analog film-based world. Systems must be flexible and configurable on a per-user basis and they must include fault-tolerance, redundancy, and error-tracking capabilities.

In the future, radiology can help to drive the changes that will greatly impact all of health care. Medical image management systems are maturing outside of the radiology department, providing hospital enterprise-wide access to clinical images and information via the Intranet as well as web access from outside the enterprise via a secure Internet connection. The web will change the way people communicate and perform their duties. Web-based PACS applications will become the norm offering ubiquitous distribution of and access to clinical data. Computer workstations will become less costly, more reliable, and have more intuitive GUIs. All relevant medical information systems will become more tightly integrated with each other, sharing and maintaining user, patient, image, and application sensitivity such that multiple distinct applications perform virtually as one.

Future PACS are likely to be on the less expensive off-the-shelf PC platform using industry standards. PACS display stations are likely to be configured with fewer numbers of monitors—two within radiology and image-intensive specialty areas and one out in the enterprise. Small and medium sized community hospitals, private practices, outpatient centers in rural areas, and some indigent care facilities will begin realizing the benefits of PACS and digital medical imaging through better access to high quality diagnostic imaging services.

PACS functionality will be incorporated into handheld devices for some applications, and wireless transmission will mature in the clinical arena. Improved integration with other information technologies into the total electronic medical record (EMR), including automated speech recognition systems, will enable a more efficient filmless environment as well as a paperless workflow.

Advanced image processing utility and translation from the research environment to clinical applications will increase. 3D displays, the use of color and video will increase as will the incorporation of computer-aided detection and decision support through outcomes research and evidence-based medicine will become more prevalent. Multimodality functional and molecular imaging will mature clinically, and value-added applications for specialties outside of diagnostic imaging will increase. Virtual reality imaging presentations and image-guided surgery applications are likely to become more commonly used clinically.

It is likely that the radiological interpretation process will need to transform in order to handle the information and image data overload currently plaguing medical imaging. This image interpretation paradigm shift will be required in order to evaluate, manage, and exploit the massive amounts of data acquired in a more timely, efficient, and accurate manner. Discovery and development of this new paradigm will require research into technological, environmental, and human factors. Interdisciplinary research into several broad areas will be necessary to make progress and ultimately to improve the quality and safety of patient care with respect to medical imaging. These areas are likely to include studies in human perception, image processing and computer-aided detection, visualization, navigation and usability of devices, databases and integration, and evaluation and validation of methods and performance. The result of this transformation will affect several key processes in radiology, including image interpretation, communication of imaging results, workflow and efficiency within health-care enterprises, diagnostic accuracy and a reduction in medical errors, and, ultimately, the overall quality of patient care (53).

Twentieth century medical imaging was film-based in which images were interpreted on analog viewboxes, film was stored as the legal imaging record. Film had to be manually disturbed from one location to another and could be accessed in only one physical location at a time. Twenty-first century medical imaging will be characterized by digital image acquisition, softcopy computer interpretation, digital image archives, and electronic distribution. It is anticipated that the use of PACS and other information technology tools will enable the filmless, paperless, errorless era of imaging in medicine.

INTRODUCTION

Piezoelectric sensors are generally referred to as analytical devices for detection of chemical or biological agents with piezoelectric quartz crystals (PQCs) as transducers. The origin of piezoelectric sensors can be traced back to 1880 when Jacques and Pierre Curie discovered normal and converse piezoelectric effects (1). In the former, the application of a mechanical stress to the surface of quartz and some other crystals induces an electric potential across the crystal; in the latter, conversely, the application of a voltage across the crystal results in an internal mechanical

strain. The converse piezoelectric effect is the basis of all piezoelectric sensors.

PQCs have been widely used in oscillators and filter circuits for high-precision frequency control. The use of PQCs as a mass sensor is based on the work of Sauerbrey (2), which established a linear relationship between the decrease in resonant frequency and the increase in surface mass loading of a PQC. Because of its high sensitivity for mass detection, a piezoelectric sensor is usually called quartz crystal microbalance (QCM). QCM was originally and is still used to measure thickness of coatings in vacuum and air. The first example for application of QCM to analytical chemistry was reported by King in 1964 (3). He coated PQCs with various materials and used them as a sorption detector in gas chromatography to detect and measure the composition of vapors and gases. The applications of piezoelectric sensors were limited to the determination of environmental and other gas species for a long time. The liquid-phase measurements began in the 1980s when new oscillator technology emerged and advanced to make PQCs oscillate in solution as stably as in gas. Then, numerous piezoelectric chemical sensors and biosensor have been reported.

Piezoelectric sensors, characterized by their simplicity, low cost, high mass-detection sensitivity, and versatility, have found increasing applications in biomedical analyses. The objective of this article is to briefly present the theory, equipment, and applications of piezoelectric sensors in the biomedical area. Interested readers are referred to some key review articles (4–9) for more theoretical and technical details of piezoelectric sensors.

THEORY

Typically, a piezoelectric sensor is fabricated by modifying a PQC with a layer of sensing material, chemical or biological, that has specific affinity to a target analyte. The specific binding between the sensing material and the target analyte causes a change in the resonant frequency of PQC that is proportional to the amount of target analyte adsorbed or bound on the sensor surface, which can be correlated to the concentration of target analyte in the original sample.

A typical PQC consists of a quartz crystal wafer and two excitation electrodes plated on opposite sides of the crystal. The wafer is cut from a natural or synthetic crystal of quartz. The electromechanical coupling and stresses resulting from an applied electric field depend on the crystal symmetry, cut angle, and electrode configuration (4). Different modes of electromechanical coupling lead to different types of acoustic waves, including thickness shear mode (TSM), surface acoustic wave (SAW), shear horizontal (SH) SAW, SH acoustic plate mode (APM), and flexural plate wave (FPW).

The TSM device, widely referred to as QCM, is the simplest and most popular piezoelectric sensor. Hence, we will focus on TSM piezoelectric sensors in this article. A TSM sensor typically uses AT-cut quartz as a piezoelectric substrate, which has a minimal temperature coefficient and is obtained by cutting quartz crystals at approximately 35° from the z-axis of the crystal. Figure 1

Figure 1. Schematic of an AT-cut piezoelectric quartz crystal.

shows the schematic of an AT-cut PQC. When an alternating electric field is applied across an AT-cut quartz crystal through the excitation electrodes, the crystal produces a shear vibration in the x -axis direction parallel to the electric field and propagation of a transverse shear wave through the crystal in the thickness direction. The resonant frequency of the vibration is determined by the properties of the crystal and the contacting medium.

Mass Response

Most piezoelectric sensors are used as mass sensors that are based on the Sauerbrey equation (2):

$$\Delta F = \frac{-2F_0^2}{A\sqrt{\mu_q\rho_q}}\Delta M \quad (1)$$

where ΔF is the frequency change measured (Hz), F_0 is the resonant frequency of the fundamental mode of the crystal (Hz), A is the area of the gold disk coated onto the crystal (cm^2), ρ_q is the density of the quartz crystal ($2.648 \text{ g}\cdot\text{cm}^{-3}$), μ_q is the shear modulus of quartz ($2.947 \times 10^{11} \text{ g}\cdot\text{cm}^{-1}\cdot\text{s}^{-2}$), and ΔM is the mass change (g). The Sauerbrey equation is applicable only to a thin ($\sim 1 \mu\text{m}$) and elastic film coupled to the crystal surface, where the mass loading can be up to 0.05% of the crystal mass.

According to the Sauerbrey equation, the magnitude of frequency decrease corresponding to a mass increase is proportional to F_0^2 ; i.e. the higher the fundamental resonant frequency, the higher the mass sensitivity. Typical AT-cut PQCs have $F_0 = 5 \sim 30 \text{ MHz}$ with a frequency resolution of $\sim 0.1 \text{ Hz}$ and a mass sensitivity of $0.056 \sim 2.04 \text{ Hz}\cdot\text{cm}^2\cdot\text{ng}^{-1}$. Thinner crystal wafers have higher F_0 and thus have higher mass sensitivity, but they are also more fragile and thus are more difficult to manufacture and handle. For one of the most commonly used AT-cut PQCs, $F_0 = 9 \text{ MHz}$, $A = 0.2 \text{ cm}^2$, and the detectable mass is 1.09 ng per Hz , which is approximately 100 times higher than that of an electronic fine-balance with a sensitivity of $0.1 \mu\text{g}$. As AT-cut piezoelectric sensors can sensitively detect mass change at nanogram levels, they are frequently referred to as quartz crystal microbalances (QCMs) or nanobalances.

However, as a mass sensor, the QCM does not have selectivity. To make a selective QCM chemical sensor or biosensor, the QCM must be coated with a film of chemical or biological recognition material that is selective to a target analyte.

Viscosity-Density Effect

When a QCM is employed in liquid phase, in addition to the mass change, it also responds to other factors such as liquid density and viscosity, surface energy, viscoelasticity, roughness, and surface charge density. For a QCM with only one side in contact with a Newtonian liquid, ΔF is linearly proportional to the squared root of the product of viscosity (η_L) and density (ρ_L) of the liquid (10):

$$\Delta F = -F_0^{3/2} \sqrt{\rho_L \eta_L / \pi \mu_q \rho_q} \quad (2)$$

For a QCM with simultaneous mass and liquid loading, ΔF can be expressed as (11)

$$\Delta F = -\frac{2F_0^2}{\sqrt{\mu_q \rho_q}} (\Delta M/A + \sqrt{\rho_L \eta_L / 4\pi F_0}) \quad (3)$$

In equation 3, the first term is equivalent to the Sauerbrey equation, and the second term is equivalent to Kanazawa equation. Equation 3 indicates the additive nature of mass and viscosity-density effects in changing the resonant frequency. It also shows that it is impossible to distinguish the mass effect from the viscosity-density effect when only the resonant frequency is monitored.

Some piezoelectric sensors are based on the density-viscosity change rather than on the elastic pure mass change. For example, a piezoelectric sensor was used to detect *E. coli* based on the gelation of *Tachypleus* amoebocyte lysate (TAL) (12), and the detection range is $2.7 \times 10^4 - 2.7 \times 10^8$ cells·mL⁻¹. Gee et al. (13) used a piezoelectric sensor for measuring microbial polymer production and growth of an environmental isolate obtained from river sediment contaminated with petroleum hydrocarbons. The increasing amount of produced polymer corresponded to an increase in the viscosity of the liquid, which was directly measurable as the fluid contacts the surface of the quartz crystal in the sensor system. These methods, although they lack specificity, are advantageous in that coating on the PQC surface is unnecessary.

Equivalent Circuit Analysis

Equivalent circuit analysis can provide more detailed information about the surface/interface changes of a piezoelectric sensor (11,14–17). A PQC can be represented by a Butterworth–Van Dyke (BVD) model (Fig. 2), which is composed of a static capacitance (C_0) in parallel with a motional branch containing a motional inductance (L_m), a motional capacitance (C_m), and a motional resistance (R_m) in series. Each parameter has its distinct physical meaning: C_0 reflects the dielectric properties between the electrodes located on opposite sides of the insulating quartz crystal; C_m represents the energy stored during oscillation, which corresponds to the mechanical elasticity of the vibrating body; L_m is related to the displaced mass; and R_m is the energy dissipation during oscillation, which is closely related to viscoelasticity of the deposited films and viscosity-density of the adjacent liquid.

Figure 2. Butterworth–Van Dyke model of a piezoelectric quartz crystal.

The BVD model can be described by the following admittance equations:

$$Y(\omega) = G(\omega) + jB(\omega) \quad (4)$$

$$G(\omega) = \frac{R_m}{R_m^2 + (\omega L_m - 1/\omega C_m)^2} \quad (5)$$

$$B(\omega) = -\frac{(\omega L_m - 1/\omega C_m)}{R_m^2 + (\omega L_m - 1/\omega C_m)^2} + \omega C_0 \quad (6)$$

where Y is admittance, i.e., the reciprocal of impedance. Y is a complex quantity, its real part G is conductance, and its imaginary part B is susceptance. Both G and B are a function of the scanning frequency f ($\omega = 2\pi f$) and the four equivalent circuit parameters. These parameters are determined by physical properties of the quartz crystal, perturbing mass layer and contacting liquid, and can be obtained by fitting the measured impedance/admittance data to the BVD model using the admittance equations. Figure 3 shows typical admittance spectra of an unperturbed 8 MHz AT-cut PQC in air. The fitted results of F_0 , R_m , L_m , C_m , and C_0 were 7.99 MHz, 9.6 Ω , 17.9 mH, 22.2 fF, and 8.2 pF (including parasitic capacitance in the test fixture) for the quartz crystal (18).

High-frequency admittance/impedance analysis has been extensively used in surface/interface studies. A simpler way to provide insights into the viscoelastic properties of a bound surface mass is to simultaneously monitor F_0 and R_m or F_0 and the dissipation factor D using a quartz crystal analyzer that is much less expensive than the impedance analyzer. This method has been applied to study the behavior of adherent cells in response to chemical, biological, or physical changes in the environment.

For a QCM in contact with liquid, the change of motional resistance was first derived by Muramatsu et al. (14) as follows:

$$\Delta R = (2\pi F_0 \rho_L \eta_L)^{1/2} A/k^2 \quad (7)$$

where k is the electromechanical coupling factor.

Simultaneous measurements of ΔF and ΔR can differentiate an elastic mass effect from the viscosity-induced effect. ΔR is a good measure of the viscoelastic change. For an elastic mass change, ΔR will be zero and ΔF will be linearly proportional to the mass change in accordance with the Sauerbrey equation. For a QCM with only one side in contact with a Newtonian liquid, both ΔF and ΔR are linearly proportional to the squared root of the product

Figure 3. Typical conductance and susceptance spectra of an unperturbed 8 MHz AT-cut PQC in air.

of viscosity and density of the liquid. Therefore, a pure viscosity-density change will result in a linear $\Delta F \sim \Delta R$ plot. In the presence of a viscoelastic change, the $\Delta R \sim \Delta F$ plot will lie between the pure viscosity-density effect line and the elastic mass effect line or even above the former (8,18).

EQUIPMENT AND EXPERIMENTS

Traditionally, a piezoelectric sensor (resonator) is driven by a homemade oscillator, and the oscillation frequency is measured by a frequency counter that is connected to a recorder or computer for data collection. The Pierce oscillator with a fundamental mode AT-cut resonator is the most popular oscillator design type and operates with the piezoelectric sensor as an inductive element. Now such oscillators are commercially available. One of the suppliers is International Crystal Manufacturing (Oklahoma City, OK), which produces a standard (clock) oscillator for gas-phase QCMs and lever oscillator for liquid-phase QCMs.

Highly sophisticated, automatic, and microprocessor-controlled piezoelectric detectors or QCM instruments are commercially available from several manufacturers (19). The main commercial systems include QCA-917- and 922 quartz crystal analyzers (Princeton Applied Research, Oak Ridge, TN), EQCM 400 series electrochemical quartz crystal microbalances (CH Instruments, Austin, TX), EQCN-700 and -900 electrochemical quartz crystal nanobalances (Elchema, Potsdam, NY), the PZ-1000 immuno-biosensor system and PZ-105 gas phase piezoelectric detector (Universal Sensors, Metairie, LA), RQCM research QCM (Maxtek, Santa Fe Springs, CA), and Mark series cryogenic and thermally controlled QCMs (QCM Research, Lake Forest, CA). These systems are designed to reliably measure mass change up to $\sim 100 \mu\text{g}$ with a resolution of $\sim 1 \text{ ng}\cdot\text{cm}^{-2}$. Most of them are programmed and controlled by easy-to-use Windows-based software (Microsoft Corporation, Redmond, WA). The QCA 922, designed for EQCM with a potentiostat or stand-alone

operation, can simultaneously measure resonant frequency and resistance of QCM. The RQCM can measure crystal frequency and crystal resistance for up to three crystals simultaneously. Moreover, high-frequency impedance/admittance analyzers such as E4991A (Agilent Technologies, Palo Alto, CA) can be used to obtain the impedance/admittance spectra of the quartz crystal and to acquire the equivalent circuit parameters by fitting the impedance/admittance data to the BVD model as described earlier.

Previously, for liquid-phase applications, the dip-and-dry approach is made in the measurement of piezoelectric sensors, in which the resonant frequency of the same sensor is measured in gas phase before and after the sample solution is dipped and dried. This approach does not need a special fixture to mount the crystal; however, it is unsuitable for automation and has poor reproducibility. By mounting the crystal to a dip or well cell, like those from Princeton Applied Research and International Quartz Manufacturing, and letting only one side of the crystal exposed to the test solution, it is possible to monitor the frequency change in solution in real time.

Flow-through QCM biosensors have drawn increasing attention due to its ease for automation. For example, Su and Li (20) developed a flow-through QCM immunosensor system for automatic detection of *Salmonella typhimurium*. The QCM immunosensor was fabricated by immobilizing anti-*Salmonella* antibodies on the surface of an 8 MHz AT-cut quartz crystal with Protein A method, and then installed into a $70 \mu\text{L}$ flow-through detection cell. The flow cell was composed of acrylic, with upper and lower pieces held together by two screws with O-rings. One face of the sensor was exposed to the $70 \mu\text{L}$ chamber that was connected to a peristaltic pump and multiposition switching valve. The flow cell was designed to reduce the potential of air bubbles remaining on the crystal after filling from the dry state and to allow air bubbles in the liquid phase to pass out without sticking to the crystal. The oscillation frequency of the QCM sensor was monitored in real time by a Model 400 EQCM system controlled by a laptop PC

Figure 4. Components of an automatic QCM immunosensor system (top) and the flow cell (bottom).

under the Windows environment. Both the pump and the valve were controlled by a DVSP programmable timer. A schematic diagram of the whole QCM sensor system is illustrated in Fig. 4. The operation of this QCM sensor system was totally automated. As shown in Fig. 5, negative frequency shifts exist between every two neighboring phosphate buffered saline solution (PBS) baselines, which were attributed to the specific adsorption of target bacteria onto the biosensor surface.

APPLICATIONS

Piezoelectric sensors, as simple yet powerful tools, have been extensively employed in detection of chemical and biological agents as well as in the study of chemical, electrochemical, and biological interfacial processes. An online

search from SciFinder Scholar (Chemical Abstracts) with the keyword “quartz crystal microbalance” resulted in 4722 references, and 2203 of them are journal articles published during 2000–2005. These studies were conducted to develop (1) antibody/antigen-based biosensors (immunosensors) for detecting biomacromolecules, viruses, cells, as well as small molecules; (2) DNA/RNA probe-based biosensors (genosensors) for *in situ* detection of nucleic acid hybridization; (3) biosensors based on immobilized enzymes, proteins, receptors, lipids, or whole cells; and (4) chemical sensors based on inorganic or organic films for measurements of organic vapors, metal ions, and drugs. Also piezoelectric sensors reported in these studies were used for (1) studies of adsorption of biomolecules and living cells by bare QCM or QCM with functionalized surfaces; and (2) QCM/EQCM investigation/analyses of interfacial phenomena and processes, including self-assembled monolayers (SAMs), films formed using the layer-by-layer assembly technique, molecularly imprinted polymers, biopolymer films, micellar systems, ion transfer at and ion exchange in thin polymer films, doping reactions of conducting polymers, electrodedeposition of metals, and dissolution of metal films.

In the following sections, immunosensors and genosensors, which are most relevant and important to biomedicine, are chosen to discuss the applications of piezoelectric sensors. Some review articles (4–8,21,22) are available for more comprehensive information about applications of piezoelectric sensors.

Immunosensors

One important feature of piezoelectric sensors is that they can be designed as label-free immunosensors. The

Figure 5. Typical output of an automatic QCM immunosensor system for detection of *S. typhimurium*.

immunosensors taking advantage of antibody-antigen affinity reaction are among the most promising biosensors due to their high specificity and versatility. Conventional immunosensors generally involve the formation of a sandwich immuno-complex consisting of an immobilized primary antibody, captured target analyte, and labeled secondary antibody followed by an optical or electrochemical measurement to detect the label directly or indirectly. Piezoelectric immunosensors do not need a labeled antibody and are thus much simpler and easier in operation than the sandwich immunosensors.

The first piezoelectric immunosensor is reported by Shons et al. (23), who modified a quartz crystal with bovine serum albumin (BSA) and used it to detect anti-BSA antibodies. Since then, numerous piezoelectric immunosensors have been reported for the detection of various analytes from small molecules to biological macromolecules, whole viruses, and cells. In brief, a piezoelectric immunosensor is fabricated by immobilizing a specific antibody/antigen on the surface of an AT-cut PQC. When the immunosensing surface is exposed to a sample solution, a binding reaction occurs between the immobilized antibody/antigen and its complementary part (target analyte). The binding event can be monitored *in situ* by QCM based on the change of surface mass loading and/or other properties such as viscoelasticity, and thus, the target species is quantitatively detected. Figure 6 illustrates the stepwise assembly and the principle of piezoelectric immunosensor for direct detection of the binding of target analyte and immobilized antibody.

Microbial detection is probably the most common area in which piezoelectric immunosensors are applied. Current practice for effective treatment of infectious diseases without abuse of antibiotics relies on rapid identification of specific pathogens in clinical diagnostics. Nevertheless, conventional methods for microbial detection are inadequate due to being tedious and laborious. Although traditional culture methods hypothetically allow the detection of a single cell, they are extremely time-consuming, typically requiring at least 24

hours and multistep tests to confirm the analysis. Even current rapid methods such as enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction (PCR) still take several hours to generate only tentative results and require skilled personnel.

Numerous piezoelectric immunosensors have been reported for rapid and specific detection of pathogenic bacteria as alternatives to the conventional methods since the pioneer work of Muramatsu et al. (24), which involved the determination of *Candida albicans* with an AT-cut PQC coated with a specific antibody. Piezoelectric immunosensors have been developed for detection of different bacteria including *S. typhimurium*, *S. paratyphi*, *E. coli*, *E. coli* K12, *Chlamydia trachomatis*, *Yersinia pestis*, *Candida albicans*, and *Shigella dysenteriae* (25–27). The lower limits of detection typically ranged between 10^5 and 10^7 cells mL^{-1} along with a detection time of tens of minutes to several hours.

QCM has been used to detect various infectious viruses. In the study by König and Gratzel (28), Herpes simplex types 1 and 2, Varicella-zoster virus, Cytomegalovirus, and Epstein-Barr virus were detected using a reusable QCM immunosensor with a detection range from 10^4 to 10^9 cells. They reported that a similar QCM immunosensor could detect Rotavirus and Adenovirus with a linear detection range from 10^6 to 10^{10} cells (25) as well as hepatitis A and B viruses (29). Kosslinger et al. (30) demonstrated the feasibility of detecting HIV viruses using a QCM sensor. Antibodies specific to the HIV were absorbed on the crystal surface, and a serum sample could be detected in 10 min in a flow QCM system.

A piezoelectric immunosensor was developed for the detection of cortisol in a range of 36–3628 ppb (31). Cortisol antibodies were covalently bound onto the Au electrode of a 10 MHz crystal with a water-insoluble polymer and thyroxine antibodies.

Piezoelectric immunosensors have also been frequently reported for determination of biological macromolecules. For example, Kurosawa et al. (32) constructed a high-affinity

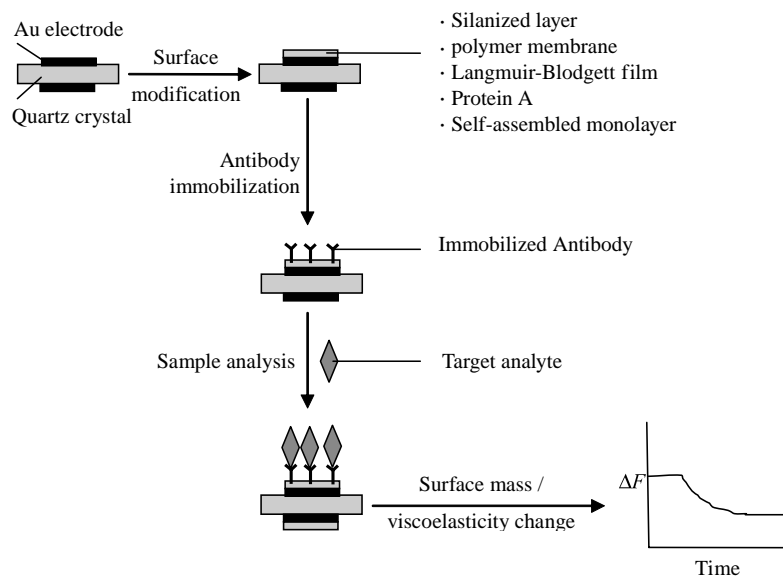

Figure 6. Mechanism of a piezoelectric immunosensor for direct detection of the binding of target analyte and immobilized antibody.

piezoelectric immunosensor using anti-C-reactive protein (CRP) antibody and its fragments for CRP detection. When anti-CRP F(ab')₂-IgG antibody was immobilized on the PQC, the detection limit and the linearity of CRP calibration curve were achieved at concentrations from 0.001 to 100 $\mu\text{g}\cdot\text{dL}^{-1}$ even in serum samples.

Antibody immobilization is vital in successful development of a piezoelectric immunosensor. The current immobilization methods are mainly based on a silanized layer, polymer membrane, Langmuir–Blodgett film, Protein A, and SAM. Protein A, due to its natural affinity toward the Fc region of IgG molecules, has been commonly used to orient antibodies for immunoassays. The orient immobilization has the advantage that it does not block the active sites of the antibodies for binding of target antigens. The procedure for antibody immobilization based on Protein A is simple. Briefly, the Au surface of PQC is coated first with Protein A, and then the antibody is bound to the immobilized Protein A directly. The SAM technique offers one of the simplest ways to provide a reproducible, ultra-thin, and well-ordered layer suitable for further modification with antibodies, which has the potential of improving detection sensitivity, speed, and reproducibility.

Analytical applications of piezoelectric immunosensors based on the direct binding between immobilized antibodies/antigens and target analytes are attractive, owing to the versatility and simplicity of the method. However, the sensitivity of these approaches is relatively low due to the relatively small numbers of analyte entities that can specifically bind to the limited number of antibody/antigen sites on the surface. Some amplification techniques have been investigated for the sensitivity of piezoelectric immunosensors. Ebersole and Ward (33) reported an amplified mass immunosorbent assay with a QCM for the detection of adenosine 5'-phosphosulfate (APS). The enzymatic amplification led to significant enhancement of the detection sensitivity; levels of approximately 5 $\text{ng}\cdot\text{mL}^{-1}$ (10^{-14} M) APS reductase could be detected, whereas the direct binding of APS reductase at even more elevated concentrations could not be measured. A sensitive QCM immunosensor was developed by incorporating the Au nanoparticle-amplified sandwiched immunoassay and silver enhancement reaction (34). Au nanoparticle-promoted silver (I) reduction and silver metal deposition resulted in about a two-orders-of-magnitude improvement in human IgG quantification. Su and Li (18) described a piezoelectric immunosensor for the detection of *S. typhimurium* with simultaneous measurements of the changes in resonant frequency and motional resistance (ΔF and ΔR). In the direct detection of *S. typhimurium*, ΔF and ΔR were proportional to the cell concentration in the range of 10^5 to 10^8 and 10^6 to 10^8 $\text{cells}\cdot\text{mL}^{-1}$, respectively. Using anti-*Salmonella* magnetic microbeads as a separator/concentrator for sample pretreatment as well as a marker for signal amplification, the detection limit was lowered to 10^2 $\text{cells}\cdot\text{mL}^{-1}$ based on the ΔR measurements.

Genosensors

Piezoelectric genosensors are fabricated by immobilizing a single-stranded (ss) DNA/RNA probe on the PQC surface.

Figure 7. Illustration of piezoelectric genosensor for *in situ* detection of DNA hybridization.

Specific hybridization between the immobilized DNA/RNA probe and its complementary strand in sample causes a change in the resonant frequency of the QCM. Various methods have been used for the immobilization of DNA probes onto the QCM surface. Among these, the SAM method is most commonly used because it offers an ordered, stable, and convenient immobilization. Thiolated oligonucleotides can directly form a SAM on the gold surface of the QCM electrode via the Au-thiolate bond. Figure 7 is an illustration of the piezoelectric genosensor for DNA hybridization detection.

DNA/RNA probes have been applied to detect pathogenic microorganisms in clinical samples. Bacterial and viral pathogens are detectable because of their unique nucleic acid sequences. The DNA/RNA probing process is usually preceded by PCR amplification as target nucleic acid may be present in a sample in very small quantities. Most PCR formats are followed by the detection of amplicons using gel electrophoresis or the membrane-based hybridization method. The former lacks of sensitivity; the latter is more specific, but it requires multistep processing and is thus time-consuming.

Over the past decade, many attempts have been made to develop biosensors for sensitive and reliable detection of DNA hybridization. Fawcett et al. (35) were the first to develop a piezoelectric DNA sensor. Piezoelectric genosensors, due to their simplicity and cost effectiveness, have been recently applied to detect gene mutation, genetically modified organisms, and bacterial pathogens. Su et al. (36) described a piezoelectric DNA sensor for detection of point mutation and insertion mutations in DNA. The method involved the immobilization of ssDNA probes on QCM, the hybridization of target DNA to form homoduplex or heteroduplex DNA, and finally the application of MutS for the mutation recognition. By measuring the MutS binding signal, DNA containing a T:G mismatch or unpaired base was discriminated against perfectly matched DNA at a target concentration ranging from 1 nM to 5 μM .

The sensitivity of piezoelectric genosensors may be improved through optimizations of probe immobilization or by means of signal amplification using anti-dsDNA antibodies, liposomes, enzymes, or nanoparticles. A nanoparticle is an effective marker for mass amplification as it has relatively greater mass in comparison with a DNA molecule. Amplified with nanoparticles, the limit of DNA detection by QCM can be lowered for several orders to as low as 10^{-16} M (37). Mao et al. (38) developed a piezoelectric genosensor for the detection of *E. coli* O157:H7 with nanoparticle amplification, in which thiolated ssDNA probes specific to *E. coli* O157:H7 *eaeA* gene were

immobilized onto the QCM surface through self-assembly and streptavidin conjugated Fe₃O₄ nanoparticles were used as "mass enhancers" to amplify the detection signal. As low as 10⁻¹² M synthesized oligonucleotides and 2.67 × 10² cells·mL⁻¹ of *E. coli* O157:H7 could be detected by the piezoelectric genosensor.

CONCLUSIONS

Piezoelectric sensors, as sensitive mass sensors or QCMs, have been applied to detect and measure a broad variety of biomedical analytes in both gas and liquid phases based on the adsorption/desorption of target analyte(s) on/from the sensor surface, in which the selectivity is controlled by the sensing material. Piezoelectric sensors are more than pure mass sensors as they are also capable of detecting subtle changes in the solution–surface interface that can be due to density-viscosity changes in the solution, viscoelastic changes in the bound interfacial material, and changes in the surface free energy. The most attractive advantage of QCMs is that they are suitable for label-free detection and flow-through, in real-time detection. However, using the direct detection approach, the sensitivity of QCM is inadequate for some applications in biomedical analysis such as detection of low levels of pathogens and other biological agents in clinical samples. The lack of sensitivity may be addressed by employing amplification techniques as introduced earlier, by using piezoelectric films and bulk silicon micromachining techniques to manufacture high-frequency QCMs (21), or by designing devices of other acoustic wave modes such as SAW, APM, and FPW.

INTRODUCTION

From the beginning of time, breathing has been important since it has been the most common indicator of life. The Bible indicates that God infused life into man by “blowing into his nostrils the breath of life” (1). Not surprisingly then, the way in which we breathe is an important indicator of our health. Consequently, the medical profession has tried to learn our physical condition by focusing on the behavior of the respiratory system. Two main mechanisms take place in the breathing process: (1) Movement of gases from the nose and mouth to the alveoli, and (2) CO₂ and O₂ gas exchange at the alveoli. An interesting historical perspective, standardization of pulmonary function tests (PFTs) and the associated equipment received a great push from the mobile PFT trucks that were part of a campaign to eliminate lung cancer in the United States in the 1950s. Even today, PFTs are often used as a preliminary screen for lung cancer.

This section focuses on the equipment used to make flow and volume measurements in the first category: pneumotachometers, also known as respirometers, spirometers, or simply flowmeters.

There are two clinical areas where flow measurement devices are used. These are (1) the field of spirometry (2–4), dealing with the actual performance of the respiratory system as reflected by the volumes that the lung can

realize, and the speed in which these volumes can be moved in and out of the lungs. Indicators such as tidal volume (TV or V_T) and vital capacity (VC) provide a glimpse of the range of motion of the lungs. Similarly, parameters, such as FEV₁ (forced expiratory volume in 1 s) and FEF_{25–75%} (forced expiratory flow at the mid-portion of forced vital capacity). Notice that these parameters are the result of: (a) the patient's ability to cooperate, (b) condition of the diaphragm, the respiratory system's main workhorse, (c) range of motion of the lungs, and (d) the mechanical components associated with the respiratory pathways (size of the conducting airways). (2) The field of parameter estimation (5–12), dealing specifically with the noninvasive measurement of components descriptive of the mechanical characteristics of the respiratory apparatus. These parameters include resistance, compliance, and inertance. One advantage of this approach is its independence from the patient's ability to cooperate. This approach is particularly useful in unconscious, and very young or very old patient populations. However, this approach requires a much higher level of computation.

Before proceeding with a presentation on pneumotachometer, some definitions and conventions are appropriate.

Open and Closed Systems

In many pulmonary function tests, the test procedure requires that the subject inhales maximally, then place the pneumotachometer in then mouth, and then exhales as fast as possible. This type of set up is referred to as an “open” system since no exhaled air is rebreathed. In other types of pulmonary function testing, the patient exchanges air back and forth with a reservoir. This later system is referred to as a “closed” system.

Variable Used for Flow

The most common variable used to describe flow is \dot{V} . The “dot” comes from the mathematical notation of differentiation with respect to time, originally developed by Sir Isaac Newton, or

$$\dot{V} = \frac{dV}{dt}$$

which implies that flow, \dot{V} , is the time rate or change of lung volume, V.

Polarity

Spirometer tests consider expiratory flow as positive while parameter estimation procedures look at inspiration as positive. Perhaps it is reflective that most spirometer tests are performed during expiration while in parameter estimation procedures, inspiration is the primary arena.

DEVICES FOR MEASURING RESPIRATORY FLOW

This section presents devices that have and continue to be used for measuring respiratory flow and volume. Even though some of them are not used as often, they are part of the toolbox that clinicians and researchers have used in getting a handle in the respiratory system.

Volume Displacement Type

This type of device, often called volumetric type, captures the volume of gas coming out of the subject's mouth with an expanding reservoir whose degree of expansion can be recorded either mechanically or electronically. Flow can be obtained by differentiating the changing volume. This type of instrument is still used in many pulmonary function facilities and exercise physiology laboratories, since they offer the highest accuracy available. There two types that use a water seal: (1) the counterbalanced bell and (2) the lightweight bell over a water seal (often called the Stead–Wells spirometer after the individuals who requested the device. These are shown in Fig. 1. Even

Figure 1. Water seal spirometer.

Figure 2. Non-water seal spirometers: (a) wedge type, (b) the bellows, and the (c) rolling diaphragm.

though these devices have served the medical community well, their bulkiness and expense have motivated biomedical equipment developers to design smaller, more portable nonvolumetric units, even though they are not as accurate as the volumetric type. Three other variations of the volume displacement type exist: the wedge type, the bellows, and the rolling diaphragm, as shown in Fig. 2 (13).

Other Applications of Volume Displacement Type. The water seal spirometers have also been used to monitor breathing over longer periods of time. Simply closing the circuit creates some problems since O_2 in the air is being consumed while and the mixture becomes progressively CO_2 rich. To solve this problem, the bell is originally filled with O_2 , and a CO_2 scrubber (Baralyme, a trade name for generic BaO) is inserted into the circuit. After a few seconds, additional oxygen is inserted into the circuit. The setup and the resulting the waveform are shown in Fig. 3. This device has found applications to evaluate the metabolic rate (proportional to O_2 consumption).

This device has also been used to measure compliance, the elasticity of the respiratory system (RS). It is carried out by adding a series of weights on top of the spirometer bell, which increases the overall system pressure (14,15). The corresponding change in system volume

Figure 3. Closed-circuit spirometer.

detected at the bell, which corresponds to the increase in lung volume, is measured. The resulting respiratory compliance is given by

$$C_{RS} = \frac{\Delta V}{\Delta P}$$

This approach has been automated by Crawford (16). Notice that the resulting compliance, the compliance of the respiratory system, C_{RS} , captures both the compliance of the lungs, C_L , and the compliance of the chest wall C_{CW} :

$$\frac{1}{C_{RS}} = \frac{1}{C_L} + \frac{1}{C_{CW}}$$

and the lung compliance is made up of the compliance of the left and right lobes.

$$C_L = C_{L-left} + C_{L-right}$$

The following type of pneumotachometers measure flow directly, instead of measuring change in volume. These devices electronically integrate the flow signal to obtain volume.

FLUID RESISTANCE TYPE OF PNEUMOTACHOMETERS

Fleish Pneumotachometers

Another device that has been and continues to be used extensively is the Fleish (or Fleisch) pneumotachometer (17). It consists of a fluid resistive device through which the air passes. The pressure drop across a fluid resistive element created by the respiratory flow is applied to a pressure transducer. Since there is a linear correlation between the measured pressure drop and flow, flow can be determined from the pressure drop. This approach has also been the primary workhorse of pulmonary instrumentation. There are two areas of concern with this type of device: (1) the linearity of the correlation between pressure drop and volumetric flow, and (2) the potential condensation of vapor droplets in the resistive element. Both of these factors can affect the device's accuracy. The American Thoracic Society (ATS), the medical section of the American Lung Association (18), has published standards regarding the required accuracy of the equipment (5% in

some tests, while 3% in others) They have also established the conditions in which the results should be reported: BTPS. [BTPS stands for body conditions: normal body temperature (37°C) ambient pressure saturated with water vapor].

Methods for Obtaining a Linear Flow-Pressure Drop Relationship. The design of the fluid resistive element in the Fleish pneumotachometer produces laminar flow. Three general approaches have been implemented to obtain this linearity. The first one uses capillary tubing placed in parallel (bundle); The second method uses a coiled metal strip with capillary tubing-like corrugations; The third one uses a porous medium, for example, a screen or paper similar to what is used in a vacuum cleaner bag.

In the capillary version, if the flow is laminar, the resulting pressure drop is given by

$$\Delta p = \frac{128 \mu L}{N \pi D^4} \dot{V}$$

where Δp is the pressure drop, L is the length of the capillaries, N is the number of capillaries, D is the diameter of the capillaries, and μ is the absolute viscosity. The above equation can be expressed as

$$\Delta p = R \dot{V}$$

where R is the linear fluid resistive coefficient. Even though effort is taken to make the flow laminar, there are always some turbulent components. This turbulent behavior occurs primarily at the entrance and exit of the capillary tube bundle.

If the pressure drop is created with a square-edge orifice, the flow most likely will be turbulent, and the pressure drop is given by

$$\Delta p = \frac{\rho}{2C_D A^2} \dot{V}^2$$

where ρ is the density, C_D is the discharge coefficient, and A is the area of the orifice. Since this function is truly an odd function [$f(-x) = -f(x)$], the even function above [$f(-x) = f(x)$] is modified by means of the absolute value sign is

$$\Delta p = \frac{\rho}{2C_D A^2} |\dot{V}| \dot{V}$$

The above equation can be expressed as

$$\Delta p = k |\dot{V}| \dot{V}$$

where k is the nonlinear (quadratic) fluid resistive coefficient. In actual practice, most fluid resistors can be described as a combination of laminar and turbulent components:

$$\Delta p = R \dot{V} + k |\dot{V}| \dot{V}$$

where R and k are the linear and nonlinear (quadratic) fluid resistive coefficients. The expression for flow in terms of pressure drop is

$$\dot{V} = \frac{-R + \sqrt{R^2 + 4k\Delta p}}{2k}$$

The reader might suggest to themselves: Why not simply use a square-edge orifice and linearize the resulting signal (i.e., take the square root of the resulting pressure to obtain flow)? In some cases this is done, however, it presents some challenges. If the dynamic range of the flow (maximum flow to minimum flow) is 10–1, the resulting range of the corresponding pressure drops would be 100–1, a pressure signal that would be either too small (and consequently being difficult to measure) or too large (and consequently offering some detectable resistance to the patient).

The other concern with any fluid resistance type flowmeter is condensation. If the fluid resistive element of the flowmeter is at a lower temperature than the air exhaled from the subject (37 °C, saturated), there is a likelihood that the water vapor present in the air would condense on the fluid resistive element, changing the flow–pressure drop relationship. To avoid this problem, most Fleish-like pneumotachometers use a heating element to keep the fluid resistive element hotter than the flow. Despite these drawbacks, fluid resistance type pneumotachometers continue to be one of the most popular methods of measuring respiratory flow.

Osborne Pneumotachometer

The last section introduced problems associated with a square edge orifice for producing the necessary pressure drop. An innovative idea that overcomes these problems is the variable area Osborne flowmeter (19,20). In this flowmeter, the resistive element consists of a thin disk with a flap cut into it, as shown in Fig. 4. As the flow attempts to pass through the space between the flap and the disk, the flap bends, increasing the effective area of the orifice. As a result, the square-type relationship between flow and pressure no longer occurs; instead a linear one is obtained. The specific pressure–flow relationship is captured electronically at the time of calibration and later used to obtain flow from the measured pressure drop.

NONFLUID RESISTANCE TYPE OF PNEUMOTACHOMETERS

Respirometers

Another type of flow and volume indicator is called the Wright respirometer (21,22). It operates on the principle that the moving gas imparts movement on a rotating vane. In the newer units, the motion of the vane is sensed electronically. This type of device is often classified as turbine type.

Figure 4. Flow element of the Osborne flowmeter (Adapted from Ref. (20).

Figure 5. Ultrasound acoustic flowmeter. (Adapted from easy one literature, ndd medical technologies).

Another similar device made by the Wright company (13) records flow instead of expired volume. As flow passes through the device, it simultaneously deflects a vane that as it moves it opens additional passageways through which the flow exits. This mechanical unit is used for measuring peak flow.

Ultrasound–Acoustic Pneumotachometers

This flowmeter uses the Doppler phenomenon, which states that sound travels faster if the medium is also moving. It is very attractive since it provides a property-independent measurement of flow, that is, the measurement is independent of gas composition, pressure, temperature, and humidity. It does not compensate for changes to the air as it enters the respiratory system. (See Calibration section). Until recently, this type of flowmeter was too expensive for regular clinical use. One implementation (23) utilizes a sound pulse along a path that intersects the respiratory flow at an angle, as shown in Fig. 5. A pair of transmitters sends and receives sound in an alternating fashion. The sound pulse gets to the receiver faster if the sound wave is traveling in the same direction as the measured flow. On the other hand, the sound pulse that opposes the direction the respiratory flow takes longer. The difference between these two transit times is used for calculating flow.

Thermal Units

Another class of flowmeter uses thermistors (24,25) to measure flow. Thermistors are electrical resistors made of a material whose resistance decreases with temperature. As the flow passes by the thermistor bead, it attempts to decrease its temperature, which translates to an increase in resistance. An electronic circuit supplies the necessary current to maintain the thermistor at a constant temperature. As a result, the change in current is proportional to gas flow. Often these units are referred to as the hot-wire anemometer type.

Vortex Shedding Flowmeter

Whenever a flow field passes a structure (bluff body), it produces eddies (turbulence) past the structure (26,27). For a particular flow range, the frequency of the shedding is proportional to flow. This principle has been used to measure flow. The flowmeter made by Bourns Medical Systems (28) uses an ultrasonic transducer–receiver pair

Figure 6. Ohio vortex (Bluff Body) respiration monitor. (Adapted from Ref. 13).

that detects the vortex created by the flow, and converts it to an electric signal. The manufacturer of the device claims that gas composition, temperature, and humidity will not affect the measurement process.

Flutter Flowmeter

Whenever flow passes a flexible structure, there is a possibility of a fluid–structure interaction, which makes the structure vibrate. This phenomenon is often called flutter. In aircraft, this is a major concern because wings that experience this phenomenon can break off; consequently aircraft designers have learned to avoid such a condition. On the other hand, developers of respiratory flowmeters have taken advantage of this principle to measure flow. The Ohio Vortex Respiration Monitor shown in Fig. 6 utilizes a light beam–photoelectric eye to capture the resulting vibration and convert it to flow.

Lift Force Gas Flow Sensor

Airfoils, (the shape of the wing in an aircraft), produce lift when subjected to a flow field. Svedin (29–31) is using this concept to measure respiratory gasses in medical applications. The sensor consists of two plates with polysilicon strain gages connected to a Wheatstone bridge. The plates deflect in response to the resulting lift force, in a direction normal to the flow field. One of the claims made by the developers of this device is the sensor's relative insensitivity to inertial forces.

Fluidic Oscillator

Fluidics is a technology that was invented in 1959 and has been used in analogue and digital applications (32,33). It is very similar to pneumatics, but few or no moving parts are used. The devices can also be operated using liquids. The device that gave birth to the technology is the fluid amplifier, a device that with no moving parts can amplify a pressure differential. Figure 7 shows a cross-section of an amplifier, made by staking several perforated stainless steel sheets. Several amplifiers can be staged to achieve gains close to one-half of a million. The most successful fluidics device is the windshield water spray found in most cars. The windshield cleaning fluid or water enters into a cavity that makes the exiting jets oscillate, as shown in Fig. 8. Many applications are possible with this novel technology (34). It must be clarified that prior to the advent of MEMS and microchannels, the word “fluidics” was used

Figure 7. Fluidic fluid amplifier.

only in dealing specifically with this type of devices. Today, any small channel carrying a fluid is called a fluidic device or a microfluidic channel.

The fluidic oscillator flowmeter (unidirectional) offers much promise. It is constructed by configuring a fluid amplifier with feedback: the outputs are connected to the inputs, as shown in Fig. 9. This produces an oscillation whose frequency is proportional to flow. Even though this type of flowmeter has not been specifically used to measure respiratory flow, its performance has been demonstrated successfully as a flow sensor in gasoline delivery systems (35). It aspirates the displaced air in the fuel tank through small holes in the delivery nozzle. It withdraws a volumetric flow equal to the gasoline volumetric flow delivered to the tank. The purpose of course is to minimize the discharge of unburned hydrocarbons into the atmosphere.

Figure 8. Fluidic windshield water spray.

Figure 9. Amplifier with positive feedback: fluidic oscillator.

COMMERCIALY AVAILABLE SPIROMETERS

For a list of most of the commercially available spirometers, see the online source of information by ADVANCE for Managers of Respiratory Care (36) and American Association of Respiratory Care (37).

CALIBRATION

Calibration of Volume Displacement Type Spirometers

This type of volumetric device (Figs. 1 and 2) rarely loses calibration since the geometry is fixed, especially in the type where the measurements of the volume changes are recorded by means of a pen writing on a revolving graph. Even in systems that have electronic position sensors, due to the robustness of these components, recalibration is seldom necessary. However, recalibration should be done on a regular basis to insure the absence of artifacts such as leaks, rough spots, and so on.

The most common method for performing this procedure is the calibrated syringe: a large piston cylinder device that

Figure 10. Syringe calibration procedure.

allows the piston to move within two stops and delivering a fixed volume (typically 3L). The calibration process consists of pulling the piston out to the outer stop, connecting the syringe to the spirometer, and gently pushing the piston to the other stop. The resulting volume indication should be that of the calibrated syringe volume.

Calibration of Spirometers other than the Volume Displacement Type

There are three approaches for calibrating pneumotachometer that do not utilize volume displacement. They are (1) syringe, (2) wet test gas meter; and (3) comparison with a standard calibration flowmeter.

Syringe Approach. In performing this calibration procedure, it is assumed that the pneumotachometer is integrated into a data acquisition–calibration system. To perform the calibration, a fixed volume is passed through the pneumotachometer using a calibrated syringe, typically 3L. The data acquisition system records the resulting flow signal, \dot{V}_M , as shown schematically in Fig. 10. Then it integrates it (i.e., finds the area under the curve) to obtain the measured volume:

$$V_M = \int_0^T \dot{V}_M dt$$

Then it determines the correction factor, K , so that:

$$KV_M = 3$$

Afterward it uses K to adjust the measured flow:

$$\dot{V}_{TRUE} = K\dot{V}_M$$

This approach assumes that the relationship between pressure drop and flow are linear. The user should consult the user's manual, since some of the pneumotachometers automatically adjust for BTPS.

Wet Test Gas Meter. This device is similar to the gas meter found in homes and industrial sites (38). It consists of a series of constant volume chambers that are filled by the incoming flow. They are attached to a rotating structure that enables the chambers to go through the following sequence: (1) fill the chamber with the incoming air, (2) create a water seal at the bottom of the chamber, (3) move the sealed chamber to the exhaust side, and (4) release the volume in the chamber to the outside. As a result, the incoming flow imparts a rotation that is observable from the outside by means of rotating hands. Consequently, there is a 1:1 correlation between the volume that passes

through the device and the number of rotations indicated by the hand. To perform a calibration test, a known flow of gas is passed through the Wet Test Gas Meter and the flow recorded:

$$\dot{V} = \frac{(\text{number of revolutions})(\text{volume/revolution})}{\text{time required for above revolutions}}$$

Immediately afterward, the same flow is passed through the pneumotachometer under calibration. The constant flow is produced by applying a source of high pressure to a needle valve. Since the pressure resistance created by the Wet Test Gas Meter or the pneumotachometer is very small (a couple of inches of water), the flow is determined by the upstream pressure, P_s and the size of the orifice in the needle valve. The resulting output signal, e , is recorded, as shown in Fig. 11. The procedure is repeated for various needle valve settings to produce a curve similar to the one

Figure 11. Calibration procedure using the Wet Test Gas Meter.

Figure 12. Calibration using a Laboratory grade Flowmeter.

shown in Fig. 11 that can then be used to obtain either a linear approximation or a polynomial fit. Afterward, the calculated flow is adjusted for conversion into standard conditions: BTPS [normal body temperature (36 °C) ambient pressure saturated with water vapor]. This type of calibration device has an accuracy of $\pm 0.5\%$.

Calibration Using a Laboratory Grade Flowmeter. This method is possible when a laboratory-grade flowmeter is available. As done in the Wet Test Gas Meter, a series of flows are passed through both the laboratory grade flowmeter and the pneumotachometer under test, as shown in Fig. 12. The output of the pneumotachometer under test is made to agree with the flow indicated by the laboratory grade flowmeter.

Piston Prover. Flow meters can also be calibrated using a piston prover (39). This device consists of a precision bore glass tube with a piston, that moves due to the displacement of the gas whose flow rate is being measured. The piston, which is slightly smaller than the bore of the tube, has a groove filled with mercury to create a leak-less, low friction seal. The flow is determined by the time that it takes for the piston to travel between two reference positions, timed using light beams. This device has an accuracy

of better than $\pm 0.2\%$. NIST provides calibration services for flowmeters using this technique and apparatus.

Soap Bubble Technique. From time to time, researchers need to measure a particular flow, but do not have the specialized calibration equipment required. In cases like this, the soap bubble technique can be used. It is implemented by placing a soap film across the open end of a constant, cross-section tube. The other end of the tube is connected to a barb fitting that will easily receive a plastic tubing through which the flow to be measured is passing. Next, the soap film is moved toward the other end (the side with the fitting), by using a source of vacuum that is momentarily connected to the end with the fitting. Then, the tubing with the flow to be measured is connected to fitting, and the time that it takes for the soap film to travel between two reference positions is recorded. This information is then used to calculate flow. This technique resembles the piston prover, except that a soap film is used instead of a piston.

PNEUMOTACHOMETER DYNAMIC CHARACTERISTICS

Another important characteristic of a pneumotachometer is its ability to measure rapidly changing flows. If one

Figure 13. Block diagram of procedure used for obtaining a frequency response test.

attempts to measure a fast changing flow signal with a flowmeter that does not have the adequate dynamic characteristics or “frequency response”, one would obtain inaccurate results. One of the most common vehicles for capturing a device’s frequency response is called the Bode Plot (40). This section addresses the general test procedure and presentation format used for obtaining a frequency response or Bode plot. Afterward, it presents the method used for performing a frequency response test on flowmeters.

One of the fundamental properties of a linear system is that if the system is excited with a sinusoidal input signal, after the transients die out, its output will also exhibit a sinusoidal behavior. A frequency response test consists of applying sinusoids of different frequencies and measuring the amplitude of the output and the phase difference between the input and output. Figure 13a shows a sinu-

soidal generator producing a sine wave with amplitude A and frequency f_i , being applied to a linear system. It also shows the corresponding output, another sinusoid of the same frequency, but with amplitude B_i and phase Φ_i . This procedure is repeated for different frequencies in order to obtain a table as shown Fig. 13b. Notice that the ratio of the output–input amplitude is calculated as well as $20 \log$ of this ratio. This latter quantity has units called dB or deciBels in honor of the communication pioneer, Alexander Graham Bell. The Bode plot, which is actually made up of two plots, presents this information in graphical form. The magnitude plot shows the amplitude ratio in dB (i.e., $20 \log B_i/A$) on the vertical axis and the frequency [$\omega = 2\pi f$], in a logarithmic scale, on the horizontal axis. This is shown in Fig. 13c. Similarly, the Phase Bode Plot shows the phase against the various input frequencies. This is shown in Fig. 13d. The particular plot shown here is descriptive of a

Figure 14. Test setup used for measuring frequency response of a pneumotachometer.

device that has low pass characteristics. This means that it passes signals of low frequencies at a constant gain (flat or horizontal portion), but attenuates ones that are of high frequencies (sloped portion of the graph). For any particular pneumotachometer application, it is desirable to use one that is flat in the range of frequencies that will be present in flow waveform that is to be measured. As an example of this, the ATS Standardization of Spirometry (18) stipulates, "Measuring PEF requires an instrument that has a frequency response that is flat ($\pm 5\%$) up to 12 Hz".

The reader may question the emphasis on sinusoidal inputs when in the real world, very few signals are sinusoidal. Representation in terms of sinusoids provides a general framework for dealing with any type of periodic signals, periodic function can be decomposed into a summation of sinusoids (Fourier Series).

Performing a frequency response test on a pneumotachometer is more challenging than for an electronic device where both the input and output are electronic signals that are easily measurable. Development of this experimental procedure for pneumotachometers has been refined by Jackson and Vinegar (41). The test set up can be represented as shown in Fig. 14. For purposes of this explanation, assume that the pneumotachometer being tested is of the Fleish type, a fluid resistance with a pressure transducer for measurement of the pressure drop. To perform the frequency response test, a small loudspeaker is used to generate the sinusoidal flow that is applied to the pneumotachometer under test. On the other side of the pneumotachometer, a large, rigid tank is connected. Notice that because the tank is filled with ambient air, a compressible fluid, flow enters and exits it. Of course, when the flow enters the tank, the pressure in it increases, and when the flow exits, the pressure decreases. The experi-

mental procedure requires a second pressure transducer that measures the pressure inside the tank. This signal is used to calculate the flow in and out of the tank. Referring to Fig. 14, $e_{\dot{V}_{\text{measured}}}$ is the pneumotachometer output signal (the output voltage of the pressure transducer connected to the pneumotachometer) and $e_{\text{tank pressure}}$ is the tank's pressure transducer output signal. The flow into the tank is given by

$$\dot{V}_{\text{true}} = K_1 \frac{d(e_{\text{tank pressure}})}{dt}$$

A frequency response test is performed by varying the frequency of the loudspeaker, collecting the data and plotting it in Bode format. The response is flat as long as the ratio of $e_{\dot{V}_{\text{measured}}}/\dot{V}_{\text{true}}$ is constant.

CORRECTION FOR STANDARD CONDITIONS

Often the state in which the flow is measured is not reflective of the physiological conditions in which flow becomes meaningful. In other cases the calibration of the flowmeter takes place under a different set of conditions than what the flowmeter will experience in the clinical setting. In both cases, one needs to correct the resulting measurements to accurately capture the true physiological event happening. To illustrate the correction process, an example is provided here. Consider a pneumotachometer that is to be used for measurement of inspiratory flow. Further assume that the pneumotachometer has been calibrated with room air, using the standard 3L syringe. Consequently, there is no need to correct the flowmeter reading since it will measure properly the flow that passes through it during the test. That is, the conditions for calibration and clinical testing are the same. However,

Figure 15. Correction for volume expansion due to increase in temperature and humidity.

when the air enters the respiratory system, it experiences two changes: its temperature increases from room temperature to body temperature, and the humidity from 0% (assuming a very dry day) to 100% RH. Both of these processes need to be taken into consideration if it is desired to know the actual volume that is expanding the alveoli. In reality, both processes are happening simultaneously, but for purposes of this example, we will assume that the air is heated first and then it becomes saturated. Both of these transformations cause the air volume to expand. Figure 15 shows the expansion process.

The increase in temperature causes the air to expand (Dalton’s law of gasses). The correction factor for temperature is

$$CF_{\text{Temperature}} = \frac{T_{\text{body}} + 273.16\text{ }^{\circ}\text{C}}{T_{\text{inlet}} + 273.16\text{ }^{\circ}\text{C}}$$

Assuming that the inlet temperature is 21.1 °C (70 °F) and that the body temperature 37 °C (98.6 °F) this correction factor $CF_{\text{Temperature}}$ is 1.05.

The increase in humidity also creates an expansion. It is due to the effect of water vapor on the partial pressures. The total pressure of the dry gas is equal to the sum of the partial of its three main constituents N_2 , O_2 , and CO_2 .

$$P_{\text{total}} = P_{N_2} + P_{O_2} + P_{CO_2}$$

However, as the air travels through the airways, it is humidified. We assume that the total pressure remains constant as the air moves through the airways. Now the total pressure becomes:

$$P_{\text{total}} = P_{H_2O} + P_{N_2} + P_{O_2} + P_{CO_2}$$

The presence of the partial pressure of the water vapor (P_{H_2O}) causes the sum of partial pressures of the last three constituents to decrease. This in turn causes the volume to expand. Thus the correction factor expression for humidity is

$$CF_{\text{HUMIDITY}} = \frac{P_{\text{ambient}}}{P_{\text{ambient}} - P_{\text{sat}}}$$

Assume that the ambient barometric pressure is 29.92 mmHg (98.3 kPa) and at a body temperature of 36 °C, the water vapor pressure is 1.78 mmHg (6 kPa). Substituting these values into the previous equation produces a correction factor CF_{HUMIDITY} of 1.06.

Combining both factors, the total correction factor becomes 1.12. This means that every milliliter that enters the mouth expands by 12% by the time that it reaches the alveoli. Consequently, measured flows need to be increased by 12%.

Comments about Complexities in the Measurement and Correction Process

More accurate (than the upper limits established by the ATS), bidirectional flow measurement is a challenging task when using pneumotachometers other than the volumetric type. This is true since the air volume varies due to density changes (resulting from temperature and composition differences of the incoming and outgoing air). The composition of inspired and expired air is shown in Table 1. The problem is made even more complicated if Fleish-type pneumotachometers are used, since now viscosity (the critical variable in the flow–pressure drop relationship) is influenced by both temperature and gas composition.

OVERVIEW OF DESIGN SPECIFICATIONS

This section presents some of the technical specifications of Fleish-type pneumotachometers, specifically those manufactured by Hans Rudolph a major manufacturer of respiratory components (42). These characteristics are shown in Table 2.

It is difficult to describe accuracy of each device in detail, since it depends not only on the hardware (i.e., resistive fluid sensor element) and the measurement process, but also on the correction factors that are applied (gas composition,

Table 1. Normal Gas Concentrations of Air^a

Source of sample	Nitrogen (N ₂),%	Oxygen (O ₂),%	Carbon Dioxide (CO ₂),%	Water Vapor (H ₂ O),%
Inspired air (dry)	78.65	20.9	0.04	0.5
Alveolar air (saturated)	75.45	13.2	5.2	6.2
Expired air (saturated)	74.8	15.3	3.7	6.2

temperature, relative humidity, differences between atmospheric conditions at the time of calibration and those at the time of use, and corrections for quadratic-type pressure drop). As mentioned before, most manufacturers simply indicate that their products meet the ATSS standards.

INDIRECT TECHNIQUES FOR MEASURING FLOW

There are various methods that provide an estimate of respiratory flow, by means of an indirect measurement. These techniques find an application in cases where continuous connection to a pneumotach through a mouthpiece or mark is not feasible.

INDUCTIVE PLETHYSMOGRAPHY

Respiratory inductive plethysmography (RIP) has been used for many years for respiratory monitoring. Used in intensive care units worldwide for monitoring respiratory activity, primarily tidal volume. During inspiration, due to the bucket-handle effect of the ribs and the outward displacement of the abdomen, there is an increase in the cross-sectional area of the rib cage and abdomen, which translates into an increase in circumference (or more accurately, perimeter). This increase in perimeter is measured using elastic bands and correlated to a specific lung volume increase, or often used as a simple, relative measurement of lung volume expansion.

This technique used by the LifeShirt (44) is a vest-like, portable physiological monitoring system. In the LifeShirt, “two parallel, sinusoidal arrays of insulated wires embedded in elastic bands are woven into a flexible garment. Extremely low voltage electrical current is passed through the wire creating an oscillating circuit. As the body chambers expand and contract, the electrical sensors generate different magnetic fields that are converted into proportional voltage changes over time (i.e., waveforms)”. For calibration, which is done immediately after putting on the vest, the user breathes into a fixed-volume, calibration bag. Then the associated tidal volume is correlated to the measured body’s expansion.

Respiratory Sounds

There is a correlation between respiratory flow and breath sounds. This method has been pursued for many years and

continues to be an ongoing topic for research (45,46). Tracheal breath sounds are preferred by many investigators since they are louder than chest sounds and since there is more correlation of flow at the trachea and less filtering from the chest wall (47).

The U.S. Army (48) has been extremely active in developing physiological monitoring systems based on the sounds detected at the neck. Their motivation for this research is based on the premise that continuous monitoring of the soldier’s health “can provide exceptional improvement to survivability, mobility, and lethality” (49). This group has generated a considerable amount of methodology as well as easy-to-build sensors and equipment for this application (50,51).

Some development has been done to obtain an estimate of actual flow from respiratory sounds (instantaneous measurement of the magnitude and direction of respiratory flow) (52). This is possible since inspiration and expiration have different “sounds”, due to the asymmetrical nature of the respiratory passageways. This approach is implemented by initially, simultaneously measuring both tracheal sounds (using a small microphone attached to the neck) and actual flow (using a standard pneumotachometer). After recording data for 1–2 min, these two waveforms that are fed into a computer program that produces a correlation algorithm, which can be used subsequently to predict flow (magnitude and direction) from the tracheal sounds. The long-term aim of this effort is detection of SIDS candidacy. The basic concept is that there might be a flow patterns/signature that could be construed as an early-predictor of SIDS. This test would be done during the first night that a newborn spends at the hospital. If a suspicious pattern is found, then a baby monitor could be sent home with the baby. It could also find application in the analysis the breathing patterns of athletes (in which a mouthpiece-tachometer is not feasible).

SUMMARY

Pneumotachometers have contributed and will continue to contribute significantly to our understanding of the respiratory system. They are an essential tool in the fight against respiratory diseases. In addition new applications are being developed that aim at the prevention of disease.

INTRODUCTION

Few techniques rival the impact that the polymerase chain reaction (PCR) has made in the age of molecular biology. Cloning and deoxyribonucleic acid (DNA) sequencing are other such techniques that have become embedded into everyday life on the molecular biologist's bench. Over 60 books alone (not to mention the tens of thousands of research articles) have been devoted to the strategies, methods and applications of PCR for the identification, detection and diagnosis of genetic and infectious diseases. Rightfully so, the inventor of PCR, Kary B. Mullis, was awarded the Nobel Prize in Chemistry for his discovery of the technique in 1993. However, PCR has not been without controversy. In 1989, DuPont challenged the validity of the Cetus PCR patents in federal court and with the Office of Patents and Trade Marks, and by 1991 the Cetus patents were unanimously upheld and later sold to Hoffman La Roche for \$300 million. More recently, in 1993, Promega has challenged the validity of the Hoffmann La Roche *Taq* DNA polymerase patent that is currently pending. In this article, we attempt to provide a comprehensive overview for the molecular biologist when applying PCR to his/her application of interest.

DNA POLYMERASE REACTION

The DNA replication is an inherent process for the generation and evolution of future progeny in all living organisms. At the heart of this process is the DNA polymerase that primarily synthesizes new strands of DNA in a 5'→3' direction from a single-stranded template. Most native DNA polymerases, however, are polyfunctional and show 5'-exonuclease and/or 3'-exonuclease activities that are important for cellular DNA repair and proofreading functions. Numerous molecular biology applications have harnessed these activities, such as labelling DNA by nick translation and TaqMan assays (see below), and endrepair of sheared DNA fragments and improving DNA synthesis fidelities, respectively. The PCR is an elegant, but simple, technique for the *In vitro* amplification of target DNA utilizing DNA polymerase and two specific oligonucleotide or primer sequences flanking the region of interest. PCR is a cyclic process of double-strand separation of DNA by heat denaturation, specific hybridization or annealing of short oligonucleotide primers to singlestranded DNA, and synthesis by DNA polymerase (1,2). Each cycle doubles the region marked by the primer sequences. By sequential iteration of the process, PCR exponentially generates up to a billion of copies of the target within just a few hours (Fig. 1).

The specificity of PCR is highly dependent on the careful design of unique primers with respect to the genome under investigation and the nucleotide composition of the primer sequences. Theoretically, a 16-mer (4^{16}) is of sufficient length to represent all unique primer sequences from a completely random genome size of 3 billion base pairs. In the real world, however, all genomes are not random and contain varying degrees of repetitive elements. For the human genome, Alus, LINEs (long interspersed DNA elements) and low complexity repeats are frequently observed and should be avoided in primer design when possible. There are a few simple rules for designing primer sequences that work well in PCR. In practice, PCR primers should be between 18 and 25 nucleotides long, have roughly an equal number of the four nucleotides, and show a G + C composition of 50–60%. Commercially available oligonucleotide synthesizers that show phosphamidite coupling efficiencies > 98% mean that primers of this size can usually be used in PCR without purification. A variety of computer programs are available for selecting primer sequences from a target region. Many of these programs will reveal internal hairpin structures and self-annealing primer sequences, but manual inspection of the oligonucleotide is still necessary to maximize successful PCR amplifications.

The concentrations of the PCR cocktail ingredients are also important for product specificity, fidelity and yield. In addition to *Taq* DNA polymerase and primers, the PCR mixture contains the cofactor magnesium ion (Mg^{2+}), the four 2'-deoxyribonucleoside-5'-triphosphates (dNTPs) and the buffer. In general, PCR reagent concentrations that are too high from standard conditions result in nonspecific products with high misincorporation errors, and those that are too low result in insufficient product. A typical 50 μ L PCR cocktail that contains 0.4 μ mol·L⁻¹ of each primer, 200 μ mol·L⁻¹ of each dNTP, 1.5 mmol·L⁻¹ $MgCl_2$, and 1.25 units *Taq* DNA polymerase in 10 mmol·L⁻¹ tris-HCl, pH 8.3, 50 mmol·L⁻¹ KCl buffer works well for most PCR applications. The optimal Mg^{2+} concentration, however, may need to be determined empirically for difficult target templates. The performance and fidelity of *Taq* DNA polymerase are sensitive to the free Mg^{2+} concentration (3), which ionically interacts with not only the dNTPs but also with the primers, the template DNA, ethylenediaminetetraacetic acid (EDTA), and other chelating agents. In most cases, the Mg^{2+} concentration will range from 1.0 to 4.0 mmol·L⁻¹.

The number of cycles and the cycle temperature-length of time for template denaturation and primer annealing and extension are important parameters for high quality PCR results. The optimal number of cycles is dependent on the starting concentration or copy number of the target DNA and typically ranges from 25 to 35 cycles. Too many cycles will significantly increase the amount of nonspecific PCR products. For low copy number targets, such as the integrated provirus of *Human immunodeficiency virus type 1* (HIV-1) from human genomic DNA, two rounds of PCR are employed first using an outer primer pair set followed by an internal (nested) primer pair set flanking the region of interest to yield positive and specific PCR products. Brief, but effective denaturation conditions, that

Figure 1. The PCR amplification cycle.

is 94–97 °C for 15–30 s, are necessary as *Taq* DNA polymerase has a half-life of only 40 min at 95 °C. Annealing conditions, on the other hand, are dependent on the concentration, base composition and the length of the oligonucleotide and typically range between 55 and 68 °C for 30–60 s. The length of the amplified target is directly proportional to the primer extension length of time. Primer extension is performed between 68 and 72 °C and, as a rule of thumb, is ~ 60 s for every 1 kb.

Crude extracts from blood, cerebral spinal fluid, urine, buccal smears, bacterial colonies, yeast spores, and so on are routinely used as sources of DNA for PCR templates. Due to the high sensitivity of PCR, rapid isolation protocols, such as heat and detergent disruptions, and enzymatic digestion of biological samples have been frequently used. Caution should be invoked when using crude extracts as starting materials for PCR amplifications because a number of impurities are known to inhibit *Taq* DNA polymerase. These include red blood cell components, sodium dodecyl sulfate (SDS), high salts, EDTA and too much DNA. Since only a few hundred target molecules are needed for successful PCRs, in most cases, these impurities

can be effectively removed by simply diluting the starting material. Each sample should then be tested with control primers that specifically amplify a known target to determine the integrity of the crude extract. Alternatively, the isolation of the desired organism, such as HIV-1, human *Hepatitis A virus*, influenza virus, cytomegalovirus, and so on, or the isolation of specific cell fractions, such as peripheral blood mononuclear cells, can significantly increase the sensitivity and specificity of the PCR amplifications.

SENSITIVITY AND CONTAMINATION OF POLYMERASE CHAIN REACTION

Contamination is the dark side of the PCR force. The exquisite sensitivity of PCR can result in contamination from even a single molecule of foreign or exogenous DNA (4,5). To minimize false positives, standard operating procedures have been described, including the physical isolation of PCR reagents from the preparation of DNA templates and PCR products, using autoclaved solutions, premixing and aliquoting reagents, the use of disposable

gloves, avoiding splashes, the use of positive displacement pipettes, adding DNA last, and carefully choosing positive and negative controls (6). Contamination is likely to surface for DNA samples that are difficult to amplify because of sequence content, or due to poor primer design and chemical impurities in DNA extractions. This is especially true for low copy number targets or degraded samples, as greater numbers of amplification cycles are generally required to achieve the desired product. In these cases, residual amounts of exogenous DNAs can compete and override the amplification process, resulting in spurious data. The best approach to challenge dubious results is to repeat the experiment with scrupulous care to details and controls. Biological samples collected at a single time point should be divided into multiple aliquots such that independent DNA extractions and PCR experiments can be performed to verify and validate initial results. Data should be discarded if inconsistent positive and negative PCR results occur upon repetition of the experiment. While negative controls can rule out reagent contamination, sporadic contamination can go unchecked. The probability of repeating spurious contamination in a consistent manner is extremely low.

There are three sources of contaminating DNA: (1) carryover contamination from previously amplified PCR products; (2) cross-contamination between multiple source materials; and (3) plasmid contamination from a recombinant clone that contains the target sequence. Of the three, carryover contamination is considered to be the major source of contamination because of the relative abundance of amplified target sequences. The substitution of dUTP for dTTP in the PCR cocktail has been routinely used as a method of preventing carryover contamination. Pretreatment of subsequent PCR mixtures prior to thermal cycling with uracil DNA glycosylase results in the removal of dU from any carryover PCR product, but does not affect the template DNA or dUTP. The dU removal creates an abasic site that is heat labile and degrades during thermal cycling, thus preventing carryover amplification. Moreover, ultraviolet (UV) light can reduce work surface and reagent contamination. Cross-contamination between samples is more difficult to diagnose, and suspicious results should be repeated from independent DNA extracts and PCR experiments for samples in question. Plasmid contamination, on the other hand, can be identified by sequence analysis and comparison to all laboratory plasmid sequences.

POLYMERASE CHAIN REACTION INTRODUCES MUTATIONS

The power and ease of PCR, however, were not fully appreciated until the introduction of the thermostable DNA polymerase isolated from *Thermus aquaticus* (*Taq*) (7) and automated instrumentation in 1988. It was here that PCR could be run in fully closed and automated systems. Fresh Klenow DNA polymerase did not have to be added at each cycle and PCR could be performed at higher annealing and extension temperatures, which

increased the specificity and yields of the reactions while minimizing the risks of contamination. A hot start PCR further enhances specificity by preventing the formation of nonspecific products that arise during the initial steps of thermal cycling in PCR.

Taq DNA polymerase has been shown to incorporate nucleotides incorrectly at a frequency of 1 in 9000 bases by a mutation reversion assay (8). From sequence analysis of cloned PCR products, a slightly higher error frequency was determined (1 in 4000–5000 bp) for *Taq* DNA polymerase (9). The fidelity of DNA synthesis for *Taq* DNA polymerase, however, can vary significantly with changes in free Mg^{2+} concentration, changes in the pH of the buffer, or an imbalance in the four dNTP concentrations. Polymerase misincorporation errors are minimized when the four dNTPs are equimolar and between 50 and 200 $\mu\text{mol}\cdot\text{L}^{-1}$ (9). Since *Taq* DNA polymerase lacks a 3'-exonuclease activity, misincorporated bases typically cause chain termination of DNA synthesis that are not propagated in subsequent PCR cycles. In a worst-case scenario, a mutation occurring during the first round of PCR from a single target molecule and propagated thereafter would exist at a frequency of 25% in the final PCR product. Since hundreds of target copies are routinely used as starting DNA in PCR and most misincorporations terminate DNA synthesis, the observed error frequency is $\ll 25\%$.

Cloning of full-length genes from PCR products, however, has been problematic because PCR-induced mutations can cause amino acid substitutions in the wildtype sequence. Thus, significant effort must be employed in the complete sequencing of multiple PCR clones to identify mutation-free clones or ones that contain synonymous substitutions that do not change the protein coding sequence. Accordingly, thermostable DNA polymerases that contain a 3'-exonuclease (3'-exo) activity for proof-reading of misincorporated bases have been recently introduced and include DNA polymerases isolated from *Pyrococcus furiosus* (*Pfu*), *Thermococcus litoralis* (*Vent*), *Pyrococcus* species GB-D (Deep Vent) and *Pyrococcus woesei* (*Pwo*). The error frequencies of these DNA polymerases are two- and sixfold $<$ *Taq* DNA polymerase (10), but these polymerases are difficult for routine use, as the 3'-exonuclease activity can easily degrade the single-stranded PCR primers. 3'-Exo DNA polymerases, however, have been successfully used in long PCR in combination with *Taq* DNA polymerase and show an approximately twofold lower error frequency than *Taq* DNA polymerase alone (10).

POLYMERASE CHAIN REACTION LENGTH LIMITATIONS

For most applications, standard PCR conditions can reliably amplify target sizes up to 3–4 kb from a variety of source materials. Target sizes $>$ 5 kb, however, have been described in the literature using standard PCR conditions, but generally yield low quantities of PCR product. The PCR size limitation can be attributed to the misincorporation of nucleotides that occurred 1 in 4000–5000 bp that ultimately reduced the efficiency of amplifying longer target regions. A breakthrough in long PCR came through the combined use of two thermostable DNA

polymerases, one of which contains a 3'-exonuclease activity (11,12). The principle for long PCR is that the *Taq* DNA polymerase performs the high fidelity DNA synthesis part of PCR, coupled with the proofreading activity of *Pfu*, *Vent* or *Pwo* DNA polymerases. Once the nucleotide error is corrected, *Taq* DNA polymerase can then complete the synthesis of long PCR templates. From empirical studies, only a trace amount of the 3'-exo DNA polymerase, roughly 1% to that of *Taq* DNA polymerase or another DNA polymerase isolated from *Thermus thermophilus* (*Tth*), is needed to perform long PCRs > 20 kb. Other important factors for long PCR are the isolation of high quality, high molecular weight DNA and protection against template damage, such as depurination during thermal cycling. The use of the cosolvents glycerol and dimethyl sulfoxide (DMSO) have been shown to protect against DNA damage by efficiently lowering the denaturation temperature by several degrees centigrade. The rule of thumb for primer extensions still applies for long PCRs ($60 \text{ s} \cdot \text{kb}^{-1}$), although for targets > 20 kb, times extension should not exceed $22 \text{ min cycle}^{-1}$. The complexity and size of the genome under investigation can also affect the size of long PCR products. For example, PCR product lengths of 42 kb have been described for the amplification of λ bacteriophage DNA (11,12), compared with a 22 kb PCR product obtained from the human β -globin gene cluster (12).

CREATION OF NOVEL RECOMBINANT MOLECULES BY POLYMERASE CHAIN REACTION

Polymerase chain reaction can amplify both single- and double-stranded DNA templates as well as complementary DNA (cDNA) from the reverse transcription of messenger ribonucleic acid (mRNA) templates. Because of the flexibility of automated DNA synthesis, *In vitro* mutagenesis experiments can easily be performed by PCR. Recombinant PCR products can be created via the primer sequences by tolerated mismatches between the primer and the template DNA or by 5'-add-on sequences. Primer mediated mutagenesis can accommodate any nucleotide substitutions and small insertions or deletions of genetic material. The desired genetic alteration can be moved to any position within the target region by use of two overlapping PCR products with similar mutagenized ends (Fig. 2, left). This is accomplished by denaturing and reannealing the two overlapping PCR products to form heteroduplexes that have 3'-recessed ends. Following the extension of the 3'-recessed ends by *Taq* DNA polymerase, the full-length recombinant product is reamplified with the outer primers only to enrich selectively the full-length recombinant PCR product. 5'-Add-on adapters can also be used to join two unrelated DNA sequences, such as the splicing of an exogenous promoter sequence with a gene of interest (Fig. 2, right). The promoter-gene sequences are joined at the

Figure 2. Creation of mutagenized or recombinant PCR products via primer mismatches (left) or 5'-add-on sequences (right).

desired junction by 5'-add-on gene specific and 5'-add-on promoter-specific adapters that can PCR amplify the promoter and the gene targets, respectively. Heteroduplexes can then be formed, as described above, from the two overlapping PCR products, which are then selectively amplified with outer primers to generate the desired full-length recombinant PCR product.

POLYMERASE CHAIN REACTION AS A DETECTION SYSTEM

Polymerase chain reaction is a powerful tool for the detection of human polymorphic variation that has been associated with hereditary diseases. Many PCR techniques have been described that can discriminate between wild-type and mutant alleles, but in this section only a few of the most frequently used techniques are discussed. Of these, DNA sequencing of PCR products is the most widely used and most sensitive method for the detection of both novel and known polymorphic differences between individuals. Complementing scanning technologies, however, have been developed for the rapid detection of allelic differences because of the high costs associated with DNA sequencing and the ability to process large numbers of samples. Single-strand conformation polymorphism (SSCP) has been commonly used as a technique for the identification of genetic polymorphisms. Following PCR, the product is heat denatured and subjected to native or nondenaturing gel electrophoresis. Allelic differences between samples are detected as mobility band shifts by radioactive and non-radioactive labeling procedures. PCR-SSCP, however, is limited in fragment size to ~ 200 bp because the accuracy in discriminating between different alleles diminishes significantly with an increase in the fragment length.

Multiplex PCR allows for the simultaneous amplification of multiple target regions and has been particularly useful for the detection of exon deletion(s) in X-linked disorders, such as Duchenne muscular dystrophy (13) and Lesch-Nyhan syndrome (14). The multiplex PCR products are resolved by gel electrophoresis and are visualized by ethidium bromide staining. The absence of specific PCR product(s) is diagnostic of exon deletion(s) in affected males, and half-dosage PCR products are diagnostic of carrier mothers (15). Moreover, up to 46 primer pairs have been simultaneously amplified by multiplex PCR with excellent success (90%) for the large-scale identification of human single nucleotide polymorphisms (SNPs) by hybridization to high density DNA chip arrays.

Genetic polymorphisms can also be identified by immobilizing the PCR product on to a nylon membrane in a dot blot format and probing by hybridization with an allele-specific oligonucleotide (ASO) that contains a 5'-biotin group. The ASO hybridization is detected by adding streptavidin-horseradish peroxidase, which binds to the biotinylated probe, followed by a colorimeter assay. The colorimeter ASO assay has been applied to the genotyping of human leucocyte antigen (HLA)-DQA alleles and the detection of β -thalassaemia mutations. More recently, multiplex PCR and colorimeter ASO methodologies have been combined in a reverse fashion, in which ASOs are immobilized on to nylon membrane strips and probed

against biotinylated gene-specific multiplex PCR reactions. Allele-specific PCR products are detected by hybridization and conversion of a colourless substrate to a blue precipitate for the simultaneous genotyping of HLA-DQA 1, low density lipoprotein receptor, glycophorin A, hemoglobin G gammaglobin, D7S8, and groupspecific component.

Lastly, *In situ* PCR enables the amplification of target sequences from sections of formalin-fixed, paraffin-embedded tissue specimens to determine the levels of gene expression in specific cell types that otherwise could not be detected by conventional *In situ* hybridization. The PCR is performed directly on glass slides by overlaying the PCR mixture on to the specimen, sealing the slides to prevent evaporation, and temperature cycling using a thermal sensor or modified thermal cycler that holds glass slides.

DEGENERATE POLYMERASE CHAIN REACTION

Degenerate PCR is a powerful strategy for obtaining novel full-length cDNA sequences from limited amino acid sequence information (16). The PCR primer sequences are derived from the reverse translation of 6–9 amino acid codons, which will result in varying levels of degeneracy except for methionine and tryptophan residues. Careful attention should be exercised in the design of degenerate primers because increasing the primer complexity (i.e., using codons that show more than twofold degeneracy) will typically result in an increase in nonspecific PCR products. One approach in reducing the complexity of the degenerate primer is the use of codon bias for the particular organism from which the gene will be cloned. Alternatively, the alignment of orthologous gene sequences from other species can greatly improve the specificity of cloning the gene of interest by revealing evolutionarily conserved domains. Once the optimal primer sequence is determined, the mixture of oligonucleotides can be simultaneously synthesized and will represent all possible amino acid combinations of the degenerate sequence. The specificity of PCR should then selectively amplify the correct primer sequences to generate a gene or gene family-specific probe from which the full-length cDNA can be obtained. Degenerate PCR has been successfully used in the screening of novel gene family members such as G-protein-coupled receptors, nuclear steroid receptors and protein tyrosine kinases.

ANCIENT DNA

Phylogenetics is the study of evolutionary relationships between specimens that are inferred from contemporaneous sequences. The ability to obtain DNA sequences from specimens or even fossils that are millions of years old could equip the phylogeneticist with a powerful means of directly testing an a priori hypothesis. Following death of the tissue or organism, however, DNA is rapidly degraded by, presumably, nuclease activities and hydrolytic processes, resulting in short fragment sizes that are generally no longer than 100–150 bp. Moreover, this old DNA is largely modified by oxidative processes and by intermolecular crosslinks that render it unsuitable for cloning by standard molecular biology procedures. Short PCRs,

however, have been successfully performed from DNA samples isolated from archival and ancient specimens (17).

Museums hold vast collections of archived hospital files of patient specimens and of different species that have been collected over the last century. In a recent study, phylogenetic analyses of DNA sequences were performed from reverse transcriptase PCR (RT-PCR) of formalin-fixed, paraffin-embedded tissue specimens obtained from U.S. servicemen killed in the 1918 Spanish influenza pandemic. Viral sequences from three different gene regions were consistent with a novel H1N1 *Influenza A virus* that was most closely related to influenza strains that infect humans and swine, but not wild waterfowl, considered to be the natural reservoir for the influenza virus (18). Moreover, PCR and DNA sequencing have been performed on DNA extractions of archaeological findings, such as amplifying mitochondrial DNA sequences from a 7000 year old human brain, amplifying both mitochondrial and nuclear DNA sequences from bone specimens from a 14,000 year old saber-toothed cat, and amplifying chloroplast DNA sequences from fossil leaf samples from a 17 million-year-old Miocene *Magnolia* species.

QUANTITATIVE POLYMERASE CHAIN REACTION

Quantitative PCR (QPCR) has been widely used for detecting and diagnosing genetic deletions, for studying gene expression and for estimating the viral load of HIV-1. While DNA quantitation by multiplex PCR has been previously described (15), the quantitation of RNA has been wide reaching for the latter two areas. For many applications, estimating the relative amount of PCR product is sufficient to describe a biological observation. The absolute quantitation of RNA molecules, however, has been more difficult than for DNA because of the difficulty of generating accurate controls. Internal standards derived from synthetic RNA or cRNA have been designed to contain the same primer sequences as the target but yield a different-sized PCR product that can be easily separated by gel electrophoresis. cRNAs are not only coamplified with target sequences, but also coreverse transcribed to account for the variable efficiencies of cDNA syntheses. Moreover, QPCR is typically performed in the exponential or log phase of the amplification process (typically 14–22 cycles) to obtain accurate quantitative results. The absolute amount of target mRNA can be quantitated by serial dilutions of the target/internal control mixture and by extrapolating against the standard curve.

Both the variable range of initial target amounts and the presence of various inhibitors can, however, adversely affect the kinetics and efficiencies of PCR. Alternatively, a strategy based on a quantitative competitive (QC) approach has been used to minimize the effects of these variables. Known quantities of the competitor template, which contains the same primer sequences as the target but differs in size, are introduced into replicate PCRs containing identical quantities of the target. The point at which the intensities of the PCR products derived from the target sequence and the competitor template are equivalent is used to estimate the amount of target sequence in the original sample (19).

Recently, real-time QPCR and QCPCR (20) using a 5'-nuclease fluorogenic or TaqMan assay (21) has been developed to measure accurately the starting amounts of target sequences. Unlike gel electrophoresis, real-time QPCR has the unique advantage of being a closed-tube system, which can significantly reduce carryover contamination. Using this technique, one can easily monitor and quantitate the accumulation of PCR products during log phase amplification. The TaqMan assay utilizes dual reporter and quencher fluorescent dyes that are attached to a nonextendible probe sequence. During the extension phase of PCR, the 5'-nuclease activity of *Taq* DNA polymerase cleaves the hybridized fluorogenic probe, which releases the reporter signal and is measured during each cycle. In addition to real-time QPCR, TaqMan assays have broad utility for the identification of SNPs.

RELATED NUCLEIC ACID AMPLIFICATION PROCEDURES

Other *in vitro* systems can amplify nucleic acid targets such as the transcription-based amplification system (TAS) (6), its more recent version called the self-sustained sequence replication (3SR) (22) and the ligation-dependent Q β -replication assay (23). These methods are best suited for the detection and semiquantitation of RNA target sequences. The strategy for TAS and 3SR is a continuous series of reverse transcription and transcription reactions that mimic retroviral replication by amplifying specific RNA sequences via cDNA intermediates. The primers contain 5'- add-on sequences for T7, T3, or SP6 promoters that are incorporated into the cDNA intermediates. The rapid kinetics of transcription-based amplifications is an attractive feature of these systems, which can amplify up to 10^7 molecules in 60 min. Short amplify products, however, which are due to incomplete transcription of the target region and incomplete RNase H digestion of the RNA–DNA hybrids, can be problematic in the TAS and 3SR assays.

Unlike PCR, TAS, or 3SR assays, the ligation-dependent Q β -replication assay results in the amplification of probe, not target, sequences. This assay utilizes a single hybridization to the target sequence, which is embedded within, and divided between, a pair of adjacently positioned midvariant (MDV-1) RNA probes. MDV-1 RNA is the naturally occurring template for the bacteriophage Q β RNA replicase. Following the isolation of the probe–target hybrids, ligation of the binary probes creates a full-length amplifiable MDV-1 RNA reporter. When Q β replicase is added, newly synthesized MDV-1 RNA molecules are amplified from ligated binary probes that originally hybridized to the target sequence (23). Similar to TAS and 3SR, the Q β -replication assay shows rapid kinetics, generating up to 10^9 molecules in 30 min, and all three methods have been successfully used for the detection and quantitation of HIV-1 RNA molecules.

LIGATION CHAIN REACTION

The ligase chain reaction (LCR) can also amplify short DNA regions of interest by iterative cycles of denaturation

and annealing/ligation steps (24). The LCR utilizes four primers: two adjacent ones that specifically hybridize to one strand of target DNA and a complementary set of adjacent primers that hybridize to the opposite strand. LCR primers must contain a 5'-end phosphate group, such that thermostable ligase (24) can join the 3'-end hydroxyl group of the upstream primer to the 5'-end phosphate group of the downstream primer. Successful ligations of adjacent primers can subsequently act as the LCR template, resulting in an exponential amplification of the target region. The LCR is well suited for the detection of SNPs because a single-nucleotide mismatch at the 3' end of the upstream primer will not ligate and amplify, thus discriminating it from the correct base. Although LCR is generally not quantitative, linear amplifications using one set of adjacent primers, called the ligase detection reaction, can be quantitative. Coupled to PCR, linear ligation assays can also be used as a mutation detection system for the identification of SNPs using both wild-type-specific and mutant-specific primers in separate reactions. The oligonucleotide ligase assay was first reported to detect SNPs from both cloned and clinical materials using a 5'-end biotin group attached to the upstream primer and a non-isotopic label attached to the downstream primer (25). Allele-specific hybridizations and ligations can be separated by immobilization to a streptavidin-coated solid support and directly imaged under appropriate conditions without the need for gel electrophoretic analysis.

SUMMARY

Some of the general concepts and practices of PCR have been reviewed here. Not only has PCR made a major and significant impact on basic and clinical research, but it has also been well accepted and utilized in forensic science. For any scientific methodology to be accepted in the courts as evidence, it must satisfy four criteria: that the method (1) be subject to empirical testing, (2) be subject to peer review and publication, (3) has a known error rate, and (4) is generally accepted in the scientific community. The application of PCR has been admitted in the U.S. courts as evidence in criminal cases for the analysis of human DNA sequences, and in January 1997 as evidence for the phylogenetic analysis of HIV DNA sequences (26). Clearly, the scope of applications for PCR seems endless and it is truly a remarkable technique that has been widely used in molecular biology.

INTRODUCTION

This article aims to provide basic and contemporary information on polymeric materials used in medical devices and instrumentation. The fundamental concepts and features of polymeric materials are introduced in the first section. In the second section, the major commodity polymers used in medicine are reviewed in terms of their basic chemical and physical properties. The main part of this article, however, is devoted to polymers in biomedical engineering applications, including tissue engineering and drug delivery systems.

Polymers are a very important class of materials. A polymer can be defined as a long-chain molecule that is composed of a large number of repeating units of identical structure. Some polymers, (e.g., proteins, cellulose, and starch) are found in Nature, while many others, including polyethylene, polystyrene, and polycarbonate, are produced only by synthetic routes. Hundreds of thousands of polymers have been synthesized since the birth of polymer science. Today, polymeric materials are used in nearly all areas of daily life.

Polymers can simply be divided into two distinct groups based on their thermal processing behavior: thermoplastics and thermosets. Thermoplastics are linear or branched polymers, and they soften or melt when heated, so that they can be molded and remolded by heating. This property allows for easy processing and recycling. In comparison, thermosets are three-dimensional (3D) network polymers, and cannot be remelted. Once these polymers are formed, reheating will cause the material to scorch.

In addition to classification based on processing characteristics, polymers may also be grouped based on the chemical structure of their backbone. Polymers with one

identical repeating unit in their chains are called homopolymers. The term copolymer is often used to describe a polymer with two or more repeating units. The sequence of repeating units along the polymer chain can form different structures, and copolymers can be further classified as random copolymers, alternating copolymers, block copolymers, and graft copolymers. In random copolymers, the sequence distribution of the repeating units is random, while in alternating copolymers the repeating unit are arranged alternately along the polymer chain. A block copolymer is one in which identical repeating units are clustered in blocks along the chain. In graft copolymers, the blocks of one type of repeating unit are attached as side chains to the backbone chains.

Unlike simple pure compounds, most polymers are not composed of identical molecules. A typical synthetic polymer sample contains chains with a wide distribution of chain lengths. Therefore, polymer molecular weights are usually given as averages. The number average molecular weight (M_n), which is calculated from the mole fraction distribution of different sized molecules in a sample, and the weight average molecular weight (M_w), which is calculated from the weight fraction distribution of different sized molecules, are two commonly used values. The statistical nature of polymerization reaction makes it impossible to characterize a polymer by a single molecular weight. A measure of the breadth of the molecular weight distribution is given by the ratios of molecular weight averages. The most commonly used ratio is M_w/M_n . As the weight dispersion of molecules in a sample narrows, M_w approaches M_n , and in the unlikely case that all the polymer molecules have identical weights, the ratio M_w/M_n becomes unity. Most commercial polymers have the molecular weight distribution of 1.5–10. In general, increasing molecular weight corresponds to increasing physical properties and decreasing polymer processability.

In many cases, individual polymer chains are randomly coiled and intertwined with no molecular order or structure. Such a physical state is termed amorphous. Amorphous polymers exhibit two distinctly different types of mechanical behavior. Some, like poly(methyl methacrylate, PMMA) and polystyrene are hard, rigid, glassy plastics at room temperature, while others, like polybutadiene and poly(ethyl acrylate), are soft, flexible, rubbery materials at room temperature. There is a temperature, or range of temperatures, below which an amorphous polymer is in a glassy state, and above which it is rubbery. This temperature is called the glass transition temperature (T_g). The value of T_g for a specific polymer will depend on the structure of the polymer. Side groups attached to the polymer chain will generally hinder rotation in the polymer backbone, necessitating higher temperatures to give enough energy to enable rotation to occur.

For most polymers, the T_g constitutes their most important mechanical properties. At low temperatures ($< T_g$), an amorphous polymer is glass-like, with a value of Young's modulus in the range of 10^9 – 10^{10} Pa, and it will break or yield at strains greater than a few percent. When the temperature is $> T_g$, the polymer becomes rubber-like, with a modulus in the range of 10^5 – 10^6 Pa, and it may withstand large extensions with no permanent deformation. At even

higher temperatures, the polymer may undergo permanent deformation under load and behave like a highly viscous liquid. In the T_g range, the polymer is neither glassy nor rubber-like. It has an intermediate modulus and has viscoelastic properties.

CHEMICAL AND PHYSICAL PROPERTIES OF MAJOR COMMODITY POLYMERS

This section reviews the major polymers used in medical applications, with a brief discussion of chemical as well as physical properties and their application. They are grouped as homopolymers or copolymers.

Homopolymers

Polyacrylates (e.g., PMMA) and poly(hydroxyethyl methacrylate) (PHEMA), are used for hard and soft contact lenses because of their excellent physical, coloring properties, and ease in fabrication. The PMMA polymer is a hydrophobic, linear chain polymer that is glassy at room temperature. It has very good light transmittance, toughness, and stability, making it an excellent material for intraocular lenses and hard contact lenses. The PHEMA polymer is used for soft contact lenses. With the addition of a $-CH_2OH$ group to the methyl methacrylate side group of the PMMA structure, the polymer becomes hydrophilic. Typically, PHEMA is cross-linked with ethylene glycol dimethylacrylate (EGDM) to prevent the polymer from dissolving when hydrated. When fully hydrated, PHEMA is a hydrogel with potential use in advanced technology applications (e.g., biomedical separation and biomedical devices).

Polyolefins, which include polyethylene (PE) and polypropylene (PP), are linear chain polymers. Polyethylene is a highly crystalline polymer that is used in its high density form for biomedical applications because low density forms cannot withstand sterilization temperatures. The high density form is used for drains and catheters. The ultra-high molecular weight form (UHMWPE) is used in orthopedic implants for load-bearing surfaces in total hip and knee joints. The material has good toughness, creep properties, resistance to environmental attack, and relatively low cost. The PP is related to PE by the addition of a methyl group along the polymer chain. It has similar properties to PE (e.g., high rigidity, good chemical resistance, and tensile strength) and is used for many of the same applications. It also has a high flex life, which is superior to PE and is therefore used for finger joint prostheses.

Polytetrafluoroethylene (PTFE), commonly known as Teflon, is similar in structure to PE except that the hydrogen in PE is substituted with fluorine. This polymer has a high crystallinity (> 94%), high density, low modulus of elasticity, and tensile strength. It is a very stable polymer and difficult to process. The material also has very low surface tension and friction coefficient. It is used for vascular graft applications due to the lack of adherence of blood components.

Poly(vinyl chloride) (PVC) is typically used for tubing for blood transfusions, feeding, and dialysis. Pure PVC is hard and brittle. However, for these applications, the addition of

plasticizers makes it soft and flexible. Issues concerning these plasticizers exist because they can be extracted during long-term use, making PVC less flexible over time.

Poly(dimethyl siloxane) (PDMS), or silicone rubber, is a versatile material. Low molecular weight polymers have low viscosity and can be cross-linked to make a higher molecular weight rubber-like material. It has a silicon-oxygen backbone instead of a carbon backbone. The material is less temperature sensitive than other rubbers because of its lower T_g . It also has excellent flexibility and stability. The applications of PDMS are widespread (e.g., catheter and drainage tubing, insulation for pacemaker leads, a component in some vascular graft systems, prostheses for finger joints, blood vessels, breast implants, outer ears, chin and nose implants). Since its oxygen permeability is very high, PDMS is also used in membrane oxygenators.

Polyamides, commonly known as nylons, are linear-chain polymers containing $-CONH-$ groups. With the presence of these groups, the chains attract strongly to one another by hydrogen bonding. Increasing numbers of $-CONH-$ groups and a high degree of crystallinity improves physical properties (e.g., strength and fiber forming ability). They are used for surgical sutures.

Polycarbonates are tough, amorphous, clear materials produced by the polymerization of biphenol A and phosgene. It is used as lenses for eyeglasses and safety glasses, and housings for oxygenators and heart-lung bypass machines.

Copolymers

Poly(glycolide lactide) (PGL) are random copolymers used in resorbable surgical sutures. The PGL is polymerized by a ring-opening reaction of glycolide and lactide and is gradually resorbed in the body due to the ester linkages in the polymer backbone via hydrolysis.

A copolymer of tetrafluoroethylene and hexafluoropropylene (FEP) is used similarly to PTFE. The advantage of FEP is that it is easier to process than PTFE, but still retains excellent chemical inertness and a low coefficient of friction. The FEP has a crystalline melting temperature of 265 °C, whereas PTFE is 375 °C.

Polyurethanes are copolymers, which contain "hard" and "soft" blocks. The "hard" blocks are composed of a diisocyanate and a chain extender, with a T_g above room temperature, and has a glassy or semi-crystalline character. The "soft" blocks are typically polyether or polyester polyols with a T_g below room temperature. Thus, the material also has rubbery characteristics. Polyurethanes are tough elastomers with good fatigue and blood-containing properties. They are typically used for pacemaker lead insulation, vascular grafts, heart assist balloon pumps, and artificial heart bladders.

POLYMERS IN BIOMEDICAL ENGINEERING APPLICATIONS

Polymers Used in Tissue Engineering

Synthetic Polymers. The most widely used synthetic polymers for tissue engineering products, either under

development or on the market, are poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and their copolymers PLGA. Both PLA and PGA are linear aliphatic polyesters formed by ring-opening polymerization with a metal catalyst. The PLA can also be obtained from the renewable agricultural source, corn and degrades in two phases: hydrolysis and metabolization. The PLA and PGA polymers have similar chemical structures except that the PLA has a methyl pendant group. Both degrade by simple hydrolysis of their ester linkages. The PGA can also be broken down by nonspecific esterases and carboxypeptidases. The degradation rate is dependent on initial molecular weight, exposed surface area, crystallinity, and, in the case of copolymers, the PLA/PGA ratio present. PGA is highly crystalline, having a high melting point, and a low solubility in organic solvents. It is also hydrophilic in nature, losing its mechanical strength over a period of 2–4 weeks in the body.

The PLGA was developed to achieve a wider range of possible applications for PGA. Due to the extra methyl group in lactic acid, PLA is more hydrophobic and has a slower rate of backbone hydrolysis than PGA. The PLA is also more soluble in organic solvents. The copolymer PLGA degradation depends on the exact ratio of PLA and PGA present in the polymer. The PLGA polymer is less crystalline and tends to degrade more rapidly than either PGA or PLA. Lactic acid is a chiral molecule that exists in two stereoisomeric forms that yield four morphologically distinct polymers. Both *d*-PLA and *l*-PLA are two stereoregular polymers *d,l*-PLA is the racemic polymer and *meso*-PLA can be obtained from *d,l*-lactide. The amorphous polymer is *d,l*-PLA and is used typically for drug delivery applications where it is important to have a homogenous dispersion of the active agents within a monobasic matrix. The *l*-PLA polymer is semi-crystalline and most commonly used because the degradation product of *l*(+)-lactic acid is the naturally occurring stereoisomer of lactic acid. It is typically used for high mechanical strength and toughness applications (e.g., orthopaedics).

Some of the other synthetic polymers currently under investigation for tissue engineering applications are described briefly. Polycaprolactone (PCL) is a synthetic aliphatic polyester with a melting point (T_m) of 55–65 °C. Degradation of PCL is a slow process that occurs either by hydrolysis or enzymatic degradation *in vivo*. The slow degradation rate of PCL is particularly interesting for long-term implants and controlled release application. Poly(hydroxy butyrate) (PHB) and its copolymers are semi-crystalline thermoplastic polyester made from renewable natural sources. *In vivo*, PHB degrades into hydroxybutyric acid that is a normal constituent of human blood. The PHB homopolymer is highly crystalline and has a high degradation rate. Its biodegradation and biocompatibility properties have led to research on its prospective use as a material for coronary stents, wound dressings, and drug delivery. Poly(propylene fumarate) (PPF) is an unsaturated linear polyester formed by the copolymerization of fumaric acid and propylene glycol. These polymer networks degrade by hydrolysis of the ester linkage to water-soluble products, namely, propylene glycol, poly(acrylic acid-co-fumaric acid), and fumaric acid. Due to its unsaturated sites along the polymer backbone, which

are labile and can be cross-linked *in situ*, PPF is currently being evaluated for filling skeletal defects of varying shapes and sizes. Polyphosphoesters (PPE) are biodegradable polymers with physicochemical properties that can be altered by the manipulation of either the backbone or the side-chain structure. This property of PPE makes them potential drug delivery vehicles for low molecular drugs, proteins, deoxyribonucleic acid DNA plasmids, and as tissue engineering scaffolds. Since the phosphoester bond in a PPE backbone is cleaved by water, the more readily water penetrates, with greater bond cleavage and faster degradation rate. The products of hydrolytic breakdown of PPE are phosphate, alcohol, and diol. Polyphosphazenes are inorganic polymers having a phosphorus–nitrogen alternating backbone and each phosphorus atom is attached to two organic or organometallic side groups. They degrade by hydrolysis into phosphate, amino acid, and ammonia. The potential application is in low molecular weight drug release and in formulation of proteins and peptides. Polyanhydrides are a class of degradable polymers synthesized from photopolymerizable multimethacrylate monomers. Many polyanhydrides degrade from the surface by hydrolysis of the anhydride linkages. The rate of hydrolysis is controlled by the polymer backbone chemistry. They are useful for controlled drug delivery as they degrade uniformly into nontoxic metabolites. Polyorthoesters (POE), another class of biodegradable and biocompatible polymers, can be designed to possess a surface-dominant erosion mechanism. Acidic byproducts autocatalyzed the degradation process resulting in increased degradation rates than nonacidic byproducts. The POE, which is susceptible to acid-catalysed hydrolysis, has attracted considerable interest for the controlled delivery of therapeutic agents within biodegradable matrices.

Natural Polymers. Collagen is a widely used natural polymer in tissue engineering. It is a structural protein, being a significant constituent of the natural extracellular matrix. It has a triple-helical molecular structure that arises from the repetitious amino acid (glycine, proline, and hydroxyproline) sequence. *In vivo*, collagen in healthy tissues is resistant to attack by most proteases except specialized enzymes called collagenases that degrade the collagen molecules. Collagen can be used alone or in combination with other extracellular matrix components (e.g., glycosaminoglycan and growth factors) to improve cell attachment and proliferation. It has been tested as a carrier material in tissue engineering applications.

Other natural polymers under investigation for tissue engineering applications are described briefly. Gelatin, denatured collagen, is obtained by the partial hydrolysis of collagen. It can form a specific triple-stranded helical structure. The rate of the formation of a helical structure depends on many factors (e.g., the presence of covalent cross-bonds, gelatin molecular weight, the presence of amino acids, and the gelatin concentration in the solution). Gelatin is used in pharmaceuticals, wound dressings, and bioadhesives due to its good cell viability and lack of antigenicity. It has some potential for use in tissue engineering applications. Silk is a fibrous protein characterized by a highly repetitive primary sequence of glycine and

alanine that leads to significant homogeneity in secondary structure, β -sheets in the case of many of the silks. Silk is biodegradable due to its susceptibility to proteolytic enzymes. Silk studies *in vitro* have demonstrated that protease cocktails and chymotrypsin are capable of enzymatically degrading silk. The mechanical properties of silk provide an important set of material options in the fields of controlled release, biomaterials, and scaffolds for tissue engineering. Alginate is a straight-chain polysaccharide composed of two monomers, mannuronic acid and guluronic acid residues, in varying proportions. Alginate forms stable gels on contact with certain divalent cations, such as calcium, barium, and strontium. Alginate is widely used as an instant gel for bone tissue engineering. Chitosan, a copolymer of glucosamine and *N*-acetylglucosamine is a crystalline polysaccharide. It is synthesized by the deacetylation of chitin. Chitosan degrades mainly through lysozyme-mediated hydrolysis, with the degradation rate being inversely related to the degree of crystallinity. Chitosan has excellent potential as a structural base material for a variety of tissue engineering application, wound dressings, drug delivery systems, and space-filling implants. Hyaluronate, a glycosaminoglycan is a straight-chain polymer composed of glucuronic acid and acetylglucosamine. It contributes to tissue hydrodynamics, movement, and proliferation of cells *in vivo*. Hyaluronan is enzymatically degraded into monosaccharides. It has been used in the treatment of osteoarthritis, dermal implants, and prevention of postsurgical adhesions.

Polymeric Scaffold Fabrication Techniques (6–8). Scaffolds for tissue engineering, in general, are porous to maximize cell attachment, nutrient transport, and tissue growth. A variety of processing technologies have been developed to fabricate porous 3D polymeric scaffolds for tissue engineering. These techniques mainly include solvent casting and particulate leaching, gas-foaming processing, electrospinning technique, rapid prototyping, and thermally induced phase-separation technique, which are described below.

Solvent casting and particulate leaching is a simple, but commonly used method for fabricating scaffolds. This method involves mixing water soluble salt (e.g., sodium chloride, sodium citrate) particles into a biodegradable polymer solution. The mixture is then cast into the desired shape mold. After the solvent is removed by evaporation or lyophilization, the salt particles are leached out and leave a porous structure. This method has advantages of simple operation and adequate control of pore size and porosity by salt/polymer ratio and particle size of the added salt. However, the interconnectivity between pores inside the scaffold is often low, which seems to be problematic for cell seeding and culture.

Gas foaming is marked by the ability to form highly porous polymer scaffold foams without using organic solvents. In this approach, carbon dioxide is usually used as a foaming agent for the formation of polymer foam. This approach allows the incorporation of heat sensitive pharmaceuticals and biological agents. The disadvantage of this method is that it yields mostly a nonporous surface and closed-pore structure.

Electrospinning is a fabrication process for tissue engineering that use an electric field to control the formation and deposition of polymer fibers onto a target substrate. In electrospinning, a polymer solution or melt is injected with an electrical potential to create a charge imbalance. At a critical voltage, the charge imbalance begins to overcome the surface tension of the polymer source, and forms an electrically charged jet. The jet within the electric field is directed toward the ground target, during which time the solvent evaporates and fibers are formed. This electrospinning technique can fabricate fibrous polymer scaffolds composed of fiber diameters ranging from several microns down to several hundred nanometers.

Rapid prototyping is a technology based on the advanced development of computer science and manufacturing industry. The main advantage of these techniques is their ability to produce complex products rapidly from a computer-aided design (CAD) model. The limitation of this method is that the resolution is determined by the jet size, which makes it difficult to design and fabricate scaffolds with fine microstructure. The controlled thermally induced phase-separation process was first used for the preparation of porous polymer membranes. This technique was recently utilized to fabricate biodegradable 3D polymer scaffolds. In this approach, the polymer is first dissolved in a solvent (e.g., dioxane) at a high temperature. Liquid–liquid or solid–liquid phase separation is induced by lowering the solution temperature. Subsequent removal of the solidified solvent-rich phase by sublimation leaves a porous polymer scaffold. The pore morphology and microstructure of the porous scaffolds varies depending on the polymer, solvent, concentration of the polymer solution, and phase separation temperature. One advantage of this method is that scaffolds fabricated with the technique have higher mechanical strength than those of the same porosity made with the well-documented salt-leaching technique.

Polymers for Drug Delivery. Over the past decade, the use of polymeric materials for the administration of pharmaceuticals and as biomedical devices has dramatically increased (9–11). One important medical application of polymeric materials is in the area of drug delivery systems. There are a few polymer molecules having a drug function, however, in most cases when polymers are used in drug delivery systems, they serve as a carrier of drugs. Table 1 lists some of the important biodegradable and nonbiodegradable polymers used in drug delivery systems.

Table 1. Typical Biodegradable and Nonbiodegradable Polymers Used in Controlled Release Systems

Nonbiodegradable Polymers	Biodegradable Polymers
Polyacrylates	Polyglycolides
Polyurethanes	Poly lactides
Polyethylenes	Polyanhydrides
Polysiloxanes	Polyorthoesters
	Polycaprolactones
	Poly(β -hydroxybutyrate)
	Polyphosphazenes
	Polysaccharides

Most of the above biodegradable and nonbiodegradable polymers have been discussed in the previous sections; therefore, they are not described further here.

Stimuli-Responsive Hydrogels for Drug Delivery. Hydrogels have been used as carriers for a variety of drug molecules (10). A hydrogel is a network of hydrophilic polymers that are cross-linked by either covalent or physical bonds. It distinguishes itself from other polymer networks in that it swells dramatically in the presence of abundant water. The physicochemical and mechanical properties can be easily controlled, and hydrogels can be made to respond to changes in external factors.

In recent years, temporal control of drug delivery has been of great interest to achieve improved drug therapies. Stimuli-responsive hydrogels exhibit sharp changes in behavior in response to an external stimulus (e.g., temperature, pH, solvents, salts, chemical or biochemical agents, and electrical field). The stimuli-responsive hydrogels have the ability to sense external environmental changes, judge the degree of external signal, and trigger the release of appropriate amounts of drug. Such properties have made it very useful for temporal control of drug delivery (12,13).

Temperature-Sensitive Hydrogels. Temperature is the most widely used stimulus in environmentally responsive polymer systems. Temperature-sensitive hydrogels can respond to the change of environmental temperature. The change of temperature is not only relatively easy to control, but also easily applicable both *in vitro* and *in vivo*. Poly(*N*-isopropylacrylamide) (PNIPA) is representative of the group of temperature-responsive polymers that have a lower critical solution temperature (LCST), defined as the critical temperature at which a polymer solution undergoes phase transition from a soluble to an insoluble state above the critical temperature. The PNIPA exhibits a sharp phase transition in water at ~ 32 °C, which can be shifted to body temperatures by the presence of hydrophilic monomers (e.g., acrylic acid). Reversely, the introduction of a hydrophobic constituent to PNIPA would lower the LCST of the resulting copolymer.

When PNIPA chains are chemically cross-linked by a cross-linker (e.g., *N,N'*-methylenebisacrylamide and ethylene glycol dimethacrylate), the PNIPA hydrogel is formed, which swells, but does not dissolve in water. The PNIPA hydrogel undergoes a sharp swelling-shrinking transition near the LCST, instead of sol-gel phase separation. The sharp volume decrease of the PNIPA hydrogel above the LCST results in the formation of a dense, shrunken layer on the hydrogel surface, which hinders water permeation from inside the gel into the environment. The PNIPA hydrogels have been studied to the delivery of antithrombotic agents (e.g., heparin), at the site of a blood clot, utilizing biological conditions to trigger drug release. Drug release from the PNIPA hydrogels at temperatures below LCST is governed by diffusion, while above this temperature drug release is stopped, due to the dense layer formation on the hydrogel surface.

Some types of block copolymers made of poly(ethylene oxide) (PEO) and poly(propylene oxide) (PPO) also possess an inverse temperature sensitive property. Because of

their LCST at around body temperature, they have been widely used in the development of controlled drug delivery systems based on the sol-gel phase transition at the body temperature.

pH-Sensitive Hydrogels. Polymers with a large number of ionizable groups are called polyelectrolytes. The pH-sensitive hydrogels are cross-linked polyelectrolytes containing either acidic or basic pendent groups, which show sudden changes in their swelling behavior as a result of changing the external pH. The pendant groups in the pH-sensitive hydrogels can ionize in aqueous media of appropriate pH value. As the degree of ionization increases (via increasing or decreasing pH value in the aqueous media), the number of fixed charges on the polymer chains increases, resulting in increased electrostatic repulsions between the chains. As a result of the electrostatic repulsions, the uptake of water in the network is increased and thus the hydrogels have higher swelling ratios. The swelling of pH-sensitive hydrogels can also be controlled by ionic strength and copolymerizing neutral comonomers, which provide certain hydrophobicity to the polymer chain. The pH-sensitive hydrogels have been used to develop control release formulations for oral administration. For polycationic hydrogels, the swelling is minimal at neutral pH, thus minimizing drug release from the hydrogels. The drug is released in the stomach as hydrogels swell in the low pH environment. This property has been used to prevent release of foul-tasting drugs into the neutral pH environment of the mouth.

Sometimes, it is desirable that hydrogels with certain compositions can respond to more than one environmental stimulus (e.g., temperature and pH). Hydrogel copolymers of *N*-isopropylacrylamide and acrylic acid with appropriate compositions have been designed to sense small changes in blood stream pH and temperature to deliver antithrombotic agents (e.g., streptokinase or heparin) to the site of a blood clot.

Electrosensitive Hydrogels. The electrosensitive hydrogels, which are capable of reversible swelling and shrinking under a change in electric potential, are usually made of polyelectrolytes. The electric sensitivity of the polyelectrolyte hydrogels occurs in the presence of ions in solution. In the presence of an applied electric field, the ions (both cations and counterions) move to the positive or negative electrode, while the polyions of the hydrogels cannot move. This results in a change in the ion concentration-dependent osmotic pressure, and hydrogels either swell or shrink to reach its new equilibrium. The electrosensitive hydrogels exhibit reversible swelling-shrinking behavior in response to on-off switching of an electric stimulus. Thus, drug molecules within the polyelectrolyte hydrogels might be squeezed out from the electric-induced gel contraction along with the solvent flow.

Other Stimuli-Sensitive Hydrogels. Hydrogels that respond to specific molecules found in the body are especially useful for some drug delivery purposes. One such hydrogel is glucose-sensitive hydrogel, which has potential applications in the development of self-regulating insulin delivery systems.

POROUS MATERIALS FOR BIOLOGICAL APPLICATIONS

GRACE E. PARK
THOMAS J. WEBSTER
Purdue University
West Lafayette, Indiana

INTRODUCTION

Porous materials have received much attention in the scientific community because of their ability to interact with biological ions and molecules not only at their surfaces, but also throughout their bulk (1). Because of this intrigue, traditional applications of porous materials have involved catalysis, bioseparations, adsorption of select species, and ion exchange (1). As the tissue engineering field has emerged due to the continuous need for better implan-

table materials, porous materials have also found their niche in regenerative medicine. Specifically, porous materials have been employed as implants for various parts of the body (e.g., bone, cartilage, vasculature, central and peripheral nervous systems, bladder, and skin) either as stand-alone regenerative devices or as drug delivery vehicles to promote tissue growth. Problems associated with current implants and the need for better porous biomaterials in numerous anatomical locations are described below.

Most significantly, estimated annual U.S. healthcare costs related to tissue loss or to organ failure surpassed \$400 billion in 1997 (2). An estimated 11 million people in the United States have received at least one medical implant device; specifically, orthopedic implants (including fracture, fixation, and artificial joint devices) constitute the majority of these and accounted for 51.3% of all implants in 1992 (3). Among joint-replacement procedures, hip and knee surgeries represented 90% of the total and in 1988 were performed 310,000 times in the United States alone (3). Implanting an orthopedic material can be a costly procedure involving considerable patient discomfort, both of which can increase if surgical revisions become necessary after an orthopedic or dental implant is rejected by the host tissue, is insufficiently integrated into juxtaposed bone, and/or fails under physiological loading conditions. Unfortunately, the average lifetime of an orthopedic implant is only 15 years due to many factors including the lack of osseointegration into surrounding bone. Current metallic implants are for the most part nonporous with subsequent poor surface properties to promote new bone ingrowth quickly.

The reason for such a high number of implanted orthopedic–musculoskeletal devices stems from numerous bone diseases. For example, approximately one out of seven Americans suffer from some form of arthritis, which is an inflammatory condition due to wear and tear in the joint (4). The cost of arthritis and rheumatic diseases reaches \$86.2 billion a year, according to a study by the Arthritis Foundation and the National Institutes of Arthritis and Musculoskeletal and Skin Diseases (NIAMS) (5). Although a very common disease, repairing damaged articular cartilage is challenging due to its limited ability to self-repair as a result of its avascularity. In fact, one of the most popular surgical techniques to repair cartilage is not through the use of a biomaterial, but rather is a surgical technique that further injures cartilage to induce scar tissue formation. This scar tissue is intended to serve as new cartilage, but since it does not match the mechanical properties of cartilage tissue, patients receiving such treatments usually suffer from additional complications and pain after only 5 years of this procedure.

The story is not any better for vascular diseases requiring biomaterial intervention. Specifically, the leading cause of death in the United States is vascular disease (including atherosclerosis), affecting ~ 58 million people (6). Atherosclerosis, which is hardening of the arteries, is caused by accumulation of cholesterol, fatty molecules, and other substances inside the vessel wall as the lumen becomes gradually narrower. Consequently, complete blockage of the lumen may result, inhibiting the blood flow

through that blood vessel. Treatments for these conditions require the use of a vascular graft, initially seeking autologous (or taken from an individual's own tissue) materials. For those patients receiving a synthetic vascular graft, success rates for vessels < 7 mm approaches only 25% after 5 years. Current biomaterials used as small diameter vascular grafts are usually nonporous and result in the eventual reaccumulation of undesirable substances that clog the vessel lumen to block blood flow.

Neurological problems also necessitate the use of biomaterials. For example, Parkinson's disease, Huntington's disease, Alzheimer's disease, and epilepsy prevail as common central nervous system (CNS) degenerative pathologies, especially targeting the aging population. While most of these diseases may cause a form of dementia (a mental deterioration), Alzheimer's disease involves the loss of nerve cells related to memory and mental functions, whereas Parkinson's and Huntington's disease affect the mind and body. Among these, > 1.5 million Americans have been affected by Parkinson's disease (6) and ~ 24.4 million people are diagnosed with Alzheimer's disease and stroke, costing $> \$174$ billion annually (7). These diseases, however, account for only those affecting a portion of the CNS: the brain. Equally as troubling are spinal cord disfunctions. Spinal cord injuries can seriously cause damage to a person's quality of life, contributing to $\sim 200,000$ Americans with this disability and expenses of up to $\$250,000$ a year per individual as reported in 1996 (8). Various treatment methods, such as the use of pharmaceutical agents, electrical stimulation probes, and bridges or conduits to physically connect damaged regions of the spinal cord have been developed and improved. However, few clinically approved porous biomaterials are available for treating peripheral and central nerve damage. This is despite the fact that pores in biomaterials could be very useful for guiding nerve fibers through damaged tissues.

Bladder is another organ that could benefit from the use of porous biomaterials. Urinary cancer stands as one of the most common forms of bladder disease, which is the second most common malignancy of the genitourinary tract and the fourth leading cause of cancer among American men (9). Conventional treatment methods include the resection of the cancerous portion of the bladder wall in conjunction with intravesical immunochemotherapy (10). However, these treatments have been less than successful due to local and systemic toxicity of chemotherapy agents (11) and possible recurrence of the cancer (12–14). The best approach to resolve these problems is to completely remove the bladder wall, which clearly leads to the need for a replacement porous biomaterial with highly effective designs matching the material and mechanical properties of the native bladder tissue.

The above statistics highlight the current state of diseases in numerous organs and the potential effect porous biomaterials could have in treating these ailments. It is currently believed that porous biomaterials may be the solution to healing these damaged organs if designed appropriately. The next section will emphasize the features a successful porous biomaterial should have for regenerating tissues.

FEATURES OF THE NEXT GENERATION OF SUCCESSFUL POROUS BIOMATERIALS

An ideal porous scaffold for regenerating the tissues—organs mentioned in the previous section should have these characteristics (15,16): a highly porous three-dimensional (3D) interconnected network of pores for cell infiltration and subsequent tissue ingrowth; biodegradable or bioresorbable in a controllable manner with a rate that matches that of tissue growth; appropriate surface chemistry to promote desirable cell adhesion, proliferation, and differentiation; permeable for transporting sufficient amount of nutrients and metabolic waste to and from cells; mechanical properties that match that of the tissues surrounding the biomaterial *in situ*; and ease of processibility for various desired shapes and sizes to match specific tissue abnormality.

Several studies have confirmed that biomaterial pore size, interconnectivity, and permeability (among other properties) play a crucial role in tissue repair (17–19). Specifically, from the aforementioned list, in the following sections surface, mechanical, degradation, porosity, pore size, and pore interconnectivity properties important for the success of porous biomaterials are elaborated.

Surface Properties

Porous Biomaterial Surface Interactions With the Biological Milieu. Assuming that the porous biomaterial has a clean surface after synthesis (Fig. 1a), the surface will be contaminated with various substances in air (e.g., hydrocarbons, sulfur, and nitrogen compounds) immediately before implantation (Fig. 1a and b) (20). Sterilization and/or introducing coatings can remove or reduce the level of contaminants. The initial interaction between an implant and the biological milieu *In vivo* occurs with water molecules (Fig. 1d) as a mono- or bilayer forms on the surface depending on the porous biomaterial's surface hydrophilicity (or binding strength of water molecules to the implant surface) (21). Water layers form within nanoseconds as other ions contained in body fluids (e.g., Cl^- and Na^+) interact with the adsorbed water molecules depending on the porous biomaterial surface chemistry (Fig. 1e). It is also possible that water interactions containing ions can penetrate the bulk porous biomaterial. Subsequently, proteins adsorb to their surfaces via initial adsorption, and then possible protein conformational changes or denaturation occurs (Fig. 1f). Replacement of these initial proteins with other proteins contained in bodily fluids may occur when biomolecules with stronger binding affinities approach the surface at a later time. Final conformations of the adsorbed proteins may differ from what occurred initially (Fig. 1g). Cells then interact with or bind to the adsorbed proteins on the porous biomaterial surface (Fig. 1h). The type of cells attached to proteins adsorbed on material surfaces and their subsequent activities will determine the tissue formed on the surface (Fig. 1i).

Protein Interactions with Porous Biomaterials

Protein Structure. Clearly, as just mentioned, one of the key events that will determine porous biomaterial success or failure is initial protein adsorption. To further explore

Figure 1. Schematic of the porous biomaterial–tissue interface. (Adapted from Ref. 20) (a) An initially clean porous biomaterial surface possesses surface atoms. (b) A porous biomaterial surface is contaminated with molecules from the ambient environment. (c) The surface is cleaned and passivated by saturation of dangling bonds. (d) A water bilayer forms immediately after implantation. (e) Hydrated ions (e.g., Na⁺, and Cl⁻, and Ca²⁺) are incorporated into the water layer. (f) Proteins adsorb onto the surface depending on their concentration and size as well as properties of the porous biomaterial surface. (g) Various types of proteins adsorb to the surface at different conformations. (h) Cells bind to the proteins that adsorbed on the porous biomaterial surface. (i) Activity of the cells at the interface determines the type of tissue formed at that site.

this, first protein structure must be discussed. There are four levels of protein structure: primary, secondary, tertiary, and quaternary structures. It is important to understand how these different types of protein structures influence initial interactions with surfaces and consequently control cellular adhesion. The primary structure of a protein is its linear sequence of amino acids. Each amino acid is linked to another through peptide bonds. Some amino acids have side chains that are charged or are neutral. Those of particular importance in aqueous solutions exhibit polar characteristics. Other amino acids change their properties depending on the pH of the solution they reside in. Therefore, it should not be surprising that proteins exist with a wide range of properties as

shown in Table 1. Table 1 describes the diverse nature of proteins in terms of size, shape, stability, and surface activity. To emphasize this diversity in protein properties, note the different interactions of albumin compared to fibrinogen on polyethylene (Table 1). Albumin is a cell nonadhesive protein while fibrinogen adsorption enhances a series of events leading to blood clot formation, a common problem of porous biomaterials in vascular applications.

Secondary protein structure consists of ordered structures in the protein chain. Two main secondary structures of proteins are the α -helix and β -pleated sheet. The degree of these structures may vary in a single protein and they are controlled by hydrogen-bonding mechanisms, which

Table 1. Diverse Properties of Proteins^a

Protein	Function	Location	Size, kDa	Shape, nm	Stability	Surface Activity
Albumin	Carrier	Blood	65	4.2 × 14.1	Denatures at 60 °C	Low on polyethylene
Fibrinogen	Clotting	Blood	340	46.0 × 6. (trinodular string)	Denatures at 56 °C	High on polyethylene
IgG	Antibody	Blood	165	T-shaped		Low on polyethylene
Lysozyme	Bacterial lysis	Tear; hen egg	14.6	4.5 × 3.0 (globular)	$\Delta G_n = -14 \text{ kcal}\cdot\text{mol}^{-1}$	High on negatively charged surfaces
Hemoglobin	Oxygen carrier	Red blood cells	65	5.5 (spherical)	Normal form	Very high on polyethylene
Hemoglobin S	Oxygen carrier	Sickle red blood cells	65	5.5 (spherical)	Less than hemoglobin	Much higher air–water activity than hemoglobin
Myoglobin	Oxygen carrier	Muscle	16.7	4.5 × 3.5 × 2.5 spherical)	$\Delta G_n = -12 \text{ kcal}\cdot\text{mol}^{-1}$	
Collagen	Matrix factor	Tissue	285	300.0 × 1.5 (triple helical rod)	melts at 39 °C	
Bacteriorhodopsin	Membrane protein		26	3.0–4.0 long	$\Delta G_n = -8.8 \text{ kcal}\cdot\text{mol}^{-1}$ denatures at 55 °C	High at cell membrane
Tryptophan Synthase alpha Subunit (wild type)	Enzyme		27		$\Delta G_n = -16.8 \text{ kcal}\cdot\text{mol}^{-1}$	High air–water activity compared to ovalbumin
Tryptophan Synthase Variant alpha Subunit	Enzyme		27			Much less active at air–water interface than wild type

^aSee Ref. 22.

are electrostatic attractions between oxygen of one chemical group and hydrogen of another chemical group.

Tertiary protein structures are the overall 3D shape of the protein that can be quite ordered or extremely complicated. The tertiary structure of proteins is a consequence of its primary structure as it depends on the spontaneous interactions between different amino acids and, under aqueous conditions, the spontaneous interactions between amino acids and water. There are four main interactions among residues of amino acids that contribute to the tertiary structure of proteins, each with different strengths: covalent, ionic, hydrogen, and van der Waals bonds. Of these interactions, covalent bonds are the strongest, ionic bonds are also strong (occurring between chemical groups with opposite charges), and van der Waals forces resulting from interactions between hydrophobic molecules are the weakest. However, the most influential bonds on protein tertiary structure are the weakest bonds: hydrogen bonds and van der Waals bonds. This is true since, compared to covalent and ionic bonds, these weaker bonds have many more opportunities for interacting in protein tertiary structure. In addition, because proteins exist in aqueous media, residues of amino acids must interact with water, which is a highly polar compound that forms strong hydrogen bonds. Therefore, the most stable structure of proteins in aqueous media is globular, having hydrophobic areas in the center and hydrophilic areas in the outer layer. Thus, although a generalization, it is possible that the adsorption of proteins to a porous biomaterial surface will be influenced by the presence of these hydrophilic amino acids on the outside of proteins in solution. However, when proteins come in contact with solid surfaces (e.g., porous biomaterials), protein structure will drastically change.

Only proteins that possess numerous subunits have quaternary structure. How these subunits interact will determine the quaternary structure of the protein. Interactions between amino acids on the exterior of the tertiary structure (mostly hydrophilic) will influence the quaternary structure, but certainly some hydrophobic interactions will also occur at the surface and impact quaternary structure.

Under certain extreme conditions (e.g., conditions that are outside of the physiological range or outside the range of 0–45 °C, pH 5–8, and in aqueous solutions of ~ 0.15 M ionic strength), proteins may lose their normal structure (23). In other words, under such conditions, the spherical or globular tertiary structure most soluble proteins assume in aqueous media will unfold or denature. The structure of denatured proteins has been described as a random coil structure similar to those found in synthetic polymers (23). Since the structure of the protein has changed from that of a hydrophilic–hydrophobic exterior–interior to a more random arrangement, often times denatured proteins lose their solubility, become less dense (folded protein structures have densities of ~ 1.4 g·cm⁻³), and lose their bioactivity (23). Although there have been many examples of protein denaturation in solution, in general, only few

cases of full protein denaturation on porous biomaterial surfaces have been reported (23). That is, generally, proteins adsorbed at the solid-liquid interface are not fully denatured and retain some degree of structure necessary to mediate cell adhesion.

Protein Interactions Mediated by Surfaces. Soluble proteins present in biological fluids (e.g., blood plasma) are the type of proteins that are involved in immediate adsorption to surfaces (24). In contrast, insoluble proteins that comprise tissues (like collagen and elastin) are not normally free to diffuse to a solid surface; these proteins may, however, appear on solid surfaces of implantable devices due to synthesis and deposition by cells (23). As mentioned, in seconds to minutes, a monolayer of adsorbed protein will form on solid surfaces (23). The concentration of proteins adsorbed on a material surface is often 1000 times greater than in the bulk phase (23). Thus, extreme competition exists for protein adsorption due to a limited space available on the surface. Because of their diverse properties just described, proteins do not adsorb indiscriminately to every material surface; that is, complimentary properties of the surface and of the protein as well as the relative bulk concentration of each protein determine the driving forces for adsorption (25,26). Moreover, this initial interaction is extremely important since some proteins are not free to rotate once adsorbed to material surfaces due to multiple bonding mechanisms. Thus, immediately upon adsorption, proteins are somewhat fixed in a preferred orientation or bioactivity to the bulk media that contains cells (23). Some porous biomaterial surface properties that have influenced protein adsorption events include chemistry (i.e., ceramic versus polymer), wettability (i.e., hydrophilicity compared to hydrophobicity), roughness, and charge as will be discussed later.

One of the major differences between a flat two-dimensional (2D) substrate surface and that of a 3D porous material is tortuosity. Clearly, protein interactions are

much different on materials due to tortuosity. Specifically, a curved porous surface allows for greater surface area, enhanced interactions between adjacent electrons of the atoms on the surface of the pores, increased localization of point charges, and the potential for greater surface energy due to a larger juxtaposition of localized surface defects. Collectively, all of these differences between a nonporous and porous biomaterial provide for a much more complex environment for interactions between proteins and pore surfaces. It is the challenge of the porous biomaterial community to understand this challenge and thus design scaffolds that control select protein interactions.

Protein-Mediated Cell Adhesion. Interactions of proteins (both their adsorption and orientation or conformation) on porous biomaterials mediate cell adhesion. These interactions lead to extreme consequences for the ultimate function of an implanted device (27,28). An example of the importance of protein orientation for the adhesion of cells is illustrated in Fig. 2. A typical cell is pictured in this figure with integrin receptors that bind to select amino acid sequences exposed once a protein adsorbs to a surface (Fig. 1h). It is the ability of the cell to recognize such exposed amino acids that will determine whether a cell adheres or not. For example, many investigators are designing porous biomaterials to be more cytocompatible. However, it is the adhesion of select cells that must be emphasized. That is, many attempts have been made to immobilize select cell adhesive epitopes in proteins (e.g., the amino acid sequence arginine-glycine-aspartic acid or RGD) onto polymeric tissue engineering scaffolds. But, once implanted into bone, not only do desirable osteoblasts adhere, but so do undesirable fibroblasts (cells that contribute to soft not bony tissue juxtaposition).

Not only will cell adhesion be influenced by the exposure of amino acids in adsorbed proteins, but so will subsequent cell functions (e.g., extracellular matrix deposition). This is true since for anchorage-dependent cells, adhesion is a

Figure 2. Influence of protein conformation on cell integrin binding. Cell adhesion and its subsequent activity will be determined by the type of integrins that the cell uses to adhere to adsorbed proteins. (Adapted and redrawn from Ref. 35.)

crucial prerequisite for subsequent cell functions. Moreover, specific intracellular messages that control subsequent cell functions are transferred inside the cell depending on which integrin receptors are utilized by the cell to adhere to adsorbed proteins. For example, a recent study by Price et al. (29), demonstrated that new bone growth was promoted when osteoblasts adhere via heparin sulfate proteoglycan binding mechanisms (as opposed to RGD) to vitronectin adsorbed on porous ceramic scaffolds.

In this manner, it is clear that cells interact with their external environment through mechanical, electrical, and chemical signals transmitted through the cell membrane. As mentioned, cell adhesion is established through cell-binding regions of extracellular matrix proteins and respective cell-membrane-intercalated receptors (i.e., integrins) among other mechanisms. Integrins are a family of transmembrane heterodimeric glycoproteins that are receptors for specific epitopes of extracellular matrix proteins and for other cell-surface molecules (30). Integrins exist as a dimer complex composed of an α -subunit (120–180 kDa) noncovalently associated with a β -subunit (90–110 kDa) (31). Several of these integrins have been identified that are concentrated at loci, called focal adhesion sites, of close proximity between cells and extracellular matrices on substrates (31). Focal adhesion sites are points of aggregation of, and are physically associated with, intracellular cytoskeletal molecules that control, direct, and modulate cell function in response to extracellular signals (32).

However, integrin–protein interactions are not the only mechanisms by which cells adhere. Several articles suggested that *In vivo* (6) and *In vitro* (33,34) osteoblasts (bone-forming cells) attach to an implanted material through cell membrane heparin sulfate proteoglycan interactions with, for example, heparin-binding sites on fibronectin and collagen. Moreover, Nakamura and Ozawa (6) immunohistochemically detected heparin sulfate on the membranes of osteoblasts attached to bone matrix.

Whatever the method of cell attachment, protein orientation will alter from surface to surface, since neither proteins nor materials are homogeneous in properties or structure on the exterior. The existence of protein regions that are largely acidic–basic or hydrophilic–hydrophobic or have select amino acids exposed to the media will greatly influence how that protein adsorbs to a surface and, thus, its orientation. Similarly, ceramics, metals, polymers, and composites thereof have vastly different chemistries and atomic bonding mechanisms (i.e., ionic, metallic, and covalent) to influence protein interactions. The initial interactions between proteins important for cell functions and the design of better porous biomaterials is emphasized in the next section.

Design of Better Porous Biomaterial Surfaces. As mentioned, not only do properties of proteins determine the degree of their interactions with surfaces, but properties of the media and surface (specifically, wettability, surface energy, chemistry, roughness, etc.) also influence the degree of protein interactions (35). Clearly, altering surface properties to control such protein events for mediating

cell function leading to tissue regeneration is at the heart of the research of many biomaterial scientists and engineers. Surface properties are so important because proteins have relatively large sizes and correspondingly large numbers of charged amino acid residues of different acidity/basicity well distributed on their exteriors. The polyelectrolytic property of proteins provides for exciting design criteria in surfaces to maximize or minimize specific protein interaction. Not surprisingly, at a neutral or slightly charged surface and at a pH in which the net charge on the protein is minimal, most proteins will exhibit maximum adsorption (23). For surfaces with a large net charge, initial protein interactions will be dominated by the degree of the opposite charge on the surface (23,35).

Consideration of the spatial organization of amino acids can be used in the design of surfaces to enhance protein interactions (36). As previously mentioned, for some proteins, hydrophilic and hydrophobic amino acids are present primarily on the exterior and interior, respectively. This spatial arrangement has a direct consequence on the initial interactions of these proteins with surfaces. For example, a surface that initiates interactions with the exterior hydrophilic amino acid residues in that type of a protein may promote its adsorption. In contrast, for the interior hydrophobic amino acid residues to interact with material surfaces, which may contain desirable cell adhesive epitopes (e.g., RGD), the soluble protein may have to unfold or lose tertiary structure. For this reason, one approach to increase the adsorption of a protein whose external amino acids are largely hydrophilic, would be to design a material surface which exhibits polar properties. The same can be said for any type of protein; that is, through an understanding of the amino acids that reside on the protein exterior when in the appropriate biological milieu, a complementary surface can be designed. It is important to note, though, that this is a generalization as many proteins have a diverse collection of hydrophilic–hydrophobic amino acids externally that must be considered. In addition, as previously mentioned, proteins adsorb to surfaces in a competitive manner in which the adsorption of one protein will influence that of another.

Several studies have confirmed these speculations that properties (chemistry, charge, topography, etc.) of porous biomaterial surfaces dictate select interactions (type, concentration, and conformation–bioactivity, etc.) of proteins (24,37–40). It has been reported in the literature that changes in the type and concentration (up to 2100, 84, and 53% for albumin (40), fibronectin (41), and vitronectin (34), respectively) of protein adsorption on material surfaces depends on material surface properties, such as chemistry (i.e., polymer, metal, or ceramic), hydrophilicity–hydrophobicity, roughness, and surface energy. Consequently, since protein interactions can be controlled on porous biomaterial surfaces, so can cell adhesion. For example, a common porous biomaterial [poly(lactic-co-glycolic acid) or PLGA] has been modified to increase the adsorption of vitronectin and fibronectin through NaOH treatments (42–44). Since both vitronectin and fibronectin mediate osteoblast, vascular cell, and bladder cell adhesion, these NaOH treated PLGA scaffolds have found a home in numerous tissue engineering applications.

However, for the field of porous biomaterials to advance even further, instead of broadly speaking of protein adsorption on surfaces, researchers need to investigate and design succinct regions of surfaces to promote protein adsorption considering the complexities of their properties. Only when porous biomaterials are considered from the context of protein interactions necessary for desirable cell interactions, will better tissue engineering materials be formulated.

Mechanical Properties and Degradation Byproducts

Although porous biomaterial surface properties determine cell attachment, mechanical strength of the scaffold and the mechanical environment it provides plays an equally important role in enhancing subsequent cell functions leading to tissue growth (45). Mechanical forces felt by cell membrane molecules are interconnected to the cytoskeleton that can influence messenger ribonucleic acid (mRNA) and subsequent synthesis of intracellular proteins (all the way to the nucleus where gene expression can be changed). It is for these reasons that mechanical properties must also be carefully controlled in porous biomaterials. For example, a study of various mechanical stimuli placed on equine articular chondrocytes within nonwoven polyglycolic acid (PGA) mesh scaffolds indicated that when the stimuli were removed, after a period of 1 week, the mechanical integrity of the resulting tissue construct was lost (46). This result implies that the mechanical stimuli applied to cells within a porous biomaterial may influence the biomechanical functionality of the regenerated tissue.

Although most agree that the mechanical properties of a porous biomaterial should match those of the physiological tissue they are intending to replace, the specific parameters and values desirable in these studies vary. For bone tissue engineering, for example, Yaszemski et al. (47) stated that scaffolds should possess mechanical stiffness matching the low range values of trabecular bone (50–100 MPa), whereas Huttmacher's design principle (15,48) suggests matching the native tissue stiffness (10–1500 Mpa for trabecular bone (49)). Clearly, this wide range in mechanical values can provide for much different porous biomaterial efficacies and a consensus needs to be established.

Once deciding on the optimal mechanical properties needed in scaffold structures, there are numerous design parameters that can be exploited to match such values. For example, for a fibrous mesh, a decrease in fiber diameter increases mechanical strength due to an increase in fiber density (50). Obviously, increasing percent porosity and the diameters of individual pores can also be used to decrease the strength of scaffolds to match desired values. These properties not only influence inherent mechanical properties of scaffolds, but they can also be used to manipulate cell functions.

Specifically, Maroudas postulated that the scaffold surface rigidity or stiffness enhances cell adhesiveness and cell spreading (51). Pelham and Wang (52) have shown that focal adhesion contacts in cells and their migration on acrylamide gels are controlled by scaffold flexibility. They also suggested that tyrosine phosphorylation might be

involved, activated by local tension at cell adhesion sites (53). Recently, Ohya et al. (54) studied the effects of hydrogel mechanical properties on cell adhesiveness and found that the higher the strength of the hydrogel formulation, the greater the capability to withstand cell traction forces, thereby resulting in greater cell spreading. These authors also noticed that cells preferred to adhere to stiffer regions within the hydrogel.

Common pore shapes in porous biomaterials include tube-like, spherical, and randomly spaced shapes. Differences in cell attachment, growth, migration, and matrix deposition by cells have all been observed depending on pore structure. Specifically, certain cell types prefer a select pore structure in accordance to their physiological matrix environment. For example, orthopedic tissue engineering scaffolds should have spherical pores with a high porosity to allow for immediate bone ingrowth, while maintaining the mechanical strength and integrity necessary due to their harsh mechanical environments *In vivo* (36). Porous biomaterial pore shapes are critically related to pore interconnectivity. Not only does pore interconnectivity in a porous biomaterial affect nutrient–waste diffusion, but it also influences cell growth. Bignon et al. (55) observed that the density of pore interconnections determines cellular colonization rates; meaning that the larger the macropores (within limits), the fewer pore interconnections that have to be transversed by the cells thus resulting in higher colonization rates. Of course, guided cell growth or migration is possible through deliberate pore shape and interconnectivity. For example, tube-like or fibrous pore shapes may promote neurite extension from neurons in specific directions. Studies have also shown that cells prefer discontinuities within a porous material in terms of growth and migration; clearly pores provide such discontinuities (56–58).

In addition, maintaining mechanical strength and structural integrity of porous biomaterials are crucial because scaffolds may be crushed when implanted or may degrade over time. Mechanical properties are especially important to characterize when they change over time. A thorough knowledge of the degradation process of the porous materials of interest (including degradation byproducts) should be mapped in order to control the mechanical stability and the degradation rate until the native tissue is formed at the site of implantation.

For porous biomaterials, a range of biodegradation choices exist, from nondegradable metals to degradable ceramics and polymers. Importantly as well, degradation rates of porous materials have in some cases been shown to be faster compared to solid block polymers (59,60) because acidic byproducts become trapped inside the bulk as they degrade, therefore causing an autocatalytic effect. Of course, trapping of acidic byproducts in polymeric scaffolds can have detrimental consequences on cell health. Porous degradable polymers, such as PGA, polylactic acid, PLGA, and polycaprolactone (PCL) degrade via nonenzymatic random hydrolytic breaking of ester linkages. Sung et al. (61) studied the degradation of PLGA and PCL scaffolds *In vitro* and *In vivo*. They found a significant decrease in the molecular weight of these polymers within 1 month *In vitro* and, as expected, at a much faster rate *In vivo*.

Specifically, the influence of acidic byproducts from these polymeric scaffolds on cell health was investigated by measuring the pH of the media in which the polymers resided compared to the media in which tissue culture polystyrene (TCPS) was cultured. Changes in the media pH occurred only for PLGA (reducing it by 5) whereas no significant changes were measured during TCPS or PCL culture for up to 28 days (61).

Moreover, an *In vivo* study by Hedberg et al. (62) determined that soluble acidic products from degradable polymers lead to an increased recruitment of inflammatory cells compared to that induced by the scaffold itself. This was evidenced by the fact that a minimal inflammatory response was observed at the site of bone growth juxtaposed to the surface of polymeric scaffolds, whereas a major inflammatory response was observed in the scaffold where there was significant degradation. However, Sung et al. (61) suggested that an inflammatory response can be beneficial towards angiogenesis that is highly desirable to remove harmful degradation products from the interior of a polymer scaffold. This clearly demonstrates the need for controlling polymer degradation products in order to elicit a desirable response from host tissue (63). Collectively, such studies highlight the necessity for a better understanding of material degradation products on cell health.

In addition, according to Wu and Ding (64), the molecular weight of a porous PLGA scaffold decreases during degradation, which not only creates a more acidic local environment, but also leads to other changes. In their study, degradation was divided into three stages, marking distinct characteristics in mechanical properties (Fig. 3). In the first stage (I), the mechanical strength increased as the porous scaffold dimensions decreased while the weight remained constant; this can be interpreted simply as the change of porous biomaterial dimensions resulting in mechanical property increases. Increased elastic modulus of porous PLGA scaffolds with degradation time was also observed in another study by Zhang and Ma (65) who contributed this to decreased porosity of the foams with time. In the second stage (II), a dramatic decrease in mechanical properties were observed, which was correlated with an increased presence of low molecular weight

degradation products (64). The third stage (III) was characterized by the breakdown of the scaffold's structural integrity and associated rapid weight loss due to pH decreases from acidic degradation products. Understanding of these three distinct phases of mechanical property degradation for every proposed porous biomaterial is imperative. In addition, more studies are needed that correlate cell function at each stage of mechanical property changes in porous biomaterials as they degrade.

The Role of Porosity, Pore Size, and Interconnectivity

Among other properties (e.g., the aforementioned mechanical properties), porosity can also influence how cells behave in a scaffold. Open pore structures are desirable in most tissue engineering applications, providing enhanced cell seeding, cell attachment, proliferation, extracellular matrix production, and tissue ingrowth. For example, for orthopedic applications, both *In vitro* and *In vivo* studies demonstrated exceptional osteoblast proliferation and differentiation leading to new bone growth in PLGA foams with 90% porosity (66,67). In addition, a study by Sherwood et al. (68) reported that osteochondral composite scaffolds with 90% porosity at the cartilage portion allowed full incorporation of the chondrocytes (cartilagesynthesizing cells) into the scaffold.

Permeability, or high interconnectivity of pores is a crucial property for a porous biomaterial due to its influence on cellular communication (16), adaptation to mechanical stimulation (45), and prevention of the accumulation of acidic degradation byproducts (69,70). It also allows for uniform cell seeding and distribution, as well as proper diffusion of nutrients and metabolic wastes. Studies have shown that when tissues become thicker than 100–200 μm , the oxygen supply to cells becomes limited in a static environment (71,72). Thus, interconnectivity of pores is an extremely important design consideration to increase tissue growth into porous biomaterials.

In addition, as mentioned in the section above, the increased tortuosity present in porous biomaterials will influence protein interactions and, thus, manipulate cellular functions. Specifically, because of altered initial protein interactions, certain cell types (e.g., chondrocytes) perform much better on porous compared to flat (or non-porous) biomaterials (42). Moreover, macroporosity (pore diameters $> 50 \mu\text{m}$) influences the type of cells adhering to a polymeric scaffold. For example, large pores (100–200 μm diameter) have been shown to enhance bone ingrowth compared to smaller pores (10–75 μm diameter) in which undesirable fibrous soft tissue formation has been observed (73). Yuan et al. (74) added that pore sizes $< 10 \mu\text{m}$ promotes bone ingrowth due to optimal initial protein adsorption events possibly because of their greater surface areas. Furthermore, Bignon et al. (55) demonstrated greater cell spreading on biomaterials with micro (pore diameters $< 10 \mu\text{m}$) compared to macroporosity. Importantly as well, pore wall roughness is influenced by pore size that may be providing greater roughness to promote cell functions. Studies are needed to carefully control pore wall roughness to make accurate comparisons between scaffolds of various degrees of pore sizes. Since

Figure 3. Three stages of mechanical strength degradation in porous biomaterials. (Adapted and redrawn from Ref. 64.)

very small topographical changes have been shown to alter cell functions (75), surface roughness values in the nanometer regime could also be incorporated into porous biomaterials regardless of their pore sizes to significantly enhance protein–surface and protein–cell interactions (42,76). Fabrication methods that can provide for the manipulation of pore properties is further emphasized here.

POROUS BIOMATERIAL FABRICATION METHODS

Various methods for fabricating porous biomaterials have been explored to date. Examples for forming polymeric porous scaffolds include solvent casting with particulate leaching, gas-foaming processes, emulsion freeze drying, freeze-extraction, electrospinning, rapid-prototyping, and thermally induced phase separation. Although polymers receive the most attention in porous biomaterial applications, porous ceramics, and metals have been recently receiving much attention. This is mostly because ceramics and metals have a long history of implantation, so methods that can improve their cytocompatibility properties (e.g., by creating pores) are highly desirable. For ceramic and metallic porous biomaterials, electrophoretic deposition, salt leaching, microsphere (polymer) melt out, and anodization have been commonly employed. These methods will be briefly described in the following sections.

Cellular Solids

Current methods, such as solvent casting, gas foaming, vacuum drying, and thermally induced phase separation (TIPS) in conjunction with particulate leaching techniques create cellular solids (77). These methods can create porous constructs easily and in an inexpensive manner (78,79). In solvent casting, a pellet or powder form of a polymer is dissolved in a solvent. Then, water-soluble salt particles (e.g., sodium chloride, sodium citrate) or other particulate materials [e.g., gelatin, paraffin (79)] are added to the polymer solution. The solvent is removed through evaporation or lyophilization and then particles are leached out through the use of water or another solvent (depending on the particle chemistry) to create the desired porous structure. The advantages of these methods include simplicity and the ability to control pore size and porosity. However, the pore shape is limited to the shape of the porogen and the pore interconnectivity is poor; thus, the porogen may not be completely removed from the construct (80). Furthermore, uneven dispersion or settling of the particles within the constructs may occur. Lastly, these first generation approaches rarely provided the succinct spatial ability to control protein adsorption necessary for the next generation of more successful biomaterials.

For the gas-foaming process, a gas, usually carbon dioxide (CO₂), is utilized instead of using an organic solvent at high pressures to create a highly porous structure (80–82). Again, these techniques are easy to implement and are inexpensive. However, a polymer with highly amorphous fractions can be processed with this technique even though the interconnectivity of the pores is very low, only ~ 10–30% (18).

Thermally induced phase separation produces a highly porous material using a solvent at elevated temperatures followed by lowering the temperatures to separate the solution into liquid–liquid or solid–liquid phases. Then, the unwanted solvent is removed through sublimation (65,83). Although high mechanical strength may be obtained with this technique, the pore size created with TIPS normally ranges from 10–100 μm, which does not satisfy the permeability requirements for the removal and entry of cellular wastes and nutrients, respectively.

The emulsion freeze-drying method was developed by Whang et al. (84). A porous structure is obtained through homogenization of a polymer, organic solvent, and water mixture; rapidly cooling the mixture to maintain the liquid state structure; and then removing the solvent, and water by freeze-drying (80). In Whang's study, 90% or greater porosity and up to 200 μm diameter pores were created. However, this method is user and technique sensitive, meaning that pore structures and associated interconnectivities greatly depend on the processing method. The freeze-extraction method is a modified version of the freeze-drying technique, in which the solvent in the frozen polymer solution is replaced with a nonsolvent at temperatures below the freezing point of the polymer solution. This procedure removes the solvent before the drying stage (85).

Electrospinning Technique

In electrospinning, an electric field directs polymer fibers to form and deposit onto a substrate of interest (86,87). Specifically, an electric potential is applied as the polymer solution is injected, which ultimately forms an electrically charged jet of polymer landing on the target substrate. The solvent evaporates and porous polymer fibers are formed. Fibrous polymer scaffolds with diameters of several hundred nanometers can be fabricated using this method, thus, simulating the physiological fibrous structure of such proteins like collagen that comprise tissues. Only films and cylindrical shapes of the porous material have been created through this technique, therefore, further investigations are needed. But in addition to creating biologically inspired nanometer fibers an advantage of this process is its ability to coat an existing implant material. Thus, this technique could be used to modify the surface properties of currently used implant materials to promote cell functions.

Rapid Prototyping

Rapid prototyping is a computer-guided manufacturing system that can produce complex designs rapidly. One of the prototyping techniques is called 3D printing (3-DP) and it has been used to fabricate biodegradable polymer scaffolds for tissue engineering purposes (88). This technique produces porous biomaterials by ink-jet printing a binder onto sequential powder layers. Importantly, growth factors, proteins, cells, and other biological factors can be incorporated into the porous biomaterial without risking inactivation because the process is performed at room temperature. However, a disadvantage of this process so far includes porous biomaterial size limitations (due to the size of the ink jet). This can also limit the creation of desirable fine details or nanostructures on the polymer.

Microsphere Burnt Out

The microsphere burnt out method is similar to the previously described salt leaching method except that polymer microspheres are utilized instead of a salt porogen. This method is useful for ceramic materials that require a sintering process at very high temperatures (approaching 1000°C) at which point the polymer melts. As a very simple and easy method, it also has the disadvantages of the need for large amounts of the microspheres to create high pore interconnectivity; this results in poor mechanical properties.

Electrophoretic Deposition

Another attractive method for creating porous ceramics is electrophoretic deposition (or EPD). Due to a relatively simple setup and accommodation of complex designs and shapes, EPD has received much attention for processing fine particles, especially for coating applications (89). For this process, Ma used a graphite cathode and a stainless steel anode in the EPD cell while a current was applied to induce deposition of the particles onto a designated material. In this study, hydroxyapatite 3D porous biomaterials were fabricated. Hydroxyapatite is the main inorganic component of bone and, thus, has experienced wide spread use in orthopedic applications. This simple powder consolidation method requires no additives and high pore interconnectivity can be achieved with sufficient mechanical strength. However, this process can be costly when designing a large sample.

Anodization

Although not many methods exist to create porous metals, anodization is one that is gaining in popularity. Anodization involves the application of a voltage to a metal submerged in an electrolyte solution. Anodization has been used to create various pore sizes (from 10 nm to 1 μ m) and shapes on two popular orthopedic metal chemistries: titanium and aluminum. In both cases, compared to respective unanodized metals, increased osteoblast functions have been reported on anodized titanium and aluminum (90,91). In addition, a study by Chang et al. (90) demonstrated that under certain anodization conditions porous nanotubes were created in titanium that further increased osteoblast adhesion. Although more testing is required, these studies highlight the fact that anodization is a fast and inexpensive method for creating pores in metals necessary for promoting bone growth.

Chemical Vapor Deposition

Another technique used to create porous metals is chemical vapor deposition. Chemical vapor deposition has been mostly used to fabricate porous tantalum for orthopedic applications. Tantalum is a new metal to the orthopedic field that possesses exceptional cytocompatibility properties. Tantalum porous biomaterials have been synthesized using vitreous carbon as the skeleton structure material (92). Tantalum was then coated onto the template and the template was removed by either chemical or heat treatments. Chemical vapor deposition is a common technique

used in the coating industry and can easily be utilized for the fabrication of porous materials as long as a template or a mold is provided.

FUTURE DIRECTIONS IN THE DESIGN OF MORE EFFECTIVE POROUS BIOMATERIALS

Although there are numerous avenues, investigators are pursuing to improve the efficacy of porous biomaterials, one approach that involves the incorporation of nanotechnology seems to be working. Nanotechnology embraces a system whose core of materials is in the range of nanometers (1 nm). The application of nanomaterials for medical diagnosis, treatment of failing organ systems, or prevention and cure of human diseases can generally be referred to as nanomedicine. The commonly accepted concept refers to nanomaterials as that material with the basic structural unit in the range of 1–100 nm (nanostructured), crystalline solids with grain sizes 1–100 nm (nanocrystals), extremely fine powders with an average particle size in the range 1–100 nm (nanopowders), and fibers with a diameter in the range 1–100 nm (nanofibers). There have been many attempts to improve health through the use of nanotechnology, but perhaps the closest to clinical applications involves nanostructured biomaterials.

The greatest advantage of nanobiomedical implants in a biological context centers on scientific activities that seek to mimic the nanomorphology that proteins create in natural tissues. As seen in Figs. 4 and 5, bone and vascular tissue possesses numerous nanometer surface features due to the presence of entities like collagen and other proteins (93). Dimensions of some additional proteins found in the extracellular matrix of numerous tissues are found in Table 2 (94). As can be seen, the fundamental dimensions of these proteins (and all proteins) are in the nanometer regime. Clearly, when assembled into an extracellular matrix that comprises a tissue, these proteins provide a diverse surface with numerous nanostructured features for cellular interactions. Since some of these proteins are also soluble and present in bodily fluids, they will initially adsorb to implanted materials to provide for a highly nanostructured surface roughness for cellular interactions. It is for these reasons that cells of our body are accustomed to interacting with nanostructured surfaces. This is in stark contrast to most conventional porous biomaterials that are smooth at the nanoscale.

Aside from mimicking the surface roughness of natural tissues, there are other more scientific reasons to consider porous nanostructured biomaterials for tissue regeneration. Specifically, surface properties (e.g., area, charge, and topography) depend on the surface feature sizes of a material (95,96). In this respect, nanophase materials that, by their very nature, possess higher areas with increased portions of defects [e.g., edge/corner sites and grain or particle boundaries (95,96)] have special advantageous properties that are being exploited by porous biomaterial scientists for applications involving proteins and cells. As mentioned, proteins have complex structures and charges. Thus, surfaces with biologically inspired nanometer roughness provide control over protein interactions that were not

Figure 4. An AFM image of the surface of bovine cortical bone. Numerous nanometer features of bone duplicated in porous biomaterials are showing progress in orthopedic applications.

possible with conventional porous materials. Advances of porous nanostructured biomaterials pertinent to orthopedic, cartilage, vascular, central and peripheral nervous systems, and bladder applications will be briefly discussed in the sections below.

Orthopedic Applications

Nanophase ceramics (including alumina, titania, and hydroxyapatite), metals (e.g., titanium, titanium aluminum alloys, and cobalt chromium alloys), polymers (specifically, PLGA, polyether urethane, and polycaprolactone), and composites thereof have been explored for orthopedic applications (22,97,98). For these studies, nanophase surface features in ceramics and metals were created by using

constituent nanometer particles, whereas nanostructured polymers were created using chemical etching techniques. In all of these studies, regardless of the manner in which the materials were synthesized, results indicated that nanophase materials enhanced osteoblast functions (e.g., attachment, proliferation, production of extracellular matrix proteins, and deposition of bone) compared to their respective conventional formulations (Fig. 6).

In addition, other porous biomaterials with nanostructured surface features [e.g., carbon nanotubes in polymer composites (Fig. 7) and porous helical rosette carbon nanotubes (Fig. 8)], increased osteoblast functions over conventionally used PLGA scaffolds (99,100). Interestingly, as opposed to conventional porous biomaterials, helical rosette carbon nanotubes self-assemble into a porous biomaterial, which when heated to temperatures only slightly above body temperature solidify (100); thus, these materials could be formulated immediately before implantation to match the dimensions of any bony defect. These novel porous helical rosette nanotubes also allow for optimal pore interconnectivity for the transfer of nutrients and waste to and from cells (100).

Figure 5. Cast replica of vascular tissue demonstrating nanometer roughness. (Adapted from Ref. 93.) Vascular tissue has numerous irregular nanometer features that when duplicated in porous biomaterials show progress in vascular applications.

Table 2. Nanometer Dimensions of Extracellular Matrix Proteins^a

Protein	Characteristic Dimensions
Fibronectin	Dimer of two identical subunits; 60–70 nm long; 2–3 nm wide
Vitronectin	Linear molecule 15 nm long
Laminin	Cruciform configuration with one 50 nm long arm and two 35 nm short arms; total length 50 nm; total width 70 nm
Collagen	Triple helical linear protein consisting of 2 $\alpha(1)$ -chains and one $\alpha(2)$; 300 nm long; 0.5 nm wide; 67 nm periodicity

^aSee Ref. 94.

Figure 6. The scanning electron microscopy (SEM) images of PLGA composites containing either conventional or nanophase titania. Increased bone regeneration has been measured in polymer composites containing nanometer compared to conventional ceramics. Bar = 10 μ m.

Cartilage Applications

Such pore interconnectivity is also crucial for cartilage forming cells, chondrocytes, since chondrocytes reside far apart from each other and their main communication is through their extracellular matrix. Recently, a porous biomaterial matrix fabricated via solvent casting and particulate leaching to create nanometer surface roughness was tested for cartilage applications (42). The polymer used was PLGA and it was modified to possess nanometer surface features through soaking for 10 min in 10 N NaOH (Fig. 9). Compared to conventional PLGA, results showed increased chondrocyte adhesion, proliferation, and synthesis of a cartilage extracellular matrix (as noted by collagen and glycosaminoglycan synthesis) (42).

Vascular and Bladder Applications

Not only do osteoblasts and chondrocytes interact better with nanophase materials, but so do other cells such as vascular (including endothelial and vascular smooth muscle cells) and bladder cells. For example, Miller et al. (43) and Thapa et al. (44) created nanometer surface features on PLGA films by developing novel molds of NaOH treated PLGA (Fig. 10). When compared to PLGA films without nanometer surface features, vascular smooth muscle cell,

Figure 7. The SEM image of a polyether urethane composite containing nanophase carbon fibers. Increased bone regeneration has been measured in polymer composites containing nanometer compared to conventional carbon fibers. Bar = 1 μ m.

Figure 8. The transmission electron microscopy (TEM) micrograph of porous helical rosette carbon nanotubes. Individual outer-tube diameters are 4.6 ± 0.09 nm. Increased bone regeneration has been measured in helical rosette nanotubes compared to currently used titanium implants.

endothelial cell, and bladder smooth muscle cell functions were enhanced on the nanostructured PLGA. For bladder applications, Pattison et al. (76) created NaOH induced nanostructures onto 3D PLGA scaffolds and also observed greater bladder smooth muscle cell adhesion, proliferation, and collagen synthesis. Their studies have further demonstrated increased fibronectin and vitronectin adsorption on nanostructured PLGA compared to conventional PLGA, thus, providing a key mechanism for why vascular and bladder cell adhesion is enhanced on nanostructured PLGA surfaces (43). In addition, PCL and polyurethane have been modified to possess nanostructured surface features by NaOH and HNO₃ treatments, respectively; increased vascular and bladder cell functions have been measured on these treated compared to nontreated polymers (43,44). Such studies highlight the versatility of modifying numerous polymers to possess nanostructured features for enhanced vascular and bladder applications.

Figure 9. The SEM images of PLGA possessing conventional and nanoscale surface roughness. Nanoscale surface roughness was created by fabricating molds of PLGA etched in 10 N NaOH for 10 min. Increased functions of chondrocytes, vascular cells, and bladder cells have been measured on polymers with nanoscale compared to conventional surface features. Bar = 1 μ m.

Figure 10. Fluorescent microscopy image of neuron axon alignment corresponding with aligned carbon nanofibers in polyether urethane composites. The arrow indicates carbon nanofiber alignment. Bar = 20 μm .

Central and Peripheral Nervous System Applications

Finally, McKenzie et al. (101) also provided evidence that biomaterials created to have numerous nanometer features can decrease glial scar tissue formation while at the same time increase interactions with neurons. These materials were created by combining carbon nanofibers to polyether urethane. In addition, these investigators have aligned carbon nanofibers in such porous structures to control the direction of axon extension from neurons. In this manner, such porous nanostructured biomaterials could be used to regenerate electrical activity in damaged areas of the brain.

CONCLUSIONS

All these indications point to the conclusion that a successful implantable porous biomaterial should possess properties and structures that simulate the formation of an extracellular matrix similar to that of the target organ it intends to replace. Equally as important for porous biomaterials are appropriate mechanical strength, mechanical structural integrity, degradation rate, permeability, porosity, pore structure, pore interconnectivity, surface energy, surface roughness, and surface chemistry. These all play a role in the function of an optimal porous biomaterial to regenerate tissue. Importantly, to date, to address some of these material properties, several processing techniques have been developed. Although much more needs to be learned concerning the most important aspects of tissue regeneration on porous biomaterials, proper attachment of the appropriate cell is crucial. This is mediated by initial protein interactions that must be the focus of future endeavors to design more effective porous biomaterials. Recent evidence has been provided that porous biomaterials with

nanostructured surface roughness might just control initial protein interactions pertinent for enhancing cell functions necessary to improve the efficacy of orthopedic, cartilage, vascular, central and peripheral nervous system, and bladder applications.

INTRODUCTION: FROM MEDICAL TO MOLECULAR IMAGING

Medical imaging conventionally refers to the non invasive or minimally invasive techniques employed to view internal organs of the body, typically for diagnosing disease. In a broader sense, it refers to a field that enables acquisition, processing, analysis, transmission, storage, display, and

archiving of images of internal body parts for interpretation and patient management (diagnosis, disease staging and evaluation, treatment planning and follow-up). Medical imaging was practically born with the discovery of the X rays by W. C. Roentgen in 1895 and has since based its success on observation and the accumulated experience of the examining physician.

Molecular imaging is a natural outgrowth of the medical imaging field. Recent advances in molecular biology have resulted in an improved understanding of many disease and natural processes. Consequently, molecular imaging links the empirical diagnostics and experimentally tried treatment management protocols with the fundamental understanding of the underlying processes that generate the observed results. As discoveries of the molecular basis of disease unfold, one top research priority is the development of imaging techniques to assess the molecular basis of cell dysfunction and of novel molecular therapy. Molecular imaging techniques are ideally based on technologies that have an intrinsically high resolution (spatial and temporal) and allow the detection of low concentrations of target biomolecules involved, such as nuclear medicine imaging (Positron Emission Tomography, PET; Single-Photon Emission Tomography, SPET), magnetic resonance imaging (MRI) and spectroscopy (MRS), optical tomography, autoradiography, or acoustical imaging.

The examination of biochemical processes with an imaging technology is of vital importance for modern medicine. As, in most cases, the location and extent of a disease is unknown, the first objective is an efficient means of searching throughout the body to determine its location. Imaging is an extremely efficient process for accomplishing this aim, because data are presented in pictorial form to the most efficient human sensory system for search, identification, and interpretation: the visual system. Recognition depends on the type of information in the image, both in terms of interpreting what it means and how sensitive it is to identifying the presence of disease.

PET stands in the forefront of molecular imaging and allows the quantitative evaluation of the distribution of several pharmaceuticals in a target area *in vivo*. PET is a unique diagnostic imaging technique for measuring the metabolic activity of cells in the human body. It produces images of the body's basic biochemistry and biological activity in a noninvasive way, combining techniques applied in nuclear medicine with the precise localization achieved by computerized image reconstruction. PET is therefore a powerful diagnostic test that is having a major impact on the diagnosis and treatment of disease, as well as on patient management.

PET images can demonstrate pathological changes and detect and stage tumors long before they would be revealed with other conventional imaging modalities. Traditional diagnostic techniques, such as X rays, computerized tomography (CT) scans, or MRI, produce anatomical images of what the internal organs look like. The premise with these techniques is that a visible structural change exists in anatomy caused by disease. However, biochemical processes are also altered with disease and may occur before a change in gross anatomy occurs. Furthermore, PET can provide medical doctors with important early information

about very subtle changes of function in the brain and heart, due to disease-related modifications in tissue perfusion, cell metabolic rates heart disease, or neurological disorders (Alzheimer's, Parkinson's, epilepsy, dementia, etc.), allowing physicians to diagnose and treat these diseases earlier and, consequently, more efficiently and accurately, according to the axiom "the earlier the diagnosis, the better chance for treatment." PET can also help physicians monitor a patient's response to treatment, as well as identify distant metastases that can affect treatment, helping curtail ineffective treatments and reduce unnecessary invasive procedures. The field of PET has been emerging today into clinical diagnostic medicine and is approved by many insurance carriers for coverage.

HISTORY OF PET

The positron emission and detection of the radiation produced was a known technique that dates back to the early days of the twentieth century. However, it is only in the last few decades, with the booming development of fast electronic circuits and powerful computer systems, that this knowledge could be used in practice as a valuable diagnostic tool: The electronic circuits used in PET should be able to detect the coincidental arrival of two high energy photons (a timing resolution of the order of few nanoseconds), and the image reconstruction requires modern computer systems in order to produce an accurate image of the activity distribution within a clinically reasonable time.

In the beginning of the 1950s, researchers at the Massachusetts General Hospital (MGH) in Boston and the Duke University in Durham proposed the idea that, in spite of the short half-lives of the, by that time recently discovered, positron-emitting radionuclides, they offered an attractive method for the regional study of metabolism due to their commonality. A single-detector pair brain probe was then developed at MGH and used in experiments. However, it was not until the early 1960s that these positron-emitting radionuclides began to gain popularity, when a number of centers such as the MGH in Boston, the Sloan Kettering Institute in New York, Ohio State University, and the University of California at Berkeley began to use cyclotrons. At the same time, the first image reconstruction techniques were proposed by researchers at MGH, and, in the early 1970s, the concept of computerized tomography (CT) was presented by Hounsfield, who later was awarded with the Nobel Prize.

In the early 1970s, the first PET scanners were developed at the MGH, the Brookhaven National Laboratory, the Washington University, and the Montreal Neurological Institute in Canada, used then as research tools. At the same time, a private company (EG&G OTREC, Oak Ridge, TN, USA) got involved in the developments of the first ring PET scanners, joined in the market a couple of years later by TCC (The Cyclotron Corporation, Berkeley, CA, USA), and in 1976 the first commercial PET scanner was delivered at the University of California, Los Angeles (UCLA). A year later, Scanditronix from Sweden brought Europe into PET. The first PET scanners used single slices when

performing tomographs, with transaxial resolution greater than 2 cm full-width half-maximum (FWHM) and used NaI crystal material. Such systems were installed at several research institutions, apart from the ones mentioned above, like the University of California at Berkeley, the Lawrence Berkeley Laboratory, and the University of Pennsylvania.

By the end of 1970s, PET had shown its potential for application to clinical medicine. The following generation of PET scanners reduced detector size and added additional rings to allow for simultaneous acquisition of multiple slices. The slice resolutions improved from greater than 2 cm FWHM to less than 1 cm FWHM. As time progressed, more detectors and photomultiplier tubes (PMTs) were added to these machines to increase their sensitivity and resolution. In the mid-1980s, the first BGO pixelated detector blocks were presented. At the same time, the first dedicated medical PET cyclotron units with automated radiopharmaceutical delivery systems were commercially available.

At the end of 1980s, the major medical imaging companies (mainly Siemens with CTI PET, Inc., and General Electric with Scanditronix) began investing in PET. The first whole-body PET scanners have been presented and research in new detector materials led to significant discoveries (LSO, etc.) in the beginning of the 1990s. Since then, PET has shown a steady increase in acceptance for clinical application, both medically and administratively, and PET centers are being installed worldwide at an increasing pace. PET is now a well-established medical imaging technique that assists in the diagnosis and management of many diseases.

More details on the history of PET instrumentation and the related developments can be found in References 1 and 2.

PHYSICAL PRINCIPLES OF PET

PET images molecules of substances with a specific biological activity. In order to monitor their distribution, kinetic characteristics, and behavior of (pharmaceuticals) within the body, these substances are tagged with radioactive compounds (with short half-life and at extremely low concentrations) (3). These radiopharmaceuticals are chosen to have a desired biological activity, depending on the metabolic activity of the organ under study, and are introduced to the subject by injection or inhalation.

The most commonly used radionuclides are listed in Table 1 and are compounds that constitute, or are consumed by, the living body, like carbon, nitrogen, and oxy-

Table 1. The Most Commonly Used Radionuclides in PET

Radionuclide	Half-life
Carbon-11	20.3 min
Nitrogen-13	9.97 min
Oxygen-15	2.03 min
Fluorine-18	1.83 h
Gallium-68	1.83 h
Rubidium-82	1.26 min

Table 2. Major PET Radiopharmaceuticals and their Specific Medical Applications

Agent	Images
F-18 fluorodeoxyglucose	Regional glucose metabolism
F-18 sodium fluoride	Bone tumors
C-11 methionine	Amino acid uptake/protein synthesis
C-11 choline	Cell membrane proliferation
C-11 deoxyglucose	Regional brain metabolism
O-15 oxygen	Metabolic rate of oxygen use/OEF
C-11 carbon monoxide	Cerebral blood volume
O-15 carbon monoxide	Cerebral blood volume
O-15 water	Cerebral blood flow
O-15 carbon dioxide (Inhaled)	Cerebral blood flow
C-11 butanol	Cerebral blood flow
C-11 N-methylspiperone	Dopamine D2 and Serotonin S2 receptors
F-18 N-methylspiperone	D2 and S2 receptors
C-11 raclopride	D2 receptors
F-18 spiperone	D2 receptors
Br-76 bromospiperone	D2 receptors
C-11 carfentanil	Opiate mu receptors
C-11 flumazenil	Benzodiazepine (GABA) receptors

gen. They are isotopes of biologically significant chemical elements that exist in all living tissues of the body and in almost all nutrients. Therefore, the above radionuclides are easily incorporated in the metabolic process and serve as tracers of the metabolic behavior of the body part, which can be studied *in vivo*.

Table 2 shows a list of the major radiopharmaceuticals used as PET agents with their specific medical applications. The most common radiopharmaceutical used in PET studies today is fluorodeoxyglucose (FDG) (4), a chemical compound similar to glucose, with the difference that one of the -OH groups has been replaced by F-18. Carbon-11 can also be used as a radiotracer to glucose. The short half-lives of these particles allow the subject and the people handling them to receive only a low radiation dose.

The identification and detection of the presence of the molecules of the radiotracer in a specified location within the source (i.e., the body under study) is performed by a chain of events, based on physical principles and data processing techniques, which are schematically depicted in Fig. 1 and briefly described below.

A positron is emitted during the radioactive decay process, annihilates with an electron, and, as a result, a pair of γ rays is emitted (two high energy photons of 511 keV each). The two γ rays fly off in almost opposite directions (according to the momentum conservation laws), penetrate the surrounding tissues, and can be recorded outside the subject's body by scintillation detectors placed on a circular or polygonal detector arrangement, which forms a PET tomograph. When the γ ray hits a scintillation detector material, it then deposits its energy in that crystal by undergoing photoelectric effect, which is an atomic absorption process where an atom totally absorbs the energy of an incident photon (5). This energy is then used to eject an orbital electron (photoelectron) from the atom and is,

Figure 1. This schematic depicts the chain of events that described the physical properties of high energy gamma pair emission from positron-emitting radioisotopes. All radioisotopes used with PET decay by positron emission. Positrons are positively charged electrons. Positron emission stabilizes the nucleus of unstable radioisotopes by removing a positive charge through the conversion of a proton into a neutron. An emitted positron travels a short distance (*positron range*, which depends on the energy of the positron) and collides with an ordinary electron of a nearby atom in an annihilation reaction. When the two particles annihilate, their mass turns into two 511 keV gamma rays that are emitted at 180° to each other. When detected, the 180° emission of two gamma rays following the disintegration of positronium is called a coincidence line. Coincidence lines provide a unique detection scheme for forming tomographic images with PET.

therefore, transformed in visible light. This light can be detected by specialized devices (photomultiplier tubes, PMT) that capture and transform it into an electronic signal, shaped at a later stage by the electronic circuits of the tomograph to an electronic pulse, which provides information about the timing of the arrival of the incident γ ray and its energy. Figure 2 summarizes the principles of gamma ray event detection in PET described here.

Figure 2. Scintillation detectors coupled to photomultiplier tubes are placed around the detector ring of the scanner. An annihilation event (*) inside the field of view (FOV) produces two γ rays that get detected by a pair of detectors. The event is identified to occur inside a specific detector tube (dashed stripe) by the electronic devices (constant fraction discriminators, CFD, and the coincidence detection circuit) that connect every pair of detectors.

By measuring a coincidence photon, the detector array in a PET system identifies that an annihilation event occurred inside the volume defined between the surfaces of the pair of detectors that registered the coincidence event. At the end of a PET scan, for each pair of detectors, a number of coincidence events that have been identified exist. This information represents the radioactivity in the subject viewed at different angles, when sorted in closely spaced parallel lines. In order to reconstruct the activity density inside the source from its projections (events registered at each detector pair), a mathematical reconstruction algorithm is applied by computer. The collected data are corrected for scatter, attenuation, and accidental coincidences; normalized for the differences in detector efficiencies, and reconstruct the spatial distribution of the radioactivity density inside the organ or the system under study in the form of a 2D or 3D image. The result is a digital image of the source, where the value of each picture element (pixel) or, in modern 3D tomograph systems, volume element (voxel) is proportional to the activity density inside the source at the area (or volume) that corresponds to this pixel/voxel. This image can be directly displayed on a screen. Further analysis of the data and processing of the produced images can be carried out with the use of a computing system.

A high energy photon produced by an annihilation event can deviate from its original trajectory if it gets involved in Compton scattering inside the subject's body, a collision between a photon and a loosely bound outer-shell orbital electron of an atom. In this case, because the incident photon energy greatly exceeds the binding energy of the electron to the atom, the interaction can be considered as a collision between the photon and a "free" electron. The photon does not disappear in Compton scattering, but it is deflected through a scattering angle θ and some of its energy is transferred to the electron (recoil electron) (5). In the case this ray gets detected in coincidence with the second gamma produced at the same event, then this event will be counted to have occurred in a detector tube that will not contain the original annihilation site: This is an erroneous event (scattered event).

It is also possible that this ray will never reach a detector crystal and, therefore, get lost. This type of Compton scattering, along with photoelectric absorption of the produced gamma rays inside the source, where they have been generated, are the major sources of attenuation of the emitted radioactivity.

The physics of positron emission allow for attenuation correction of the collected data, which can produce a quantitatively (but also qualitatively) accurate image that may resolve small lesions, especially when these lie deep within the body. In order to correct for attenuation, two additional measurements are typically performed: the blank scan and the transmission scan. The blank scan is recorded using an external source without the patient, representing the unattenuated case. For the transmission scan, the patient and the bed are placed into the scanner and the attenuated data are measured using the external source. The attenuation correction factors (ACF) can be calculated as the ratio of the measured counts without and with the attenuating object. The disadvantages of attenuation correction are that it

requires more time for image acquisition and the potential exists to add noise to the image if the attenuation measurements become misaligned by patient motion or if inadequate statistics in the transmission scan are collected. As a result of noise, transmission measurements are usually smoothed prior to the division. Otherwise, the noise in the ACF propagates to the corrected emission sinogram. The drawback of smoothing is that the resulting blurring of ACFs propagates to the emission sinogram as well. Techniques for the reduction of noise propagation include, as an example, classification techniques for the main tissue categories observed in the transmission images (segmentation) or the use of iterative methods for the reconstruction of the transmission images (6).

Compton scattering can also occur inside the detector crystal before the ray undergoes (the desirable) photoelectric effect. In that case, it is possible that the ray will escape the detector material and deposit its energy in an adjacent scintillator, causing the detected event to be mispositioned. Another source of erroneously counted events is the coincidental arrival at the detector ring of two single gamma rays coming from two different annihilation events (random or accidental coincidence). When three or more γ rays arrive at the detector ring within the time coincidence window set by the electronic circuitry of the scanner for the coincidence detection, then these gammas must be rejected, because it is not possible to recognize, in that case, the pairs of photons that came from the same annihilation event (7).

The high energy gamma rays have increased penetrating abilities and can be detected coming from deep-lying organs better than α particles or electrons (β particles), which can penetrate only a few millimeters of tissue and, therefore, cannot get outside the body to the radiation detector (5). Imaging system detectors must, therefore, have good detection efficiency for γ rays. It is also desirable that they have energy discrimination capability, so that γ rays that have lost energy by Compton scattering within the body can be rejected and a good timing resolution to accurately measure the time difference of the arrival of two photons. Sodium iodide (NaI), BaF₂ (barium fluoride), and BGO (bismuth germanate oxide) provide both of these features at a reasonable cost (5). Research for new scintillator materials, like LSO (lutetium oxyorthosilicate) (8), GSO (germanate oxide) (9), PbCO₃ (lead carbonate) (10), PbSO₄ (lead sulfate) (11), CeF₃ (cerium fluoride) (12), YAlO (13), and LuAlO (14), is very active in an effort to produce faster detector crystals with good stopping power and light output.

Table 3 summarizes some of the main physical properties of the scintillators used for PET: NaI(Tl), BGO, BaF₂,

CsF, GSO, and LSO. In order to interpret this table, assume the following:

- An elevated density guarantees a high stopping power for the high energy 511 keV annihilation photons and consequently assures elevated detection efficiency. High stopping power also allows the use of crystals of small dimensions, which means an improved spatial resolution of the tomograph.
- High scintillation efficiency, due to a good intrinsic energy resolution of the crystal, leads to a good energy resolution of the detection system, which leads to a better discrimination of scatter.
- A fast scintillation (described by a short scintillation constant decay time) translates to a low dead time of the system and, therefore, to good count rate performance. Moreover, this property directly influences the temporal resolution (uncertainty of the moment of detection), on which depends the choice of the length of the time coincidence resolution window and, therefore, the rate of accidental coincidences.

The comparison of the characteristics of scintillation crystals shows that the ideal scintillator for PET must have the temporal characteristics (decay time) of BaF₂, the density (stopping power) of BGO, and the scintillation efficiency (light output) of NaI(Tl) (15). It also reveals that the newest crystals GSO and LSO are very promising for PET applications.

Originally, NaI was the detector of choice for nuclear medicine imaging cameras and is still in use by some manufacturers of gamma cameras, SPET, and even PET systems. NaI is a scintillation crystal discovered in 1949 with very high scintillation efficiency but a stopping power too low for high energy photons; therefore, NaI has very low sensitivity. In the 1980s, BGO emerged as the detector of choice for PET scanners, a material with considerably lower light output than NaI but, on the other side, twice as dense and, therefore, able to detect high energy photons more effectively. LSO was discovered in the early 1990s and exhibits a very fast scintillation time (40 ns), which provides significantly reduced detector dead time and consequently higher count-rate capabilities, which is essential in clinical PET imaging in order to use the injected activity most efficiently and to make the emission scan time as short as possible, meaning the patient spends less time immobile on the tomograph's bed without compromising the image quality.

In the optimization of the design of a PET tomograph, an important aspect is the way crystals are assembled and the

Table 3. Scintillation Crystal Characteristics

	NaI	BGO	BaF ₂	CsF	LSO	GSO
Density (g/cm ³)	3.67	7.13	4.87	4.64	7.40	6.71
Relative scintillation efficiency	100	20	16	6	75	30
Decay constant (ns)	250	300	0.6	2.5	40	60
Hygroscopic	Yes	No	No	Yes	No	No

way they are coupled to the photomultiplier tubes. Various strategies have been developed, including:

- one-to-one connection crystal-PMT (5);
- detector blocks, where a crystal array (mainly BGO or LSO) is coupled to a smaller number of PMTs (15,16);
- NaI(Tl) crystals of large dimensions coupled to a grid of PMT (Anger logic, common to gamma cameras) (17);
- the most recent design of a system of GSO crystals coupled to light guides to a PMT grid (18).

Scintillation detectors have been the dominant element in high energy gamma ray detection for PET. However, other technologies have also been applied, explored, and developed for this purpose. One of the oldest alternative technologies is the High Density Avalanche Chamber (HIDAC) PET system (19), which consists of a Multiwire Proportional Chamber (MWPC) with the provision of laminated cathodes containing interleaved lead and insulating sheets and mechanically drilled with a dense matrix of small holes. Ionization resulting from photons interacting with the lead is trapped by, amplified in, and extracted from, the holes by a strong electric field into the MWPC. On arrival at an anode wire, further avalanching occurs. Coordinate readout may be obtained from orthogonal strips on the cathodes. The result is precise, 2D localization of the incident gamma rays. Every hole on the cathodes acts as an independent counter. By stacking these MWPCs, millions of these counters are integrated to form a large-area radiation camera with a high spatial resolution.

The resolution of a PET scanner primarily depends on the size of the detectors and on the range of positrons in matter (distance traveled by the positron in the tissue before interacting with a free electron, see also Fig. 1). For most of the positron emitters, the maximum range is 2–20 mm. However, the effect on spatial resolution is much smaller, because positrons are emitted with a spectrum of energies and only a small fraction travel the maximum range, and, in addition, in case of 2D acquisitions, the range of the third dimension is compressed. Another limitation in the resolution is that the paired annihilation photons are not emitted precisely 180° from each other, because the e^+e^- system is not at complete rest. Other components of the system resolution are the sampling scheme used, the interactions between more than one crystal due to intercrystal scatter, the penetration of annihilation photons from off-axis sources to the detector crystals, the reconstruction technique used, the filters applied, and the organ and patient motion during the scan.

Three types of spatial resolution exist in a typical ring PET system, defined by a full-width at half-maximum (FWHM): the radial, tangential, and axial resolutions. The radial, or in-slice, resolution deteriorates as we move from the center of the FOV and is best at the center. The same happens for the tangential resolution, which is measured along a line vertical to a radial line, at different radial distances. In systems with more than one detector

ring, the axial resolution, or slice thickness, is measured along the axis of the tomograph.

A major source of error during the coincidence detection is the fact that not all the annihilation events are registered correctly as mentioned earlier. Additional accidental coincidences can result from poor shielding or backscatter and from ordinary γ rays from the radionuclide administered. The random and scattered coincidences are registered together with the true coincidences, obtained when a pair of gammas is correctly identified and classified to the appropriate detector tube, and are sources of background noise and image distortion.

In order to keep the number of scattered coincidences low, a discriminator should be used. A discriminator primarily generates timing pulses upon the arrival of a photon, but also can verify the total energy of the illuminating ray is above a preset energy threshold. Scattered rays have already deposited part of their energy and, therefore, can be identified.

Furthermore, the choice of the appropriate time coincidence (or coincidence resolving time) window is essential: It has to be narrow enough to keep the number of random coincidences as low as possible but also wide enough to include all valid coincidence pulses. In the existing PET units, the timing accuracy is of the order of tenths of nanoseconds.

A PET scanner can be designed to image one single organ, such as the brain or the heart, or can be able to image any organ in the body, including whole-body scans. Whole-body studies with F-18-FDG consist of repeated PET acquisitions at contiguous bed positions in order to provide 3D images (axial, sagittal, coronal, and oblique cut planes) covering one considerable portion of the patient's body (Fig. 3), which facilitates the search for metastases in oncological diagnostics (20).

Figure 3. A whole-body F-18-FDG PET image of a normal subject (no pathological situation diagnosed). Areas with high metabolic activity (brain, myocardium) or with high concentration of the radioactive tracer (bladder) are visible. [Courtesy of A. Maldonado and M.A. Pozo from the Centro PET Complutense, Madrid, Spain.]

Figure 4. Sequential images from an F-18-FDG PET brain study of a normal individual. Red-yellow areas correspond to the high metabolic activity in the gray matter (cortex). [Courtesy of A. Maldonado and M.A. Pozo from the Centro PET Complutense, Madrid, Spain.]

Most PET systems today are whole-body systems (i.e., they have a typical transaxial FOV of 60 cm). This FOV is adequate to handle most patients. The axial FOV of most PET systems today is limited to approximately 10–15 cm (21). This relatively narrow axial FOV imposes some limitation on the imaging procedures that can be performed clinically. It also requires more accurate positioning of the patient in comparison with conventional nuclear medicine procedures. For a clinical system, it would be desirable to extend the axial FOV to 15–20 cm, which would, for instance, allow full brain (Fig. 4) and heart imaging in a single frame and more efficient whole-body imaging. As the detectors contribute a significant portion of the total cost of the scanner, however, this would bring into question what would be an acceptable cost for the PET scanner.

MANUFACTURING OF RADIOPHARMACEUTICALS

A cyclotron is a particle accelerator that produces positron-emitting elements or short-lived radioisotopes. These radioisotopes can then be incorporated into other chemical compounds that are synthesized into a final product that can be injected into a person. These radioisotopes are used to “label” compounds so it can later be identified where in the body the radiopharmaceutical is being distributed. The compounds that are being labeled are organic molecules

normally used in the body, such as sugar, neurotransmitters, and so on (22).

First, the cyclotron bombards nonradioactive elements in the target with accelerated particles, which converts these elements into positron-emitting radioactive isotopes of fluorine, nitrogen, oxygen, or carbon. The major radioactive isotope produced at almost all sites is fluorine-18 (F-18), which has a half-life of 110 min. F-18 thus produced from the cyclotron is delivered to a chemical synthesis unit called the chemical processing unit, which is where F-18 is incorporated into a precursor to produce the final product FDG, the labeled sugar molecule. This entire process is fully automated and performed in the cyclotron lab. When a dose is needed, it is transported to the PET scan room by various means, depending on the distance between the production site and the PET tomograph and ranging from a dedicated pneumatic tube system to long-distance transport via air or road.

APPLICATIONS OF PET

Molecular imaging opens the way for medical doctors to successfully pursue the origin of disease. As long as disease is of unknown origin, more tests and exams are needed, something that means increased health-care costs, in addition to the patient’s discomfort and pain. PET can

accurately identify the source of many of the most common cancers, heart diseases, and neurological diseases, eliminating the need for redundant tests, exploratory surgeries, and drug overload of the patient. PET produces powerful images of the body's biological functions and reveals the mysteries of health and disease (23).

PET can be used to obtain information about the tissue perfusion using inert tracers (e.g., O-15 labeled water), the metabolism with metabolically active tracers (e.g., F-18-FDG), or the kinetic of a cytostatic drug (e.g., F-18-Fluorouracil).

In cardiology (22), this imaging technique represents the most accurate test to reveal coronary artery disease or rule out its presence. Traditionally, when a patient shows signs or symptoms of heart disease, his or her physician will prescribe a thallium stress test as the initial diagnostic study. The conventional thallium stress test, however, is often not as accurate as a PET scan. PET images can show inadequate blood flow to the heart during stress that can pass undetected by other noninvasive cardiac tests. A PET study could enable patients to avoid cardiac catheterization when a conventional perfusion or echocardiographic stress test is equivocal. A PET scan shows myocardial viability in addition to perfusion abnormality. More specifically, PET exams for metabolism and perfusion of the heart tissues can determine the need for heart transplant, in case both are absent in a large area of the heart, or confirm with certainty that simple bypass surgery would be enough, when metabolism is maintained even if blood flow is significantly reduced. As metabolism indicates that tissue is still alive, complicated heart transplantation can be avoided and coronary bypass would have great chances to improve cardiac function. Documented studies have shown that thallium stress testing overestimates irreversible myocardial damage in at least 30% of cases, which can result in the patient being placed on the transplant list rather than receiving bypass surgery or angioplasty. No other diagnostic test can more precisely assess myocardial viability than PET. The most recent developments in cardiac PET have been summarized in Reference 3.

PET can reveal abnormal patterns in the brain and is, therefore, a valuable tool for assessing patients with various forms of dementia (3,22). PET images of the brain can detect Parkinson's disease: A labeled aminoacid (F-DOPA) is used as tracer at a PET examination in order to determine if the brain has a deficiency in dopamine synthesis. If it does not, Parkinson's disease can be ruled out and possible tremors in the patient's muscles will be treated in a different manner. Although the only definitive test for Alzheimer's disease (AD) is autopsy, PET can supply important diagnostic information. When comparing a normal brain versus an AD-affected brain on a PET scan, a distinctive and very consistent image pattern appears in the area of the AD-affected brain, where certain brain regions have low metabolism at the early stages of the disease, allowing early detection several years before diagnosis can be confirmed by a physician. PET can also help to differentiate Alzheimer's from other confounding types of dementia or depression (29). Conventionally, the confirmation of AD was a long process of elimination that averaged between two and three years of diagnostic and cognitive

testing. PET can help to shorten this process by identifying distinctive patterns earlier in the course of the disease. Furthermore, PET allows the accurate identification of epileptogenic brain tissue (because of its reduced glucose metabolic rates) and can successfully lead the surgical removal of the epileptic foci.

In oncology (3,22), in which the clear majority the total PET examinations refer, this technique inspects all organs and systems of the body to search for cancer in a single examination. PET is very accurate in distinguishing malignant tumors from benign growths. It can help detect recurrent brain tumors and tumors of the lung, breast, lymph nodes, skin, colon, and other organs. The information obtained from PET studies can be used to determine what combination of treatment is most likely to be successful in treating a patient's tumor, as it can efficiently determine the resistance of a specific cancer to the drugs applied and, consequently, can dynamically optimize the treatment management and follow-up of the patient on an individual basis. With this technique, it is possible to evaluate if a tumor has been successfully destroyed after therapy, as anatomical follow-up imaging is often not in the position to assess if a residue is still active or has definitely been eliminated after chemotherapy, radiation, or surgery.

A summary of the current status and future aspects of PET for cancer detection, as it has been recently presented by the Health Technology Advisory Committee is as follows (23):

Brain Cancer: F-18-FDG PET in brain tumor imaging may be useful, but its clinical application has yet to be established. F-18-FDG PET does not appear to be able to define tumor histology. Additional studies are warranted regarding the value of F-18-FDG PET in detecting Central Nervous System (CNS) and nonCNS brain metastasis, differentiating malignant from nonmalignant lesions, detecting disease recurrence in subjects who have undergone intensive radiotherapy, and in pediatric brain tumors. As a result of the paucity of data on radiotracers other than F-18-FDG, further studies will be required to validate the use of PET brain scanning with these radiotracers.

Head and Neck Cancer: Studies suggest that F-18-FDG PET is superior to MRI but comparable with CT in identifying the presence, absence, or recurrence of cancer.

Pituitary Cancer, Thyroid Cancer, Urinary Cancer, Kidney Cancer: The paucity of data on the use of PET in pituitary tumors, thyroid tumors, urinary cancer, and kidney cancer prevents conclusions regarding its value at this time.

Lung Cancer: Numerous studies evaluating PET for lung cancer applications demonstrate that PET, using F-18-FDG as a radiotracer, is effective and may be more effective than other noninvasive techniques, particularly CT, in differentiating benign and malignant pulmonary lesions. Thus, F-18-FDG PET appears to be an effective means of diagnosing lung cancer, whether a primary disease or a secondary metastatic disease, and detecting disease recurrence following lung cancer therapy.

Breast Cancer: Preliminary data suggest that F-18-FDG PET can differentiate benign from malignant breast lesions, when used in breast cancer staging, and can

determine the presence of axillary node involvement. Although data are scarce regarding the use of PET in monitoring the effects of breast cancer therapy, available data suggest that both F-18-FDG PET and C-11-MET PET may be useful for breast cancer and may show response earlier than conventional methods. Regardless, due to the small study samples and limited amount of available data, further studies will be required to confirm the efficacy of PET for breast cancer imaging.

Esophageal Cancer: F-18-FDG PET may be valuable in the staging of esophageal cancer. Evidence is limited by the small number of subjects in each study and the lack of additional trials.

Pancreatic Cancer: Studies indicate that PET may have a role in the imaging of pancreatic tumors, but further study is needed to verify this indication.

Renal Cancer: F-18-FDG PET shows promise for evaluating renal masses, but confirmation is required.

Ovarian Cancer: Preliminary data suggest a potential role for F-18-FDG PET in ovarian cancer; however, further studies are required to confirm these findings.

Prostate Cancer: Although F-18-FDG PET has been used in certain prostate cancer cases, it is possible that the use of radiotracers other than F-18-FDG may be of more value. However, insufficient data exists at this time to draw conclusions regarding the use of PET in prostate cancer.

Testicular Cancer: With limited data, no conclusions can be made at this time.

Malignant Melanoma: Additional studies are needed to determine the role of PET in the imaging of malignant melanoma.

Colorectal Cancer: F-18-FDG PET may be a valuable tool for colorectal cancer in diagnosis, preoperative staging, and monitoring for recurrent disease or treatment response. However, further study is required to confirm these findings.

Neuroendocrine Gastrointestinal Cancer: PET proved superior to CT in detecting, delineating, and visualizing lesions. The study claimed that PET had a superior role, but further study is required to confirm this finding.

Malignant Lymphoma: Studies comparing F-18-FDG PET with alternative techniques found PET to be more accurate than CT, ^{99m}Tc-MIBI SPET, and ¹¹¹In-somatostatin scintigraphy in detecting untreated and treated lymphoma. Supportive evidence is limited to a few trials that are hampered by small study samples. No conclusions can be drawn at this time regarding the efficacy of PET for malignant lymphoma.

A major use of PET is its ability for kinetic imaging analyses. This term refers to the measurement of tracer uptake over time. An image of tracer activity distribution is a good starting point for obtaining more useful information such as regional blood flow or regional glucose metabolism. The process of taking PET images of radioactivity distribution and then using tracer kinetic modeling to extract useful information is termed image analysis. The tracer kinetic method with radiolabeled compounds is a primary and fundamental principle underlying PET and autoradiography. It has also been essential to the investigation of basic chemical and functional processes in biochemistry,

biology, physiology, anatomy, molecular biology, and pharmacology. Tracer kinetic methods also form the basis in *in vivo* imaging studies in nuclear medicine (24).

Besides its direct clinical applications, PET imaging is emerging as a powerful tool for use by the pharmaceutical industry in drug discovery and development (25). The role of small animal PET imaging (26) studies in rodents for the discovery of PET tracers for human use is significant, as it has the potential for permitting higher throughput screening of novel tracers in transgenic mice as well as the confounding effects resulting from potential species differences on receptor affinity, blood-brain barrier (BBB) transport, metabolism, and clearance. This setting is expected to allow new and unique experimental laboratory studies to be performed.

Other recent developments include dedicated mammography devices (known as positron emission mammographs, PEM) for breast functional imaging (27). Furthermore, the first PET/CT tomographs have made their way to the market (28). These are devices that house a positron tomograph and a CT scanner in a single device, allowing the acquisition and visualization of registered images detailing both anatomy and biological processes at the molecular level of internal organs and tissue, without the need of multiple examinations and further image processing to achieve similar results.

IMAGE INTERPRETATION

One of the final steps in the processing chain of the PET study is to produce a final layout of the images for the diagnosing physician. The conventional way of presenting the image data is to produce a transparency film (X-ray film) of the images on the computer display. In addition to the image data, the film should also be labeled with demographic data about the study, such as patient name and scan type. As this information is usually stored in the image files together with the image data, the labeling and layout of the images on the display can be automated in software. With the rapid development of local area networks, films may soon no longer be necessary. Instead, the images can be read from a display system located in the reading room, which has access to the PET image data through a computer network. Referring physicians do, in most cases, require a hard copy of the study, which can be accomplished using X ray films. With recent improvements in printer technology, high quality color output may also be a low cost alternative to the traditional film.

PROCEDURE FOR A PET SCAN

Most patients will be in the PET center for 2 or 3 h, depending on the type of study being conducted. The patient is informed as to when to stop eating before the test. Drinking lots of water is recommended before the scan. The patients also need to inform the PET center if they are diabetic or claustrophobic. In general, before the scan is performed, a catheter is placed in the arm so that the radioactive tracer can be injected. A glucose test will also be performed. Depending on the type of study conducted,

scanning may take place before and after the injection is given. After the tracer is given, the patient waits for approximately 40–60 min before the final scan is done.

PET SCAN AND ASSOCIATED RISKS

The radiation exposure of PET is similar to that of having a CT scan or any other standard nuclear medicine procedure involving heart or lung scans. No pain or discomfort results from the scan. The half-life of F-18 is so short that by the time the patient leaves the PET center, almost no activity remains in the body. Patients typically do not experience any reactions as a result of the PET scan, because the tracer material is processed by the body naturally. Therefore, no side effects are expected. Of course, as with any other nuclear medicine procedure, when breast-feeding or pregnant, a PET scan must be performed under special conditions.

CURRENT STATUS AND FUTURE ASPECTS IN PET INSTRUMENTATION

Technological developments and research in the field of PET instrumentation are currently marking a fast evolution (30). New PET systems have been designed and developed with whole-body scanning capabilities. These systems are clearly designed for oncological studies (currently almost entirely performed in the clinical practice with the use of F-18-FDG), which represent maybe more than 80% of the total PET examinations performed worldwide. Therefore, a clear shift has occurred from the earliest systems, which were then mostly oriented to neurological applications.

The main requirement, which drive current R&D activities both in academia and in industry, is to increase the diagnostic accuracy (lesion detectability) of the technique and, at the same time, decrease the cost of a PET system installation, operation, and maintenance, which would allow the widespread use of PET in the clinical practice. In order to achieve this goal, an optimal balance should be found between high performance specifications and cost efficiency for the newly designed tomographs.

In particular, very high resolution 3D PET imaging (with applications in brain imaging, positron emission mammography, as well as small animal imaging) has demanded further advances in scintillation detector development, image reconstruction, and data correction methodology.

Table 4 lists the major performance characteristics of some last-generation tomographs for human whole-body

studies, based on different design architectures and operating in 3D acquisition mode. For 2D acquisitions, lead or tungsten septa are placed between the detectors to absorb scattered radiation (out of slice activity). The septa reduce the amount of scatter to 10–15% of the total counts acquired and improve image contrast. For 3D acquisitions, the septa are removed and each individual detector is sensitive to radiation from a much larger area (30). This mode allows a significant increase of the detection efficiency of the order of a factor 5–6 over the 2D mode and therefore, provides an increase of the SNR in the produced images, an aspect of extreme importance in whole-body studies. 3D PET imaging can, in addition, significantly reduce the amount of tracer activity needed for the exam and shorten the acquisition time, thus reducing the time during which the patient must remain immobile on the tomograph’s bed.

A limitation of the 3D mode, however, is an increase of the scatter component (almost one out of every two of the detected events has been scattered in the source or even inside the scintillation detectors) as well as of the number of the detected accidental coincidences (randoms) (30). A good energy resolution is therefore imperative in 3D PET systems, in order to reduce the scatter component (by correctly identifying detected γ rays with deposited energy lower than 511 keV). Furthermore, these systems must be able to manage high count rates in order to match the radioactivity present in the FOV. High temporal resolution in PET (high count rate) also permits dynamic imaging (repeated studies at short time intervals). With high count rates, pulses receiving a detector block can “pile-up” and the detector may become paralyzed, which decreases the sensitivity and detection efficiency of the tomograph. In addition, when scanning in a high counting rate environment, the random counting rate increases much more rapidly than does the true counting rate as a function of radioactivity in and near the FOV. In general, in 3D mode, an increased number of random events is detected, which degrades the image quality. Appropriate scatter and randoms corrections must therefore be applied to 3D-acquired data (31). Considering the nature of the scatter correction process and the heterogeneity of the activity distribution in the thoracic and abdominal areas (which are of particular interest for whole-body F-18-FDG PET studies), the use of scatter correction techniques is not yet consolidated and their effectiveness regarding the quality and quantitative accuracy of whole-body PET studies demands more research work.

The performance of a 3D-enabled PET tomograph is, therefore, the result of a compromise between the various physical parameters considered (spatial resolution,

Table 4. Performance Characteristics of PET Scanners in 3D Mode (15)

	Philips C-PET	GE Advance	ECAT HR+	ECAT Accel	Philips Allegro
Crystal	NaI	BGO	BGO	LSO	GSO
Crystal dimensions (mm)	500 × 300 × 25	4.0 × 8.2 × 30	4.0 × 4.4 × 30	6.8 × 6.8 × 20	4.0 × 6.0 × 20
Spatial resolution FWHM, mm (10 cm)	6.4	5.4	5.4	6.7	5.9
Efficiency (kpcs/Ci/cc)	450	1060	900	900	> 800
% Scatter fraction	25	35	36	36	25
50% Dead time (kpcs/Ci)	0.2	0.9	0.6	-	0.6

detection efficiency, energy resolution, and linearity of count rate). In the modern design of such systems, the primary objective evolves from the optimization of the spatial resolution and the efficiency (typical of tomographs for cerebral applications) to the optimization of the balance between energy resolution and count rate performance. The size of the scintillation detector crystals, which together with the photomultiplier tubes constitute the main elements in the design of a PET system, determines the intrinsic spatial resolution of the tomograph. The volume of each crystal has a minimum, defined by the current technological limitations, but, at the same time, should be large enough to include a sufficient mass of material so that a significant number of the incident high energy γ rays are absorbed and converted to visible (detectable) light. A very small detector crystal could result transparent to γ rays, which would decrease the system's sensitivity.

Spatial resolution, an area of interest in the design of PET systems, refers to the development and implementation of techniques for the correction of the effect of "depth of interaction" (DOI) parallax error, which limits the uniformity of the spatial resolution in the FOV for PET tomographs with rings of detector block arrays (18). In such systems, the length of the detector crystals is about ten times as long as their width in order to improve detection efficiency. Therefore, PET measurements exhibit shift-variant characteristics, such as broadened sensitivity functions of each detector pair from center to edge of FOV and for oblique lines of response. Spatial uniformity can be restored if the DOI of the incident photons is known. A number of techniques for deriving DOI information from PET detectors have been proposed, including the use of a phoswich technique (32) (detector arrangements, composed from scintillation crystal layers; e.g., LSO/GSO phoswich block detector, where the distinct temporal characteristics of the crystals used allow to identify the DOI), extracting the DOI information by controlling the light-sharing between two crystals, coupling of two ends of the detection crystals to separate photodetectors, and extracting DOI information from a 3D matrix detector (33). Other approaches include the application of a light-absorbing band around each crystal, the introduction of a light-absorbing material between sections of the detector or use of a Multipixel Hybrid Photomultiplier (M-HPD) (34). When fully available in commercial tomographs, the implementation of correction techniques for DOI will allow the improvement of the spatial resolution and an ultimate optimization in the design of scintillation detection systems.

In order to draw a full advantage from the increase of the detection efficiency offered by 3D PET, developments in the field of the image formation are equally necessary. The acquired PET data are not an image of the activity distribution in the source but rather projections of it. The unknown image must be estimated from the available data computationally. Great interest is turned nowadays to completely 3D iterative image-reconstruction techniques (21). The more interesting feature of iterative techniques consists of the possibility to incorporate to the reconstruction process the statistical model of the process of acquisition and detection. In spite of their high computational cost, iterative techniques offer greater flexibility in the

data processing, particularly of data with elevated statistical noise. The implementation of these reconstruction algorithms on clusters of workstations, grid platforms, or other high performance computing systems is an area of state-of-the-art research (35).

In spite of the fact that the clinical impact of the attenuation correction for whole-body F-18-FDG PET studies is still under discussion and study, iterative image-reconstruction techniques combined with correction for measured attenuation seem to offer various advantages:

- anatomical localization and spatial definition of lesions are improved,
- the geometric distortions observed can be compensated and corrected (requirement for being able to proceed to the co-recording with anatomical images – CT, MRI, and so on),
- the tracer uptake can be quantified.

An issue of greater technological interest for its major impact on oncological diagnosis is the development of integrated multimodality systems PET/CT (36). A PET/CT system consists of a PET tomograph and a CT tomograph, both of the last generation, assembled in a single gantry, controlled from a single workstation, with one unique patient bed. A PET/CT system allows the acquisition of PET and CT images in a unique examination with significant advantages:

- reduction of the examination time,
- integrated diagnosis by means of combined use of information from PET and CT,
- accurate interpretation of the PET functional images based on anatomical CT images (functional-anatomic correlation),
- improvement of the PET functional image quality using the anatomical information from CT (reconstruction with iterative techniques of the PET data with the use of the anatomical CT information as a priori information, for attenuation correction, and for accurate scatter correction, and for the correction of the partial volume effect),
- elimination of the radionuclide source for transmission scanning and elimination of the need for periodic replacement of decayed transmission sources.

The development of commercial PET/CT systems is quite recent, and the number of such systems installed and operational is still limited. Beyond the evaluation of the clinical effectiveness of such systems, various technical aspects still demand additional studies based on the clinical experience. The techniques of patient positioning must be optimized (arm position, etc.). The correction for attenuation based on CT studies must be validated (calibration of the attenuation-correction coefficients based on CT to the 511 keV energy window). The alignment of CT and PET studies must be verified, in particular regarding the acquisition protocols (conditions of apnea in CT studies and free respiration in PET studies). Furthermore, the

performance of these complex and expensive systems should be compared with the performance of currently available software-based solutions for the co-registration and fusion of multimodality images (PET with CT, but also PET with MRI, ultrasound, etc.), which are shown to produce very accurate results, at least for brain studies.

Apart from whole-body human examinations, a challenging area of state-of-the-art research at the limits of current PET technology is the development of dedicated tomographs for small animal studies (25). In such systems, spatial resolution plays a crucial role as they are applied in the investigation of new pharmaceuticals and the development of new PET probes, as well as in the field of modern molecular biology, a scientific area that is currently focusing its interest toward imaging of laboratory mice and rats. As both the resolution and the sensitivity of small animal PET scanners are still limited by detector technology, image reconstruction algorithms, and scanner geometry, significant improvements may be expected in the performance of small animal PET scanners, whether prototype or commercial systems. In addition, multimodality imaging systems that will provide biological and anatomical information in an integrated setting, according to the model of PET/CT (or even PET/MR, etc.) systems already commercially available for human studies, should soon become available. The role of small animal PET in modern biology and pharmaceutical discovery and evaluation is in the process of being established, and it is likely that in vivo information of great value will be obtained. In addition, it is probable that the demanding requirements that small animal studies place on PET will result in technical advances and new technologies, which will dramatically improve the spatial resolution and image quality of clinical PET scanners for humans.

People today expect quality medical care at a reasonable cost, with accurate diagnosis and treatment, without having to undergo multiple exams and painful surgical exploration, and with fast and reliable results. Molecular imaging techniques, such as PET, display the biological basis of function in the organ systems of the human body unobtainable through any other means (37). PET is changing the way doctors manage care of their patients for some of today's most devastating medical conditions.

INTRODUCTION

Prostate seed implantation is a radiation therapy procedure by means of which small radioactive sources (colloquially referred to as “seeds”) are permanently implanted in the tumor-bearing tissue. In the absence of more specific information concerning the location within the prostate of tumor deposits, the goal of the implant is to deliver a minimum dose to the entire prostate gland while minimizing the dose to any adjacent healthy tissues, in particular, the urethra and rectum. As cause-specific death in prostate cancer is predominantly the result of distant metastasis (and not local failure), the *raison d'être* of prostate implantation must be the notion of some causal link, as opposed to

mere association, between local control and distant disease (1–3). Whether this is indeed the case, remains at this time controversial (4).

The absorbed dose in the target as well as its spatial and temporal configuration is the only treatment tool available to the radiation oncologist. Consequently, patient eligibility for permanent prostate implants is based on the physician’s ability to physically deliver the dose to the target, in other words, placing the seeds at relevant locations within or near the gland. Guidelines for patient selection consist of stage (T1–T2 disease) and prostate volume (less than about 50 cm³). (*Staging* refers to the size and location of the tumor, whether tumor cells have spread to the lymph nodes, whether cancer cells have metastasized to other parts of the body and to the abnormality of the tumor cells – this latter is referred to as *grade* and quantified by the Gleason score. Thus, T1 refers to a clinically inapparent tumor (not visible or palpable), and T2 refers to a low-grade tumor confined within the prostate. Pretreatment with androgen-ablation therapy is sometimes used to reduce the prostate volume.) Counter-indications for brachytherapy are short life expectancy (<5 years), the presence of metastatic disease, prior transurethral resection of the prostate (TURP), prostatitis, acute voiding symptoms, and inflammatory bowel disease (5).

The treatment may be delivered as monotherapy (implant alone) or in combination with external beam radiation therapy (EBRT) depending on whether the disease is confined (in which case monotherapy is administered) or extends beyond the prostate. Indications for combined treatment are extracapsular extension (ECE) and/or seminal vesicle invasion (SVI). It has been suggested that the patient’s prognosis category as defined by pretreatment stage, Gleason score, and prostate specific antigen (PSA) may be taken as an indication of the likelihood that the disease did not spread outside the prostate; essentially, the lower the risk, the larger the probability of a confined tumor. Two classification schemes are currently in use. According to one proposal, low-risk patients are those with T1–T2b stage, Gleason 2–6, and PSA of less than 10 ng/mL. Intermediate-risk patients have one unfavorable factor: PSA larger than 10 ng/mL, Gleason score 7 or larger, or T2c or greater. High-risk patients have at least two unfavorable risk factors. The other sorting idea considers the risk low when PSA ≤ 10 ng/mL, Gleason <7, and T1a or T2a; intermediate when 10.1 < PSA ≤ 20, Gleason = 7 or T2b, and high otherwise (6,7).

The implant is a three-step process: First, using an imaging study of the prostate, the treatment planner calculates the number and location of seeds within the prostate volume that will result in a dose distribution in agreement with the prescribed constraints. The implantation is performed as a one-off outpatient surgical procedure. A post-implant evaluation, based on which the dosimetric quality of the implant is assessed, follows the treatment.

As with the other treatment choices (radical prostatectomy, EBRT), the survival benefits of transperineal permanent interstitial implantation among men with early, localized prostate cancer are uncertain (8,9). This state of affairs is compounded by the fact that the treatment of prostate cancer by either modality is accompanied by the

risk of (occasionally permanent) rectal and urinary toxicity, as well as sexual dysfunction (10–12). (Brachytherapy may be less likely to result in impotence in urinary incontinence than other forms of treatment.) Thus, for many patients with early, localized prostate cancer (the typical brachytherapy candidate), the decision to undergo a treatment of questionable benefit yet tangibly impacting on their quality of life (QOL) is understandably difficult; as a result, diminishing the risk of complications, and at the same time maintaining good dosimetric coverage of the tumor, remains the overriding concern in prostate brachytherapy.

In this article, we shall provide a step-by-step tutorial on permanent prostate implants, (by necessity) as practiced at the Memorial Sloan Kettering Cancer Center (MSKCC).

PREPLANNING OR INTRAOPERATIVE PLANNING?

Two modalities are currently in use for planning prostate implants. Preplanning refers to the situation where the treatment plan is completed several weeks before the actual implantation. The American Brachytherapy Society (ABS) discourages this approach, essentially because of well-recognized problems that may develop at the time the plan is implemented (5). For instance:

1. It is difficult to duplicate the patient position in the operating room (OR) to match the patient position during the preplanning simulation.
2. Patient geometry can change over time; for instance, urine in the bladder or feces in the rectum may swell the prostate.
3. A pretreatment plan may prove impossible to implement due to the needle site being blocked by the pubic symphysis.

The alternative to preplanning, which we and others strongly advocate, is to perform the plan in the OR using ultrasound (US) images of the treatment volumes acquired with the patient on the operating table in the implantation position (13–19). The ability to obtain a dose-optimized plan within a reasonable time (say, 10 minutes or less) is the key to intraoperative approach. Clearly, a manual (i.e., trial and error) approach to finding optimal seed positions in the OR will not do. The *sine qua non* condition of OR-based planning is then the availability of a computer-optimized planning technique, as described below.

ISOTOPE SELECTION AND DOSE PRESCRIPTION

The two isotopes commonly used for permanent prostate implants are ^{125}I (mean photon energy $E_\gamma = 27$ keV, half life $T_{1/2} = 60$ days) and ^{103}Pd ($E_\gamma = 21$ keV, $T_{1/2} = 17$ days). An important property these isotopes share is their low effective energies. At these energy levels, practically all decay radiation emitted by the implanted sources is absorbed in the patient's body. This enables the patient to be discharged shortly after the implant procedure without fear of posing a radiation hazard to the general public or to the patient's family.

Dose prescription in prostate brachytherapy makes use of the concept of *minimum peripheral dose* (mPD), which is defined as the largest isodose surface that completely surrounds the clinical target (20). The total dose prescription for patients treated at MSKCC is 144 Gy (mPD) for ^{125}I and 140 Gy for ^{103}Pd (21). The initial dose rate $\dot{D}(0)$ corresponding to these values can be calculated from

$$D_{\text{total}} = \frac{T_{1/2}}{\ln(2)} \dot{D}(0) \quad (1)$$

Thus, for ^{125}I , one has $\dot{D}(0) = 7$ cGy/h, whereas for ^{103}Pd , the corresponding value is 24 cGy/h. Based on radiobiological considerations it was hypothesized that the higher initial dose rate of ^{103}Pd may be more appropriate for rapidly proliferating tumor cells. Gleason score is taken as marker for such cells, hence, the notion that ^{103}Pd should preferentially be used for high-grade tumors. Retrospective studies have failed to demonstrate any clinical (22,23) or dosimetric difference between the two isotopes. (One may also note that in the United States, the price of a typical ^{125}I seed is about half the price of a ^{103}Pd seed; as well, a typical implant would use, say, 75 ^{125}I seeds as against some 100–110 ^{103}Pd seeds.)

A second difference between the two isotopes is the potential for somewhat larger relative biological effectiveness (RBE) of the ^{103}Pd compared with ^{125}I (24,25).

THE PHYSICAL CHARACTERISTICS OF ^{125}I AND ^{103}Pd

^{125}I is produced in a reactor by irradiating ^{124}Xe with neutrons to form ^{125}Xe . ^{125}Xe has a 16.9 h half-life and decays to ^{125}I via electron capture. ^{125}I in turn decays to an excited state of ^{125}Te via electron capture. The excited ^{125}Te nucleus immediately releases its excess energy in the form of a 35.5 keV gamma photon in 6.66% of the transformations, with the energy of the remaining 93.34% of the transformations being released as internal conversion electrons (26). The rearrangement of the orbital electrons results in the emission of characteristic X rays and Auger electrons. The Auger electrons are blocked by the encapsulation of the source and do not directly contribute to patient dose. As a result of the lower energy characteristic X-ray emissions, the average photon energy of ^{125}I is 28 keV.

^{103}Pd is produced in a reactor by irradiating stable ^{102}Pd with neutrons. ^{103}Pd decays with a 17 day half-life to excited states of ^{103}Rh via electron capture. The excited ^{103}Rh nuclei lose nearly all of their excess energy via internal conversion (26). The rearrangement of the orbital electrons results in the generation of characteristic X rays and Auger electrons. As is the case with ^{125}I sources, the Auger electrons are blocked by the encapsulation and do not directly contribute to patient dose.

The radioactive sources must be fabricated to high-quality control standards. The sources must remain biocompatible *in vivo* for decades. To prevent the internal contents of the sources from diffusing into the body tissues, the integrity of the source encapsulation must also remain sound for a period of decades. The physical size of the sources must be sufficiently small to allow their interstitial

implantation without causing undue tissue trauma or interfering with physiologic function. In addition to biocompatibility issues, the sources must be physically strong enough to maintain their shape and integrity during sterilization, routine handling, and implantation. As well as to the need for physical ruggedness, the encapsulation must be made of a material that will not absorb an undue fraction of the emitted photons. For the purpose of source localization on radiographs and computed tomography (CT) images, it is desirable for the sources to be radio-opaque while causing minimal imaging artifacts.

For meeting the aforementioned requirements, titanium is the material of choice for source encapsulation. Titanium is as strong as steel but 45% lighter. It is only 60% heavier than aluminum but twice as strong. This metal is also highly resistant to sea water. As human tissues have a high degree of salinity, titanium can maintain its integrity *in vivo* for the remainder of the patient's life. Titanium has an atomic number of 22, low enough not to cause serious artifacts on CT images. Due to the high strength of titanium, the encapsulation can be made thin, minimizing absorption of the emitted photons. The main drawback of titanium is that it is expensive, significantly adding to the cost of the radioactive source.

The actual internal structure of the radioactive sources is vendor specific. The thickness of the titanium encapsulation ranges from 0.04 to 0.06 mm (26). In the classic Amersham 6711 source, the radioactive material is adsorbed to the surface of a silver rod. A schematic representation of this source is shown in Fig. 1. The silver serves as a radio-opaque marker. In other source models, the radioactive material is adsorbed onto resin beads, impregnated in ceramic material, or coated by other means onto various substrates. Most ^{125}I and ^{103}Pd radioactive sources include radio-opaque marker material. Gold, silver, tungsten, and lead are the commonly employed marker materials used in ^{125}I and ^{103}Pd sources. The differences in the internal structures of the radioactive sources result in vendor-specific dose distributions. These differences result in differing photon energy spectra, source anisotropy, and self-absorption properties. The dosimetric properties of ^{125}I and ^{103}Pd sources are discussed in the next section.

DOSIMETRY

Before any radioactive source can be employed in a clinical implant procedure, the dose distribution around the source

Figure 1. Schematic representation of an Amersham 6711 ^{125}I source.

in question must be known. One obvious requirement is that the accuracy of the dose calculations be as high as possible. Another useful requirement is wide acceptance of the dosimetric formalism applied. A universal dose formalism simplifies comparison of treatment outcomes of implants performed by different institutions and helps establish universal treatment protocols.

To assure accurate dosimetric calculations, the following physical properties must be ascertained:

1. Photon interactions with structures inside the source and encapsulation.
2. Geometric distribution of radioactive material within the source.
3. Photon interactions with the tissues encompassing the source.
4. Reduction of radiation intensity as a function of distance from the source.

Photon interactions within the source have a noticeable effect on the shape, intensity, and energy spectrum of the dose distribution surrounding the source. These internal photon interactions affect the anisotropy of the emitted radiation. (Source anisotropy is a measure of angular dependence of the dose distributions surrounding the source.) For a point source with no asymmetric self-absorption, dose would only be a function of distance from the source without any angular dependence. Photon interactions inside the source also influence the energy spectrum of the emitted photons. Depending on the physical construction and materials used to fabricate the source, the emission spectra will vary among different source models. Lower energy photons will be preferentially attenuated compared with higher energy photons. The degree of filtration is dependent on the construction of the source. Another alteration to the intrinsic spectrum of the radioactive material is the generation of characteristic X rays by photoelectric interaction with the materials inside the source. One noteworthy example of spectral variations among different ^{125}I source models is the use of silver as the radio-opaque marker used by certain manufacturers. Silver has a K-edge that occurs at 25 keV (27,28). As the intrinsic photon emissions of ^{125}I are in this energy range, the photoelectric cross section for interaction with the silver marker is high. As a result, ^{125}I sources using silver as the radio-opaque marker will have a local peak around 25 keV in their emission spectra. ^{125}I sources using another element for radio-opacity will not exhibit a 25 keV peak in their emission spectra. Differences in source construction also influence the degree of Compton scattering, further altering the emission spectra. The geometric distribution of the radioactive material inside the source will affect the angular dependence of the dose distributions around the source as well as the dose reduction as a function of distance from the source. This effect will be investigated when source geometry factors are discussed later in this section.

Another important factor that must be calculated by a dose formalism is tissue attenuation as a function of distance from the source. Tissue attenuation is a function of how the emission photons interact with the tissues. When using ^{125}I or ^{103}Pd sources, the predominant interactions

are Compton scattering and photoelectric effect. In soft tissue, the probabilities of photoelectric and Compton interactions are equal at a photon energy of about 25 keV (28). The dose decreases with distance from the source due to these photon interactions.

The simplest dosimetric formalism is to assume point-source geometry, neglecting angular dependencies on the dose distributions. In this formalism, the dose is strictly a function distance from the source. Two components are assumed to contribute to the resulting dose at a given point. One component is the dose falloff due the geometric shape of the radioactive source. For a point source, this falloff component is the inverse square law, namely $1/r^2$. This dose falloff occurs irrespective of any photon interactions in the medium surrounding the source. It is solely dependent on the photon fluence intensity being geometrically reduced by the inverse square law. The second component of dose falloff results from photon interactions in the surrounding medium. One analytical approach to modeling this phenomenon is to assume that the dose reduction follows a simple exponential function, namely $F(r) = e^{-\mu r}$ where μ is an average linear attenuation coefficient for the energy spectrum of the emitted photons. It is also assumed that dose is directly proportional to the source activity A . The equation for calculating the dose using this formalism is

$$D(r) = \Gamma A f_{\text{med}} T_{\text{av}} \frac{e^{-\mu r}}{r^2} \quad (2)$$

where D represents the dose at distance r and A is the source activity. The factors Γ and f_{med} are the exposure rate constant and the tissue f -factor, respectively. The f -factor converts the exposure in air to absorbed dose in a small piece of tissue just large enough to assure electronic equilibrium. T_{av} is the average life an isotope atom exists before undergoing a nuclear transformation and μ is the effective linear attenuation coefficient. This analytical equation suffers from two drawbacks, the first being that this exponential equation is only rigorously correct for narrow-beam geometries. In deriving this equation, it is implicitly assumed that all photons that interact with the medium are removed from the beam and that no further interactions of scattered photons occur in the path of the beam. The geometry of a radioactive source in a medium is clearly not narrow-beam. Compton photons do in fact interact with the medium in the beam and hence contribute to dose. A second drawback of using an exponential is the implicit assumption that the photons are mono-energetic, clearly not the case for either ^{125}I or ^{103}Pd emissions. Although this formalism is not rigorously correct for the reasons stated, it has been used for many years in brachytherapy treatment planning. By empirically determining values for Γ and μ , the discrepancies of calculated and measured doses could be made acceptably small. In the years that this equation was used, modern instrumentation was not available for precise dose measurement, computers were slow, and the standards of conformance were not as stringent as today.

The accuracy of the formalism can be improved by replacing the exponential equation with a data table. The values in the table consist of experimentally measured doses in water at known distances, multiplied by the

square of the distance. Photon interactions in water are similar to those in soft tissue. The dose at any arbitrary distance from the source is calculated via linear interpolation of the tabulated data and by dividing by the square of the distance. Using tabulated data solves the two problems associated with the exponential function. As tabulated data were derived from measurements in the true broad-beam geometry of the source, the formalism inherently accounts for the dose occurring from Compton-scattered photons as well as the primary photons. As a table could be created for any source model, the data will inherently account for the energy spectrum of the emitted photons. An added benefit provided by the table is that it accounts for the selective tissue filtration of lower energy photons with increasing depths. As the emission spectra vary among different source models, the tissue filtration will also likewise vary.

A more sophisticated formalism can be developed by accounting for the geometric distribution of the radioactive material inside the source. The most natural extension of the formalism is the assumption that the radioactive material is distributed as a line source. Although the distribution of the radioactive material in many commercially available sources is not a true uniform line, the line source model is still a more accurate and realistic representation than the point source model. Applying a line source model significantly complicates the dosimetric computations. When applying the point source model, only the distance from the source to the calculation point need be known to uniquely determine the dose. By contrast, using a line source model requires that the angular orientation in addition to the distance of each dose calculation point in relation to the source be known. The angular orientation of the calculation point with respect to the source needs to be calculated using analytic geometry.

The angular dependence of the dose distribution around a source is the result of two separate processes. The first results from the distribution of the radioactive material inside the source, and the second results from the angular dependence of attenuation of the photons within the source. To develop a formalism based on a line source, it is easiest to start by calculating the dose to a differential piece of tissue in empty space. It is assumed that there is no attenuation in the tissue and that electronic equilibrium exists. As tissue effects will be introduced at a later stage, this assumption does not compromise the rigor of the development of the formalism. At this stage, the self-absorption and tissue attenuation will not be considered.

The angular dependence of dose resulting from the geometric distribution of the radioactive material can be modeled by a line source. A schematic representation of a line source is shown in Fig. 2.

For any point P one can define a two-dimensional coordinate system as shown in Fig. 2. With such a coordinate system defined, the dose to any point P from the line source can be calculated. It is seen from Fig. 2 that the following formulation holds:

$$\begin{aligned} X &= -r \cos \theta; & Y &= r \sin \theta; & r &= Y / \sin \theta; & \tan \theta &= -Y/X; \\ X &= -Y / \tan \theta \end{aligned} \quad (3)$$

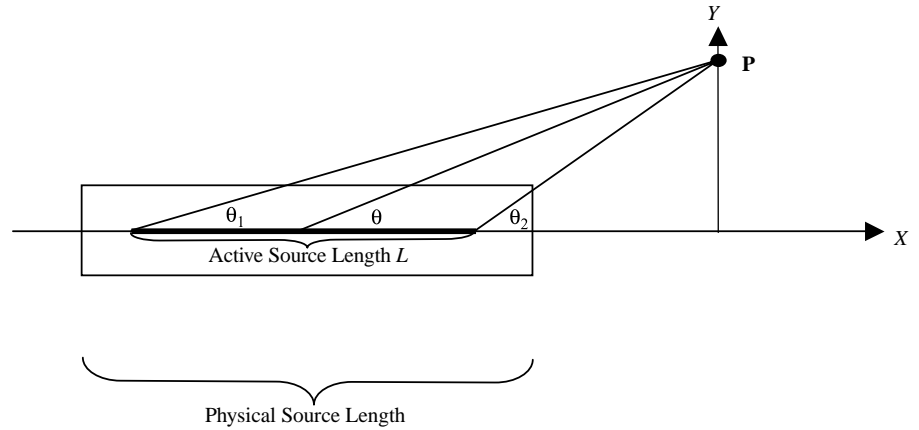

Figure 2. Dose to a point P from a line source. Physical length includes encapsulation. Active length only includes length of radioactive material.

The differential length dX is calculated to be

$$dX = Y(\tan \theta)^{-2}(\sec \theta)^{-2}d\theta = Y(\sin \theta)^{-2}d\theta \quad (4)$$

The total activity A of the line source is assumed to be uniformly deposited along the active length L of the source. Under ideal conditions, the dose to a differential piece of tissue at point P in free space is given by

$$D(r) = A\Gamma f_{med} \frac{T_{av}}{r^2} \quad (5)$$

To calculate the dose from the line source shown in Fig. 2, the source can be considered a continuum of differential point sources resulting in

$$dD = \frac{A}{L}\Gamma f_{med}T_{av} \frac{dX}{r^2} = \frac{A}{L}\Gamma f_{med}T_{av} \frac{d\theta}{Y} \quad (6)$$

The total dose to point P is thus

$$D = \frac{A}{L}\Gamma f_{med}T_{av} \int_{\theta_1}^{\theta_2} \frac{d\theta}{Y} = \frac{A}{L}\Gamma f_{med}T_{av} \frac{\theta_2 - \theta_1}{r \sin \theta} \quad (7)$$

By using equation 7, it is now possible to account for the linear distribution of radioactive material inside the source. In clinical brachytherapy, however, one is generally interested in knowing the dose when the source is in the patient and not in free space. This means that the photon interactions with the surrounding tissues must be factored into the analysis. Additionally, the self-absorption of the source must be taken into account. Unlike the linear distribution of the radioactive material, the self-absorption and tissue interactions are not amenable to a rigorous treatment. These data must be derived either from direct measurement or from Monte Carlo simulation, or a combination of the two. The data tables would need to be two-dimensional to account for the distance from the calculation point to the source as well as the angular orientation of the calculation point to the center of the source. As the active length of the source is known, the values of θ_1 and θ_2 are uniquely determined. Once these data tables are available, the component of the dose due to geometric distribution of the radioactive material can be removed from the data by dividing the tabulated doses by the ideal line source dependency. Reviewing equation 7, one can separate the terms involving the linear distribu-

tion of the radioactive material. Doing this yields the following:

$$G = \frac{\theta_2 - \theta_1}{Lr \sin \theta} \quad (8)$$

where G is referred to as the *geometry factor*. Dividing the tabulated doses by G removes the line source contribution. Removing the geometry factor reduces the dependency of the data on distance from the source, enabling the use of smaller data tables for attaining the same degree of accuracy. The data tables still account for the tissue interactions and self-absorption. For permanent implant brachytherapy, the data tables can be in the form of total dose per unit source activity (or air kerma strength) because the implant time is infinite and the isotope half-life is known. The new formalism can be summarized as follows:

1. For each point P in space, define a two-dimensional coordinate system and compute the distances to the centers of each implanted source and compute the respective angles θ , θ_1 , and θ_2 .
2. Use equation 8 to calculate the geometry factors at point P for each implanted source.
3. Interpolate the data tables based on the distances and angles for each implanted source calculated in step 1.
4. For each implanted source, multiply the respective geometry factor, source activity (or air kerma strength), and interpolated table value together. Each product represents the dose to point P for each implanted source.
5. Sum the individual doses to obtain total dose at point P.

These calculations are tedious and time consuming if performed by hand. The only feasible way forward is to code the formalism in software and have the computer perform the computations. In this way, a finely spaced three-dimensional data grid of calculation points can be rapidly calculated. The dose at any arbitrary point in space can be calculated by interpolating the three-dimensional grid of calculated doses. This will be discussed in a later section devoted to treatment planning.

The dose formalisms discussed thus far are but a small sample of the calculation methods used in brachytherapy

treatment planning. They were discussed to serve as illustrative examples and to provide a brief introduction to the physics involved in the development of dosimetry formalisms. Over the years, many different dosimetry formalisms have been proposed and implemented. By the early 1990s, treatment planning computers have become ubiquitous in radiotherapy departments. With many such systems in use, questions began to arise regarding the accuracy, consistency, and general agreement of the calculated doses generated by these systems. It was obvious that there were differences in the values calculated by these treatment planning systems as each system implemented its own dosimetric algorithm. During this same period, researchers also proposed new formalisms based on physical quantities not widely used in brachytherapy treatment planning. As a result of these issues, the American Association of Physicists in Medicine (AAPM) decided that the time had come to develop a standardized brachytherapy formalism. The adoption of such a formalism would standardize the dosimetric calculations, reducing the differences in values calculated by different treatment planning systems. The doses calculated among different institutions will be in closer agreement, enabling more realistic comparisons of different brachytherapy protocols.

The AAPM Radiation Therapy Committee Task Group 43 established a new recommended formalism. This formalism was published in 1995(26). The Task Group 43 (TG43) formalism is a radical departure from most established methodologies used up to that time. In following the new formalism, changes in dosimetric values in some instances were of sufficient magnitude to mandate changes in prescription doses for maintaining clinical consistency with older formalisms.

The most fundamental change recommended by TG43 is to use air kerma strength S_k in lieu of activity. The activity of a radioactive source is the number of disintegrations per unit time. As a fundamental unit, activity in and of itself does not provide any information regarding the nature of the energy deposition of the decay emissions. Traditional dosimetry formalisms need to use exposure rate constants and f -factors to convert from activity to exposure in air to dose deposited in tissue. The exposure rate constant is also isotope-specific.

Air kerma strength is defined as follows. A mass of air, dm , is placed a distance r_{ref} from the source along the perpendicular bisector. The source and air mass are in a vacuum. *Air kerma strength* is the kerma rate in mass dm multiplied by the square of the distance r_{ref} . Unlike activity, which is only applicable to radioactive isotopes, air kerma strength can be applied to any source of uncharged particles. For example, the radiation output from a linear accelerator or X-ray tube can also be quantified in terms of air kerma strength.

Another new quantity used by TG43 is the *dose rate constant* Λ defined as the dose rate to water at a distance of 1 cm from the perpendicular bisector of the source. Using the dose rate constant represents another departure from basing absorbed dose on exposure to air. It is a trend in the medical physics community to move toward basing dosimetric calculations and measurements on dose to water.

The dose rate constant replaces the exposure rate constant used in older brachytherapy formalisms.

For modeling the contribution of the geometric distribution of the radioactive material inside the source, TG43 endorses the use of either a point source representation (inverse square law) or a line source representation (equation 8). These geometric factors have been in use before the advent of the TG43 report.

The interactions of the emitted photons in tissues are modeled by a new function defined by TG43, namely the radial dose function $g(r)$. The function $g(r)$ is given by the following equation:

$$g(r) = \frac{dD(r, \vartheta_0)/dt G(r_0, \vartheta_0)}{dD(r_0, \vartheta_0)/dt G(r, \vartheta_0)} \quad (9)$$

where D is the dose at a point along the perpendicular bisector at a distance r from the source and G is the geometry factor that is equal to either the inverse square law or equation 8. In equation 9, θ_0 is equal to $\pi/2$. The radial distance r_0 is the reference distance to which all TG43 parameters are normalized. In practice, r_0 is taken to be 1 cm. It must be stressed that $g(r)$ is only defined along the perpendicular bisector of the source. It can be seen that when r is equal to r_0 , $g(r)$ equals 1. The factors in equation 9 involving G remove the dependency of the geometric distribution of radioactive material inside the source on $g(r)$. The radial dose function models the interactions of the photons with tissues along the transverse axis of the source. In practical implementations of TG43, $g(r)$ is based on tabulated values, which in turn are based on measured data or Monte Carlo simulations. In some implementations, analytic functions are fit to the data, whereas in others, the value of the radial dose function is calculated via interpolation.

Another phenomenon that needs to be modeled is the anisotropic nature of the radiation resulting from photon interactions inside the source. If there were no interactions of the radiation within the source, all of the angular dependence of the radiation pattern would result from the geometry factor, assuming the source is in a homogeneous medium. In reality, however, self-absorption is significant, especially at the low energies of ^{125}I and ^{103}Pd .

In the original TG43 report, three methods of modeling source anisotropy were proposed. The most general of these models is the source anisotropy function $F(r, \theta)$. This function is defined as follows:

$$F(r, \vartheta) = \frac{dD(r, \vartheta)/dt G(r, \vartheta_0)}{dD(r, \vartheta_0)/dt G(r, \vartheta)} \quad (10)$$

This function in effect is the ratio of the dose rate at an arbitrary distance from the source r and angle θ multiplied by the ratio of the geometry factor at a distance r but on the transverse axis and the geometry factor at the location r and θ . This function quantifies the angular variation of the dose distribution removing the contribution of the geometry function. In most practical implementations, the anisotropy function is calculated via bilinear interpolation of a two-dimensional data table.

A second method for modeling source anisotropy is to represent source anisotropy as a function of only the

distance from the source. In this case, the dose rate is averaged over all values of solid angle from 0 through 4π steradians. The one-dimensional function is referred to as the anisotropy factor $\phi_{\text{an}}(r)$. By taking advantage of the cylindrical symmetry of radioactive sources, the solid angle integral for defining this factor reduces to the following:

$$\phi_{\text{an}}(r) = \frac{1}{2dD(r, \vartheta)/dt} \int_0^\pi \frac{dD(r, \vartheta)}{dt} \sin \vartheta d\vartheta \quad (11)$$

One fundamental difference between defining $\phi_{\text{an}}(r)$ and $F(r, \theta)$ should be pointed out. The geometry factor is not removed from $\phi_{\text{an}}(r)$ as is the case for $F(r, \theta)$. From a numerical standpoint, the average value of the geometry factor taken over 4π steradians is nearly equal to the nominal value of $G(r, \theta_0)$. This is especially true for distances greater than the active length of the source. Moreover, $\phi_{\text{an}}(r)$ is an average value that will result in an inevitable error in the actual dose calculation. Factoring out the geometry factor would not significantly improve the accuracy of the dosimetry. If the geometry factor contribution was in fact removed, two anisotropy factors would need to be calculated, one for point source geometry and the other for line source. The main motivating factor for defining $\phi_{\text{an}}(r)$ is to accommodate existing treatment planning systems that do not support two-dimensional dose calculations. Given a choice, using $F(r, \theta)$ is preferred as it is rigorous.

A third anisotropy correction method prescribed by the original TG43 report is the use of an anisotropy constant ϕ_{an} that is an average value independent of distance. The original TG43 report was updated in 2004. In the updated report, use of anisotropy constants was made obsolete and is no longer considered consistent with current standards of practice. A more detailed discussion of the TG43 update is discussed below.

Application of the TG43 formalism can be summarized by the following equations where all of the terms have been discussed:

$$dD(r, \vartheta) = S_K \Lambda \frac{G(r, \vartheta_0)}{G(r_0, \vartheta_0)} g(r) F(r, \vartheta) \quad (12)$$

Equation 12 is the rigorous implementation of the original TG43 formalism. A simpler implementation of equation 12 for use in treatment planning systems not supporting two-dimensional dose calculations is the following:

$$dD(r, \vartheta) = S_K \Lambda \frac{G(r, \vartheta_0)}{G(r_0, \vartheta_0)} g(r) \phi_{\text{an}}(r) \quad (13)$$

The third equation using the anisotropy constant is as follows:

$$dD(r, \vartheta) = S_K \Lambda \frac{G(r, \vartheta_0)}{G(r_0, \vartheta_0)} g(r) \phi_{\text{an}} \quad (14)$$

Use of equation 18 is no longer recommended in the updated TG43 protocol. All treatment planning systems need to be capable of performing one-dimensional calculations. It is thus always possible to use the anisotropy factor $\phi_{\text{an}}(r)$. In some treatment planning systems, the product of

the radial dose function and the anisotropy factor may need to be used if only one distance-dependent term is used for calculating the dosimetry.

To end this section, a brief discussion of the updated TG43 formalism is presented. This update was published in 2004, 9 years after the original TG43 report (29,30). In the original formalism, the same radial dose functions were used irrespective of geometry factor. In the new formalism, two sets of radial dose functions are recommended. One radial dose function is to be used for point source geometry, whereas the other is to be used for line source geometry. Although the updated and original reports define the radial dose function using the same equation, the published values could be used for both geometry factors. To improve the consistency of the dose calculations, two sets of radial dose functions are now recommended. The choice of geometry factor dictates which radial dose function is to be used. Further refinements were also made in the tabulated values presented. In the intervening 9 years between the original report and the update, several new radioactive sources were introduced. The updated report includes published data for use with the newer source models. In the new report, the use of anisotropy constants is no longer recommended.

ULTRASOUND-GUIDED IMPLANTATION TECHNIQUE

The implantation proceeds as follows. The patient is placed in the extended lithotomy position. An ultrasound probe is positioned in the rectum, and needles are inserted along the periphery of the prostate using a perineal template as a guide. Trans-axial images of the prostate are acquired at 0.5 cm spacing (from base to apex), transferred to the treatment planning system using a PC-based video capture system, and calibrated. For each US image, prostate and urethra contours as well as the anterior position of the rectal wall are entered. Needle positions are identified on the ultrasound images and correlated with the US template locations. The contours, dose reference points, needle coordinates, and data describing the isotope/activity available along with predetermined dose constraints and their respective weights serve as input for the dose optimization algorithm.

TREATMENT PLANNING

A commissioned treatment planning system is the minimum equipment required for performing brachytherapy treatment planning. State-of-the-art treatment planning systems are based on modern computer hardware and software. Practically all modern brachytherapy treatment systems implement the TG43 dosimetry formalism for low-energy radioactive sources. These systems provide interfaces to imaging scanners such as CT, US, and magnetic resonance imaging. Having a scanner interface presents the opportunity of superimposing the dosimetric information on the anatomical images. It is a simple matter to superimpose dosimetric and anatomic information on a series of images. In most situations, the anatomical images are parallel to one another. The treatment planning computer calculates the doses to a three-dimensional grid of

Figure 3. Isodoses superimposed on an ultrasound image of the prostate. The thick white contour line delineates the prostate. The inner isodose lines depict higher dose levels than outer contours. Note the conformity of the green prescription isodose with the shape of the prostate. The inner white contour is the urethra. Note avoidance of the 120% isodose contour with the urethra, a radio-sensitive critical structure.

points spatially registered with the anatomic images. After the dosimetric calculations are completed, the dose distributions are represented as a series of colored contour lines commonly known as isodoses. Isodoses are analogous to the contour lines of a mountain on a topographical map. In the case of a mountain, the contour lines represent locations of equal elevation. In a similar manner, isodoses represent the locus of points of equal dose. An example of isodose contour lines superimposed on an axial ultrasound of the prostate is shown in Fig. 3.

In Fig. 3, the outermost yellow contour line represents 50% of the prescribed dose. This is the lowest dose level shown in the figure. Similarly, the innermost lavender contour represents 150% of the prescribed dose. Usually, but not always, the inner isodoses represent higher doses than the outer contours. On a topographical map of a mountain, the inner contour lines represent higher elevations than the outer contours.

Viewing isodose contours superimposed on anatomical images provides a means for visually evaluating the conformity of the dose distributions with the target anatomy. Ideally, the prescription isodose line should exactly conform to the shape of the target volume. This goal is not generally achievable although it can be approached. In Fig. 3, the green contour is the prescription isodose line. There is close conformity of the green isodose line with the prostate. In addition to being able to visually evaluate the conformity of the prescription isodose with the anatomy, it is also possible to ascertain doses received to critical structures. In the case of the prostate, the critical structures where excessive doses should be avoided are the rectum and urethra. Referring to Fig. 3, it is observed that the urethra receives less than 120% of the prescription dose. To properly evaluate a treatment plan, the isodoses on all images must be reviewed. Some slices may manifest excel-

lent conformity and satisfactory critical structure doses, whereas reviewing other images may reveal unsatisfactory dose distributions.

In traditional prostate brachytherapy treatment planning, the physicist manually selects source and needle locations in an attempt to optimize the treatment plan. This entails maximizing the conformity of the prescription isodose with the prostate and minimizing the doses received by the critical structures. This is a tedious, time-consuming process because the conformity and critical structure conditions must be simultaneously met on all slices. Often, improvement on one slice degrades the dosimetry on another. There is no universal standard regarding what constitutes an acceptable treatment plan. There are differing opinions both among individual physicians and treatment centers. These differences generally pertain to acceptable dose values covering the prostate and critical structures. Despite these differences, however, the aim of treatment planning is to maximize the coverage of the prescription dose to the prostate and minimize the doses to the critical structures.

A popular graphical method for evaluating treatment plans is known as a cumulative dose volume histogram, commonly referred to as a DVH. A cumulative DVH is a graph of the volume of a target or critical structure as a function of minimum dose received by the volume. A typical cumulative DVH plot is shown in Fig. 4. Referring to this figure, it is observed that at low doses, the volume covered is essentially 100%. This shows that the target as well as the adjacent critical structures receive a significant dose. In Fig. 4, the blue graph represents the DVH for the urethra. It is observed in this graph that around 95% of the urethra receives doses exceeding 50% of the prescription. As the urethra traverses the prostate, it is physically impossible for the urethra not to receive a significant dose

Figure 4. Typical cumulative DVH for a prostate implant.

without sacrificing the dose to the prostate. In well-designed treatment plans, the urethral doses are minimized. The specific criteria depend on the preferences of the physician or institution.

As was briefly indicated, manually optimizing prostate treatment plans is a time-consuming process. To address this issue, the authors developed an automated treatment planning and optimization system. The optimizer used in this system is based on a genetic algorithm (GA) (13,19). GAs are a genre of optimization algorithms that attempt to find the optimal solution of a problem based on evolutionary natural selection (31–34). In the case of the intraoperative optimizer, a population of bit streams is used to represent a population of treatment plans. Each bit stream is a one-dimensional array of numbers whose values are either one or zero. The length of the arrays is equal to the total number of potential source locations in the implant. The three-dimensional coordinates of each potential source location are known and fixed. If a source is present at a potential site, the bit for the corresponding site location is one. Conversely, if a source is not present at a potential site, the corresponding bit in the stream is set to zero. In this way, the treatment planning problem is encoded in a form amenable to genetic optimization.

To determine “how good” is the plan represented by a bit stream, an objective function is defined. The job of the objective function is to calculate a score, representing a figure of merit. The larger the score, the better the treatment plan, as determined by the criteria defined in the objective function. For instance (19), let PD be the prescription dose; the *prostate score* is the number of (uniformity) points that satisfy $PD \leq D \leq 1.6 PD$, the *urethral score* is the number of points in the urethra for which $D \leq 1.2 PD$, and the *rectal score* sums up all points in the rectum for which $D \leq 0.78 PD$. From this one obtains

a *raw score*:

$$\text{Raw score} = 5 \times (\text{prostate score}) + 35 \times (\text{rectal score}) + 50 \times (\text{urethral score})$$

and a *final score* (used in the optimization algorithm), which is a linear function of the raw score [$=A \times (\text{raw score}) + B$].

The objective function is defined to increase the score for greater coverage of the prescription dose to the prostate. On the other hand, as the doses to the rectum and urethra increase, the score is decreased. As can be observed, there are conflicting requirements and the score reflects all of these conditions.

At the beginning of execution, the bit streams are randomly assigned arbitrary bit patterns. During execution of the GA, these bit streams are gradually “evolved” into higher scoring streams, indicating improvements in the treatment plans they represent. In an attempt to improve the scores of a population of treatment plans, the GA mimics biological evolutionary processes. Crossover, mutation, and survival-of-the-fittest are simulated by the GA in an attempt to maximize the scores received by the population. Two bit streams in the population are selected to act as “parents.” Crossover is implemented by interchanging corresponding randomly selected bits between the parents. Mutation is affected by inverting a very small ($\sim 1\%$) number of bits in the two bit streams. The modified bit streams are evaluated and replace the two lowest-scoring chromosomes in the population.

In biological evolution, the fitter species has a higher likelihood of survival compared with the lesser fit species. This means that although the lesser fit species has a nonzero probability of survival, species that are better suited to their environments have higher survival probabilities.

Natural selection is simulated in the GA by favoring higher scoring bit streams to act as parents. In 50% of the parent selections, the two highest scoring bit streams are selected to act as parents. In the other 50% of the selections, two bit streams are randomly selected, irrespective of their score. The parents undergo crossover and mutation and replace the two lowest-scoring bit streams in the population. After this process is repeated several thousands of times, a population of high scoring bit streams is generated. This in turn translates into a population of optimized treatment plans. The highest scoring treatment plan is selected to be used for the implant.

The GA can generally generate a treatment plan in under 5 min. Actual execution times depend on the size of the prostate and the number of needles used for implanting the radioactive sources.

Other optimization algorithms used in prostate brachytherapy are simulated annealing (35,36) and branch-and-bound (13–15).

SECONDARY DOSE VERIFICATION

Once the plan is approved by the clinician a second physicist must independently verify and formally approve the plan. An estimate of the total number of seeds can be obtained with the following equations, which give—for a given average dimension of the volume to be implanted, d_{avg} —the total source strength S_K required (37):

For a ^{125}I permanent implant and a prescription dose of 144 Gy:

$$\frac{S_k}{U} = \begin{cases} 5.709 \left(\frac{d_{avg}}{\text{cm}}\right) & d_{avg} \leq 3 \text{ cm} \\ 1.524 \left(\frac{d_{avg}}{\text{cm}}\right)^{2.2} & d_{avg} > 3 \text{ cm} \end{cases} \quad (15)$$

For a ^{103}Pd permanent implant and a prescription dose of 140 Gy:

$$\frac{S_k}{U} = \begin{cases} 29.41 \left(\frac{d_{avg}}{\text{cm}}\right) & d_{avg} \leq 3 \text{ cm} \\ 5.395 \left(\frac{d_{avg}}{\text{cm}}\right)^{2.56} & d_{avg} > 3 \text{ cm} \end{cases} \quad (16)$$

One evaluates the total number of radioactive sources needed by dividing the total required source strength S_K by the single-seed strength used in that implant. In general, one seeks agreement of 10% or better between the planned and the expected number of seeds.

The plan verification must also determine that the correct prescription dose was used and that input data to the planning software was correctly entered.

DOSE ESCALATION TO PROSTATE SUBVOLUMES

If information is available on tumor burden in specific subvolumes of the prostate, dose escalation to these voxels is recommended. For instance, it has been hypothesized that regions of the prostate where the choline/citrate ratio, as determined by magnetic resonance spectroscopy (MRS),

is elevated may contain clinically significant cancer (38–42). In general, “clinically significant” refers to cancer cells that are fast proliferating and/or radioresistant (features associated with local failure) or of high grade and thus with a potentially larger probability of distant dissemination. There is limited evidence of a correlation between choline levels and histological grade (Gleason score). As well, biochemical arguments have been invoked to support the expectation that a larger value of this ratio is expected to reflect an increased rate of cell proliferation although no direct proof exists yet.

As applied at MSKCC, the implementation of an MRS-based dose escalation amounts to increasing the dose to the MRS-positive voxels to 200% of the prescription dose (with no upper limit) while keeping the urethral and rectal dose within the usual range of constraints (14).

POST-IMPLANT ANALYSIS

At MSKCC, post-implant evaluation is performed the day of the implant. The number of seeds implanted is confirmed with a pair of planar radiographic films. A CT study (3 mm slices) is then obtained, and anatomical structures are marked out on each slice. The coordinates of the center of each seed are determined by using appropriate computer software (Interplant Post-implant Analysis System, Version 1.0: Burdette Medical Systems, Inc., Champaign, IL). With the seeds thus identified, (DVHs) are calculated for each structure of interest and compared with the original plan.

CLOSING WORDS: KNOWN PROBLEMS AND POSSIBLE FIXES

Permanent brachytherapy prostate implants are now a well-accepted treatment modality for early stage prostate cancer. The two major limitations of this procedure are higher incidence of urethral complications (when compared with external-beam radiotherapy) and — for some patients — lower than prescribed delivered doses. In this section, we list several unresolved issues that may be responsible for this state of affairs and suggest possible solutions.

Post-implant evaluations of permanent prostate implants often indicate significant differences between the intended plan and its actual implementation. Although an experienced physician can minimize the magnitude of these differences, many factors controlling execution of the plan (e.g., bleeding, tissue swelling) are subject to random fluctuations. This often leads to a higher than intended dose to urethra and rectum and/or lower or higher doses to the prostate, especially at the periphery of the gland. In our view, this discrepancy represents the most important obstacle and challenge that currently needs to be overcome to achieve consistent application of a low urethral and rectal dose range and thereby reduce morbidity after prostate brachytherapy. In a series of recent articles the concept of intraoperative dynamic dosimetric optimization has been proposed (43–46). The idea is to re-optimize the plan several times during the implantation based on the actual

positions of the seeds already implanted. The key problem is obtaining in real time (and within a reasonable time interval — 5 min or less) the coordinates of the implanted seeds in the system of reference used for planning. Visualization of the actual seed positions on the intraoperative ultrasound image is difficult, if not impossible, to achieve because of significant artifacts noted on the ultrasound image from needles and/or hemorrhage within the gland.

One can reconstruct seed coordinates from fluoroscopic images taken at three different angles (43,44) or, equivalently, from a CT study obtained in the OR for instance, using a C-arm with CT capabilities. CT-based systems that perform seed segmentation do exist (e.g., Variseed from Varian Medical Systems, Inc, Charlottesville, VA; Interplant Post-implant Analysis System, Burdette Medical Systems, Inc., Champaign, IL), but at this time they do not seem to have the capability of performing this task on the fly and at the same time maintain the required seed-detection reliability.

A second problem concerns the effect of changes in prostate volume (edema shrinkage) as well as seed migration after implantation and the effect this has on a treatment plan that is based on the geometry of the target at the time of implantation. A method of planning that incorporates temporal changes in the target-seed configuration during dose delivery and makes use of the concept of effective volume has been developed by Lee and Zaider (47).

The preceding enumeration of problems has been brief and (admittedly) selective, but we hope to motivate the reader to take a careful look at these important issues. The desideratum of dosimetric conformality in permanent prostate implants remains a topic of active interest in the brachytherapy community, and no doubt the last word on this subject has not yet been spoken.

PULMONARY PHYSIOLOGY

JOHN DEMENKOFF
Mayo Clinic, Dept. of Anesthesia
Scottsdale, Arizona

INTRODUCTION

Present day pulmonary function testing is available in all hospitals and in a less sophisticated form in many physicians' offices. Such was not the case until the 1940s, when the fruits of physiological research dating back 150 years blossomed on the heels of World War II. This so-called golden age of pulmonary physiology spurred many of the currently available lung function tests which are used for diagnosis and treatment of existing lung disease; screening for early pulmonary disease; evaluation of respiratory symptoms such as cough and shortness of breath; performance of disability evaluations; preoperative assessment of thoracic and other surgical patients; determination of level of cardiopulmonary fitness; monitoring of adverse pulmonary effect of certain drug therapies.

Over the years, many have contributed to an understanding of the lung and how it works in health as well as in disease. These discoveries have provided building blocks of knowledge which form the basis of current modern pulmonary function testing.

PRE-1940S

Leonardo DaVinci: This genius drew detailed anatomical illustrations clearly depicting a bellows function of the respiratory muscles.

John Malysed: In 1674, he constructed a model of the chest and lungs with a bladder enclosed inside a

simple bellows with the neck outside. With a glass plate on one side, one could watch the bladder inflate and deflate when the bellows operated.

John Hutchinson: In 1848, he developed a spirometer and measured the vital capacity in thousands of normal subjects (1). He also differentiated normal and abnormal results quantitatively, thus ushering in a diagnostic use for pulmonary testing.

Humphrey Davey: Discoverer of hydrogen gas in the early 1800s. This led the way for measuring various lung volumes and compartments other than Hutchinson's vital capacity. Davey built his own spirometer, filled it part way with hydrogen, and breathed it back and forth "for seven quick breaths", finally exhaling fully into the spirometer. Then by measuring the amount and concentration of hydrogen in the spirometer and assuming an equal concentration in his lungs, he calculated the amount of air in his lungs at the end of full exhalation, known today as the residual volume. Modern day lung volume determinations use the inert gas helium with a slightly different protocol, but the fundamental principles remain the same.

Marie Krogh: Prior to 1915, many eminent physiologists believed that oxygen was actively secreted by the lungs into the blood stream. Marie Krogh challenged this popular notion with her diffusion experiments using carbon monoxide. She devised a single breath test in which a subject first fully exhaled to residual volume, then inspired deeply from a spirometer containing 1% carbon monoxide. After an initial exhalation and a six second breath hold, the subject completed a full exhalation. Krogh measured the alveolar gas before and after the six-second breath hold and calculated the uptake of carbon monoxide by the bloodstream.

The amount of CO transfer was noted to be entirely by the process of diffusion and proportional to the pressure differential across the alveolar capillary membrane ($P_1 - P_2$). Because CO binds so tightly to the hemoglobin molecule, P_2 is small. The driving pressure P_1 can be easily calculated. Krogh took advantage of these factors in devising her test, which confirmed the importance of diffusion, not secretion, in the lung.

For many reasons open to speculation, the importance of Krogh's work was not fully appreciated nor developed clinically until the 1940s. The reader is referred to a delightful discourse on such medical curiosities in Ref. 2.

POST-1940S AND THE GOLD AGE OF PULMONARY PHYSIOLOGY

What occurred in the 1940s was a combination of intellect and pluck driven by military contracts and government funds. The resulting research and understanding of lung physiology paved the way for development of current-day pulmonary function laboratories. Some of the more brilli-

ant, resourceful and ingenious researchers of this time are listed below.

Julius Comroe

Chairman, Department Physiology and Pharmacology, University of Pennsylvania, 1946–1957. Director of Cardiovascular Research Institute, University of California, San Francisco, 1957–1983. At both of these institutions, Dr. Comroe developed and fostered world-renowned faculty who studied multiple facets of pulmonary physiology. While at the University of Pennsylvania, Comroe demonstrated his ingenuity by adapting a used surplus bomber nose cone as a body plethymograph. He wanted to apply Boyle's Law to the measurement of lung volumes, air flow, and airway resistance. His work ushered in modern-day plethysmography. His text, *Physiology of Respiration* (2) remains a classic.

Herman Rahn, Wallace O. Fenn, Arthur Otis

These remarkable men formed the core of a research effort at the University of Rochester. An account of this creative ground work is found in Ref. 3, and is rich in historical facts. In the 1940s, pneumotachographs had to be fabricated by individual research groups. In the Rochester group's first model, a cluster of soda straws encased in a brass tube served as the flow resistance element. In later versions, they used as resistive elements glass wool enclosed in a lady's hair net. Their contributions are evident today, as many of their postdoctoral fellows and research associates have gone on and taught the next generation of pulmonary specialists.

Andre Frederick Cournand, Dickinson Woodrow Richards

Both shared the 1956 Nobel Prize in medicine and physiology, and formed the famous Bellevue Hospital Cardiopulmonary Lab at Columbia University. Their observations regarding prolonged nitrogen washout in the lungs of emphysematous patients fostered the clinical use of diagnostic pulmonary function tests. They also established normal values and formulated testing protocols. They pioneered catheterization of the right heart, making way for analysis of mixed venous blood and more accurate cardiac output and pulmonary blood flow via the direct Fick technique.

Pulmonary blood flow

$$= \frac{\text{O}_2 \text{ consumption}}{\text{Arterial-mixed venous O}_2 \text{ difference}}$$

Current interventional cardiology, and the understanding of complex interrelatedness of pulmonary diseases on the heart, stem from these studies done in the 1950s at Columbia.

Since the mid-1960s, pulmonary function testing has evolved more slowly. Tests that are reproducible, well tolerated by patients, and offer helpful clinical information have been further refined by advances in instrumentation and computerization.

With the advent of rapidly responding gas analyzers, highly accurate and calibrated pneumotachographs, and sophisticated computer software, the study of lung function during exercise has become possible. The complex interactions of metabolic-cardiopulmonary systems is discussed below, in the section on exercise physiology. While a boon to performance-minded athletes, these tests also shed light on limitation of exercise tolerance due to diseases of the heart and lung.

From the time of DaVinci to the present, great strides have been made in the understanding of lung function and its measurement. Now simple acts, such as blowing out a candle or coughing, are known to be dependent on elastic recoil of the lungs and complex airways dynamics. Both properties of the lung are measured with pulmonary function testing.

Each test discussed in the following text carries with it a rich historical and intellectual story line.

PHYSIOLOGICAL PRINCIPLES UNDERLYING MODERN PULMONARY FUNCTION TESTS

The interpretation and analysis of pulmonary function tests is often conveyed in physiological terms rather than as specific medical diagnoses. As such important underlying physiological concepts are presented that will provide a deeper understanding of pulmonary function test results. Many of these concepts have been developed and refined over time and represent a legacy of scientific achievement.

SINGLE BREATH NITROGEN WASHOUT

Aptly named, this test measures the nitrogen concentration of a normal exhalation after a deep inhalation of 100% oxygen. It was developed by Fowler in 1948 to measure the anatomic dead space $V_{danatomical}$.

During normal tidal breathing, a part of each breath remains in the conducting airways of the upper airway and tracheobronchial tree. It never reaches the alveoli; therefore it does not participate in gas exchange and is referred to as anatomical dead space. The fraction of total ventilation (O_E) that reaches gas exchanging space of alveoli is called alveolar ventilation or O_A .

$$O_A = O_E - f \times V_{danatomical}$$

where f = respiratory frequency

In Fowlers method (Fig. 1), a simultaneous recording of nitrogen and exhaled volume is made after a deep inhalation of pure oxygen.

At the start of expiration, the gas comes from the anatomical dead space, which contains no nitrogen. Along the course of the S-shaped N_2 washout, a front between the alveolar air and dead space air can be determined (see Graphical depiction below).

The anatomical dead space is related to body weight and is ~ 150 mL for a normal man. The extrathoracic fraction, mouth and pharynx, contributes 66 mL with a range of 35–105 mL, depending on jaw and neck position. Anatomic dead space represents an inefficiency of the design of the

Figure 1. Fowler’s method. For determination of anatomic dead space. See text for description. The flat portion of the curve is called the alveolar plateau and represents pure alveolar gas.

respiratory system. With each breath, a significant volume of air must be moved, requiring work, for which no benefit is derived.

PHYSIOLOGICAL DEAD SPACE BOHR EQUATION

Inefficiencies also occur at the level of the alveoli where some air reaches the alveoli, but gas exchange never occurs. For example, the upper lobes in a normal resting upright lung are well-ventilated, but not perfused.

This is wasted ventilation, and when added to the anatomic dead space is designated as the physiological dead space. This can be measured by application of the Bohr equation (4). If one complete expiration is collected in a bag, the amount of carbon dioxide is $[F_E CO_2 \times V_T]$. This volume of CO_2 comes partly from the nonexchanging dead space, which has a volume from the inspired air $[V_D \times F_I CO_2]$, plus the volume from alveolar gas $F_A CO_2 \times [V_T - V_D]$.

$$[F_E CO_2 \times V_T] = F_I CO_2 \times V_D + F_A CO_2 [V_T - V_D]$$

$$F_A CO_2 = \frac{V_T \times F_E CO_2 - V_D F_I CO_2}{V_T - V_D}$$

$$V_D = \frac{[F_A CO_2 - F_E CO_2] V_T}{F_A CO_2 - F_I CO_2}$$

If inspired, CO_2 is zero then $F_I CO_2 = 0$.

Hence,

$$V_D = \frac{F_A CO_2 - F_E CO_2}{F_A CO_2} V_T$$

$$\frac{V_D}{V_T} = \frac{F_A CO_2 - F_E CO_2}{F_A CO_2}$$

$F_A CO_2$ = Alveolar CO_2 fractional concentration measured by obtaining an alveolar sample.

$F_{E\text{CO}_2}$ = Mixed expired CO_2 fractional concentration measured from a collection of expired air; Douglas bag or mixing chamber.

The parameter V_D/V_T is called the dead space to tidal volume ratio where the dead space is physiologic and includes the anatomic dead space. It is an efficiency rating, typically 0.3 in normals and up to 0.5 or so in patients with emphysema. In the latter case, 50% of the breath is wasted and does not participate in gas exchange.

FORCED EXPIRATION AND DYNAMIC COMPRESSION

The most familiar maneuver that utilizes a maximal expiratory effort is a cough. The resulting dynamic airway compression facilitates clearance of bronchial secretions. Even at maximal exercise, such flow rates are not attained, thus demonstrating an impressive reserve in flow characteristics of the lung.

The complex mechanics of forced exhalations were elucidated by the work of Hyatt, Schilder, and Fry. They described a maximal expiratory flow volume curve, where instantaneous expiratory flow is plotted against volume instead of time (as is done with FEV_1). Flow reaches a maximum at 80% of vital capacity and reaches zero at residual volume. The curve is shown to be effort-dependent >75% of VC and effort-independent <75%.

Once dynamic compression occurs, the lung behaves as a Starling Resistor (Fig. 2). The flow then depends on the elastic recoil of the lung and airway resistance upstream from the compressed lung segment. Under these conditions, an increase in effort produces no increase in flow.

DIFFUSION AND DIFFUSING

The purpose of the lung is to deliver oxygen to the blood stream and remove the byproduct of metabolism, carbon dioxide. This process begins with mass transport of oxygen down conducting tubes of diminishing caliber called bronchi, bronchioles, terminal bronchioles, and finally air sacs or alveoli. Simple diffusion then occurs at the interface between the walls of the alveoli and pulmonary capillaries. The 300 million or so alveoli in the human lung

Figure 2. A Starling Resistor that is a mechanical analog for dynamic compression of the airways. The collapsible tubing in the chamber represents small airways. The pressure P_2 is pleural pressure during a forced vital capacity maneuver which collapses the airways at the equal pressure point, that is, $P_2 > P_3$. The pressure P_1 represents the elastic recoil of the lungs. Flow is proportional to $P_1 - P_2$.

Figure 3. The process of diffusion and Fick's law of diffusion. Within the lung P_1 would represent the alveolar space and P_2 the capillary space.

create a surface area for diffusion of 85 m^2 . The rate at which gas, either oxygen or carbon dioxide that transverses this membrane follows Fick's law of diffusion and is proportional to the surface area of the sheet and inversely proportional to its thickness.

The diffusion coefficient is proportional to the solubility of the gas and inversely proportional to the square root of the molecular weight (Fig. 3).

$$\dot{V}_{\text{gas}} = \frac{A}{T} \times D(P_1 - P_2)$$

$$D = \frac{\text{Sol}}{\sqrt{\text{MW}}}$$

where MW = molecular weight

When applying this formula to the special case of oxygen diffusion the partial pressure of oxygen in the alveolus ($P_{A\text{O}_2}$) or driving pressure (P_1) is 100 mmHg (13.2 kPa) while that in the pulmonary capillary (P_2) is 40 mmHg (5.3 kPa). The amount of oxygen transferred depends in part on this pressure differential ($P_1 - P_2$); 100 mmHg (13.2 kPa) minus 40 mmHg (5.3 kPa), which results in a diffusion gradient of 60 mmHg (7.9 kPa). In addition the thickness of the alveolar-capillary membrane (normally 0.3μ) appears to be of equal importance. When this membrane is thickened by disease states, such as pneumonia, pulmonary fibrosis, asbestosis, or silicosis, oxygen transfer is considerably impaired.

The complexity of oxygen diffusion becomes apparent when one considers that red blood cells carrying the hemoglobin molecule typically spend only 0.75 s in the pulmonary capillary. Given a normal driving pressure ($P_1 - P_2$) of 60 mmHg (7.9 kPa) and a healthy alveolar-capillary membrane ($0.3 \mu\text{m}$ thick) equilibrium ($P_1 = P_2$) will occur in 0.25 s. In other words, as blood exits the gas exchange space it will have gone from a PO_2 of 40 mmHg (5.3 kPa)–100 mmHg (13.2 kPa) rapidly.

Various lung diseases can compromise the elegant process of diffusion outlined above. In some the alveolar oxygen level is reduced thereby diminishing the driving pressure. In others diffusion is impaired by a thickened alveolar capillary membrane. And finally, with exertion, as blood flow increases, the time available to load oxygen onto the hemoglobin molecule is reduced. Any one or combination of these factors can lead to a reduction in the diffusion of oxygen.

Having said this, the actual measurement of the diffusing capacity of the lung for oxygen as a clinically useful

pulmonary function test has proved difficult to develop. This is due to the fact that the capillary oxygen pressure is ever increasing as P_2 approaches P_1 creating a back pressure thus slowing diffusion as red cells travel along the pulmonary capillary bed. The parameter P_2 can be calculated through a very complex and cumbersome integration method. In the final analysis, oxygen transfer then is actually significantly dependent on total flow of pulmonary capillary blood rather than diffusion alone.

Unlike oxygen, carbon monoxide transfer is diffusion-limited because it binds so tightly to hemoglobin that the partial pressure of CO in pulmonary capillary blood is low. There is little back pressure, so the amount of carbon monoxide transferred is related only to the driving pressure P_1 ($P_2 \approx 0$), which is the alveolar pressure P_A of carbon monoxide.

$$O_{\text{gas}} = \left(\frac{A}{T} \times D\right)(P_1 - P_2)$$

$$\frac{O_{\text{gas}}}{P_1} = \frac{A}{T} \times D$$

The above equation is simplified as follows, where D_L is called the diffused capacity of the lung and includes the area, thickness, and diffusing properties of the sheet and the gas concerned.

$$D_{\text{LCO}} = \frac{A}{T} \times D = \frac{O_{\text{CO}}}{P_1 \text{CO}} = \frac{O_{\text{CO}}}{P_A \text{CO}}$$

$$P_1 = \text{Driving pressure} = P_A \text{CO} = \text{Alveolar CO}$$

$$P_2 = 0$$

$$D_{\text{LCO}} = \frac{O_{\text{CO}}}{P_1 - P_2} \quad D_{\text{LCO}} = \frac{O_{\text{CO}}}{P_A \text{CO}}$$

GAS LAWS

By convention, pulmonary function test results are expressed either at body temperature and ambient pressure, saturated (BTPS), ambient temperature and pressure, saturated (ATPS), or standard temperature and pressure, dry (STPD). A working knowledge of gas laws is essential for accurate conversion from one state to another.

Gas inside the lung is at BTPS. The pressure is the barometric pressure (P_B), and saturated refers to the saturated water vapor pressure (P_W), which is a function of temperature. At normal body temperature (37 °C), P_W is 47 mmHg (6.2 kPa).

Gas measured in the equipment is at ambient temperature, dry (ATD) if the expired water vapor is absorbed prior to the measurement or if inspired gas is from a cylinder. Alternately, it is called ATPS if expired gas is collected, but the water vapor was not absorbed. At normal room temperature (25 °C), P_W is 22 mmHg (2.9 kPa).

Inspired gas from the atmosphere is ordinarily between ATPD and ATPS. Since buildings typically are at 50% relative humidity, P_W is 50% of 22 mmHg (1.4 kPa) or 11 mmHg (1.4 kPa).

Boyle first published his ideal gas law in 1662. It states that, for a given mass of gas at constant temperature, the

volume varies inversely with the pressure:

$$PV = RT$$

Charles’s law states that, for a given mass of gas at constant pressure, the volume varies directly with the absolute temperature. Thus V/T is a constant, where T designates a temperature on the absolute or kelvin scale.

Combining both these gas laws gives an approximation of real gases under various conditions.

$$\frac{P_1 V_1}{T_1} = \frac{P_2 V_2}{T_2}$$

Usually called the ideal gas law.

Suppose that a patient expires into a Douglas bag, which is then transferred to a laboratory at 20 °C and squeezed through a dry gas meter. From a knowledge of the number of expirations collected and the respiratory frequency, the volume of gas at 20 °C corresponding to the minute volume ventilation O_E can be calculated. If the minute volume was 6 L at ATPS then, by use of the combined gas law equation, volumes can be adjusted to BTPS and STPD.

Assume that the patient’s body temperature is 37 °C, the saturated water vapor pressure is 18 mmHg (2.4 kPa) at 20 °C and 47 mmHg (6.2 kPa) at 37 °C and that the barometric pressure is 760 mmHg (101 kPa). Because water vapor does not follow the ideal gas law, its partial pressure is subtracted.

$$\frac{(760 - 18)}{273 + 20} \times 6 = \frac{(760 - 47) \times V_2}{273 + 37}$$

So that

$$V_2 = \frac{742 \times 6 \times 310}{713 \times 293} = 6.61 \text{ L BTPS}$$

The same volume of 6 L measured under atmospheric conditions would represent 5.45 L under STPD, that is, 760 mmHg (101 kPa) and 0 °C.

$$\frac{(760 - 18)}{273 + 20} \times 6 = \frac{760}{273} \times V_3$$

$$V_3 = \frac{742 \times 6 \times 273}{760 \times 293} = 5.45 \text{ L ATPD}$$

BTPS is used for lung volumes and ventilation O_E , ATPS for maximal inspiratory and expiratory flow, and STPD for oxygen consumption and carbon dioxide output.

CALCULATION OF OXYGEN UPTAKE

Oxygen uptake is the difference between oxygen breathed in and the amount in the exhaled air.

$$O_{O_2} = (O_I \cdot F_I O_2) - (O_E \cdot F_E O_2)$$

Where O_{O_2} is the oxygen uptake in liter per minute; O_I is the inspired minute volume ($\text{L} \cdot \text{min}^{-1}$), $F_E O_2$ is the mixed expired oxygen fraction, and $F_I O_2$ is the inspired oxygen fraction. Because the volume of inspired air is slightly greater than expired air (more O_2 consumed than carbon

dioxide, CO₂, is produced), a correction factor using measured nitrogen is used.

$$O_I = O_E \left(\frac{F_E N_2}{F_I N_2} \right)$$

This has been attributed to the British researcher and is referred to as the Haldane Transformation. It is used to calculate the inspired volume when only O_E is measured, the latter being much easier to measure than the former.

Substituting this correction factor into the original equation,

$$O_{O_2} = \left(O_E \times \left(\frac{F_E N_2}{F_I N_2} \right) \times F_{I O_2} \right) - (O_E \times F_E O_2)$$

since $F_E N_2 = (1 - F_E O_2 - F_E CO_2)$, this becomes

$$O_{O_2} = \left(O_E \frac{(1 - F_E O_2 - F_E CO_2) \times 0.2093}{0.7904} \right) - O_E \times F_E O_2$$

reducing to

$$O_{O_2} = O_E ((1 - F_E O_2 - F_E CO_2) \times 0.265) - (F_E O_2)$$

By convention, O_{O₂} is expressed under standard conditions (STPD).

During a standard cardiopulmonary exercise stress, all the variables on the right side of the equation are measured as follows:

O_E Douglas bag for collection
or
Pneumotachograph interfaced with a computer for exercise testing

F_EO₂ Measured from Douglas bag at rest
or
Mixing chamber for exercise testing

F_ECO₂ Measured from Douglas bag at rest
or
Mixing chamber for exercise testing

Calculation of carbon dioxide output O_{CO₂}

$$O_{CO_2} = O_E \times F_E CO_2$$

Because there is little CO₂ in inspired air this, calculation becomes much simpler. Again by convention, O_{CO₂} is also expressed under STPD.

Respiratory Exchange Ratio (R).

$$R = \frac{O_{CO_2}}{O_{O_2}}$$

This value is typically 0.8 during the steady state of respiration and represents the ratio of CO₂ produced to oxygen consumed by the metabolic pathways of the cell. The value of R is fixed depending on the primary source of fuel being metabolized. Pure carbohydrate gives a ratio of 0.7 and fat burns at a ratio of 1.0. A typical ratio is 0.8 and represents a mixture of the two food groups being metabolically consumed.

In the nonsteady state, the amount of CO₂ exhaled rapidly changes based on the level of hyper or hypoventila-

tion, so R may vary from 0.6 to 1.4. In addition, CO₂ produced by bicarbonate buffering of lactic acid adds to the O_{CO₂} produced by metabolism during peak exercise. This will be discussed further in the section on cardiopulmonary exercise testing.

The measurement of O_{O₂}, O_{CO₂}, and the ratio O_{CO₂}/O_{O₂} provide important information on assessing overall lung function, at rest and especially during exercise testing.

INSTRUMENTATION

Volume Measuring Devices

In order to calculate minute ventilation (O_E), and other derived variables such as O_{O₂} and O_{CO₂}, the expired volume over time is collected in a Douglas bag or meteorological (Mylar) balloon. So collected, the expired gas is then connected and emitted into a large spirometer, such as the 120 L Tissot spirometer, and the volume is measured by use of a calibration factor. The Tissot spirometer is a typical water-filled spirometer, but due to its size and the considerable inertia of the bell, it is not used for measuring tidal breathing. Smaller water-filled spirometers (9–13.5) liters have a lower airway resistance and an appropriate response time (up to 20 Hz) needed to measure forced exhalation. All water-sealed spirometers, regardless of size, are configured similarly and operate on the same principles (Fig. 4). A bell is sleeved between the inner

Figure 4. Water filled spirometer connected to a rotating Kymograph.

and outer housing. Water fills the space between the inner cylinder and outer housing, providing an airtight seal for air entering the bell. Rigid tubing connects the inner cylinder to exhaled air from the patient or collection bag. A CO₂ absorbant is placed in circuit when rebreathing maneuvers are carried out, such as resting metabolic rate or FRC determinations. When forced maneuvers, such as MVV, FVC, FEV₁ or PEFR are accomplished, the absorbant is removed, thereby reducing resistance in the expiratory system.

As air enters or leaves the spirometer the chain-suspended bell rises and falls. These movements are recorded by means of pens moving in parallel. A kymograph drum turns at a preselected pace, adding a time dimension to the volume changes. This allows measurement of the based variables such as MVV, FEV₁, FEF₂₅₋₇₅, PEF.

Another type of spirometer is the so-called dry rolling seal, also called the Ohio spirometer. A horizontal cylinder is attached to a flexible rolling seal. As air enters, the rolling seal allows the cylinder to move horizontally. Linear transducers attached to the cylinder are interfaced with a computer, allowing measurement of volume over time and flow.

Dry gasmeters typically measure inspired air to avoid accumulation of moisture on a bellows mechanism. The movement of the bellows is transmitted to a circular dial that is labeled with appropriate volumes.

A spirometer that uses a wedge-shaped bellows is called a wedge spirometer (5). The bellows expands and collapses as gas moves in and out. One side is stationary, while the other side moves a pen that records the changes. Pressure activation moves the chart horizontally, giving a time domain to the recording.

The peak flow meter (6) is a spirometer that works on a completely different principle from other spirometers. It is known as a variable orifice meter (Fig. 5), popularized as rotameter gas flow meter on anesthesia machines (7). As air enters the flow meter, a bobbin or light-weight marker is entrained in the vertical column of air. The flow meter has a variable inner orifice dimension that increases with height. The bobbin records the peak flow M , which corresponds to a particular inner orifice (r). The original peak flow meter was developed by F. M. Wright of England in 1959 and is often referred to as the Wright peak flow meter (6). It is based on Poiseuille's equation.

$$M = \frac{\pi Pr^4}{8n\ell} \quad \begin{array}{l} M = \text{flow} \\ r = \text{radius} \end{array}$$

FLOW AND VOLUME TRANSDUCERS

Instantaneous flow signals generated from flow transducers discussed below can be integrated with respect to time, thereby obtaining volume measurements. Harmonic analysis of respiratory flow phenomena has shown significant signals out to 20 C.P.S., requiring all devices to respond with fidelity at this frequency (8).

The Fleish Pneumotach (9) quantifies airflow by measuring the pressure drop across an in-line obstruction, such

Figure 5. A variable orifice flow meter.

as mesh or porous membrane (Fig. 6). The pressure drop follows Poiseuille's law and is for laminar or nonturbulent flow. To prevent nonlaminar flow, various size pneumotachographs are used for different settings, such as studying children or exercising adults.

A Pitot tube that utilizes the Venturi effect is another type of flow meter (Fig. 7). The pressures of two tubes, one facing and one perpendicular to the air stream, is measured with a differential pressure transducer. Air flow velocity is proportional to the density of the gas and to the square of the pressure difference. They do not depend on laminar flow, typically are low weight and as opposed to pneumotachographs are low resistance breathing circuits.

Figure 6. Fleisch pneumotachograph.

Figure 7. Pitot tube.

Figure 8. Hot wire anemometer.

Hot-wire anemometers measure mass flow by detecting the increase in current needed to heat a hot wire placed in the air stream as air flows over and cools the wire (Fig. 8).

A turbine transducer uses a low mass helical impeller mounted on bearings. As the impeller blade spins with airflow, an interposed light beam is broken and digital signals proportional to the flow are sent to the pressure sensor (Fig. 9).

The accuracy of each of these flow meters is potentially affected by the temperature, viscosity and density of the gas measured as well as the flow character (laminar or turbulent). When proper calibration is maintained, these devices produce a $\pm 3\%$ accuracy, as recommended by the American Thoracic Society Guidelines (10).

GAS ANALYSIS

Rapidly responding (<100 ms) gas analyzers have made breath-by-breath analysis possible. Such measurements of expired oxygen and carbon dioxide give dense data useful in interpretation of cardiopulmonary exercise stress tests. When speed of analysis is not essential, chemical analysis by the Scholander or Haldane methods provide accurate results and are considered the gold standard. Gases measured by this method are used to validate other calibrating gases.

OXYGEN ANALYZERS

Discrete oxygen analyzers commonly used are paramagnetic, fuel cell or zirconium oxide. Each are calibrated over the expected range of measurement (e.g., 12–21%) by validated control gases. Of the three mentioned, the later two respond very quickly and so are used in breath-by-breath analysis. Paramagnetism is a distinctive property of oxygen: The molecules aligning in a magnetic field and thus enhancing it. A typical use of this slower responding analyzer is measuring oxygen concentration in large collecting bags or mixing chambers. Of note, oxygen does not have suitable absorption bands in the ultraviolet (UV), infrared (IR), or visible wavelengths. The following sections discuss gases that do have these properties.

Figure 9. Turbine.

NONDISPERSIBLE INFRARED GAS ANALYZERS

This instrumentation (7,11) is used for multiple polyatomic gases including CO_2 and CO , commonly measured in pulmonary function testing. An IR beam is directed alternately through a reference and measurement cell. By means of a chopper wheel, a detector senses the alternating change in absorption of selected IR wavelengths. This signal is amplified with a high input impedance ac amplifier, rectified and displayed on a meter or digital recorder.

NITROGEN METER

The fact that nitrogen molecules can be excited in a low pressure electric discharge to emit visible light in the purple region forms the basis of the nitrogen meter (7,11). A 1500 V electric potential difference is maintained and optical filters select appropriate wavelengths in the violet range. The resulting light intensity is measured by a photocell with an amplifier.

MASS SPECTROMETER

Used primarily in research labs, mass spectrometry is capable of analyzing any gas with speed, specificity, sensitivity, and accuracy unmatched by any other method. Molecules of the sample are ionized at low pressure by a beam of electrons, and the ions are deflected in a circular path by a magnetic field. The stream of particles splits into beams of different molecular weight, any one of which can be detected by a suitably placed collector. Due to expense, mass spectrometry is not a typical part of clinical (hospital or office-based) pulmonary function testing.

PULMONARY FUNCTION TESTS

Pulmonary function tests do not provide a complete diagnostic picture. At best, they support a clinical impression that is formed by a thorough history, physical exam, and X-ray studies. Given the myriad of lung function tests available, an informed decision on the most important ones to order maximized their usefulness.

SPIROMETRY

A forced exhalation maneuver after a deep inhalation is recorded by a moving kymograph on a small water-filled spirometer. A pneumotachograph with computer interfacing could be used with equally acceptable results. A tracing of volume over time is obtained and the following measurements are derived (Fig. 10). This is called a forced vital capacity maneuver.

- | | |
|------------------------|---|
| FVC | Forced vital capacity. This value is effort dependent and depends on the full cooperation of the patient. |
| FEV₁ | From the tracing, the amount of air exhaled in the first second is measured. Patient effort is required to obtain a reliable value. |

Figure 10. A normal spirometric tracing volume versus time.

- FEV₁/FVC** This ratio is helpful in ascertaining airflow obstruction and is typically 70% in normal people.
 - FEF₂₅₋₇₅** This is a flow rate and represents the slope $\Delta V/\Delta T$ during the mid-section of the spirometer tracing. It is where dynamic compression of airways occurs (Fig. 11).
 - PEFR** Peak expiratory flow rate. The steepest slope on the curve, typically at 80% of the vital capacity maneuver.
 - MMEF** Mid-maximal expiratory flow rate is a slope taken at 50% of the vital capacity maneuver. It reflects smaller airways airflow.
- All along the spirometric curve, an infinite number of slopes can be determined, from which a flow-volume curve could be constructed. However, a flow signal from a pneumotachograph plotted against time is the preferred method of generating this data.
- SVC** Slow Vital Capacity. Instead of a forced maneuver, the vital capacity may be performed with less effort. In normals, the FVC and

Figure 11. The FEF₂₅₋₇₅ Slope $\Delta V/\Delta T$ derived from spirogram and expressed in liters per second.

SVC are equal. Because of air trapping, patients with emphysema more fully exhale with the SVC.

FLOW-VOLUME CURVES

Spirometers and flow-volume curves contain the same information, displayed differently. Below is a typical flow-volume curve generated by a pneumotachograph (Fig. 12). A forced expiratory maneuver is performed. Pneumotachographs can measure peak inspiratory flow volume curves, which are important in diagnosing obstructive supraglottic lesions. Expiratory flow-volume curves can unmask central airway tumors not appreciated on simple spirometry at 50% FVC nor seen on standard chest X ray (12).

This curve reflects phenomena in small airways where dynamic compression occurs. Normally, flow here is dependent on gas density. This fact forms the basis for flow-volume measurements after inhalation of 80% helium-20% oxygen mixtures. When overlaid, the flow-volume curves of smokers show little difference after breathing low density helium-oxygen compared to room air (79% nitrogen-21% oxygen). The density independence reflects increased resistance in diseased small airways and is a very sensitive early indication of smoking-induced lung disease.

LUNG VOLUME

There are three methods for measuring the lung volume FRC or functional residual capacity: body plethysmography, nitrogen washout(13), or helium dilution. Once the FRC is measured, residual volume can be determined by asking a patient to exhale completely from FRC to residual volume (RV). The air left in the lung is the residual volume. The total lung capacity is then determined by measuring a deep inhalation from RV (inspiratory capacity) and adding

Figure 12. Flow volume curve. Forced exhalation from TLC to RV = FVC recorded by a pneumotachograph.

Figure 13. Lung volume. Measurements by a water filled spirometer.

that to the residual volume already measured (Fig. 13).

$$RV = FRC - ERC$$

(ERC = expiratory reserve capacity)

$$TLC = RV + IC$$

(IC = inspiratory capacity)

FRC BY PLETHYSMOGRAPHY

A plethysmograph is an airtight box of known volume, similar to a telephone booth, in which a patient sits. A mouthpiece connects the patient to air outside the apparatus and pressure sensors are located within the box and within the breathing capacity. At the end of a normal tidal breath, a shutter on the mouthpiece closes and the subject is asked to make respiratory efforts. As the subject tries to inhale, the volume of the lung expands slightly while the pressure drops due to the chest (lung) expansion (Fig. 14). Applying Boyle’s law, if the pressures in the box before and after the inspiratory effort are P_1 and P_2 , respectively, V_1 is the preinspiratory box volume and ΔV is the change in volume of the box (or lung) ΔV can be obtained from the equation $P_1V_1 = P_2(V_1 + \Delta V)$.

Applying Boyle’s law to the gas in the lung, $P_3(V_2) = P_4(V_2 + \Delta V)$, where P_3 and P_4 are the mouth pressures before and after the inspiratory effort and V_2 is the FRC. Thus FRC can be obtained.

Figure 14. The FRC by whole body plethysmography utilizing Boyle’s law.

The body plethysmograph measures the total volume of compressible gas, including any that is trapped behind closed or poorly communicating airways.

The other two methods measure only volumes based on gas communicating with and open to airways. This is not an issue in normal subjects, but in diseased lungs considerable amounts of gas are trapped and do not communicate freely. Therefore the FRC values differ depending on methodology.

NITROGEN WASHOUT

If a subject quietly breathes 100% oxygen for several minutes, all the nitrogen emptied from the lung can be determined by multiplying the exhaled volume by the exhaled nitrogen concentration. Since the initial lung concentration of N_2 is 80%, the measured volume of nitrogen exhaled multiplied by 1/0.8 equals the volume of the lung prior to 100% oxygen breathing. The value of FRC can be underestimated if significant parts of the lung communicate poorly or not at all with the inspired oxygen (13).

HELIUM DILUTION

As a subject breathes from a spirometer with a known concentration of helium, after several normal breaths the helium concentration in the lung and spirometer equilibrate (Fig. 15). Since helium is insoluble in blood, none of it is absorbed, so the final equilibrium concentration is a reflection of dilution only. The amount of helium before equilibration is $(C_1 \times V_1)$ and equals that after equilibration $C_2 (V_1 + V_2)$ solving for V_2 , $V_2 = (C_1V_1/C_2) - (V_1)$. During the equilibration period oxygen is added to the spirometer and carbon dioxide is absorbed.

Although many other measurements of lung function are perhaps more useful, knowledge of the lung volumes is essential in other complex measurements such as diffusing capacity.

DIFFUSING CAPACITY

Given the challenges with measuring the diffusing capacity of the lung for oxygen, carbon monoxide as originally

Figure 15. Helium equilibration. Technique for FRC determination.

used by Marie Krogh in 1914 is used for current day measurements. There are at least seven variations of this method that have since been developed.

The most common of these is the single-breath modified Krogh technique attributed to Kety and Fowler. Both helium and carbon monoxide are inhaled. After a period of breath hold (15 s), the alveolar portion of the exhaled gas is collected and the concentration of carbon monoxide and helium is measured.

The initial alveolar carbon monoxide concentration is calculated thus:

$$F_{I\text{CO}} \times \frac{\text{He\%in expired alveolar sample}}{\text{Inspired helium percentage}} = F_{A\text{CO}}$$

$$D_{I\text{CO}} = \frac{\text{Alveolar volume STPD} \times 60}{\text{Seconds of breath hold} \times \text{PB} - 47} \times \ln\left(\frac{F_{I\text{CO alv}}}{F_{E\text{CO alv}}}\right)$$

In the above equation, the alveolar volume is measured by a helium dilution technique similar to that in lung volume determinations.

CLOSING VOLUME

This sensitive test detects early changes in lung function and reflects pathology in the small airways. Smokers have an abnormally high closing volume prior to any other pulmonary function test changes. In this test, the subject inhales a breath of 100% O₂ to TLC. During the subsequent exhalation, the nitrogen is measured through the alveolar plateau to an abrupt rise in exhaled nitrogen, so-called phase 4 (Fig. 16). This signals closure of airways in the base of the lungs and preferential emptying of upper airways. Less of the 100% oxygen inhalation is distributed to the upper lung, making it richer in nitrogen. It is this fact that creates phase 4. In some lung diseases, the closing volume is above the FRC. This means that airways close even during normal breathing and is an indication of advanced disease.

MAXIMAL VOLUNTARY VENTILATION

This test measures the volume of air moved during 15 s of repetitive forced deep maximal exhalations. A water filled

spirometer is used for measurement with a time kymographic tracing. Pneumotachographs with real time computer graphics may be used. The main requirement for accurate test results is a low resistance breathing circuit and avoidance of resonance in the system. Both problems have been overcome by modern spirometers, valves and tubing. Although this is formally a lung test, nonpulmonary factors such as motivation, muscular strength and endurance are very important and must be taken into consideration when interpreting the test. The results are expressed in liters per minute BTPS.

PEAK FLOW

Peak flow meters have the distinct advantage of being handheld, self-contained and thus very portable. This is an effort-dependent test, yet it is an excellent reflection of airways function. Its main utility is quickness and simplicity, and it is often used for the management of asthma. Much like a home glucose meter in a diabetic, the peak flow meter can give objective assessment of airways function throughout the day to help guide treatment and presage severe attacks.

Figure 16. Abrupt rise at the end of exhalation called phase (IV) correlates with the closing volume.

STANDARDIZATION OF PULMONARY FUNCTION TESTS

The American Thoracic Society published standards on spirometry in 1979 at the Snowbird Workshop. An official update was issued in 1994, which details equipment and procedural guidelines to enhance accuracy and reproducibility.

Without meticulous attention to these recommendations, the utility of all pulmonary function tests is compromised.

CARDIOPULMONARY STRESS TESTING

Cardiopulmonary stress testing (14) uncovers disorders of the respiratory system as it functions in the integrated cardiopulmonary response to the metabolic demands of increasing incremental work loads. During the course of a cardiopulmonary stress test, the following variables are measured in real time:

W	Work
f_c	Heart rate
O_{O_2}	Oxygen consumption
O_{CO_2}	Carbon dioxide production
O_E	Minute Ventilation
R	O_{CO_2}/O_{O_2}
O_E/O_{O_2}	Efficiency of ventilation
O_E/O_{CO_2}	Efficiency of ventilation
$P_{ET}O_2$	End tidal P_{O_2}
$P_{ET}CO_2$	End tidal P_{CO_2}
P_ECO_2	Mixed expired CO_2

The instrumentation required to make these breath-by-breath and time-averaged measurements are rapid responding CO_2 and O_2 meters; pneumotachograph for flows, ventilation; mixing chamber for collection of exhaled gas; ECG; ergometer cycle, arm, treadmill; computer interface with full graphics in real time.

Limits to exercise appear often in clinical medicine with the presenting problem of dyspnea or shortness of breath on exertion. The genesis of this symptom may reside within either the respiratory or cardiac systems or both simultaneously. Analysis of data obtained from cardiopulmonary stress testing can aid in clinical diagnosis.

Testing begins with an incremental ergometric work load that creates a systemic metabolic response measured as oxygen uptake or consumption. There is a strong reproducible linear relationship between the work load and oxygen consumption. It is derived from the coupling of work and mitochondrial metabolic pathways for cellular energy generation.

With increasing work loads and oxygen consumption, the total ventilation of the lung increases. This requires higher airflow which in normals, even at peak work loads, never reaches flows measured in maximal flow-volume curves. Such is not the case in obstructive lung disorders,

where reduced flow is a hallmark of the disease. Exercise is limited due to the inability to generate flows capable of sustaining the metabolic demands.

As the exercise test progresses real-time analysis of dead space can be measured. Typically the $P_ECO_2 = P_ACO_2 = P_aCO_2$ remains constant with the mixed expired CO_2 P_ECO_2 increasing. This is reflected in a decrease in the O_E/O_{CO_2} marking increased efficiency as more CO_2 is exhaled per breath. By making use of the Bohr equation:

$$V_D/V_T = \frac{F_ACO_2 - F_ECO_2}{F_ACO_2}$$

it appears that V_D/V_T or wasted ventilation decreases with increased exercise. This occurs because lung apical units not perfused but ventilated at rest now are fully perfused and participate in gas exchange. If V_D/V_T does not decrease with exercise, then it is likely based on a structural disease such as emphysema. The work of breathing at any given work load is higher in these patients in part because V_D/V_T (wasted ventilation) remains abnormally high.

As the level of incremental work load increases, the delivery of oxygen fails to meet the metabolic demands of tissues and anaerobic metabolism becomes prominent. Lactic acid is dumped into the blood stream and is quickly buffered by bicarbonate, which generates more carbon dioxide. A dramatic upsurge in O_{CO_2} marks this point and is called the anaerobic or metabolic threshold. The parameter $R(O_{CO_2}/O_{O_2})$ values that previously were 0.8 are now 1.2–1.4, indicating a combined metabolic and buffer source of carbon dioxide. Ventilation (O_E) is driven by the chemical stimulation of lactic acidosis in addition to the demands of oxygen delivery.

Data from such a stress test yields much clinically useful information and allows one to differentiate a pulmonary from a cardiac cause for exercise limitations. Cardiopulmonary deconditioning has a distinct pattern as does obesity. Low peak OO_2 and low A.T. as a percent of OO_2 max are good indications of these two conditions.

Future of Pulmonary Function Testing

No doubt, advances in instrumentation and computers will continue to refine pulmonary function testing. Miniaturization of testing equipment allows complex measurements not only in the laboratory but also in the wild. The burgeoning science of sleep medicine is an example of this.

Epidemiological studies will explore the relationship of pulmonary function to health and uncover what makes the vital capacity so vital to life. A fundamental role for FEV_1 in total mortality independent of cigarette smoking has been proposed. Whether reduced lung function leaves an individual open to oxidative stress is unknown.

If pulmonary function proves to be a long-term predictor for overall survival rates in both genders, it could be used as a tool in general health assessment.

The search for tests that implicate early potentially reversible lung disease will continue. The benefit to asymptomatic patients and society as a whole is obvious.

The long-term effects of air pollution and impact of air quality on lung health will always be of prime concern, not only to the general public, but to government officials who set air quality standards.

Perhaps pulmonary function testing will ultimately guide and protect us all.

TERMINOLOGY—DEFINITIONS—EQUATIONS

Spirometer	A measuring device for determining lung volume, its subcompartments, and expiratory flow rates.
FRC	Functional residual capacity: The volume in the lung after a normal exhalation. At this volume the recoil pressure of the lungs inward is exactly balanced with the outward recoil pressure of the chest wall.
FEV ₁	Forced expiratory volume in the first second: The amount of air expired in the first second of a forced expiratory maneuver.
TLC	Total lung capacity.
RV	Residual volume: The volume of air left in the lungs after a full exhalation.
FVC	Forced vital capacity: The amount of air exhaled during a complete exhalation.
FEF ₂₅₋₇₅	Forced expiratory flow: The mean expiratory flow measured between 75 and 25% of the vital capacity during forced exhalation.
PEFR	Peak expiratory flow rate during forced exhalation.
MVV	Maximal voluntary ventilation expressed in liters per min.
DL _{CO}	Diffusing capacity for carbon monoxide.
Flow-volume curve	A maximal exhalation measuring flow versus volume.
P _A O ₂	Alveolar oxygen partial pressure.
P _A CO ₂	Alveolar carbon dioxide partial pressure.
P _{ET} O ₂	End tidal oxygen partial pressure.
P _{ET} CO ₂	End tidal carbon dioxide partial pressure.
P _E O ₂	Mixed expired oxygen partial pressure.
P _E CO ₂	Mixed expired carbon dioxide partial pressure.
O ₀₂	Volume of oxygen take up per minute.
O _{co}	Volume of carbon dioxide output per minute.

O _E	Minute ventilation: Total volume of air expressed per minute from the lungs.
V _T	Tidal volume: The volume of a single breath.
V _D	The volume of physiological dead space.
V _D /V _T	The ratio between dead-space volume and tidal volume. This ration indicates the efficiency of ventilation.
V _A	Volume of alveolar gas in the tidal volume.
General gas law	$PV = RT$
Boyle's law	$P_1V_1 = P_2V_2$ (temperature constant)
Charles's law	$\frac{V_1}{V_2} = \frac{T_1}{T_2}$ (pressure constant)
Poiseuille's law	$V = \frac{P\pi r^4}{8n}$
	$P =$ Pressure difference across length ℓ and radius r
	$n =$ Coefficient of viscosity
Bohr equation	$V_D/V_T = \frac{P_A\text{CO}_2 - P_E\text{CO}_2}{P_A\text{CO}_2}$

INTRODUCTION

The field of patient-reported outcomes, particularly health-related quality of life (QOL), has burgeoned in the last few years (1,2). The importance assigned to the study of these outcomes has been attributed to the aging of the population and consequently higher prevalence of chronic diseases, along with the reality that medical treatment often fails to cure the disease, but may affect QOL (3). Health-related quality of life has gained attention in research and clinical trial settings (3,4).

The increasingly important role assigned by patients and clinicians to QOLs role in medical decision making has resulted in greater attention paid to the interpretation of QOL scores, particularly as it relates to clinical significance (5–7). Clinical significance relates to the clinical meaningfulness of intersubject or intrasubject changes in QOL scores. Clinical significance has been difficult to determine, in part due to the development of a myriad of QOL instruments over the past decade (8,9). Some of these have had little or no psychometric validation (1,2,6,10,11) or clinical validation (9,12). Moreover, relative to traditional clinical endpoints, like survival and systolic blood pressure, QOL as a clinical endpoint is relatively unfamiliar especially in regard to interpretation and relevance of changes in QOL scores (13).

Why is clinical significance of QOL scores important? It aids in the design of studies by helping to determine sample size calculations. Evidence of clinical significance may be used by regulatory agencies for drug approval, by clinicians to decide between treatment alternatives, by patients to make informed decisions about treatment, by the healthcare industry for formulary and reimbursement decisions, and by healthcare policy makers to make policy decisions regarding resource allotment. Early evidence of the clinical implications of QOL is evident in the links between survival and QOL components (e.g., patients' fatigue levels, social support, and group counseling) (14–17). Even a simple, single-item measure of patient global QOL can be related to patient survival (18). Changes in QOL scores

can also be linked to positive economic (19,20) and social (21) outcomes.

HISTORICAL BACKGROUND

Statistical significance as measured by a P -value is influenced by sample size and data variability. While statistical significance can be considered a prerequisite for clinical significance, only clinical significance assigns meaning to the magnitude of effect observed in any study. Historically, Cohen (22) was responsible for proposing one of the earliest criteria for identifying important change, which can be construed as clinically significant. He suggested that a small effect size (defined later in this article) was 0.2 standard deviation units, a medium effect size was 0.5, and a large effect size was 0.8. Although his intention was to provide guidance for sample size calculations in the social and behavioral science, Cohen's benchmarks have extended to healthcare research to decide whether or not a change in QOL scores is important. Current research suggests that a moderate effect size of one-half a standard deviation unit (effect size = 0.5) is typically important (23). A more recent and popular definition of clinical significance uses an anchor-based approach based on an external standard that is interpretable and appreciably correlated to the target QOL measure, in order to elucidate the meaning of change on the target QOL measure.

Embedded under the rubric of clinical significance is the minimum important difference, a lower bound on clinical significance. One definition of a minimum important difference (MID) is "the smallest difference in score in the domain of interest which patients perceive as beneficial and which would mandate, in the absence of troublesome side-effects and excessive cost, a change in the patient's management"(24). Some researchers prefer to use the term "minimally detectable difference"(25,26); other approaches have sprouted (e.g., the empirical rule effect size, ERES, method) (27,28).

No single solution to the challenging topic of assessing clinical significance exists. Nevertheless, a series of proposals has engendered understanding and appreciation of the topic. Special issues in *Statistics in Medicine* (1999, Vol. 18) and the *Journal of Consulting and Clinical Psychology* (1999, Vol. 67) have been dedicated to the topic of clinical significance of QOL and other clinical measures. Proceedings from a meeting of an international group of ~30 QOL experts were published recently in a special issue of the *Mayo Clinic Proceedings* (2002, Vol. 77) (29–35), which provides practical guidance regarding the clinical significance of QOL measures.

CHAPTER OUTLINE

This article draws largely from recent scientific literature, including the *Mayo Clinic Proceedings* (29–35) and other

sources (4), to provide an overview on the clinical significance of QOL measures.

The following section on Design and Methodology covers the different perspectives and existing methods to determine clinical significance. The next section on Examples illustrates trials in which researchers attempted to define the concept on specific QOL measures. Then the section on Recent Developments highlights new methods to determine clinical significance. Finally, the section on Concluding Remarks discusses some future directions for research.

DESIGN AND METHODOLOGY

Perspectives for Determining and Interpreting Clinical Significance

Clinical significance involves assigning meaning to study results. The process of establishing such meaning can be conceptualized in two steps: (1) understanding what changes in score mean to the concerned stakeholder (e.g., patient, clinician, clinical researcher, policy maker) and (2) making results of clinical studies interpretable and comprehensible to such stakeholders or decision makers (30,36). The term clinical in relation to significance has different meaning and implications for different stakeholders such as patients, clinicians, and society.

From the patient's perspective, clinical significance can be defined as the change in QOL scores that patients perceive as beneficial (or detrimental) and important that prompts them to seek health care or request changes in their treatment (33), or that induces patients to determine that the intervention has been successful (24). From the clinician's perspective, it can be defined as the diagnosis of the clinician as to the amount of change in QOL scores that would mandate some form of clinical intervention (37). From the societal or population perspective, clinical significance is based on the values of the group surveyed, where importance is defined by the outcomes that are deemed worthy of society's resources. Any or all of these perspectives for defining clinical significance may be applicable, but they may not always be in agreement (4).

An equally important issue is the different perspectives for interpreting clinical meaningfulness of changes in reported QOL (35). For example, a clinician may use QOL data to explain the treatment alternatives to a patient, while a health policy maker may describe to elected officials the financial impact on a patient population whose QOL has changed. Similarly, a regulatory agency and pharmaceutical company may ascertain the appropriate level of evidence for a successful research study (35). Thus QOL results must be framed, analyzed, and presented in a way that is meaningful to the pertinent audience and its respective needs. Only then will the concept be meaningful and gain greater acceptance and use over time.

METHODS TO EXPLAIN THE CLINICAL SIGNIFICANCE OF HEALTH STATUS MEASURES

Two common approaches used to establish the interpretability of QOL measures are termed anchor and distribution based. The characteristics of each approach are

described below. Several examples will be given later in the section on Examples. Interested readers are encouraged to read Lydick and Epstein (1993) [Lydick, 1993 #40] Crosby et al. (4), and Guyatt et al. (30) for an expanded discussion of the concepts presented here.

Anchor-based approaches are used to determine clinically meaningful change via cross-sectional or longitudinal methods involve comparing measures of QOL to measures with clinical relevance (4). Cross-sectional methods include several forms: (1) comparing groups that are different in terms of some disease-related criterion (38,39); (2) linking QOL to some external benchmarking criteria (40–42); (3) eliciting preference-based ratings on a pairwise basis, where one person's ratings state serves as an anchor to evaluate the other person's ratings (43); and (4) using normative information from dysfunctional and functional populations (6). Longitudinal methods involve the comparison of changes in QOL scores across time with the use of (1) global ratings of change as "heuristics" to interpret changes in QOL scores (5,24,38,44); (2) significant future medical events for establishing difference thresholds (45); and (3) comparisons of changes in HRQOL to other disease-related measures of outcome across time (46). Anchor-based methods are cataloged in Table 1.

Anchor-based methods require two properties (30): (1) anchors must be interpretable, else they will hold no meaning to clinicians or patients; and (2) anchors must share appreciable correlation with the targeted QOL measure. The biggest advantage of anchor-based approaches is the link with a meaningful external anchor (4), akin to establishing the construct validity of the measure (49). Potential problems, however, exist with this approach. These include recall biases (50), low or unknown reliability and validity of the anchor measure (51), low correlation between anchor and actual QOL change score (52–55), and complex relationships between anchors and QOL scores (56) and the challenge of defining a meaningful change in the anchor itself.

Hays and Wooley (57) recommend caution in the indiscriminate dependence and use of a single minimum important difference (MID) measure. They also list several problems in estimating MIDs: the estimated magnitude could vary depending on the distributional index (57,58), the external anchor (59), the direction of change (improvement vs. decline) (60), and the baseline value (61). In general, longitudinal methods are preferable because of their direct link with change (4).

Distribution-based approaches for determining the importance of change are based on the statistical characteristics of the obtained sample, namely, average scores and some measure variability in results. They are categorized as (1) those that are based on statistical significance using p-values (i.e., given no real change, the probability of observing this change or a more extreme change), which include the paired *t*-statistic (62) and growth curve analysis (63); (2) those that are based on sample variation (i.e., those that evaluate mean change in relation to average variation around a mean value), which include effect size (22,64), standardized response mean (SRM) (44), and responsiveness statistic (65); and (3) those that are based on the measurement precision of the instrument

Table 1. Anchor-Based Methods of Determining Change^a

Type	Method	Examples	HRQOL evaluated in relation to:	Advantages	Disadvantages
Cross-sectional	Comparison to disease-related criteria	39, 47	Disease severity or diagnosis	Can be standardized Easy to obtain	May not reflect change Groups may differ in other key variables
	Comparison to nondisease-related criteria	40, 41	Impact of life events	Easy to obtain Provides external basis for interpretation	May no reflect change Groups may differ on other key variables Relationship to HRQOL not clear
	Preference rating	43	Pairwise comparisons of health status	All health states are compared	May not reflect change Hypothetical, artificial Time Consuming
	Comparison to known populations	6	Functional or dysfunctional populations	Uses normative information	Normative information not always available Amount of change needed not specified
Longitudinal	Global ratings of change	5, 24, 38, 44	Patients' or clinicians' ratings of improvement	Easy to obtain Best measure from individual perspective Can take into account a variety of information	Does not consider measurement precision Unknown reliability Influenced by specific rating scale and anchors
	Prognosis of future events	45	Those experiencing and not experiencing some future event	Prospective Provides evidence of predictive validity	Does not consider measurement precision Difficult to obtain
	Changes in disease related outcome	48	Changes in clinical outcome	Tied to objective outcome measure Known psychometric properties	Does not consider measurement precision Assumes strong HRQOL-outcome correlation

(i.e., evaluate change in relation to variation in the instrument as opposed to variation of the sample), which includes the standard error of the mean (SEM) (7) and the reliable change index (RC) (6). Distributed-based methods are catalogued in Table 2.

An advantage of the distribution-based methods is that they provide a way of establishing change beyond random variation and statistical significance. The effect size version of the distribution-based methods is useful to interpret differences at the group level and has benchmarks of 0.20 standard deviations units as a small effect, 0.50 as a moderate effect, and 0.80 as a large effect (22,64,66). The measure that seems most promising for the purpose of establishing clinical significance at the individual patient level are the SEM and the RC. These measures are based on the measurement precision of the instrument and incorporate the reliability of the instrument (e.g., Cronbach's alpha or test-retest reliability), and the standard deviation of scores. In principle, SEM and RC are sample invariant. Researchers have favored Cronbach's alpha over test-retest reliability to calculate reliability for the SEM (7,30,67), because this is more conveniently available over test-retest data.

Distribution methods are particularly helpful when used together with meaningful anchors, which enhances validity, and hence meaning to the QOL measure. There is some encouragement to know that anchor-based measures appear to coincide with distribution-based methods. Researchers have found a correspondence between SEM

and anchor-based determinant of a minimum important difference across difference diseases (7,23,67,68). The 1 SEM benchmark corresponds with an effect size (ES) of ~0.5. Nonetheless, note that the SEM is moderated by the reliability of the measure, where measures with higher reliability are "rewarded" by lowering the effect size (ES) needed to achieve a minimally important difference. Thus the 1 SEM benchmark corresponds with an ES = 0.5, when reliability of the scale = 0.75; the correspondence shifts to 1 SEM is equivalent to an ES = 0.33, when reliability increases to 0.9, which is frequently attainable in focused assessments. A rationale for a SEM as a measure of MID is provided by Norman et al. (23) who assert that Miller's theory (69) of the limits of human discernment is linked to the threshold of 0.5 standard deviation units.

EXAMPLES

This section provides examples of studies used to determine clinical significance and presents general advice for defining and interpreting clinical significance in clinical studies. Table 3 includes several examples on the use of both anchor-based methods and distribution-based methods to establish clinical significance across a wide range of QOL measures. These examples span several disease groups, instruments, and methods for determining clinical significance. Readers are encouraged to review the cited papers for further details on these studies.

Table 2. Distribution-Based Methods of Determining Change ^a

Method	Reference	HRQOL evaluated in relation to:	Calculation	Advantages	Disadvantages
Paired <i>t</i> -statistic	62	Standard error of the mean change	$\frac{x_1 - x_0}{\sqrt{\frac{\sum (d_i - \bar{d})^2}{n(n-1)}}}$	None	Increases with sample size
Growth curve analysis	63	Standard error of the slope	$\frac{B}{\sqrt{V}}$	Not limited to pre-test and post-test scores Uses all of the available data	Increases with sample size Requires large sample sizes Assumes data missing at random
Effect size	22, 64	Pre-test standard deviation	$\frac{x_1 - x_0}{\sqrt{\frac{\sum (x_0 - \bar{x}_0)^2}{n-1}}}$	Standardized units Benchmarks for interpretation Independent of sample size	Decreases with increased baseline variability of sample Does not consider variability of change May vary widely among samples
Standardized response mean	44	Standard deviation of change	$\frac{x_1 - x_0}{\sqrt{\frac{\sum (d_i - \bar{d})^2}{n-1}}}$	Standardized units Independent of sample size Based on variability of change	Varies as a function of effectiveness of treatment
Responsiveness statistic	65	Standard deviation of change in a stable group	$\frac{x_1 - x_0}{\sqrt{\frac{\sum (d_{i \text{ stable}} - \bar{d}_{\text{stable}})^2}{n-1}}}$	Standardized units More conservative than effect size Independent of sample size Takes into account spurious change due to measurement error	Data on stable subjects frequently not available
Standard error of measurement	7	Standard error measurement	$\frac{x_1 - x_0}{\sqrt{\frac{\sum (x_0 - \bar{x}_0)^2 (1-r)}{(n-1)}}}$	Relatively stable across populations Takes into account the precision of the measure Cutoffs based on confidence intervals	Assumes measurement error to be constant across the range of possible scores
Reliable change index	6	Standard error of the measurement difference	$\frac{x_1 - x_0}{\sqrt{2(SEM)^2}}$	Relatively stable across populations Takes into account precision of measure Cutoffs based on confidence intervals	Assumes measurement error to be constant across the range of possible scores

We begin with a classic paper by Jaeschke et al. (24), one of the first papers on clinically meaningful differences determined through the anchor-based approach. The magnitude of difference considered minimally significant was an average of 0.5 per item on a 7-point scale, which was confirmed by Juniper et al. (5) on the asthma quality of life questionnaire (AQLQ). A third study, by Kazis et al. (64), examined the difference between statistical significance and clinical significance.

Using several pain studies and the Pain Intensity numerical rating scale (PI-NRS) scale, Farrar et al. (70) found a reduction of 2 points or 30% on the 11-point pain scale to be clinically significant. Using the Western Ontario and McMaster Universities Osteoarthritis Index

(WOMAC) scale for osteoarthritis, Angst et al. (71) compared estimates derived from anchor- and distribution-based approaches; they determined sample sizes for specified changes signifying worsening and, separately, improvement. Using the chronic heart failure questionnaire (CHQ), Wyrwich et al. (7) also compared anchor and distribution-based approaches in determining that 1 SEM equals the MCID of 0.5 per item determined by the anchor-based approach. Finally, using the functional assessment of cancer therapy–Lung (FACT-L) questionnaire, Cella et al. (72) showed the convergence of three different complementary approaches on clinical significance.

Taken from Sprangers et al. (34), Table 4 provides a useful checklist of questions to help in interpretation of

<p>Wyrwich et al.(1999) (67) Chronic Heart Failure Questionnaire: CHQ QOL domains Dyspnea (patient-specific 3–5 items affected by chest pain) scored as one (extreme amount) to seven (none at all) fatigue (4 items), emotional function (7 items) scored on a 7 point scale: one (worst), seven (best). baseline to follow-up (6,12,18 mths) change scores combined Anchor: Retrospective within-patient global assessment of change over last 4 weeks. “Worse”: –1 hardly any worse to –7 a very great deal worse “Better”: +1 hardly any better to a +7 a very great deal better</p>	<p>605 cardiac patients in an outpatient setting. Secondary analysis of data from a RCT. Anchor standard for MCID comes from previous research on CHQ of about 0.5 average per item change for each domain Classification of change on anchor: improved, stable, declined. Anchor-based method linked QOL change scores with classification on anchor. Classification of change on anchor Minimal clinically important: 1 to 3/ –3 to –1 Moderate clinically important: 4 to 5/–5 to –4. Large clinically important: 6 to 7/ –7 to –6.</p>	<p>1 SEM based on baseline SD and Cronbach’s alpha 1 SEM (Dyspnea)= 2.41 CHQ points per 5 items equates to 0.48 average per item 1 SEM (Fatigue)= 2.10 CHQ points per 4 items equates to 0.53 average per item 1 SEM (Emot. Func.)= 2.90 CHQ points per 7 items equates to 0.41 average per item SEM concurs highly with MCID standard of 0.50 per item.weighted kappa (1.0, 0.87, 0.91 for the 3 domains) used to assess degree of association between 1SEM and MCID.</p>	<p>Combines the anchor and distributional approaches. 1 SEM as MCID also found in independent study (7) using the Chronic Respiratory Disease Questionnaire</p>
<p>Cella et al. (2002) (22) Functional Assessment of Cancer Therapy–Lung Questionnaire: FACT-L. 7-item Lung Cancer Sub scale (LCS) its Trial Outcomes Index (TOI) adds scores on physical well-being sub scale and functional well-being sub scale of FACT-L to LCS scores</p>	<p>Randomized trial with 599 patients advanced non-small cell lung cancer 3 chemotherapeutic regimens (no difference in FACT-L) measurements at baseline and week 12 Three Complementary Approaches to MCID 1) Group means based on baseline differences in LCS and TOI scores on following anchors: prior 6-month weight loss (<5% vs.≥5%) performance status (normal vs. some symptoms) primary disease symptoms (<1 vs. <1) 2) Group means based on changes in LCS and TOI scores over time on following anchors: response to treatment (complete/partial vs. stable vs. deterioration) time to disease progression (<median time, >median time) 3) Distribution-based criteria 1/3 and 1/2 standard deviation change standard of baseline scores, at week 12 scores, change scores. one standard error of measurement (SEM) at baseline and at week 12. Patients classifies as “declined” or “improved” (if – or + change scores > 1SEM respectively) or “unchanged” (if change score<1 SEM)</p>	<p>Approximate MCID for 3 approaches converged; Cohen’s kappa used to compare between empirically derived categories (i.e., anchor-based) and distribution-based categories Clinically meaningful differences: 2 to 3 points for the LCS (on 0-to-28-point scale) 7.1 points (=2*100/28) on 0-to-100 point sale 5 to 7 points for the TOI (on 0-to-84-point scale) 6 points (=5*100/84) on 0-to-100 point scale</p>	<p>Combines and compares anchor and distributional approaches. Use of multiple clinical anchors to validate clinically meaningful difference.</p>

Table 4. Checklist for Assessing Clinical Significance over Time in QOL^a

<p>What are the characteristics of the population for whom changes in QOL are reported?</p>	<p>Is the study adequately powered?</p>	<p>Can alternative explanations account for the observed change or lack of observed change?</p>
<p>What are their disease (e.g., tumor type), treatment (e.g., duration), socio-demographic and cultural (e.g., age, ethnicity), and behavioral (e.g., alcohol use) characteristics?</p>	<p>Is the sample size appropriate for the research questions (e.g., by providing a power calculation)?</p>	<p><i>Are dissimilar baseline characteristics adequately accounted for?</i></p>
<p>To what extent are the QOL data applicable to your patients?</p>	<p>Is a rationale and/or source for the anticipated effect size specified?</p>	<p>Is the baseline QOL score used as a co-variate?</p>
<p>Is actual QOL status of individual patients reported (e.g., by providing confidence intervals, standard deviations, subgroup data, individual data plots), thus documenting the amount of individual variation in response to treatment?</p>	<p>Does the power calculation take into account: the scale range of the anticipated effect, the score distribution (i.e., magnitude and form), the number of outcome measures, and research hypothesis (i.e., equivalence versus difference)?</p>	<p>Are missing data handled adequately?</p>
<p>Is the QOL questionnaire relevant, reliable, valid, and responsive to change?</p>	<p>How are multiple QOL outcomes addressed in analyses?</p>	<p>Does the article indicate how missing items within a questionnaire are handled?</p>
<p>Is the questionnaire appropriate given the research objective and the rationale for QOL assessment?</p>	<p>Is the adopted approach of handling multiplicity explicitly described?</p>	<p>Does the article report the number of missing questionnaires at each scheduled assessment?</p>
<p>Is the questionnaire appropriate given the domains included and in light of the disease and population characteristics?</p>	<p>Which approach is taken: limiting the QOL outcomes, use of summary measures, adjustment of p-values, and/or multivariate statistical analysis and modeling?</p>	<p>Does the article report the reasons for missing questionnaires?</p>
<p>Is the questionnaire reliable and valid? Is this information reported in the article?</p>	<p>Did the interpretation of the results take the problem of multiple outcomes into account?</p>	<p>Is there an association between patients' health status and missing QOL data?</p>
<p>Is the questionnaire responsive to change? Is this information reported in the article?</p>	<p>How are multiple time-points handled?</p>	<p>If patients with incomplete data are excluded from the analysis (e.g., by using complete case methods), does the article document that these are non-ignorable missing data?</p>
<p>Is the questionnaire appropriate given practical considerations (e.g., regarding respondent burden and the availability of different language versions)?</p>	<p>Are the data presented in a meaningful and suitable way enabling an overview of QOL changes over time?</p>	<p>In cases of nonignorable missing data, are several analytical approaches presented to address possible bias in conclusions based on this QOL data set?</p>
<p>Is the questionnaire appropriate given regarding respondent burden and the availability of different language versions)?</p>	<p>Do the tabular and graphical presentations take the problems inherent in the data into account (e.g., presence of floor and ceiling effects, patient attrition)?</p>	<p>Is observed survival difference combined with QOL in evaluating change?</p>
<p>Are patients' baseline QOL scores close to the extremes of the response scale? Do the treatment groups differ in baseline QOL?</p>	<p>Are the data appropriately analyzed (e.g., are all time points included, are missing data taken into account, are pre-treatment co-variates included)?</p>	<p>If patients have died in the course of the study, is mortality accounted for in the evaluation of QOL?</p>
<p>Are the timing and frequency of assessments adequate?</p>	<p>Does the article provide sufficient information on the statistical models selected?</p>	<p>Are summary indices (e.g., QALYs, Q-TWiST) or imputation techniques used?</p>
<p>Is a baseline assessment included?</p>	<p>Does the article provide sufficient information on the statistical models selected?</p>	<p><i>Did the patient's QOL perspective change over time?</i></p>
<p>Is QOL assessed at appropriate times for determining minimally important change given the natural course of the disease?</p>	<p>Does the article provide sufficient information on the statistical models selected?</p>	<p>Are changes in patient's internal standards, values, and/or the conceptualization of QOL explicitly measured?</p>
<p>Is QOL assessed long enough to determine a clinical effect, taking disease stage into account?</p>	<p>Does the article provide sufficient information on the statistical models selected?</p>	<p>Are insignificant or small changes in QOL reported despite substantial changes in patient's health status (i.e., deterioration or improvement)?</p>
<p>Is QOL assessed at appropriate times to document treatment course, clinical events, and post-treatment effects?</p>	<p>Does the article provide sufficient information on the statistical models selected?</p>	<p>How likely is it that patients have changed their internal standards, values, and/or their conceptualization of QOL as a result of adaptation to deteriorating or improving health?</p>
<p>Are standard research design procedures followed (e.g., avoidance of respondent burden, collection of data prior to treatment or consultation)?</p>	<p>Does the article provide sufficient information on the statistical models selected?</p>	<p>How is statistical significance translated into meaningful change?</p>
<p>Is the timing of the QOL assessments similar across treatment arms?</p>	<p>Does the article provide sufficient information on the statistical models selected?</p>	<p>Does the article provide some guidance regarding the clinical importance of the observed change in QOL?</p>

longitudinal, patient-derived QOL results presented in clinical trials and the clinical literature. These questions are based on the premise that detecting meaningful change depends on the adequacy of the research design, measurement quality, and data analysis.

RECENT DEVELOPMENTS

The One-Half Standard Deviation Rule

It would be desirable to simply define, at least initially, what a clinical significant result is likely to be. Emerging research comparing anchor- and distribution-based estimates provides an evolving standard as to what to use as an initial estimate (23). The anchor-based estimates averaging 0.5 per item on a 7-point scale appear to converge with an estimate of one-half standard deviation (SD) units. This latter estimate is derived through distribution-based methods, such as the effect size approach (22,64), SEM (7,67,68), and the standardized response mean (73). Potential moderating factors that could impact these estimates upward or downward are the method used to determine minimum difference estimates, the reliability of the measure and whether patients were suffering from acute or chronic conditions (23,74)

Empirical Rule Effect Size

Sloan et al. (27,28) have taken this concept one step further in the form of the ERES by combining Cohen's effect size categorization (22) with the empirical rule from statistical theory (75). The ERES is based on Tchebyshev's theorem and states that the distribution of any QOL tool is contained within six SDs of the observed values. The ERES entails the estimation of QOL change scores in terms of SD estimates, expressed as units on the theoretical range of a QOL instrument. Thus small, moderate, and large effect sizes for comparing QOL treatment groups turn out to be 3, 8, and 13%, respectively, of the theoretical range of any QOL tool. This simple and intuitive rule to identify the magnitude of clinically significant changes is likely to be easy for clinical researchers to comprehend. The rule can facilitate the design of clinical trials in terms of sample size calculations and interim monitoring of clinical trials. The ERES framework for a priori establishment of effect sizes is sample independent and thus an improvement over sample-dependent methods (5,21,76).

However, the simplicity of the ERES method gives rise to some challenges and questions. The theoretical range of the instrument is rarely observed in its entirety, necessitating the modification of the theoretical range to more practical limits before calculating the ERES estimate for one SD as necessarily 16.7% (i.e., one-sixth of distribution of observed values) of the range. Similarly, truncated distributions, where the patient population is homogeneously ill or uniformly healthy, can be accommodated by incorporating this knowledge into the definition of the appropriate range. These guidelines for clinical treatments can be used in the absence of other information, but will need modification in their application to idiosyncratic or unique clinical settings. More research is needed to examine the general-

izability of such benchmarks across baseline patient health, severity of illness, and disease groups.

Group Change versus Individual Change

Distinctions should be made in determining the significance of change at the group versus the individual level. Every individual in a group does not experience the same change in outcomes (group level outcomes are assigned a mean change value). There is higher variability in individual responses than those of the group. Depending on the distribution of individual differences, the same group mean can have different implications for an individual (77).

The traversing of group and individual level QOL data entails procedures for moving from one level to the other involving two distinctive scientific traditions: deductive and inductive (31). A deductive approach is employed when one addresses the extent to which group data can be used to estimate clinical significance at the individual level. An inductive approach is used when one evaluates the extent to which individual change data can be brought to the group level to define clinical significance. Related to this is the fact that the lower end of a MID estimate may be useful for powering studies to detect meaningful differences between groups (with ES as low as 0.2), while the higher end of the MID estimate, especially for more sensitive tools, can be used to power studies detecting change at the individual level. Readers are advised to read Cella et al. (31) for a more detailed account.

Quality of Life as a "Soft" Endpoint

The "softness" of QOL as an endpoint, relative to say survival and tumor response, is cited as a particular barrier to implementation and interpretation of results (13). However, methodological and conceptual strides made in defining and measuring QOL, and the growing familiarity with the interpretation and potential utility of QOL data, make those concerns increasingly outdated.

Psychometric advances have been made in QOL assessment tools across disease areas (8,78–81). Funding opportunities to study QOL endpoints have allowed for study designs that are large enough to have power to detect meaningful differences (13). Moreover, accumulated experience with analyzing QOL endpoints have resulted in the recognition that their statistical challenges are no different from those of "hard" endpoints.

CONCLUDING REMARKS

Several suggestions on clinical significance are offered. First, the application of multiple strategies for determining clinical significance is recommended. Doing so would enable better interpretability and validity of clinically significant change, add to existing evidence of the magnitude of change that constitutes clinical significance, and would provide indicators of distributional parameters that create convergence or divergence in estimation of clinical significance. For example, Kolotkin et al. (46) found convergence between anchor- and distribution-based methods at

moderate level of impairment but wide disparities at mild and severe levels of impairment.

Second, more research is needed into the effect of psychometric properties (i.e., reliability, validity and responsiveness of QOL instruments) have in quantifying clinically meaningful change (4,62,82). Similarly, research into the psychometric properties of global rating and health transition scales used in anchor-based methods is also needed. Global ratings tend to be single item measures and may therefore fall short in terms of explaining complex QOL constructs. Anchoring assessment also tends to be positively correlated with post-treatment states but with near-zero correlation with pretreatment states, suggesting a recall bias (83) or response shift (84). More research is needed to address the cognitive process used by patients to retrospectively assess changes in health over time (30).

Third, baseline severity results in regression to the mean (RTM), an error-based artifact describing the statistical tendency of extreme scores to become less extreme at follow-up. Failure to take this into account may lead to false conclusions that patients with severe impairments at baseline have shown clinical significant change, when in fact this was just RTM. The RTM also has a greater impact upon data when the measure is less reliable (4,85). More research is also needed into the effect of baseline QOL impairment on magnitude of clinically meaningful change (4,47,48,66,86,87). Similar research is needed in terms of the generalizability of the standardized benchmarks for determining clinically meaningful change, especially for distribution-based methods (4,66). Specifically, how satisfactory are the evolving benchmarks (effect sizes of 0.2, 0.5, and 0.8 for small, moderate, and large change, respectively) across different dimensions of QOL (e.g., mental versus physical), different disease groups (e.g., arthritis versus cancer), respondents (e.g., patients versus clinicians), measures (e.g., generic versus disease specific) patient populations (e.g., older versus younger), or patient conditions (e.g., improving versus deteriorating)?

Finally, care must be taken in presenting results of studies in a way that is familiar to the user of the information. For example, translating clinical significance into a number needed to treat (NNT) and a proportion of patients achieving various degrees of clinical benefit relative to the control may provide a desirable way to present study results (30).

INTRODUCTION

The term radiation dose planning in radiation therapy refers to the process of designing treatment strategies for optimally delivering a desired radiation dose to the intended volume while minimizing the dose to healthy tissues as much as possible, and estimating the radiation dose throughout the irradiated volume. In pursuit of better energy deposition characteristics, higher and higher energy photon and electron sources have been developed and used throughout the history of radiation therapy. Ionizing radiation dose can be delivered externally using electron accelerators or radioactive sources, or internally by implanting radioactive sources in the tumor volume. Heavy particles (e.g., protons, neutrons, and carbons) have also been used in radiation therapy, although the high cost of these machines have limited their widespread application. Our discussion will be restricted to radiation dose planning with external photon beams generated with medical megavoltage electron linear accelerators (linacs), which is by far the most widely used method of radiation cancer treatment.

Most medical linacs are isocentrically mounted, that is, they can rotate around a horizontal axis in 360°. Combined with the rotation of the treatment couch, radiation can be directed toward the patient from all possible directions. Two pairs of collimators or jaws moving in the orthogonal direction are usually built in the linac head to collimate the beam into a square or rectangular shape with continuously variable field sizes. Figure 1 shows a typical medical linac. A treatment usually involves several beams from different directions with different beam weights and beam-modifying devices in order to deliver a uniform dose to the target and to limit dose to surrounding normal tissues. Commonly used beam-modifying devices include custom-made blocks, which further collimate the radiation beam into any arbitrary shape, and wedge filters, which are wedge-shaped metal absorbers placed in the path of the beam to cause a tilt of the resulting isodose curves in the patient. To achieve optimal results, computer-aided radiation dose planning has played an increasing role in radiation therapy.

Many steps are involved in planning a radiation treatment. One of the first steps in the process is to establish a three-dimensional (3D) patient anatomy model based on the patient's image information. Toward this goal, one needs to delineate the areas to be treated (targets) and any dose-limiting normal structures. Developments in 3D imaging, digital imaging processing, and multimodality imaging have greatly aided this process. Treatment strategies are then developed where radiation beams are chosen for optimal target coverage without delivering excessive dose to critical structures. Radiation dose throughout the irradiated volume is calculated, and the plan evaluated. Several trial and error efforts are usually required before a clinically acceptable plan is generated. Most of the treatment planning is now performed using computers with dedicated software called a treatment planning system (TPS). With the availability of fast processors and large random access memory (RAM), voluminous patient data depicting accurate 3D geometry and anatomy from a computed tomography (CT) scanner can be manipulated in a TPS, giving radiation oncologists and treatment planners better visualization of the internal structures and greater ability to tailor the treatment to the particular circumstances. Dose display and plan evaluation tools have made it easier to compare different treatment plans. This article concentrates on new developments in radiation dose planning since the first edition of this encyclopedia (1). The widespread clinical implementation of 3D planning techniques (e.g., virtual simulation, image registration, model-based dose calculation algorithms, and treatment plan optimization) have made a major impact on the current practice of radiation therapy. All of the new developments are computationally intensive and require large RAM for image processing. Their increasing role in radiation dose planning has tied closely to the development and availability of fast computers and large RAM.

VIRTUAL SIMULATION

Virtual simulation is a process of delineating target and normal organs and designing treatment field arrangements and portals on a computer, based on a detailed 3D model of a patient built from a sequence of closely spaced transverse images from a CT scanner. Virtual simulation is now widely used and has replaced conventional simulation for most of the treatment planning except in some simple or emergency cases. Conventionally, the patient simulation is done using a simulator with the patient in the treatment position. A conventional simulator duplicates a linac geometry, but uses a diagnostic kilovoltage X-ray tube to enhance image contrast. Two-dimensional (2D) projection radiographs are taken from various gantry positions that have been chosen for treatment. Target volume and normal structures are drawn on the 2D simulation films and correct positioning of the fields and shielding blocks can be obtained in relation to

Figure 1. Photograph of an isocentric medical electron linear accelerator (Elekta Precise, Elekta Inc.).

anatomical and external landmarks. These geometries are transferred to the linac for patient treatment. In contrast to conventional simulation, where the treatment fields are designed on 2D radiographs while the patient stays on the simulation table, virtual simulation relies on the 3D CT data acquired with the patient in the treatment position and using the same immobilization device as will be used for treatment. The volumetric CT data represent the “virtual” or digital patient. Target delineation and field design are then done off-line without the patient’s presence using dedicated virtual simulation workstations or treatment planning systems. Figure 2 shows a screen capture of a commercial virtual simulation package with different views that aid in visualizing the patient’s internal structures and in the selection of beams and beam portals for treatment.

A typical patient CT data set has > 100 axial slices, each of which contains 512×512 picture elements (pixels). With 16 bits per pixel, a CT data set can easily run over 50 MB. Manipulating, displaying, and storing such voluminous data sets require enormous computer resources and have only been made possible in the past two decades due to the dramatic advancements in computer hardware. Historically, the evolution of radiation therapy has been strongly dependent on the available computer and imaging technologies and this trend is expected to continue in the years to come as radiation therapy proceeds into an era of computer-controlled delivery and real time image guidance and feedback.

Figure 2. A screen capture of a commercial virtual simulation software (AcQsim 4.9.1, Philips Medical Systems) depicting the various tools available for treatment planning. (a) Axial view through the isocenter of a right posterior oblique (RPO) beam. (b) Digitally reconstructed radiograph of the RPO beam with the beam shape (yellow) and various structures projected onto it. (c) A 3D rendering of the patient’s external contour. (d) Sagittal view through the middle of the patient.

An important step in virtual simulation is the generation of digitally reconstructed radiographs (DRR) for treatment planning and verification (2). A DRR is a computer-generated beam’s-eye-view image that simulates the X-ray attenuation property and projection geometry of a conventional simulator. It is obtained by tracing the divergent path of X rays from the radiation source through the 3D patient CT data set onto a plane beyond the data set and orthogonal to the central ray. Fast ray-tracing algorithms have been developed to calculate the radiological path through a CT data set (3,4). Compared with radiographs from a conventional simulator, DRRs offer several distinct advantages. Whereas tumors and normal anatomic structures are sometimes difficult to visualize on a conventional radiograph because of the overlapping effect, they can usually be discerned much better on an axial CT image. The contours of the tumor and normal structures drawn on the CT images can be projected onto the DRR. This greatly helps the treatment planner in selecting beam geometries that will irradiate the target while avoiding critical anatomic structures. The DRRs can be generated quickly for any angular projection through the body, whereas using a simulator and film requires many minutes of patient setup and film developing for each projection. The brightness and contrast of a DRR can be digitally manipulated to bring out certain anatomic features. This can be used for patient setup verification by comparing the DRR with a radiographic image of the treatment field (portal image) obtained on the treatment machine. Figure 3 illustrates a DRR with several structures and the treatment field shape projected onto it and the corresponding portal image of the same

Figure 3. Comparison of a digitally reconstructed radiograph (a) and the corresponding portal film (b). The beam shape (yellow) was projected onto the DRR for treatment verification.

field. Such comparison verifies both the positioning of the patient and the treatment field shape.

IMAGE REGISTRATION

Radiotherapy treatment planning has been based mostly on CT images. Advantages of CT images include high spatial integrity, high spatial resolution, excellent bony structure depiction, and the ability to provide relative electron density information used for radiation dose calculation. However, CT images do not provide good soft tissue contrast. Moreover, CT images are anatomic in nature, that is, they provide snapshots of the patient's anatomy without any functional information of various organs or structures. Other imaging modalities, especially the magnetic resonance imaging (MRI) and positron emission tomography (PET), have been used increasingly in radiation therapy planning in conjunction with CT images. Magnetic resonance imaging provides better soft tissue contrast than CT images, and is the modality of choice when delineating treatment target of brain tumors. Positron emission tomography provides functional information about tumor metabolism and is a useful tool in tumor diagnosis, staging, target volume delineation and assessment of therapeutic response. However, current MRI and PET devices suffer from several drawbacks that make them unsuitable for radiotherapy planning as the sole modality. Imaging artifacts and geometric distortions exist in MR images. PET has a lower resolution than CT and contains no anatomy information of the normal structures. Information derived from MRI or PET needs to be fused or registered with the corresponding CT images for treatment planning.

Three-dimensional image registration aims at finding a geometric transformation that maps the volume elements (voxels) of one tomographic data set onto another tomographic data set of the same or different modality. Since different scans are done at different times and possibly with different patient immobilization devices, image registration is difficult to perform manually, and sophisticated computer algorithms have been developed for various registration applications (5). Some algorithms make use of common geometric features, such as points, lines, or

Figure 4. Registered MR (a) and CT (b) images of a brain tumor. The tumor (red contour) is readily seen on the MR image.

surfaces identified on both image sets to determine the transformation. These features can be extracted either manually or automatically, and the accuracy in the identification of the common features directly affects the registration accuracy. Other image registration algorithms are based on information contained in the whole image sets (e.g., the image intensity values) and seek to maximize the amount of shared information in the two data sets. Image registration between images of different modalities based on shared information methods is especially challenging as different image modalities involve entirely different physical processes, and therefore voxels of the same tissues can appear very differently on different images. For example, high voxel intensity areas on a CT image (e.g., the bone) may correspond to dark areas on a MRI image. Figure 4 shows an axial CT image of a brain with the registered MR image. The registered secondary image (MR image in this case) is interpolated and resampled to give the axial view at the same axial position as the primary CT image. Contours of the tumor and normal structures drawn on one image are transferred and displayed automatically onto the other image.

Various degrees of simplification have been assumed in the medical image registration. The simplest and widely used registration assumes that the transformation is rigid body, where only image translation and rotation is allowed with six degrees of freedom. Rigid body transformation preserves all distances in an image. The most important and successful application of rigid body registration is in the head, and particularly the brain. Image registration between MRI and CT has been the standard practice for the treatment planning of brain tumors in most cancer centers in the United States. In more general situations, where other parts of the body are involved and images are acquired under different conditions or using different modalities with the patient in different positions, more degrees of freedom are often needed. The simplest of the nonrigid body transformations, the affine transformation, introduces an additional six degrees of freedom with anisotropic scaling and skews. An affine transformation preserves collinearity (i.e., all points lying on a line initially still lie on a line after the transformation), parallelism (parallel lines stay parallel after the transformation), and ratios of distances in an image, but not necessarily angles or distances. Image registration with more degrees of freedom

than the affine transformation is an active area of research and its application in radiation therapy has so far been limited (6–8). This most general type of image registration technique is referred to as deformable image registration. Commonly used deformable models can be categorized into two categories: free form B-spline and biomechanical finite element methods. Clinically, the need for a robust deformable registration technique is ever increasing because of the recent development in image-guided radiation therapy and much research is being carried out in this area. In four-dimensional (4D) radiation therapy of breast cancer, for example, where time-resolved CT images were used to monitor anatomic changes due to breathing, reconstruction of dose to different organs relied on the registration between the voxels at different phases of the breathing cycle (9). However, a detailed discussion of the subject is clearly beyond the scope of this article and the readers are referred to the references cited above.

The drive for more accurate registration between PET and CT images has led to the development of PET–CT, a new imaging technology that combines high quality PET and CT scanners in a single device (10,11). With PET–CT, patients undergo CT and PET scans sequentially under the same immobilization with a table translation, therefore providing simultaneous anatomic and metabolic information under almost identical conditions. Image registration becomes a simple process of correcting for the known table translation. An added advantage of PET–CT over PET only is the faster scan time, where the CT scans, which only take a few minutes, are used for attenuation correction. With PET only, the attenuation correction is obtained from a transmission scan, which takes on the order of 30 min. Although incorporating functional imaging in radiotherapy treatment planning is relatively new, the interest is increasing steadily and many studies have shown that new functional information would change patient management decisions in many disease sites (12–14).

RADIATION DOSE CALCULATION

Dose calculation plays a pivotal role in radiation therapy treatment planning. To achieve the expected therapeutic results, radiation dose distribution throughout the irradiated volume should be known to a desired degree of accuracy. Generally speaking, there are two major types of dose calculation algorithms: correction and model based. Correction-based methods compute the dose distributions in patients by correcting the dose distributions of similar geometries in a homogeneous water phantom for the beam modifiers, patient contours, tissue heterogeneities, and volume scattering effect. There are several algorithms for heterogeneity corrections. Two simple one-dimensional (1D) methods are the ratio of TPR, in which only densities along primary photon path are considered, and the power-law (or Batho) method, which takes the depth of the heterogeneity with respect to the depth of the point of measurement into account. Sontag and Cunningham (15) implemented the first algorithm, often referred to as the equivalent tissue/air ratio method, to estimate scatter

dose in three dimensions and took advantage of the detailed anatomical information derived from CT images. Wong and Purdy (16) examined eight methods of photon inhomogeneity correction for their photon transport approximations and improved correction-based algorithms by introducing more realistic transport models into the calculations. The volume scattering effects (scatter dose as a function of field size and shape) are often computed by using the equivalent square field method and/or Clarkson integration (17). Some pencil beam methods, like the finite-size pencil beam algorithm (18), are also classified as the correction-based methods. Model-based algorithms simulate the treatment situation from first principle and can directly calculate the dose distributions in a patient for a given beam energy, geometry, beam modifiers, patient contour, and tissue heterogeneities. The kernel-based convolution–superposition and Monte Carlo method are representatives of the kind. These commonly used algorithms are briefly summarized below.

Correction-Based Methods

Calculation of radiation dose is conventionally done by interpolating from measured data in a water phantom and correcting for any nonstandard situations. To serve this purpose, large amounts of beam data need to be collected that would allow for data interpolation with reasonable degree of accuracy. Measurement is usually done with a computer-controlled automatic scanning system. Dose as a function of depth along the central axis of the beam and off-axis distance along the transverse directions is measured for a large number of field sizes at a fixed source-to-water surface distance (SSD). These measurements need to be repeated for both open and wedged fields. Dose as a function of depth along the central axis, when normalized to a given depth (usually the depth of maximum dose for a reference field size), is called the percentage depth dose (PDD) and was an important quantity in the early days of radiation therapy when most of the treatment setups were at a fixed SSD. Figure 5a illustrates the definition of PDD and can be measured readily with a scanning system. Modern radiotherapy with isocentric-mounted gantries typically uses fixed SAD setups. As the gantry rotates around the patient with the isocenter near the center of the tumor, the SSD (and the tumor depth) changes. The quantity most useful for dose calculation in these cases is the tissue/phantom ratio (TPR), which is defined as the ratio of dose on the central axis at depth d in a phantom to dose at the same point and field size at a reference depth d_{ref} and is shown in Fig. 5b and c. When the depth of dose maximum is chosen as d_{ref} , TPR is sometimes called the tissue-maximum ratio (TMR). Whereas PDD for the same field size varies significantly with SSD, TPR is essentially independent of SSD. Therefore, a single TPR table can be used for all SSDs. Dose calculations based on TPR or other TPR derivatives have been discussed extensively (1), especially in the textbooks of Johns and Cunningham (19) and Khan (20).

The limitations of correction-based methods are numerous. Patient geometry and internal structures can deviate significantly from a flat and homogeneous water phantom.

Figure 5. Schematic diagram illustrating the definition of the PDD and the phantom ratio (TPR). The PDD at a depth d is defined as the dose at the point, $D(Q)$, to the dose at point P , at the same SSD. It depends both on the SSD and the field size r . The TPR at depth d is defined as the ratio of dose at point S to dose at point R , at the same source-to-axis distance (SAD).

Although corrections can be made to account for the deviation, they are approximate and do not fully take into account the effect of secondary electron transport. This effect arises because secondary electrons ejected by megavoltage photons deposit a significant fraction of their energy far away from their point of origin. In regions where there is an imbalance between secondary electrons coming in and going out, such as near the interface between tissue–bone or tissue–air or in the beam penumbra, a condition known as charged particle disequilibrium exists. Correction-based methods are likely to produce erroneous results in these regions. Nowadays, correction-based dose calculation algorithms have mostly been replaced by model-based methods in commercial TPSs, where data measured in a water phantom under standard conditions are used to fit a few machine-specific model parameters, which in turn are used to calculate dose under the existing patient geometry. These include the convolution–superposition method and the Monte Carlo method. Nevertheless, correction-based methods are intuitive and have often been used as a quality assurance procedure to double-check the results of computer-generated treatment plans at one or a few calculation points for both conventional and intensity-modulated radiation therapy (21,22).

Convolution–Superposition Method

In the convolution–superposition techniques (23–27), the dose deposition is viewed as a superposition of appropriately weighted kernels of point irradiations and the superposition can be efficiently evaluated by means of convolution if the kernels are considered as spatially invariant. The kernels, representing the energy transport and dose deposition of secondary particles stemming from a point irradiation, can be calculated by Monte Carlo simulation (28). The Monte Carlo method computes dose distributions by simulating particle transport in a patient and will be described in the next section. Model-based

algorithms are capable of accounting for electronic disequilibrium, and therefore are more accurate in dealing with tissue inhomogeneity and calculating dose in the electronic disequilibrium regions.

A thorough review of dose calculations in radiation therapy has been given by Ahnesjo and Aspradakis (27). There are a few different convolution–superposition methods, which can be divided into point kernel models and pencil kernel models. Mathematically, the dose at a spatial point, $D(r)$, comprises contributions from the shower of secondary particles resulting from primary interaction sites at r' . Assuming that the direction of all incident particles is parallel to the central axis throughout the beam, the total dose deposited by a monoenergetic beam irradiating a homogeneous medium can be expressed as a convolution operation:

$$D(r) = \int T(r')A(r-r')dr'$$

where $A(r-r')$ is the dose spread kernel that describes the mean fraction of energy deposited per unit volume at r per photon interaction at r' , and $T(r')$ is the total energy released by primary X-ray interactions per unit mass, or TERMA. The above formula forms the basis for point kernel-based modes. Although the formulation of the point kernel model is simple and appealing, the demand on computer time is enormous due to the need for modeling various second-order beam characteristics. As emphasized by Ahnesjo and Aspradakis (27), there are three major issues that must be addressed for accurate dose calculation: broad primary beam spectral, beam divergence, and tissue density inhomogeneity. After all these factors are considered, the convolution–superposition dose calculation becomes a computationally intensive task. Therefore, their clinical implementation is tied closely to the availability of fast computers. The use of fast transform convolution techniques, such as the fast Fourier transform (FFT) method, to carry out the discrete convolution greatly facilitate the calculation process. Another widely accepted approach is the so-called collapsed cone convolution (26) based on an angular discretization of the kernel.

The pencil beam method is essentially a hybrid algorithm that fully accounts for beam modulations and field shapes, but relies on broad beam scaling/correction methods to handle heterogeneities and patient contour changes (18,27). The poly-energetic pencil beams are generally compiled from a linear combination of monoenergetic pencil beams within the constraints of a spectrum model to reproduce a set of depth-doses. The pencil beam kernels can also be determined by direct Monte Carlo calculation, or derived experimentally based on scatter factor differentiation.

Monte Carlo Method

Monte Carlo is a statistical simulation method that simulates the tracks of individual particles and all subsequently generated particles as they traverse the medium (28–30). The method takes into account all the relevant interactions and physical processes that take place in the medium. For each particle, the probability and types of interaction at a

point, its path length, and its direction are sampled from probability distributions governing the individual physical processes using machine-generated pseudo-random numbers. These particles and all the daughter products are followed until they either are fully absorbed or escape from the region of interest. Dose distribution and other macroscopic quantities can be calculated by simulating a large number of particle histories. Provided that the physical models used in the simulation are accurate, Monte Carlo simulation can accurately predict radiation dose distribution as it simulates particle transport and energy deposition from first principles. In particular, Monte Carlo simulation can calculate dose in regions of charged particle disequilibrium more accurately than any other existing dose calculation algorithms. For a detailed discussion on the Monte Carlo method in radiotherapy dose calculation, see the chapter on “Radiation therapy treatment planning, Monte Carlo calculations”.

An intrinsic limitation of the Monte Carlo method is that the results contain statistical noise. The statistical error of Monte Carlo calculation is proportional to $1/\sqrt{N}$, where N is the number of simulated particle histories. To obtain dose distributions with acceptably small statistical uncertainty, a large number of particle histories need to be simulated, which makes the Monte Carlo method computationally intensive. The prohibitively long computation time has been the main obstacle for its routine clinical application. However, the computer speed has been increasing exponentially (Moore’s law) since the initial application of the Monte Carlo method in medical physics in the 1970s and this trend is expected to continue. With the rapid increase in computer speed and the development of innovative variance reduction techniques (31), Monte Carlo simulation is fast becoming the next generation dose calculation engine for radiation treatment planning of photon and electron beams. The first commercial TPS that employs Monte Carlo dose calculation engine has already been released (PEREGRINE, North American Scientific) with dose calculation time on the order of minutes on two 2.4 GHz Pentium Xeon processors with a grid size of $0.5 \times 0.5 \times 0.5 \text{ cm}^3$. The clinical impact of using Monte Carlo dose calculations is a subject of considerable interest and needs to be evaluated carefully (32).

TREATMENT PLAN OPTIMIZATION

Many treatment-planning parameters affect the quality of a treatment plan. In conventional 3D conformal radiotherapy (3DCRT), the treatment parameters that are at the treatment planner’s disposal include the beam modality and energy, number of beams, beam and treatment couch angles, wedge angles and orientations, radiation-defining blocks, and the weights of each beam. Since the number of beams used in 3DCRT is usually small (3~5), clinically satisfactory plans can be produced manually in a trial-and-error fashion. Disease- and site-specific treatment techniques developed over the decades help to reduce the number of adjustable parameters significantly. With the development and clinical implementation of intensity-modulated

Figure 6. Fluence patterns of a seven-beam IMRT treatment plan of a head-and-neck case from a commercial inverse planning system (CORVUS 5.0, North American Scientific).

radiation therapy (IMRT), where the fluence of each radiation beam can be modulated arbitrarily in order to achieve a highly conformal radiation dose distribution, manual planning is not practical, and computer optimization algorithms have to be used to design complicated beam fluences (33). Figure 6 shows the fluence maps of a seven-beam IMRT plan from a commercial inverse planning system used for the treatment of a head and neck tumor. Each beam is divided into a grid of $1 \times 1 \text{ cm}$ beamlets, and each beamlet can take a fixed number of fluence levels. Such fluence modulation can be achieved with a computer-controlled multileaf collimator (MLC). The treatment planning process where the desired goals (the output) (e.g., the desired dose distribution and dose and/or dose–volume constraints, are specified first, and computer optimization is used to determine the needed beam fluences (the input) is sometimes termed inverse planning.

As with any mathematical optimization problems, inverse planning starts with the construction of an objective function. The objective function, with its value the sole measure of the quality of a plan, guides the optimization algorithm. Additional constraints can also be imposed which limit the solution space. The compromise between

delivering a high dose to the target while limiting the dose to critical structures is implicitly built into the objective function. One of the simplest forms of the objective function that has been used often is the weighted least-squares function, which can be expressed as

$$F_{\text{obj}} = \frac{1}{N} \sum_{n=1}^N r_{\sigma} [d(n) - d_0(n)]^2$$

where $d_0(n)$ and $d(n)$ are the prescribed and calculated dose distributions, respectively, n is the voxel index, N is the total number of voxels, and r_{σ} is the relative importance factor of structure σ , which controls the tradeoffs between different structures. The calculated dose to voxel n can be obtained from the weighted sum of all the beamlets as

$$d(n) = \sum_{i=1}^I \sum_{j=1}^{J(i)} w_{ij} D_{ij}(n)$$

where I is the total number of beams, $J(i)$ is the total number of beamlets of the i th beam, $D_{ij}(n)$ is the relative dose contribution from the j th beamlet of the i th beam to voxel n , and w_{ij} is the weight of the beamlet (i, j) . The parameter $D_{ij}(n)$ can be recalculated, so minimization of F_{obj} with respect to w_{ij} produces an optimal plan in the least-squares sense. The choice of the size of the dose calculation grid is an important consideration in IMRT plan optimization. While larger grid sizes reduce the model size and can speed up the computation considerably, too large a grid size will introduce aliasing artifacts. An information theory-based Fourier analysis of a 1×1 cm 6 MV photon beamlet from a medical linac predicted that an isotropic dose grid with < 2.5 mm spacing is sufficient to prevent dose errors larger than a percent (34). The tradeoffs between target coverage and critical structure sparing, which is controlled by the weighting factors r_{σ} , are usually not known *a priori*, and iterative adjustments are required to tailor the treatment plan to each particular circumstance. Algorithms aiming to automate the selection of the weighting factors have been proposed, which promises to significantly reduce the labor-intensive effort of the trial-and-error determination of the factors. In addition, the concept of intravoxel tradeoff has been introduced and an effective approach to model the tradeoff based on voxel specific weighting factors has been proposed (35,36). To obtain an adequate set of local weighting factors with a manageable amount of computing time, algorithms based on *a priori* dosimetric capability information and *a posteriori* adaptive algorithms were developed. With the introduction of intravoxel tradeoff, the IMRT dose distribution has been remarkably improved in comparison with the conventional plan obtained with structurally uniform weighting factors.

Clinical implementations of IMRT are dominated by dose- and/or dose-volume-based objective functions. Other forms of objective functions, particularly those employing biological indexes, such as the tumor control probability (TCP), normal tissue complication probability (NTCP), and equivalent uniform dose (EUD) (37,38), have also been

applied to IMRT plan optimization. The use of biological indexes is especially appealing, as these are the ultimate measures of treatment outcomes. However, there is a lack of clinical and biological data to support these models, and their clinical use at present is not warranted. For example, current TCP models do not contain spatial information, and a cold spot would have the same adverse effect on the TCP irrespective of its location. In reality, the treatment outcome very much depends on the location of the cold spot, that is, whether it is in the periphery or in the middle of the target. Moreover, the TCP-, NTCP-, and EUD-based biological models as they are currently implemented are equivalent to voxel dose-based physical models in a multicriteria framework (39). It is expected that as radiation biology research leads to more robust models, biological based models will become more widely adopted in radiation therapy treatment plan optimization.

A practical approach to bridge the gap between biologically insensible physics-based formalism and a clinically impractical biology-based model is to establish a clinical outcome driven objective function by seamlessly incorporating a clinical endpoint to guide the treatment plan optimization process. Indeed, currently available dose-based objective functions do not truly reflect the nonlinear relationship between the dose and the response of tumors and tissues. On the other hand, biologically based inverse planning involves the use of a number of model parameters whose values are not accurately known and entails a prescription in terms of biological indexes. Recently, Yang and Xing proposed an effective method for formalizing the existing clinical knowledge and integrating clinical endpoint data into inverse planning (40). In their approach, the dose-volume status of a structure was characterized by using the effective volume in the voxel domain. A new objective function was constructed with incorporation of the volumetric information of the system so that the figure of merit of a given IMRT plan depends not only on the dose deviation from the desired dose distribution, but also the dose-volume status of the involved organs. The incorporation of clinical knowledge allows us to obtain better IMRT plans that would otherwise be unattainable.

The considerable interest in developing faster and more robust IMRT optimization algorithms has led to research collaboration between the radiation oncology community and the operations research (OR) community (41). The OR community has long investigated various optimization technologies and has the expertise in addressing large scale, complex optimization problems [see, e.g., the excellent textbooks of Winston (42) and Chong and Zak (43)]. Such collaboration is expected to enhance the IMRT model and algorithm development tremendously due to the large sizes of the problems in IMRT optimization combined with the clinical need to quickly solve each optimization for interactive plan review. For example, to avoid the non-convex nature of conventional dose-volume constraints (44), Romeijn et al. introduced novel, convex dose-volume constraints that allowed them to formulate the IMRT fluence map optimization as a linear programming (LP) model (45). Using an industrial LP solver (CPLEX 8, ILOG

Inc.), a seven-field head-and-neck case with $\sim 190,000$ constraints, $\sim 221,000$ variables, and $\sim 1,100,000$ nonzero elements in the constraint matrix has been solved to global optimality in ~ 2 min of computation time on a 2.5 GHz Pentium 4 personal computer with 1 GB of RAM. While fluence map optimization has been studied extensively and clinically implemented, other challenging problems, such as finding the optimal number of beams and their angles, and fluence map optimization in the presence of organ motion, have not been solved satisfactorily. The problem of beam angle optimization has an enormous search space (46). The goodness of a chosen set of beam angles is not known until the fluence map optimization is performed. Current computer technology is not fast enough to solve such a nested optimization problem for routine clinical use. It is hoped that the collaboration with the OR community would help to develop novel and efficient algorithms in radiotherapy plan optimization.

DOSE DISPLAY AND PLAN EVALUATION

Treatment plans are evaluated based on the dose coverage and dose uniformity of the target, dose- to-sensitive normal structures, and magnitudes and locations of any hot and cold spots. This is best served by displaying the dose as isodose lines and superimposing them on the corresponding 2D image. Images can be displayed in the axial, sagittal, or coronal planes with the targets and normal structures delineated and dose distribution can be evaluated by going through the entire irradiated volume slice by slice. Figure 7 shows the isodose distribution of a head-and-neck IMRT plan in the three orthogonal planes overlaid on the corresponding CT images. Other graphic visualization tools, such as displaying the isodose in 3D as an iso-surface (47), have also been developed.

For quantitative plan evaluation, dose statistics can be calculated from the 3D dose distribution. Mean, maximum and minimum doses to the targets and mean and maximum doses to the critical structures can aid in plan selection. Dose uniformity throughout the target volume can be assessed from the standard deviations of the target dose

Figure 7. Overlay of isodose lines on an axial, coronal, and sagittal planes of a head-and-neck cancer. The IMRT plan was generated using a commercial inverse treatment planning system (CORVUS 5.0, North American Scientific). The isodose lines are, from inside out, at dose levels of 76, 72, 49.5, 40, 30, 20, and 10 Gy. The gross tumor volume (red) and the subclinical target volume (yellow) are shown as color washes to help evaluate the quality of the plan.

distribution. A conformity index, defined as the quotient of the treated volume and the planning target volume (PTV) when the treated volume totally encompasses the PTV, has been introduced (48) to quantitatively evaluate the amount of normal tissue treated. Biological model-based TCP and NTCP are now available on some commercial TPS. However, the large uncertainty in the biological models combined with the lack of clinical experience limit their application in current clinical practice.

A very useful tool in 3D plan evaluation is the calculation of cumulative dose-volume histograms (DVHs) (49). The DVHs summarize 3D dose-distribution data into 2D histograms and are helpful in rapid screening of rival plans. An example of the DVHs of various structures of a head-and-neck IMRT plan is shown in Fig. 8. The DVH of a structure is calculated as

$$\%V(D) = \frac{\sum_{d \geq D} v(d)}{V_0}$$

where $v(d)$ is the volume of a voxel in the structure receiving dose d and V_0 is the total volume of the structure. Therefore, each point $\%V(D)$ on a DVH curve represents the percent volume of the structure receiving doses $\geq D$. From the DVH, dose coverage and dose uniformity of the target(s) can easily be appreciated. The relevant dosimetric parameter to some critical structures that display serial nature such as the spinal cord and the brain stem is the maximum dose (48) and it can be read directly from the DVH. The functionality of many normal structures displays a dose-volume effect (50). For example, in trying to preserve salivary function for head-and-neck patients using IMRT, planning criteria of at least 50% volume of either parotid gland receiving doses < 30 Gy have been established (51,52). The development of \geq Grade 2 pneumonitis in patients after radiation treatment for non-small cell lung cancer was found to be significantly correlated

Figure 8. Cumulative DVH of different structures of a head-and-neck IMRT treatment plan. The prescribed doses to the targets are 72 Gy for the gross tumor volume (labeled "PTV 54 + 18") and 49.5 Gy for the subclinical target volume (labeled "PTV 49.5"). Also shown are the DVHs of the left and right parotids, the left and right submandibular glands (SMGs), and the spinal cord.

with the percent volume of the total lung exceeding 20 Gy (53). These dose–volume relations can be obtained directly from the DVH. Dose–volume histograms from two or more competing plans can also be overlaid on top of each other to facilitate plan comparison. The increasing use of DVHs in routine clinical treatment planning over the past decade is a direct result of increased computer power and fast and more accurate dose calculation algorithms which make dose calculation in the entire irradiated volume possible.

The DVH should be used with caution. Since a DVH is a 2D histogram of a 3D dose distribution, it does not provide any spatial information. For example, Fig. 8 indicates that ~2% of the volume of the target labeled “PTV 49.5” did not receive the prescribed dose of 49.5 Gy. However, the locations of the underdosed volume is unknown. While underdosed areas near the periphery of the PTV may be acceptable, they are clearly unacceptable in the middle of the PTV where the gross tumor volume is located. Thus, DVHs must replace isodose distributions. Rather, it is a tool to enhance our ability to choose between different plans. This is especially true when evaluating IMRT plans, as the dose distributions of IMRT plans are spatially independent (54,55). A good DVH is therefore a necessary but not sufficient condition for a clinically acceptable treatment plan.

SUMMARY

In the first edition of this Encyclopedia > 17 years ago (1), Dr. Radhe Mohan envisioned that rapid developments in computer technology would make CT-based 3D treatment planning, including visualization of the anatomic structures and target region in 3D, fast and accurate radiation dose calculation in the entire irradiated volume, and sophisticated graphic and analytic tools for treatment plan display and evaluation, clinically routine. Radiation therapy has certainly gone through a series of revolutionary changes over the past 17 years. Three-dimensional treatment planning is now a standard practice and has mostly replaced 2D treatment planning. Monte Carlo dose calculation, which used to be considered as a luxury research tool, is now being incorporated into treatment planning systems. The fast development and widespread clinical implementation of IMRT over the past decade have provided the radiation oncology discipline a powerful tool to deliver highly conformal doses to the tumor volume while improving sensitive structure sparing. We are just entering an era of image-guided radiation therapy with exciting new developments. Recently, these have spurred efforts toward implementation of time-resolved or 4D imaging techniques, such as 4D CT (56–58) and 4D PET (59), into radiation oncology treatment planning and delivery. Currently, 4D imaging information is mainly being used as a tool for better definition of patient specific margins in the treatment of tumors in the thorax and upper abdomen. The ultimate goal is to establish a new scheme of 4D radiation therapy, where the 4D patient model is used to guide 4D planning and treatment. While there is still a long way to go toward this goal, much

progress has been made, especially in the area of 4D inverse planning. Another important area that is under intense investigation is biologically conformal radiation therapy (BCRT) (60–62). Different from the current radiation therapy, which is aimed at producing a homogeneous target dose under the assumption of uniform biology within the target volume, BCRT takes the inhomogeneous biological information into account and produces customized non-uniform dose distributions on a patient specific basis. There are a number of challenges to accomplish the new radiation treatment paradigm, such as the determination of the distribution of biological properties of the tumor and critical structures, the prescription of the desired dose distribution for inverse planning, and the technique for inverse planning to generate most faithfully the prescribed nonuniform dose distribution. The most fundamental issue is, perhaps, how to extract the fundamental biological distribution for a given patient with biological imaging techniques and how to link the imaging information to the radiation dose distribution to maximize tumor cell killing. Hopefully, with the multi-disciplinary efforts, the issues related to molecular imaging, image quantitation, planning, and clinical decision making would be resolved in the next decade. This will lead to truly individualized radiation therapy, and eventually individualized medicine when combined with the efforts in molecular medicine.

INTRODUCTION

Cancer is a disease that touches everyone, either directly or through a close friend or relative, and radiotherapy is one of the primary modalities for treating cancer. The intent may be a full cure or to relieve pain associated with the cancer and it is either used alone or in conjunction with other techniques, such as surgery or chemotherapy. The aim of radiotherapy is to use ionizing radiation (usually either high energy photons or electrons) to destroy the tumor while at the same time sparing healthy tissues. In the delivery of such treatments the quantity of interest is the absorbed dose (defined as the energy deposited per unit mass) as it can be used to estimate the biological effect of the radiation (i.e., cell killing). Too high a dose will kill all the cancerous cells, but will produce significant side effects due to damage to other organs. Too low a dose will leave some malignant cells alive, which can develop into a new tumor. One of the primary concerns in radiotherapy is therefore delivering the correct dose to destroy the tumor with the minimum of side effects and a fine line exists between under and over dosing. The allowable error in the delivered dose depends on many factors, such as the type and location of the tumor, but for some cancers can be as little as 3–4%.

The output of the machines that produce the radiation for radiotherapy (linear accelerators, X-ray tubes, radioactive sources) must be known to a very high accuracy and a great deal of dosimetry work is carried out in the radio-

therapy clinic to monitor dose delivery. For example, before the linear accelerator (linac) can be used for patient treatment, daily checks are carried out to ensure consistency of output. *In vivo* dosimetry may be used to verify the patient dose and detailed measurements are made during weekly and monthly quality assurance sessions checking all aspects of treatment delivery. Audits are used to check that procedures are being followed correctly and to ensure national consistency.

Over recent years the number of treatment modalities has increased significantly as well as the complexities of treatment. The oncologist today can choose from an array of techniques including low energy X-ray tubes (usually used for superficial tumors); low dose rate or high dose rate brachytherapy, where different radioactive species are inserted or implanted in the body; external beam therapy using a linac (producing either photon or electron beams); protons and heavy ions; and neutrons.

The treatment can be simple, such as a single square field from a ^{60}Co unit, or complex, such as Image Guided Radiotherapy (IGRT) using a modern linac, where the patient is imaged immediately prior to treatment, the tumor volume verified and the dose delivered with a large number of shaped fields.

To cover all possible radiotherapy techniques is beyond the scope of this article, and therefore we will focus on external beam therapy using photon and electron beams, as this is most common and where dosimetry is most advanced. The aim is to give a basic grounding in radiation dosimetry for oncology together with a review of dosimetry techniques and an up-to-date bibliography where the reader can obtain further detail.

RADIATION MEASUREMENT AND QUANTITIES

In radiation oncology, we are interested in the relationship between biological damage to cells and the radiation producing the damage. Various attempts have been made to define biological dosimeters [e.g., deoxyribonucleic acid (DNA) strand breaks, chromosome aberrations], but none have resulted in a quantity that is reproducible and can be transferred from one situation to another: a primary requirement for a measurement quantity. Therefore physical quantities are used as a basis for estimating biological effects.

Fluence

The particle fluence, Φ , is defined (1) as dN/da : the number of particles dN , incident on a sphere of cross-sectional area da . The use of a sphere expresses the fact one considers the area perpendicular to the direction of each particle. The energy fluence Ψ (defined as the energy incident on a sphere of unit area) is generally of more interest for photons as it is more closely related to the dose deposited (see below).

Interaction Coefficients

The stopping power S of a material is defined as the energy lost by the charged particle (electron or positron) dE , along

an increment of path dl . Ignoring energy losses due to nuclear reactions, stopping power has two principal components, namely, that due to collisions and that due to radiative losses. The collision component includes all energy losses in particle collisions that directly produce secondary electrons and atomic excitations. It also includes energy losses due to the production of Cerenkov radiation. The radiative component includes all energy losses of the primary electron that lead to bremsstrahlung production. The collisions of the primary electrons can produce high energy secondary electrons (δ -rays) that then become involved in independent interactions. The concept of restricted mass collisional stopping power L is therefore introduced to calculate the energy transferred to a localized region of interest. This region of interest is defined by a threshold (often denoted as Δ) for the energy transferred to the secondary (charged) delta particles. Highly energetic secondary particles with energy above this threshold escape the region of interest and do not contribute to the local absorbed dose and it is assumed that electrons with energy below Δ have negligible range. The restricted stopping power (L_Δ) is therefore always lower than the unrestricted stopping power and the choice of the energy threshold depends on the problem at hand. For problems involving ionization chambers, a frequently used threshold value is 10 keV since the range of a 10 keV electron in air is approximately 2 mm (the typical dimension of the air cavity of an ionization chamber). The parameter L_Δ is also known as the linear energy transfer (LET).

In practice, mass stopping powers (S/ρ , L/ρ) are generally used so that it is easier to compare the properties of materials with very different densities (e.g., air and water). A complementary quantity is the scattering power T , which describes the increase in the mean square scattering angle of the electron beam as it passes through a material.

For photon beams, there are a much larger number of possible interactions with the medium, the dominant ones in the energy range of interest being the photoelectric effect, Compton effect, pair production, coherent (Rayleigh) scattering, and nuclear photoeffect. The total interaction cross-section is simply the sum of all the individual cross-sections. The attenuation coefficient, μ , tends to be used rather than cross-sections as it describes the probability per unit thickness that a photon will undergo an interaction while traversing a material. As for stopping powers, the effect of density is removed and for dosimetric purposes two further coefficients are defined. The mass energy-transfer coefficient μ_{tr}/ρ relates the energy transferred from the photon to kinetic energy of charged particles and is used in the determination of kerma (see below). The mass energy absorption coefficient μ_{en}/ρ takes account of the fact that some of the energy transferred to charged particles is not deposited locally, but lost as bremsstrahlung.

Kerma

Kerma (kinetic energy released per unit mass), is introduced because neutral particles (photons and neutrons)

deposit their energy in two steps: (1) interaction of the photon with an atom resulting in the transfer of energy to charged particles (predominantly electrons), and (2) deposition of that energy in the medium via Coulomb interactions (excitation and ionization). The dose contributed through direct interactions between photons or neutrons and the absorbing material will generally be negligible compared with this two-step process. Reference 1 gives the definition of kerma as:

$$K = \frac{dE_{tr}}{dm} \quad (1)$$

where dE_{tr} is the kinetic energy transferred from photons to electrons in a volume element of mass dm . Total kerma can be split into two parts: collisional and radiative kerma. Collisional kerma, K_{col} , leads to the production of electrons that dissipate their energy as ionization near electron tracks in the medium. Radiative kerma, K_{rad} , leads to the production of bremsstrahlung as the charged particles are decelerated in the medium.

For a monoenergetic photon spectrum, energy E , with fluence Φ , equation 1 becomes

$$K = \Phi E \frac{\mu_{tr}}{\rho} \quad (2)$$

where (μ_{tr}/ρ) is the mass energy transfer coefficient. For a polyenergetic photon beam, equation 2 becomes an integral over the full photon spectrum. As the photon energy increases, the maximum energy of the secondary electrons increases, the concept of a localized energy transfer begins to break down and kerma is therefore generally limited to photon energies below 3 MeV.

Absorbed Dose

The absorbed dose is defined as the mean energy imparted (absorbed) per unit mass. It is a nonstochastic quantity in that one is not measuring single events—the interaction between an incident photon or electron and a molecule—but the mean energy arising through the interaction of the radiation field with the material it passes through. As the mass of a sample decreases the energy per unit mass will become more random (stochastic). Whereas kerma is only defined for neutral particles, absorbed dose applies both to photon and electron beams.

Reference 2 applies this definition of absorbed dose in the situation where there is a small volume of the medium, which is thermally isolated from the remainder:

$$D_i = \frac{dE}{dm} = \frac{dE_h}{dm} + \frac{dE_s}{dm} \quad (3)$$

where D_i is the mean absorbed dose in the absorber of material i , and mass dm ; dE is the mean energy imparted to the absorber by the radiation beam (photons or electrons); dE_h is the energy appearing as heat; and dE_s is the energy absorbed by chemical reactions (which may be positive or negative). The left-hand relation is independent of the measurement technique while the right-hand relation represents one of the most common methods for determining dose: the measurement of heat. The unit of absorbed dose is the gray (Gy); $1 \text{ Gy} = 1 \text{ J}\cdot\text{kg}^{-1}$.

It can be inferred from the definitions above that collision kerma and absorbed dose should be related in some way, since they both deal with the deposition of energy in a localized area. If a state of charged particle equilibrium exists (and assuming no energy losses due to bremsstrahlung) then the absorbed dose will be equal to the kerma (conservation of energy). Charged particle equilibrium (CPE) exists at a point in the medium if the number and energy of charged particles entering a volume is equal to that leaving. True CPE only exists in the special case where there is no attenuation of the photon beam. In general there is always some photon attenuation, but there is said to be transient charged-particle equilibrium (TCPE), since the spectrum of charged particles changes very little as the photon beam penetrates the medium. Transient charged-particle equilibrium exists at the center of a broad photon beam at depths away from the surface (the depth at which TCPE is established depends on the incident photon energy and spectrum). For the general case, where TCPE exists and there are bremsstrahlung energy losses, the dose is given by

$$D = K_{\text{col}} = K(1 - g) \quad (4)$$

where g is the fraction of the energy that is lost to bremsstrahlung. For a ^{60}Co beam, g has a value of 0.003.

Absorbed dose is also related to the photon energy fluence at a point in a medium irradiated by a photon beam under conditions of transient charged particle equilibrium by

$$D = \Psi \left(\frac{\mu_{\text{en}}}{\rho} \right) \beta \quad (5)$$

where β is the ratio of absorbed dose to collision kerma at a point. As written, equation 5 is valid for a monoenergetic photon beam; for a realistic (broad) photon spectrum, the mass-energy absorption coefficient must be averaged over the photon fluence.

There is a charged-particle analog of equation 5. Under the restrictive conditions that (1) radiative photons escape the volume of interest and (2) secondary electrons are absorbed on the spot (or there is charged-particle equilibrium of secondary electrons), the absorbed dose to medium is given by the electron fluence multiplied by the collisional stopping power.

Dose Equivalent

This quantity is useful where the effect produced by the same absorbed dose is dependent on the particle type “delivering” the dose. This is the case in biological damage: the principal pathway for cell killing is a double-strand break of the cell’s DNA, which is much more likely for densely ionizing particles, such as protons, neutrons, and α -particles, than it is for electrons or photons. A radiation quality factor, w is therefore introduced to take account of this and the dose equivalent is defined as the absorbed dose multiplied by this quality factor. Values of w vary from 1 for photons and electrons to 20 for α -particles.

PRIMARY METHODS OF DETERMINING ABSORBED DOSE AND AIR KERMA

Due to the complexities of the measurements, the absolute determination of radiation quantities is almost exclusively the domain of national standards laboratories. Two primary International System of Units (SI) quantities are realised by national standards laboratories for radiotherapy dosimetry: air kerma and absorbed dose. Air kerma can only be measured using an air-filled ionization chamber but absorbed dose can be determined in a variety of ways.

The absolute measurement of absorbed dose has a number of problems (some fundamental, others practical) that limit the accuracy of the result and put constraints on the experimental techniques that can be used.

1. *Doses of interest are small.* The definition of absorbed is in terms of the energy absorbed in an amount of material. Radiotherapy dose levels are typically $< 10 \text{ Gy}$ ($10 \text{ J}\cdot\text{kg}^{-1}$), which represents a very small energy deposition. If one is trying to determine this energy absolutely by measuring the radiation-induced temperature rise (of the order of a few mK) there is a significant challenge in achieving uncertainties $< 0.1\%$.
2. *The quantity required is the dose in an undisturbed phantom.* In radiotherapy, the required end-point is the dose to the tumor. However, since radiation interactions are very material dependent a homogeneous phantom is the chosen medium for reference dosimetry. This immediately presents a problem in that any measuring instrument will perturb the phantom and affect the measurement one wishes to make.
3. *The quantity required is the dose at a point in this phantom.* For radiotherapy dosimetry, one is not interested in the average dose to the whole phantom (although mean dose or integral dose is required for radiation protection, when considering lifetime dose to organs, etc.). Radiotherapy treatments using photon and electron beams produce significant dose variations within a phantom; otherwise, healthy tissue could not be spared. It is therefore important to be able to measure these dose variations, which by implication requires a small detector. Such a detector will generally have a larger uncertainty than a larger detector. Care is required in designing a detector that samples the dose at a point and does not give some unwanted averaging.
4. *Scattered radiation contributes a significant proportion of the absorbed dose.* In a typical radiotherapy radiation field used for cancer treatment (e.g., a 6 MV photon beam), 15% of the dose at the point of interest is due to scattered, rather than primary, radiation. The experimental geometry is therefore very important and care must be taken in designing experiments, especially when comparing or calibrating dosimeters, so that scattered radiation is properly taken into account.

5. *Optimization of the measurement is difficult.* One of the biggest practical constraints is that in the measurement of absorbed dose one is not determining some fundamental constant or characteristic of a material. The dose is the effect of a particular radiation field at a point in a particular material and it is therefore not possible to optimise all aspects of a measurement. There are many “influence quantities” (material, energy spectrum, geometry) so that what may appear to be minor variations from the real measurement problem (dose to a tumor) can result in significant errors being introduced.

These issues also apply to the determination of air kerma.

Ionometry

An ionization chamber measures the ionization produced by the incident radiation beam in a mass of air. Historically, the first quantity to be measured was Exposure (symbol X) and is simply the charge, Q , liberated in a volume of air mass m_{air} . It is not a recommended SI unit but is related to Air Kerma by

$$K_{\text{air}} = X \frac{W}{e} \frac{1}{1-g} \tag{6}$$

where W/e is the average energy required to liberate an ion pair and g has the same definition as in equation 4. The value of W/e has been measured by a large number of experimenters of many years and there is an agreed value of 33.97 eV/ion pair (3), which is constant over widely varying conditions (air pressure, electron energy, etc.).

For low energy beams produced by X-ray tubes (< 400 kVp) exposure is measured using a free-air chamber. A typical chamber is shown in Fig. 1. By careful design and precise manufacturing of the electrodes and entrance aperture it is possible to accurately define the volume (and thus mass) of air that is irradiated. The size of the free-air chamber scales with the incident energy and for a ^{60}Co beam a free-air chamber would be impractically large: several meters in each dimension.

At energies of ^{137}Cs (663 keV) and above, one must therefore use a cavity chamber, where the volume of the air cavity is small (typically a few cm^3). One must determine the mass of air in the cavity and various designs been employed: spherical, cylindrical, and “pancake” (Fig. 2).

Until 1990, all absorbed dose measurements in the radiotherapy clinic were based on air-kerma calibrations using protocols as seen in Refs. 4 and 5. In recent years, absorbed dose-based calibrations have become available from national standards laboratories and associated protocols produced (e.g., Refs. 6–8). However, air kerma standards are still required for the dosimetry of kilovolt X-ray beams, brachytherapy, and radiation protection.

The dose to the air volume of a cavity chamber irradiated by an X- or γ -ray beam is given by

$$D_{\text{air}} = \frac{Q}{m_{\text{air}}} \frac{W}{e} \tag{7}$$

Schematic diagram of the National Physics Laboratory (NPL) primary standard free-air ionisation chamber

Figure 1. Diagram of a free-air chamber. (Courtesy NPL.)

Bragg–Gray cavity theory is then used to relate the dose in the air cavity to the dose to the medium. The conditions for application of Bragg–Gray cavity theory are

1. The cavity must be small when compared with the range of charged particles incident on it so that its presence does not perturb the fluence of charged particles in the medium.
2. The absorbed dose in the cavity is deposited solely by charged particles crossing it (i.e., photon interactions in the cavity are assumed negligible and thus ignored).

Figure 2. Schematics of three graphite-walled cavity ion chambers designed and operated at the National Research Council (NRC) - cylindrical (3C), parallel-plate (Mark IV), and spherical (3S). The 3S utilizes an aluminum electrode, while the other two chambers utilize graphite electrode.

Condition (2) implies that all electrons depositing the dose inside the cavity are produced outside the cavity and completely cross the cavity. Therefore, no secondary electrons are produced inside the cavity and no electrons stop within the cavity. The dose to the medium is obtained using a ratio of stopping powers:

$$D_{\text{med}} = \frac{Q}{m_{\text{air}}} \frac{W}{e} \left(\frac{S}{\rho} \right)_{\text{med,air}} \quad (8)$$

where $(S/\rho)_{\text{med,air}}$ is the mass stopping power ratio for the medium divided by that for air. The Bragg–Gray cavity theory does not take into account the creation of secondary (delta) electrons generated as a result of the slowing down of the primary electrons in the sensitive volume of the dosimeter. The Spencer–Attix cavity theory is a more general formulation that accounts for the creation of these electrons that have sufficient energy to produce further ionization on their own account.

Equation 8, in principle, gives a possible route to the absolute absorbed dose, if the stopping power ratio is known. The Bureau International des Poids et Mesures (BIPM) maintains such an ionometric standard for absorbed dose to graphite. This is a graphite walled ionization chamber, whose volume has been determined by mechanical means, and is described in detail by Boutillon and Peroche (9). Strictly speaking, however, this is not a primary device, as the value for the product of W/e and the stopping power ratio is taken from calorimeter measurements. Although there are independent measurements of W/e , there is a lack of measured stopping power data (see below) to provide a true measurement of absorbed dose absolutely.

As noted above, one of the difficulties in realising a primary standard cavity ion chamber is defining the effective volume of the chamber. This problem can be overcome to a certain extent by the use of an extrapolation, or gradient, chamber. In such a chamber, the absolute volume of the cavity is not known, but can be changed by a known amount, usually by changing the electrode spacing. Assuming that the chamber does not perturb the medium then the dose is given by

$$D_{\text{med}} = \frac{\Delta Q}{\Delta x} \frac{W}{e} \left(\frac{S}{\rho} \right)_{\text{med,air}} \frac{1}{A \rho_{\text{air}}} \quad (9)$$

where ΔQ is the change in the measured ionization charge for a change in the electrode spacing of Δx , A is the area of the electrode and ρ_{air} is the air density. The dose measurement becomes a relatively simple charge measurement and the problem of the determination of volume is reduced to that of determining the area of the collecting electrode. Klevenhagen (10) carried out some of the first work on gradient chambers for the determination of dose in megavoltage photon and electron beams and Zankowski and Podgorsak (11) describe a chamber where the entire device is manufactured from a plastic with similar radiation properties to water (see Fig. 3). It is a parallel plate chamber with a fixed radius and the plate separation is varied by way of a precision micrometer. The charge gradient $\Delta Q/\Delta x$ can be determined at the 0.2% level and the effective

Figure 3. Extrapolation chamber design (11).

area of the collecting electrode (determined by a capacitance measurement) has an uncertainty of 0.1%. The limiting factor for this type of device is the uncertainty in W/e and the stopping power ratio at energies other than ^{60}Co .

An extrapolation chamber is also the device of choice for β -ray brachytherapy sources (such sources are used for the treatment of ophthalmic cancers) and one can derive absorbed dose using the Bragg–Gray principle (12).

Calorimetry

A calorimeter directly measures the absorbed dose as it is defined above. Although care must be taken in the design of a calorimeter, in terms of geometry and material composition, no primary conversion factor (e.g., W/e , G-value) is required. However, the basic operating principle of calorimetry is that all the energy deposited by the radiation is expressed as heat. If this is not the case, then there is said to be a heat defect. The heat defect can be due to crystal dislocations, radiation-driven chemical reactions or some other mechanism and is strongly material dependent. It follows from equation 3 that if there is no heat defect then

$$D_i = c_p \Delta T \quad (10)$$

where c_p is the specific heat at constant pressure and ΔT is the temperature rise in the material (absorber). The size of the > element > that defines the measured dose will depend on the specific application as well as the design of the calorimeter and the material used. A material with a high thermal conductivity will require mechanically defined components (e.g., some small absorber thermally isolated from the rest of the material), while it is much easier to measure a point dose in a material with a low thermal conductivity. Inhomogeneities in the phantom will affect the scattering of the radiation beam, and therefore change the absorbed dose measured. A correction will be required to give the dose in a homogeneous medium.

The three challenges in calorimetry are therefore to (1) measure the radiation induced temperature; (2) measure a material of known specific heat capacity, and (3) make sure that what is measured is relevant to the particular application of the radiation beam. These problems have been addressed in a number of (often novel) ways over many years, but currently there are basically two types of calorimeter: graphite (e.g., see Refs. 13 and 14) and water (e.g., see Ref. 15). Graphite has some obvious advantages: it is solid and a graphite calorimeter can be made smaller and more robust than a water device. For example, McEwen and Duane (16) demonstrate a calorimeter designed to be taken routinely into radiotherapy clinics. There is no heat defect or convection to consider for graphite and the temperature rise per unit absorbed dose is much larger than that of water due to the low specific heat capacity ($c_{p,\text{graphite}} \sim 700$ $c_{p,\text{water}} \sim 4200$ $\text{J}\cdot\text{kg}^{-1}\cdot\text{C}^{-1}$). However, the high thermal conductivity is an issue and the quantity realized is absorbed dose to graphite so a conversion is required to obtain absorbed dose to water (see below). Since water is the standard reference material for radiation dosimetry the majority of standards laboratories are moving over to water calorimeters as the primary standard and the device operated at the National Research Council in Canada is shown in Fig. 4. The major problems in developing a water calorimeter are controlling convection and obtaining a stable (ideally zero) heat defect for the sample of water irradiated. The present state-of-the-art in calorimetry yields an uncertainty in absorbed dose to water of $\sim 0.3\%$ and for recent reviews of calorimetric development see Ross and Klassen (17), Williams and Rosser (19), and Seuntjens and DuSautoy (20).

Chemical Dosimetry

In chemical dosimetry, the absorbed dose is determined from some chemical change in an appropriate material and

Figure 4. Overview of the NRC sealed water calorimeter. The outer box, which provides thermal insulation, is ~ 80 cm on a side, while the water phantom is ~ 30 cm on a side. The inner-glass vessel provides a stable volume, where the purity of the water can be rigorously maintained (to control the heat defect). The radiation-induced temperature rise (typically a few mK) is measured using thermistor probes and the outer system controls the temperature at 4°C to minimize convection effects.

any well-characterized chemical reaction where the reaction product(s) can be measured with good precision may serve as the basis for the dosimeter. Chemical dosimeter systems were developed as early as 1927 and a wide range of systems have been studied. Although, in principle a chemical dosimeter is a secondary device, in that it does not directly measure the absorbed energy, it can be regarded as a primary device if the relation between absorbed energy and chemical change can be determined absolutely. This relationship is termed the radiation chemical yield and is expressed as the number of molecules or ions of product X liberated per unit absorbed energy, designated $G(X)$. Assuming that the G -value is known and is constant with dose then the absorbed dose is given by

$$D = \frac{\Delta M}{G(X)\rho} \quad (11)$$

where ΔM is the volume concentration of molecules produced by the radiation absorbed and ρ is the density of the medium.

To act as a primary dosimeter, a chemical dosimeter should be dose, dose-rate, and LET independent. Aqueous systems are preferred as they are basically water equivalent, although this introduces a containment vessel whose effect must be taken into account.

The ferrous sulfate (21) dosimeter is the most widely used and longest established dosimetry system. It demonstrates the advantages and problems of chemical dosimeters. The reaction mechanism is the oxidation of ferrous to ferric ions, in aerated sulfuric acid. The oxidation proceeds via a number of reactions involving hydroxyl radicals, hydroperoxy (HO_2) radicals, and hydrogen peroxide. The ferric ion formation is directly proportional to energy absorbed as long as some oxygen remains in the solution, hence the requirement for aeration. All the reactions are fast (< 1 min), therefore there is no aftereffect under usual γ - or electron irradiations. However, great care must be taken in the preparation of the solutions, particularly with regard to water purity as organic impurities can have a significant effect. Spontaneous oxidation of the ferrous ions occurs that can be corrected for by the use of an unirradiated sample as a control.

The concentration of ferric ions may be determined by titration, but absorption spectroscopy is generally a more convenient technique, using ultraviolet (UV) wavelengths of 304 or 224 nm. The Fricke dosimeter is dose-rate independent for ^{60}Co radiation in the range $0.1\text{--}40$ $\text{Gy}\cdot\text{s}^{-1}$ (a range that covers both radiotherapy and industrial dosimetry applications) and for linac irradiations, $G(\text{Fe}^{3+})$ production is linear up to a maximum dose-per-pulse of 2 Gy (significantly greater than radiotherapy linacs). The normal dose range is 5–350 Gy, although this can be extended by suitable modifications of the composition of the system, or of its analysis. With care, Fricke dosimetry is capable of 0.1% precision, but for absolute dosimetry one requires an accurate determination of the G -value. As with ionometry, this factor can be determined from calorimetry, but preferably one would like an independent measurement. Such a measurement is possible if one

knows the total energy in the radiation beam. Roos and Hohlfeld (22) describe the system developed at the PTB (Physikalisch Technische Bundesanstalt) in Germany based on a microtron accelerator with a very well determined electron energy and beam current. With such a system an uncertainty in the G -value (the effective response of the Fricke is actually derived in this measurement) of $< 0.4\%$ is achievable and the overall uncertainty in measuring absorbed dose to water is $\sim 0.5\%$. Other chemical dosimeter systems include ceric sulfate, oxalic acid, potassium dichromate, and alanine, which cover higher dose ranges than Fricke. However, G -values for these systems are either unknown, or have a much larger uncertainty, and therefore cannot be regarded as primary dosimeters.

Conversion of Dose Between Materials

Since dose is material dependent, the primary device one uses to measure absorbed dose may not yield the quantity required. A conversion procedure is therefore needed. If the uncertainty on this conversion is sufficiently large then the usefulness of the primary device is called into question. The majority of effort in this area has concentrated on water and graphite since graphite is commonly used for primary standard calorimeters and water is the material of interest for radiotherapy dosimetry.

For electron beams, the conversion factor is a product of two factors: a ratio of stopping powers and a fluence correction (the latter takes account the differences in scattering power between the two materials). The most accurate values for stopping powers are those given in Ref. 23, but these are based on calculation alone and a quoted uncertainty of $\sim 1\%$ for each material is given. There have been a number of attempts to measure stopping powers (e.g., Ref. 24), but these did not have the accuracy to validate the calculations. One of the problems in measuring stopping powers is that it is only possible to measure relatively small energy losses and this significantly increases the precision required if the achieved overall uncertainty is to be $< 1\%$. Faddegon et al. (25) presented a new technique using a large sodium iodide detector to directly measure elemental stopping powers and McPherson (26) reports the results of such measurements. The standard uncertainty on these measurements (0.4–0.7%) is significantly lower than the previous attempts and is at a level where the calculated values in Ref. 23 can be tested. Fluence corrections are determined either through direct measurement in phantoms of different materials or using Monte Carlo simulations (see below).

For megavoltage photon beams, there is more than one method available for converting dose from one material to another. Burns and Dale (27) describe two methods: the first making use of the photon fluence scaling theorem (28) and the second based on cavity ionization theory. Nutbrown et al. (29) repeated the experimental work of Burns and Dale and applied a third method based on extensive Monte Carlo simulations. Fricke dosimeters

can also be used to transfer the dose between materials as it can be assumed that the G -value is independent of the phantom material (27).

Monte Carlo: A Primary Technique for the Future?

There has been a rapid development of Monte Carlo techniques for radiation dosimetry in the last 10–15 years. A Monte Carlo calculation is based on radiation transport physics and tracks individual particles as they interact with the detector and phantom. By averaging over a large number of particles (typically > 10 million), statistical fluctuations can be reduced to an acceptable level. The big advantages of a Monte Carlo simulation are (1) there is no reliance on a physical artifact, such as a ion chamber or calorimeter, and (2) you are not constrained by many of the problems of physical measurement as outlined above and can derive the exact quantity you require. Calculations initially focused on determining correction factors, such as the ion chamber wall effect for air kerma standards and the effect of inhomogeneities in a medium. More recent Monte Carlo codes have included the accurate simulation of the radiation source (e.g., BEAM (30)) and the detector (e.g., EGSnrc (31)). The sophistication has reached the level where they may be considered as viable alternatives to measurements.

In considering the idea of Monte Carlo as a primary technique one can clearly not escape some absolute measurement for the primary realization of absorbed dose. For example, the absolute beam current produced by a linear accelerator or the total activity of a radioactive source would be required as an input to the simulation, but the dose itself would be calculated. If this measurement can be determined with high accuracy and the absolute uncertainties in the Monte Carlo can be reduced, then this offers a potential alternative to the present primary standards. The major limitation is the accuracy of input data for the physics models: interaction cross-sections, stopping powers, and so on are not known accurately enough. The high accuracy obtained in the determination of correction factors in dosimetry is because in those situations one does not rely in such a direct way on absolute interaction coefficients, but on differences (or ratios) in interaction coefficients, where one benefits from the cancellation of correlated uncertainties. To date, the majority of the effort has been in developing the Monte Carlo codes (improving efficiency and refining the physics modeled), but there are still significant gaps in the input data so it is not clear whether the potential for the absolute application of Monte Carlo techniques can be fulfilled.

REFERENCE OR SECONDARY DOSIMETERS

As with primary devices, there are number of different types of secondary dosimeter that are used in radiotherapy. Secondary dosimeters require calibration against a primary standard and are then used to realise absorbed dose on a more routine basis.

Figure 5. Radiograph of a NE2571 Farmer-type chamber. One can see the graphite outer wall of the cavity, aluminum central electrode, and internal construction of the stem.

Ion Chambers

Ionization chambers (particularly air-filled chambers) are the most widely used instruments in radiotherapy dosimetry. They offer a number of characteristics which are particularly suited to the measurement of therapy radiation beams - sensitivity, long-term stability, and ease-of-use. The most widely used chamber is the Farmer-type (33), an example of which is shown in Fig. 5. Chambers of this type show excellent stability (figures of $\pm 0.3\%$ over 25 years are not uncommon) with the only disadvantage being a lack of waterproofing. A waterproof sleeve is therefore required for measurements in water. Such a sleeve should be thin (< 1 mm), close fitting (no air gaps), and made from some low *Z* material to minimize any additional perturbation effect [PMMA-poly(methyl-methacrylate) is commonly used].

Parallel-plate chambers, which are usually waterproof, are recommended for the dosimetry of electron beams. The NACP design (34) is one of the most widely used (Fig. 6).

Ionization chambers are usually vented to the atmosphere and therefore an air density correction, f_{TP} , is required to normalise for variations in air temperature and pressure (T_{air} and P_{air} , respectively):

$$f_{TP} = \frac{273.15 + T_{air}}{273.15 + T_{ref}} \cdot \frac{P_{ref}}{P_{air}} \tag{12}$$

P_{ref} is taken to be 101.325 kPa, but there is no agreed value for T_{ref} . In Europe a value of 20 °C is used, while in North America the reference temperature is 22 °C. Care must therefore be taken when comparing results from different laboratories.

A correction for the humidity of the air in the chamber is not generally applied. The presence of water vapor affects the value of W/e (36), as well as stopping power and

Figure 6. Schematic of the NACP parallel-plate chamber (taken from Ref. 35). Design features include waterproof construction, low *Z* materials to minimize the perturbation correction, and large guard ring to minimize in-scatter.

mass-energy absorption coefficients. However, for relative humidities between 10 and 90% (when comparing to a standard humidity of 50%) the effect is a maximum of 0.1%.

A correction is required to account for the incomplete collection of charge due to ion recombination in the chamber volume. The correction for ion recombination is the sum of two components: initial recombination and general or volume recombination. General recombination takes place when oppositely charged ions from different ionization tracks (i.e., created by different incident ionizing particles) recombine while they drift under the influence of the electric field toward their respective electrodes. Initial recombination takes place when oppositely charged ions from the same ionization track recombine; as the name suggests, this process takes place before the electric field is able to pull the track structure apart and therefore precedes general recombination. Initial recombination is independent of dose rate but general recombination depends on the ion density in the cavity. This ion density depends on the dose rate for continuous radiation and on the dose per pulse for pulsed beams. Initial recombination is typically small (~ 0.1 – 0.2% for the usual cylindrical and parallel-plate chambers employed in radiotherapy). General recombination is typically a small effect for continuous radiation (e.g., kilovoltage X-ray beams or ^{60}Co γ -ray beams) but for pulsed beams it can often be significant, especially so for modern linear accelerators that employ large dose-per-pulse values (recombination corrections of up to 5% have been reported).

The theoretical aspects of ion recombination for pulsed and continuous radiation have been well discussed in the literature (37–39). However, in recent years a number of authors (40–42) have presented recombination data that do not agree with the standard theory. A number of possible mechanisms have been proposed, including ion multiplication, air volume change, and direct collection of primary electrons, but at present there is no consensus as to which, if any, of these is the reason for these anomalous results. Dosimetry protocols recommend that a full $1/I$ against $1/V$ plot be measured where I is the measured Ionization current and V is the polarizing voltage to establish the range of linearity where the standard theory holds and the chamber then operated at voltages to remain within that range (Fig. 7).

Ion chamber measurements must also be corrected for the effects of polarity. The polarity effect is the difference in readings obtained in the same irradiation conditions, but taken with positive and negative polarizing voltages. Boag (43) identified a number of components of the polarity effect including secondary electron emission (due to the Compton effect) that produces a negative current independent of polarity; uneven distribution of the space charge due to a difference in the drift velocity of negative and positive ions; variation of the active volume due to space charge distortions; stopping of fast electrons in the collecting electrode not balanced by the ejection of recoil electrons; and collection of current outside the chamber volume due to leakage in solid insulators. In practice, it is difficult to identify the mechanisms acting in a particular

Figure 7. Plot from Burns and McEwen (41) showing the deviation from theory (straight line) of the recombination behavior for a NACP chamber. Without extensive measurements errors of up to 1% are possible.

situation, but measurements show that the polarity effect will vary with chamber type, beam energy and modality, measurement depth and can vary with other factors, such as field size.

The polarity correction is given by

$$f_{\text{pol}} = \frac{|M^+| + |M^-|}{2|M|} \quad (13)$$

where the superscripts + or - indicate the reading (M) with collecting voltage positive and negative, respectively, and M in the denominator is the reading taken with the normal polarity used during measurements. Table 1 summarizes typical polarity corrections for chambers in different beams.

A variation on the air-filled ionization chamber is the liquid ion chamber. In this design, the air is replaced by a liquid, which offers two major advantages: a flat energy response and an increased carrier concentration (and therefore increased spatial resolution). Liquid ion chambers have been developed over many years, but their use as secondary dosimeters has been severely hampered by the volatility of the liquid (usually a short-chain hydrocarbon) resulting in loss of signal. However, recent results (47) show impressive stability and may indicate that

Table 1. Typical Polarity Corrections

Beam	Cylindrical Chambers	Parallel-Plate Chambers
Megavoltage photons	< 0.2% beyond d_{max} , more variable in build-up region	Generally < 0.3%, but can show variable behavior.
Megavoltage electrons	Up to 1% at lower end of recommended energy range (44)	< 0.2% for well-designed chambers (45). Can be significant for other chamber types (46)

liquid ion chambers have a role to play in reference dosimetry.

Fricke

The Fricke dosimeter was described in detail in the section above on primary dosimeters. As a secondary dosimeter it is used in exactly the same way, except that the G-value is effectively measured for each batch of solution by comparison with a calorimeter (48). The big disadvantages of Fricke are (1) the care needed to produce 'good' solutions, and (2) the perturbation correction required for the vessel holding the Fricke solution (usually glass or quartz) is generally large. The NRC in Canada has used Fricke to transfer the dose from water calorimeter to ionization chambers (49).

TLD

Another class of systems is thermoluminescent dosimeters (TLDs). One of the obvious advantages of such dosimeters is that they can be made very small, and are therefore ideal for plotting dose distributions. The TLD material can be used as a powder or can be formed in various shapes (chips, rods, pellets, etc.). These materials have a wide dose range, from a few tens of μGy to $\sim 1 \text{ kGy}$. The readout (measurement of the glow curve) is destructive, but the dosimeters can be reused. The equipment required is readily available and the production and readout of dosimeters is relatively simple, particularly compared to Fricke or alanine (Fig. 8).

Lithium fluoride is the most widely used system for radiotherapy applications as it has a mean atomic number close to that of tissue ($Z_{\text{eff}} = 8.2$, compared to 7.4 for tissue). It has a fairly flat response with energy (especially in the megavoltage region) and is therefore not particularly sensitive to variations in beam quality. Both CaF_2 and CaSO_4 are useful in that they have sensitivities 10–100 times greater than LiF but, because of their high Z values, they show a very rapid change in energy response at low energies. Lithium borate has a better tissue similarity ($Z_{\text{eff}} = 7.4$) but has a sensitivity of only one tenth of that of LiF. As for the other systems based on some chemical change, TLD materials require calibration against a primary dosimeter. It is not possible to determine any thermoluminescent equivalent of a G-value as the dose response depends on the annealing process and tends to be batch dependent. Typical reproducibility at the 1% level is possible routinely with an overall uncertainty of 2–3% (one standard deviation). However, Marre et al. (50) obtained a reproducibility of better than $\pm 0.5\%$ and an overall standard uncertainty in measuring absorbed dose to water of $\pm 1.6\%$. These values are approaching those of ion chambers although the delay between irradiation and readout and the care required to achieve this level of precision limit the applications for this dosimeter.

TLD is an attractive dosimeter for the dosimetry of low dose rate brachytherapy sources. The source strength is normally too low for small ionization chambers, and large volume chambers have poor spatial resolution. However, for ^{125}I , one of the commonly used isotopes in prostate

Figure 8. Glow curves from two different TLD materials. The temperature is slowly ramped to a maximum (in this case 240 °C) and the thermoluminescent intensity measured using a photomultiplier. The shape of the glow curve depends both on the material and the thermal pre-treatment (annealing).

treatment, the mean photon energy is only 27 keV and therefore the energy dependence of TLD needs to be known accurately (Fig. 9).

Since LiF is nontoxic, TLD can be used as an *In vivo* dosimeter, placed directly on the patient, to verify treatment delivery. It is a less invasive technique compared to diodes or MOSFET detectors (see below), as there are no trailing wires or associated equipment.

Alanine

Over recent years, alanine has become more widely accepted as a chemical dosimeter for radiotherapy dosimetry. It has a very wide dose range, showing a linear response from 10 Gy to 70 kGy. It is a solid dosimeter, with a density and atomic number close to that of water (close to zero perturbation) and the dosimeters are small: typically disks are 5 mm in diameter and 3 mm thick, but can be made as thin as 0.5 mm for measuring low electron energies. The energy dependence is very small. Zeng et al. (52) showed that any variation in the sensitivity of alanine

Figure 9. Energy dependence of two types of LiF TLD dosimeters (from Ref. 5). Triangles - TLD-100, diamonds - TLD-100H. LiF:Mg,Ti (TLD-100) has been a widely used dosimeter since the 1960s, LiF:Mg,Cu,P (TLD-100H) was developed in 1976, with 20–30 times greater sensitivity.

is not more than $\pm 0.5\%$ over the energy range from ^{60}Co to 25 MV X rays. The dosimeter is read out nondestructively using ESR (electron spin resonance) spectroscopy. This nondestructive read-out, together with the long-term stability of the radiation-induced signal means that alanine has a potential role as a dose record. The National Physical Laboratory in the United Kingdom offers a mailed dosimetry service for radiotherapy using alanine dosimeters.

Summary

For reference dosimetry in radiotherapy clinics the system of choice is the ion chamber. Ion chambers are simple to use, offer high precision and accuracy and give an immediate reading. Integrating dosimeters (Fricke, alanine, and TLD) tend to be used as QA checks, either internally or within a wider framework of national or international comparisons (e.g., TLD is used for both the IAEA international mailed reference dosimetry service (53) and the RPC audit scheme in North America (54)). Generally, ion chambers are calibrated against primary standards and then used to calibrate other dosimetry systems within the clinic.

CALIBRATION OF SECONDARY DOSIMETERS

Basic Formalism

An ideal secondary dosimeter will have a zero energy dependence. Calibration against a primary standard (calorimeter) would then only need to be carried out at one beam quality (e.g., ^{60}Co). Energy independence also implies that the calibration coefficient is the same in photon and electron beams since the dose in a photon beam is dependent on the secondary electron spectrum generated in-phantom. In practice, the majority of secondary dosimeters commonly in use have some energy dependence. Ionization chambers, for example, show a variation of $> 3\%$ over the energy range from ^{60}Co to 25 MV photons, with even larger variations at low X-ray energies.

The obvious method to calibrate an ion chamber in terms of absorbed dose is to compare a chamber with a primary device. However, although accelerators were being used from the 1950s for radiotherapy, there were no absorbed dose standards for megavoltage photon or electron beams until the 1970s. Absorbed dose measurements using ion chambers were therefore based on air-kerma calibrations derived at lower photon energies (either ^{60}Co or 2 MV X rays). Protocols were developed to enable users to obtain a measurement of the absorbed dose delivered by a linac in the clinic. Only in recent years have absorbed dose-based calibrations become available from national standards laboratories and associated protocols produced (e.g., Refs. 6–8). For the purpose of the following discussion, we will only deal with absorbed dose calibrations in megavoltage photon and electron beams, but the principles are basically the same for other situations (kV X rays, protons, etc.).

The basic formalism for the calibration of an ion chamber is simple. The chamber is compared against the

primary device and a calibration coefficient ($N_{D,sec}$) for that beam is derived

$$N_{D,sec} = \frac{D_{std}}{M_{sec}} \tag{14}$$

The parameter D_{std} is the dose measured by the primary device and M_{sec} the chamber reading corrected for influence quantities. This calibration coefficient will be a function of the energy of the photon or electron beam and is given in terms of a beam quality specifier, Q_{ref} . The user then derives the calibration coefficient for the user beam quality, $N_{D,ref}(Q_{user})$. Some primary laboratories only supply calibration coefficients for ^{60}Co and thus correction factors are required, which are given in dosimetry protocols (e.g., Ref. 7). An alternative approach, as used in the United Kingdom’s Code of Practice (6) is to obtain absorbed dose calibration coefficients in linac photon beams. In this case there is no need for the calculated conversion factors and an ion chamber is calibrated in a beam similar to what it will be used to measure.

A measurement is then made in the user’s radiation beam to measure the absorbed dose, D_{user} :

$$D_{user} = N_{D,sec}(Q_{user})M_{user} \tag{15}$$

where M_{user} is the chamber reading.

Implied in equations 14 and 15 is the reference depth at which the measurement is carried out. The concept of the reference depth for a calibration is much more important for electrons than photons. In a phantom irradiated by a megavoltage photon beam the secondary electron spectrum (which determines the dose) varies only slowly with depth (for depths greater than the range of incident primary electrons). By contrast, in the situation of a primary electron beam, the electron spectrum seen by the detector constantly changes from the surface to the practical range. The choice of reference depth should be both clinically relevant and reliable in terms of transferring the dose from the primary laboratory to the user’s beam. For photon

beams there may be only one or two reference depths defined for all energies while for electron beam dosimetry all modern protocols define the reference depth as a function of energy.

Potential Problems with Beam Quality Specifiers

A typical radiotherapy linac accelerates electrons to energies in the range 4–22 MeV and can also produce bremsstrahlung X-ray beams over a similar energy range. In both cases, the detector calibration coefficient will be some function of this spectrum. Since it is not generally possible to measure the energy spectrum directly a beam quality specifier (Q) is used. This is obtained by measuring some property of the radiation beam (e.g., the penetration through a material). A “good” beam quality specifier is one such that a value of Q relates uniquely to the effect of a particular spectrum. A problem arises if Q is not a good beam quality specifier, that is, there is some ambiguity in the relation between Q and the effect of the incident spectrum.

Beam Quality Specifiers for Photon Beams. Typical photon depth–dose curves from a clinical linac are shown in Fig. 10 (it should be noted that MeV tends to be used as a label for electron beams and MV for photon beams). Over the years, a number of beam quality specifiers have been proposed for megavoltage photon beams, but all relate in some way to the penetration of the photons through some material.

The most widely used parameter has been $TPR_{20,10}$ (tissue phantom ratio), which is defined as the ratio of ionization currents at measurement depths of 20 and 10 cm in water with a fixed-field size and source to chamber distance. The 10 and 20 cm points in Fig. 10 are on the downward portion of the curves, and therefore TPR is related to a measurement of the attenuation of the beam.

There has been much debate in recent years over the sufficiency of $TPR_{20,10}$ as a beam quality specifier for

Figure 10. Depth dose curve for three photon beams.

the purpose of ion chamber calibration in terms of absorbed dose to water. Rosser et al. (55) found that an error of up to 0.6% could be introduced by the incorrect application of calibration coefficients using TPR. A number of other beam quality specifiers have been put forward as alternatives to TPR including: d_{80} (the depth at which the dose is 80% of the peak dose); the HVL of water and the percentage depth dose at a depth of 10 cm, $\%dd(10)_X$ (where a 1 mm lead filter is used to correct for electron contamination). There is no consensus on this problem at the moment: the new IAEA Code of Practice (8) uses $TPR_{20,10}$ while the AAPM absorbed dose protocol (7) uses $\%dd(10)_X$. However, in practice there is no real controversy: Kalach and Rogers (56) showed that although $\%dd(10)_X$ gave better agreement for a wide range of accelerators, for the heavily filtered beams produced by modern clinical linacs, $TPR_{20,10}$ was an adequate beam quality specifier.

Beam Quality Specifiers for Electron Beams. It is potentially simpler to measure the electron spectrum from a Linac than a photon spectrum. The most accurate method is to use a calibrated magnetic spectrometer (57,58), but this technique tends to be rather time consuming and the necessary equipment is not always available. The mean energy of the electron beam can be determined via activation analysis (59,60) or the determination of the total charge and energy using a Faraday cup. However, all these systems tend to be rather complex so the actual electron spectrum (or even mean electron energy) is rarely measured.

As with photons, parameters derived from the penetration of electrons in a medium are used as a measure of electron energy. A typical electron depth-dose curve in water is shown in Fig. 11. The two most important parameters obtained from such a curve are R_{50} , defined as the depth at 50% of the peak dose; and R_p (the practical range), defined as the point where the extrapolation from the point of maximum gradient on the downward part of the curve meets the extrapolation of the bremsstrahlung background.

Figure 11. An electron beam depth-dose distribution in water showing the various range parameters. (From Ref. 61).

Considerable work has been done to relate these parameters to beam energy (see Ref. 2), and it is generally understood that R_{50} and R_p described different aspects of the incident electron spectrum. The parameter R_{50} relates to the mean electron energy, while R_p is directly related to the most probable energy. For a symmetrical, single-peaked spectrum the mean and most probable energies will be the same but, as shown by Klevenhagen (62), the spectrum incident on a phantom will be skewed towards lower energies due to scattering in air. Reference 2 shows depth-dose data for two spectra where the most probable energy is the same but with different mean energies (and different energy spreads). In this case, the two curves give the same value for the practical range, but different values for R_{50} . However, Burns et al. (63) collated a large amount of depth-dose data from a wide variety of linacs and showed that there was a direct relation between R_{50} and R_p , indicating that the majority of linacs in use today either generate symmetrical or very similar spectra.

RELATIVE DOSIMETRY AND QUALITY/VERIFICATION

For relative dosimetry or for quality (QA) measurements there are a wide range of dosimetry systems to choose from (including many discussed above as secondary dosimeters). The choice will depend on a number of factors including application (simple external beam therapy, intensity modulated radiotherapy (IMRT), brachytherapy); precision; spatial resolution and/or detector size; type of measurement (i.e., relative, QA, etc.); and immediacy (instant readout required?). However, one of the primary drivers will be practical issues such as cost, availability, complexity and setup time. With so many detectors to choose from it is difficult to give anything other than a very brief overview here.

Solid-State Detectors (1D)

Diodes. Semiconductor diodes offer increased sensitivity over air-filled ionization chambers due to the higher density of charge carriers. This means that the sensitive volume can be made ~ 100 – 1000 times smaller, giving excellent spatial resolution. The stopping power ratio silicon/water varies much less with energy than the air/water ratio, and therefore diodes are ideally suited for measuring dose distributions. The biggest problem with diodes is that the sensitivity is dose dependent and diodes need recalibrating approximately every few hundred gray. Dose diodes are available in two types: electron and photon. Photon diodes employ shielding around the sensitive volume to correct for the effects of scattered radiation in a photon beam. Uncorrected, an unshielded diode overestimates the dose at depth by as much as 15% for a 6 MV beam and Yin et al. (64) present a method to correct for the response of diodes in photon beams. Due to the potential for confusion as to the construction of a diode, dosimetry protocols usually recommend that diode measurements are validated using an ion chamber.

Diamond. Diamond detectors have been investigated for over 20 years (65,66). The spatial resolution of diamond detectors ($1\text{--}6\text{ mm}^3$) is comparable to that of commonly used silicon diode detectors with the added advantage of showing high resistance to radiation damage ($0.05\% \text{ k}\cdot\text{Gy}^{-1}$, > 100 times lower than typical diode values). As expected for a solid-state dosimeter, diamond detectors have a high sensitivity, but also a good long-term stability and low temperature dependence. Diamond has a reasonable tissue equivalence for both photon and electron beams. The majority of recent work with diamond detectors has focused on their use for small field IMRT and brachytherapy, where the high sensitivity and small size are highly advantageous. Mack et al. (67) compared a number of techniques for the dosimetry of small radiosurgery beams and found that a diamond detector gave very good results down to field sizes of $4 \times 4\text{ mm}$. However, a significant disadvantage of diamond detectors at present is the very high cost compared to other solid-state detectors. This is because at present natural diamonds are used and have to be carefully selected, since the dose linearity and polarization effects are very sensitive to impurities and defects in the crystal. However, the more recent availability of low cost, polycrystalline diamond specimens produced using chemical vapor deposition (CVD) offers the potential for improved diamond detectors with selectable size and impurities.

MOSFETs. The MOSFET dosimeter (68) is a more recent development. The dosimeter operates by measuring the threshold voltage of a MOSFET field effect transistor, which is permanently changed by the absorption of radiation (radiation damage). As an integrating detector it therefore has similar applications to TLD or alanine and the small detector area (only $0.2 \times 0.2\text{ mm}$) offers very high spatial resolution. The reproducibility is typically $\pm 2\%$.

Two-Dimensional Detectors

Radiographic Film. Film dosimetry has long been viewed as an attractive alternative to ionometric and thermoluminescent methods as an entire two-dimensional (2D) chart may be extracted from a single film exposure. In addition, film has the highest spatial resolution of any practical dosimeter and is easily set up and exposed. However, radiographic film dosimetry is not without problems - daily film calibrations are essential to obtain absolute dose results and care must be taken with film handling and processing not to introduce artifacts. A more fundamental problem is that the high atomic number of the silver halide film emulsion means that dose response relative to water varies significantly in the low energy photon range ($< 200\text{ keV}$), as can be seen in Fig. 12. This is also an issue for measurements in megavoltage photon beams where the scatter-to-primary ratio can change (e.g. off-axis). Having said this, radiographic film dosimetry is experiencing a renaissance in the radiation therapy community, driven by the need to verify the absorbed dose delivered with IMRT, where both detector resolution and 2D data acquisition are advantages.

As with any other secondary dosimeter, a calibration curve must be derived. The quantity measured using film is

Figure 12. Energy dependence of radiographic film relative to that of water.

the optical density (measured using a scanner or densitometer) and ideally this should show a linear increase with dose (Fig. 13).

Although there are obvious problems with radiographic film, alternatives for 2D dose verification have their own limitations and therefore it is likely that film will continue to play a role in dosimetry. Radiochromic film is considered tissue equivalent and energy independent, but is expensive, limited in size, and prone to large dose response nonuniformities due to the manufacturing process. Commercially available 2D ion chamber and diode arrays provide a fast and accurate evaluation, but are still limited in resolution, and therefore better used to dose verification rather than commissioning IMRT. Electronic portal imagers have the advantage of being available in many modern therapy centres but by design, they measure fluence patterns, not dose distributions in phantoms, and therefore interpretations of delivery errors could be difficult.

Radiochromic Film. A radiation-induced color change is one of the simplest dosimeters one can think of and a number of systems were developed in the early 1900s. Although widely used in the radiation processing industry, where

Figure 13. Dose linearity curve for Kodak EDR2 film (from Ref. 69). The response is very repeatable and linear for doses above 150 cGy.

the large doses can induce easy-to-detect color changes, radiochromic films have only recently begun to be used once again for radiotherapy dosimetry. The most promising to date is the GafChromic material. One of the main advantages of radiochromic films over radiographic is that they are essentially tissue equivalent so the energy response relative to water only changes very slowly with energy (Fig. 14).

As with any dosimeter there are problems in obtaining high accuracy dosimetric information. Klassen et al. (71) carried out a detailed investigation and showed that the precision was affected by the readout method, the readout temperature and wavelength as well as the polarization of the light source. However, with care, dosimetry with a relative uncertainty of < 1% is possible for doses of the order of 6 Gy.

EPIDs. Electronic portal imaging devices (EPIDs) have been gradually replacing conventional radiographic film for geometric verification in radiation therapy. The obvious advantage of using an EPID for dosimetry is that they are now standard equipment on most modern linacs. Early generations, employing liquid ion-chambers or camera-based fluoroscopy, generally produced poorer images compared to film, but it was shown that EPIDs could be used for IMRT quality assurance (e.g., leaf position verification for Multi- Leaf Collimators, or MLCs). The most recent class of EPID uses flat-panel photodiode arrays and with improved spatial resolution and higher detector efficiency are especially well suited for IMRT applications. However, to use any EPID for dosimetric IMRT requires calibration coefficients to relate pixel intensity to either fluence or dose. Calibration of the EPID is more involved than simple cross-calibration of pixel response with dose measurements made with an ion chamber in a homogeneous water phantom, but the ability to verify treatment “as it happens” is a significant advantage over other methods. Warkentin et al. (72) describe the use of a flatpanel detector for accurate pretreatment dosimetric verification of IMRT treatment fields.

Three-Dimensional Detectors

The adoption of conformal radiotherapy techniques and, in particular, IMRT, where verification of the delivered 3D dose distribution is very important, has been a major driving force in the development of 3D detection systems. Presently, there are basically three options: TLD (either as individual pellets or in powder form), film stacks (radiographic or radiochromic), and gel dosimeters.

Gel Dosimetry. Although the use of radiation sensitive gels for dosimetry measurements was suggested as early as the 1950s, the use and development of this type of dosimeter has only grown significantly in the last decade. Gel dosimeters offer a number of advantages over other 3D techniques, such as TLD or film stacks, including resolution, number of data points, energy dependence, and water equivalence (Fig. 15).

There are currently two main types of gel dosimeter: (1) Fricke gel – ferrous sulfate solution is incorporated into aqueous gel matrices of gelatin, agarose or poly (vinyl alcohol) (PVA). As for the Fricke dosimeter, there is a conversion of Fe²⁺ ions to Fe³⁺ and this change in concentration is readout via magnetic resonance imaging (MRI) or optical tomography. One of the main drawbacks of Fricke gels is that there is a rapid diffusion of the ferric ions centers within the matrix, which tends to smooth out the dose distribution. (2) Polymer gels: This system is based on the polymerisation of certain materials. Initial work focused on the materials acrylamide (AA) and N,N-methylene-bis(acrylamide) (BIS) with readout again via MRI. One of the main problems with these systems is that they are sensitive to atmospheric oxygen contamination. A newer formulation named methacrylic and ascorbic acid in gelatin initiated by copper (MAGIC) is less sensitive to the presence of oxygen and looks promising as a gel dosimeter. Perhaps the biggest problem with gel systems is that they require

Figure 15. Dose distribution for a high dose rate ¹⁹²Ir brachytherapy source measured in a flask of polymer gel dosimeter. (From Ref. 73.)

a containment vessel, which can both perturb the dose measurement and introduce imaging artefacts.

There is a very active gel dosimetry community worldwide and development continues both on gel formulations (e.g., reduce diffusion or sensitivity to impurities) and readout (e.g., CT and ultrasound have been suggested as alternative readout methods to MRI). For a recent review of the subject see Baldock (74).

CONCLUSION

This article has outlined the basic theory of radiation dosimetry and the problems involved in measuring absorbed dose. A number of primary and secondary measurement techniques have been described together with the formalism for calibrating dosimeters. Since whole textbooks have been written on this subject, this can be no more than a brief introduction to the field. Readers are referred to the extensive bibliography for further detail.

RADIATION DOSIMETRY, THREE-DIMENSIONAL

GEOFFREY S. IBBOTT
Anderson Cancer Center
Houston, Texas

INTRODUCTION

The goal of radiation therapy is to obtain the greatest possible local and regional tumor control, with the fewest complications. The response of many tissues to radiation can be characterized by a sigmoid curve. Relatively little response is seen until the dose reaches some threshold value, after which the response is quite rapid (1,2). In the region of steep response, relatively small variations in dose can yield significant differences in the response of both tumors and normal tissue (3). To minimize the variability of tissue response, the ICRU has recommended that the uncertainty in dose delivery be maintained below ~ 5% (4–6). Delivering a dose to a patient with a tolerance of 5% is not a simple matter (7). It has been estimated that the equipment used by most medical physicists to calibrate therapeutic radiation beams is itself calibrated with an overall uncertainty (expressed at the 95% confidence level) of ~ 1.5% (8). Uncertainties associated with the characterization of radiation beams, patient anatomy, and location of the target volume, as well as reproducibility of the treatment from day to day must be considered (9,10).

A comprehensive radiation therapy quality assurance program must address all sources of variability in the treatment of patients, in an effort to minimize variations. Technical aspects of quality assurance (QA) must address a wide array of issues, including the performance of simulation, treatment, and treatment planning equipment, the stability of measurement and test equipment, the accuracy and appropriateness of treatment planning calculations, and the accuracy and completeness of documentation. Technical quality assurance procedures should also address inventory, calibration, and treatment planning with brachytherapy sources. Recommendations for QA procedures can be found in a number of publications (11–23).

As the equipment used to deliver radiation therapy has evolved, methods of radiation dosimetry have also changed. Multifield, conformal radiation therapy (CRT), intensity-modulated radiation therapy (IMRT), stereotactic radio-

surgery (SRS), and stereotactic radiation therapy (SRT) all produce dose distributions that can be highly irregular in three dimensions. Conventional two-dimensional (2D) planning and dosimetry systems are not adequate to simulate and measure such distributions. Instead, new dosimetry systems are required that can record and display these complex distributions (24). This article addresses recent developments in dosimetry systems, and their advantages and complications.

QUALITY ASSURANCE PROCEDURES REQUIRING DOSIMETRY SYSTEMS

External Beam Calibration Consistency-Basic Parameters

Detector systems are required for measurement of accelerator output, for compliance with published recommendations for quality assurance. Most published recommendations suggest that accelerator output constancy be monitored on a daily basis. Consequently, a dosimeter system that is rugged, reliable, and easy to operate is required. Most recommendations for daily output consistency suggest that deviations on the order 2–5% be detectable; therefore the dosimetry system does not need extremely high accuracy.

In addition, measurements of beam flatness and symmetry are recommended on a periodic basis, often weekly. Again, as these measurements are to demonstrate consistency of operation at the 2–5% level, high precision is not required. Several of the available array dosimeters systems are suitable for such frequent QA measurements of treatment unit performance.

External Beam Treatment Delivery, Planning Verification

Several treatment applications require the verification of delivered dose with relatively high accuracy. For example, IMRT requires the precise delivery of relatively small doses through a large number of fields. Even small errors in dose delivery can accumulate and result in a large error in the final dose. Monitoring of dose delivery during IMRT is done best using a real time measuring device, such as online portal imaging. Similarly, CRT delivery demands confirmation that the correct dose has been delivered. As CRT is generally delivered through static fields, point detectors may be used to measure the delivered dose in a suitable phantom. Several of the simpler point dosimeter systems described earlier are suitable for this purpose.

Likewise, SRS and SRT delivered with accelerators may need verification, particularly as SRS is delivered in single large fractions. Again, under most circumstances, point dosimeters are suitable here. However, the characterization of radiation beams for SRS–SRT requires a dosimeter with high spatial accuracy. Several of the detector systems described above would satisfy this requirement, although questions of electronic equilibrium must be addressed (25).

Total body treatments, such as photon TBI for systemic bone marrow ablation, or total skin electron therapy for cutaneous t-cell lymphoma, may require dosimetry to confirm the correct delivery of dose under these conditions of unusual field size and distances.

External Beam Treatment Delivery In Vivo

Modern external treatment delivery requires that doses be delivered with accuracy never before required. Procedures, such as IMRT, are delivered through many field segments, each delivering a small increment of dose. A systematic error in dose delivery can result in a significant error in the final dose received by the patient. Consequently, dosimetry devices for confirming correct dose delivery are necessary. These fall into three broad classes: surface dose measurements, transmission measurements, and true *In vivo* measurements.

Brachytherapy (LDR, HDR, IVBT)

Dosimeter systems are required for at least three purposes related to brachytherapy: source characterization, confirmation of dose distributions from arrangements of multiple sources, and *In vivo* dose measurements (26,27).

Imaging Procedures

Dosimetry measurements are required in cardiology, for procedures, such as cardiac ablation, in which patients can receive significant doses. A detector to be used in imaging must not be intrusive, meaning that it must be virtually transparent to the beam. It must measure dose over a large area, although accommodation needs to be made for the possibility that the beam may be moved during irradiation. Finally, a device attached to the source of radiation, such as a dose area product meter, may be used.

REQUIRED CHARACTERISTICS OF DOSIMETERS FOR QUALITY ASSURANCE

A dosimeter for modern CRT must possess a number of important characteristics. It must be tissue equivalent, as the dosimeter itself must not perturb the dose distribution. It must have a linear dose response over a clinically useful range. Ideally, its response would be independent of dose rate and of beam modality, making it useful for mapping dose distributions from isotope units, linear accelerators, or particle accelerator beams. Some dosimeters must be able to fill a volume, or conform to a surface. This will enable the dosimeter to either mimic any portion of human anatomy, or conform to a section of an anthropomorphic phantom.

The dosimeter must either provide immediate results or be stable for a sufficiently long period to enable irradiation and analysis. Under some circumstances, the delivery of the intended dose distribution may take some time, as is the case with brachytherapy. It is important that the dosimeter remain uniformly sensitive, and unaffected in response over the time required for irradiation. Further, the dosimeter must maintain the dose-deposition information throughout the time required for analysis. For some applications, it may be desirable to transport the dosimeter to another facility for analysis. The dosimeter must remain stable during shipment, unaffected by a variety of environmental conditions, throughout the analysis.

The accuracy and precision required of dosimeters for radiation therapy measurements depend on the intended

use of the detector. Devices intended for reference calibration of treatment units should enable the determination of dose with an uncertainty of no more than 0.5%, expressed at the 95% confidence level ($k = 2$) (28,29). Dosimeters intended for verification of dose distributions should provide an uncertainty in dose measurement of no more than 2%, again expressed at the 95% confidence level ($k = 2$).

DETECTORS FOR THREE-DIMENSIONAL DOSIMETRY

Detector Arrays

A number of manufacturers have marketed arrays of conventional detectors using either ion chambers or diodes. These devices are not true three-dimensional (3D) dosimeters, but are included here because they provide 3D information through the use of one, or at most two, manipulations, such as translation across a beam. For example, linear diode arrays are available for the Scanditronix water phantom system, and for stand-alone QA device, such as the Sun Nuclear profiler. An array of ionization chambers has been described for verifying treatment planning for IMRT (30). The ion chambers are arranged in several parallel linear arrays, each one offset from the next. Twenty-four chambers, each 0.03 cm^3 in volume, are arranged in boreholes of a plastic-mounting frame. The assembly is positioned in a water phantom and maybe positioned in different orientations to allow measurements in different plains. Commercial ion chamber devices include the Thebes marketed by Nuclear Associates, an ion chamber array marketed by Wellhofer, the RBA-5 marketed by Gammex, and other devices. These devices range in number of detectors from few (four or five) to many (Fig. 1).

Plastic Scintillator

Some organic plastics fluoresce visible light when irradiated with ionizing radiation. Unlike the fluorescent screens used in imaging, organic scintillators have the

Figure 1. A diode array designed to display the intensity map of a therapy beam in real-time. (Courtesy of Sun Nuclear Corp.)

additional advantage of being approximately tissue-equivalent (31). However, this tissue-equivalence at present only exists at the energies conventionally used for megavoltage treatment. Most of the plastic scintillators currently available exhibit significant differences in the mass energy absorption coefficient relative to that of water. More recently, plastic scintillators have been developed for low energy photon dosimetry that are radiologically water-equivalent, have improved sensitivity over some others scintillators, and offer the potential for high spatial resolution (32,33).

Plastic scintillators may be used as point detectors, in which their potential for manufacturing into very small sizes yields the possibility for improved spatial resolution of measurements. Efforts also have been made to use plastic scintillators as 2D and 3D detectors (34). Two techniques have been used; the first being the use of plastic scintillators as a detector system themselves, using optical coupling through a light pipe assembly to a video detector. This method has been described previously (35–37). Significant difficulties still exist with the spatial resolution of these systems. Light emitted by the scintillator can travel some distance, in any direction, before reaching the light detector. Unless the plastic scintillator is thin, the resolution of the image will be degraded considerably. Some efforts have been to quench the light by adding dyes to the scintillator, to reduce the distance traveled by the light obliquely through the scintillator. Until this problem is resolved, the quality of the imaged dose distribution will not be adequate for radiation dosimetry.

A second technique involves the use of plastic scintillators to enhance the response of another detector, such as radiographic film (38). In this technique, radiographic film is sandwiched between sheets of organic plastic scintillator. Several investigators have noted that radiographic film has a tendency to overrespond to low energy photons (39,40). The use of an organic plastic scintillator has been proposed to enhance the response of radiographic film to higher energy photons, thus making the energy response of the film detector system more uniform.

Film

Radiographic film has long been used as a radiation detector, and as a QA device. Again, film itself is not a 3D dosimeter, but stacks of film have been used to measure dose distributions in 3D. The difficulties with film are well known; energy dependence, requirements for processing, variations from one batch to the next, dose rate dependence, positional dependence, and other issues have been discussed by a number of investigators (41). More recently, use of radiochromic film has been proposed. Radiochromic film requires no processing, has very little energy dependence, no known dose rate dependence, and requires minimal special handling techniques (42,43). The linearity of response of a recently developed model of film is shown in Fig. 2.

The use of film for verification of conformal and IMRT dose distributions has been recommended. At least one manufacturer has marketed a phantom intended for use with IMRT (see Fig. 3, for an example of such a device).

Figure 2. Energy dependence and linearity with dose of an improved radiochromic film. (Reproduced with permission from Ref. 42).

TLD Sheets and Plates

Lithium fluoride, a thermoluminescent material, has been used for many decades as a radiation detector (44). Its use has been limited principally to point measurements, because the dosimeter is provided either as extruded rods or chips, or as a powder that is encapsulated for use. Thermoluminescent dosimetry has a number of limitations, among them energy dependence, but most notably a requirement for delay between irradiation and processing. In addition, an expensive piece of equipment is required for readout of the material. The limitation of the device to point measurements has been addressed recently by the development of TLD sheets. In these, TL material is distributed in an array across a sheet of backing film. The film can be irradiated in much the same manner as conventional radiographic film, and may be immersed in a water phantom as necessary. As with film, 3D measurements can be made only by stacking multiple sheets of TL

Figure 3. A phantom marketed for evaluating IMRT dose distributions. (Courtesy of Med-Tec Corp.)

material. After irradiation, and following the requisite delay, the film is inserted into a readout device that selectively heats the individual dosimeter regions using a laser. Light is collected from the heated regions using a photomultiplier tube. Through an automated operation, a matrix of data can be obtained quickly and efficiently. However, due to the cost of the reader, this dosimetry system is presently available only as a service (Inovision, Inc.)

Electronic Portal Imaging Devices

An important aspect of quality assurance in radiation therapy involves not just the dose delivered to the patient, but the correct positioning of the patient. For many years, positioning has been verified through the use of conventional radiographic film, or through the use of video imaging techniques (45,46). Video imaging permits only a check of the relative position of external landmarks. Radiographic film permits verification of the patient position through the visualization of internal boning anatomy, but requires a delay while the film is processed. The introduction of electronic portal imaging has brought to the clinic the possibility of immediate verification of patient position. With the introduction to clinical radiation therapy of modern techniques, such as IMRT, immediate verification of correct beam delivery is crucial. The failure or incorrect programming of a multileaf collimator can result in a completely unacceptable dose distribution. With on-line portal imaging, such errors may be detectable promptly, even during treatment (47–52). A further improvement has been the introduction of transmission flat-panel detectors up- and downstream from the patient. These allow the measurement of photon beam fluence entering and exiting the patient, and the estimation of dose within the patient. When combined with images of the patient made at multiple beam angles, as is done for multifield conformal treatment, or IMRT, it may be possible to reconstruct the dose distribution actually delivered to the patient in three dimensions.

GEL DOSIMETRY

Gel dosimetry has been examined as a clinical dosimeter since the 1950s (53,54). During the last two decades, however, the number of investigators has increased rapidly, and the body of knowledge regarding gel dosimetry has expanded considerably (55,56). Gel dosimetry is still considered by some to be a research project, and the introduction of this tool into clinical use is proceeding slowly. However, the interest in, and potential of, gel dosimetry for clinical use is demonstrated by the level of participation in three successful international workshops held to date on this subject (57–59). This section reviews the development of gel dosimetry, several of the formulations that have been investigated intensively, the characteristics of gel dosimetry that make it desirable for clinical use, the postulated and demonstrated applications of gel dosimetry, and some complications, setbacks, and failures that have contributed to the slow introduction into routine clinical use.

Fricke Gels

Nuclear magnetic resonance (NMR)-based gel dosimetry was introduced by Gore who recognized that the ferrous sulfate Fricke dosimeter (60,61) could be examined with magnetic resonance rather than spectrophotometry (55). The Fricke dosimeter is based on the radiation-induced and dose dependent transformation of ferrous (Fe^{2+}) ions into ferric (Fe^{3+}) ions. These two ions have different electron paramagnetic spin states and different ionic radii (60,61). Gore realized that the NMR spin–lattice and spin–spin relaxation rates ($1/T_1$ and $1/T_2$, respectively) of the water protons in the Fricke dosimeter are dependent on the amount of ferric ion present in the solution and that, because changes in these parameters produce the contrast of MR images, radiation induced changes in the solution should be visible by MRI (55). Soon afterward, other researchers began investigating the use of Fricke solutions incorporated into gel matrices (Fricke gels) to provide spatial stability of the dosimeter (62–65). The most common matrices investigated were gelatin, agarose, and sephadex. Each of these systems had its advantages and limitations, but agarose was probably used more than any other detector system. While agarose dosimeters are more sensitive to dose than gelatin-based systems, they are more difficult to produce because they must be bubbled with oxygen to ensure a uniform dose response.

Fricke gel dosimeters have a number of advantages; principle among them is the well-described understanding of the radiation chemistry of this system. In addition, the basic and NMR processes leading to the dosimetry response are well understood (66,67). Fricke gel dosimeters are tissue equivalent over a large range of photon energies. Like other gel dosimeters, they are prepared in a liquid form so that phantoms containing heterogeneities or conforming to anthropomorphic geometries can be constructed.

However, there are a number of significant problems associated with the use of Fricke gels for radiation dosimetry. The dosimeters require high doses, on the order of 10–40 Gy, for the radiation-induced changes to be observed by magnetic resonance imaging (MRI). The ferric ions produced by absorption of radiation diffuse readily through the gel or agarose matrix, leading to a decrease in signal intensity, and a loss of spatial information (64,66–69). Imaging must be performed within ~ 2 h of irradiation to avoid serious degradation of the dosimetric detail (70). The diffusion has been reduced by replacing the gelatin matrix with a poly (vinyl alcohol) (PVA) matrix, which is less porous to the ferric ions (71). Other investigators have developed further methods to delay diffusion, although imaging must still be performed quite soon after irradiation (72). Some improvement in the diffusion of ions can be achieved by cooling the gel, but this is rarely practical in a clinical setting. Consequently, Fricke gel dosimetry has seen only limited clinical use.

Several improvements have been reported recently. For example, a Fricke gel dosimeter manufactured using a PVA cryogel technology has been described. The PVA is a common water-soluble polymer that can be cross-linked into its cryogel form by simply freezing and thawing. The cryogel is a rubber like material that holds its shape even at elevated temperatures. Preliminary reports of the PVA

Fricke gel dosimeter indicate that its ($1/T_1$) response has been found to be linear from 0 to 10 Gy, and the ion diffusion constant was found to be only 0.2–0.5 that of traditional preparations in gelatin or agarose (73,74). Representative ion diffusion constants are presented in Table 1 for several gel mixtures (68).

Some preliminary work using Fricke gel dosimetry in anthropomorphic phantoms has been reported (79). Several different gel compositions were investigated, including a lung equivalent gel that was developed with a density of $0.4 \text{ g}\cdot\text{cm}^{-3}$. This allows measurements of dose within the heterogeneity itself. However, diffusion of ions continues to be a problem with this dosimetry system.

Polymer Gels

Gels that replaced the Fricke solution with acrylic monomers were introduced in 1992 (80–82). Early work was conducted using a polyacrylamide gel based on the radiation-induced polymerization and cross-linking of bis and acrylamide. The formation of acrylic polymer chains largely resolved the problem of diffusion exhibited by Fricke gels,

as the long polymer chains were too large to diffuse rapidly. The reciprocal of T_2 , or R_2 , the relaxation rate, was found to vary proportionally with dose, and MR imaging of polymer gels was shown to yield quantitative dose distributions (81). Subsequently, alternative gel formulations have been developed in which the bis and acrylamide are replaced with acrylic acid or methacrylic acid, which has yielded increased sensitivity of the gels, and reduced toxicity (83,84). However, the polymer gels continued to show another disadvantage; their response was inhibited by the presence of oxygen. This effect was addressed though the recent introduction of a class of polymer gel dosimeters containing oxygen scavengers (85,86). Several variations of these *normoxic* gel dosimeters (so-called because they can be prepared under normoxic conditions) have been characterized (87).

To avoid the disadvantages of the Fricke gel systems, a polymerizing gel dosimetry system was developed (MGS Research, Inc., Guilford, CT). A variety of polymerizing gels have been developed, many of which are based on acrylamide or acrylic acid, and are referred to as polyacrylamide gels (PAG). The dosimeters are based on

Table 2. Composition of BANG3 Polymer Gel Dosimeter

6% Methacrylic acid
1% Sodium hydroxide
5% Gelatin
88% Water

radiation-induced chain polymerization of acrylic monomers dispersed in a tissue-equivalent gel. The BANG polymer gel system is a proprietary PAG dosimeter made of a mixture of acrylic monomers in a tissue-equivalent gel. Early BANG gels were made from acrylic acid monomers and methylene-bis(acrylamide) cross-linker. More recently, the BANG3 dosimeter was introduced, which contains methacrylic acid monomer (see Table 2, from Ref. 84). Other proprietary response modifiers were added to adjust the dose range and sensitivity. Dissolved oxygen inhibits free radical polymerization reactions and is removed from the mixture by passing nitrogen through it while the gel remains above the gelling temperature, prior to sealing the vessel. Consequently, vessels of glass or other material not permeable to oxygen must be used for irradiating and imaging the gels.

The gelling agent in the BANG dosimeter is gelatin, which is used because the transverse NMR relaxation rate of water ($R_2 = 1/T_2$) in a gelatin gel is nearly an order of magnitude lower than that in agarose gels. Therefore the background R_2 in the gel is substantially reduced, which improves its dynamic range.

MR Imaging of Polymer Gels

Irradiation of the polymer gels induces polymerization and cross-linking of the acrylic monomers. As polymer micro-particles are formed, they reduce the NMR relaxation times of neighboring water protons. Magnetic resonance imaging can be used to measure dose distributions in the gel (81,82,88). Water proton NMR (^1H NMR) transverse relaxation time T_2 can be τ determined from multiple spin-echo images. Images can be acquired using the Hahn spin-echo pulse sequence: $90^\circ - \tau - 180^\circ - \tau - \text{acquire}$ for four or more different values of τ . Typical pulse sequence parameters are TR = 2 s, TE = 11, 200, 400, and 600 ms. A field of view of 24 cm and a matrix of 128×256 can be used, with one acquisition and a 3 mm slice thickness.

More recently, it has been shown that spin-echo sequences other than the Hahn sequence described above can be used for gel imaging. Improved dose resolution can be achieved through the use of multiple spin-echo pulse sequences (89,90). Optimization of the imaging sequence is necessary, especially with regard to the number of echoes measured. The use of multiplanar imaging can reduce imaging times but can also lead to interference between image planes.

Once MR images have been obtained, they are most conveniently transferred via network to a computer for which a data analysis and display program has been written. One example of such a program has been described previously (82). The program calculates R_2 maps on the basis of multiple TE images, using a monoexponential nonlinear least-squares fit based on the Levenberg-

Figure 4. The dose dependence of the transverse relaxation rate (R_2) as a function of dose. Data from several experiments are shown indicating reproducibility over a wide range of doses (92).

Marquardt algorithm (91). The program also creates a dose-to- R_2 calibration function by fitting a polynomial to a set of dose and R_2 data points, obtained from gels irradiated in test tubes to known doses. This function can then be applied to any other R_2 map so that a dose map can be computed and displayed.

Figure 4 shows values of transverse relaxation rates (R_2) for the gels as a function of dose. The pooled data show that the dose response was highly reproducible over a wide range of doses. The dose response is well fitted by a straight line (92).

Additional experiments have shown that the response of the BANG gel can be adjusted by varying the concentration of cross-linker used per total amount of comonomer (93). Figure 5 demonstrates the relationship of R_2 to dose for five different values of the weight fraction of cross-linker per total comonomer. Figure 5b shows that, in the linear region of gel response, the greatest sensitivity of the gel was achieved at 50% cross-linker concentration. Similar data have been shown more recently for several different polymer gel mixtures (94).

The temperature of imaging has a large effect on both the gel sensitivity and its dynamic range (93,95). Dose sensitivity ($\text{s}^{-1}\cdot\text{Gy}^{-1}$) as a function of concentration of cross-linker is plotted in Fig. 6. Sensitivity is seen to reach a maximum at $\sim 50\%$ cross-linker (as described above), but sensitivity at all concentrations increases as the temperature at the time of imaging is reduced.

Figure 7 shows that the maximum R_2 achievable, and therefore the dynamic range of the gel, is dependent on the temperature at the time of imaging. While R_2^{max} increases with cross-linking, the dependence is enhanced by cooling the gel during NMR measurement.

For a number of gel compositions presently being evaluated, the fundamental chemistry and physics of response are well understood. Several gel compositions have been characterized in great detail (82,87,92,96-98). In polymer gels, for example, it is understood that the interaction of

Figure 5. (a): Relationship between R_2 and dose for five different concentrations of cross-linker per total comonomer. (b) Lower dose region of the data from (a). (Reproduced with permission from Ref. 93.)

radiation with water produces free radicals, which trigger the cross-linking of monomers into polymer chains (81,99). The polymer chains bind water protons tightly causing a change in their paramagnetic properties that is detectable by magnetic resonance imaging (92,100). The relationship between dose and relaxation rate can be influenced by several additional factors, including accuracy of the calibration curve (101) and the aging characteristics of the gel (96,102,103).

The quality of the imaging process is affected by the homogeneity of the B_1 field (104) and the presence of eddy currents (105). Some additional complications due to the distortion of MR imaging systems have been identified (106).

Optical Scanning of Polymer Gels

Dosimetric results with MR imaging have been encouraging, but the need to use expensive and often inaccessible imaging systems renders this technique somewhat impractical. In most compositions, polymerization changes the optical characteristics, and measurements of optical density can be related to absorbed dose (85,107–111).

Optical computed tomography (OCT) of polymer gels can be conducted in a similar manner to X-ray CT. To date,

OCT has been limited to transmission measurements, although the potential exists for measurements of attenuation, fluorescence, scatter, polarization and refractive index changes (112). Optical computed tomography has been performed by several investigators (107,109–113), but in general, the techniques all require the use of a cylindrical vessel to hold the gel, a tank filled with a medium matching the refractive index of the gel, and a monochromatic light source. Several of these systems use parallel-ray geometry and filtered back projection to reconstruct the image. At least one system uses a diffuse white light and cone-beam geometry (111).

An optical imaging system employing He–Ne laser CT scanning of the gel has been described (107). The scanner operates in a translate-rotate geometry and is capable of producing stacks of planar dose distributions with pixel size and slice thickness as small as 100 μm (114).

Optical scanning of several gels has been conducted using a modified version of a 3D optical CT laser scanner that was developed recently at MGS Research, Inc. (107,108,115,116). (see Fig. 8.)

The scanner, which is PC controlled, operates in a translate-rotate geometry and utilizes a single He–Ne laser

light source and a photodiode, together with a reference photodiode to account for fluctuations of the laser output intensity. The gel is mounted on a central turntable and is immersed in a liquid that matches the gel's refractive index to minimize the loss of signal from projections at the edges of the gel. The platform on which the light source and the detector are mounted moves vertically. Isotropic resolution of 1 mm is achievable using this scanner, with scan times on the order of 8 min per plane. An image of a gel exposed to an ^{192}Ir high dose-rate (HDR) source appears in Fig. 9.

Further evaluation of an OCT system has been performed, to determine the stability and reproducibility of the system (118). In addition, characterization of gels has been performed to determine the optimum sensitivity consistent with the dynamic range of the scanner (119).

X-Ray CT Scanning of Polymer Gels

The formation of polymer chains increases the physical density of the gel, and the resulting change in attenuation coefficient can be measured by measurements of X-ray transmission, such as by computed tomography (120–125). While the change in density is small, it has been shown to vary proportionally with dose (122,126). This

Figure 9. The OCT image of a polymer gel exposed to an ^{192}Ir HDR brachytherapy source. The central region was occupied by the source during irradiation and was replaced with irradiated gel for imaging (117).

Figure 10. The CT image of several vials of polymer gel irradiated to different doses. (Reproduced with permission from Ref. 128.)

change in density leads to a small change in CT number when irradiated gels are examined with CT. Recent data show that this change can be as much as $0.2 \text{ kg}\cdot\text{m}^{-3}\cdot\text{Gy}^{-1}$ (127). An image of tubes of gel irradiated to different doses appears in Fig. 10. Methods for improving the quality of X-ray imaging have been developed, and include the acquisition of multiple images, background subtraction, and filtering (126,127).

Ultrasound Imaging of Polymer Gels

Polymerization leads to changes in elasticity of the medium, and the corresponding changes in ultrasound absorption can be exploited (129–132). Ultrasound has been used to evaluate changes in density and elastic constant of a number of materials. Several different ultrasonic parameters can be measured and these can be used to characterize materials. The most commonly measured parameters attenuation and reflection coefficients, and the speed of propagation. A pulse-echo technique using one probe or a transmission technique using two probes is used to measure these parameters. These parameters can be related to structural properties of the sample including bulk density, elastic constants as well as sample inhomogeneities.

Vibrational Spectroscopic Imaging of Polymer Gels

Finally, vibrational spectroscopy can be used to demonstrate the conversion of monomers to polymer chains (133–136). Fourier transform (FT)–Raman vibration spectroscopy of polymer gel dosimeters has been investigated as a means by which the fundamental structure and properties of the dosimeters might be better understood. Raman spectroscopy has also been used to investigate the track structures of proton beams in polymer gel dosimeters (137). This study illustrated the difficulty in using polymer gel dosimeters to extract quantitative dose maps when exposed to proton radiation. Further studies will be required to determine whether Raman microscopy can be used routinely in the evaluation of polymer gel dosimeters.

CHARACTERISTICS OF GEL DOSIMETERS

Gel dosimeters have a number of characteristics that make them attractive for radiation dosimetry (138). A novel comparison of gel dosimeters with conventional dosimetry systems has been presented in the form of a spider plot (see Fig. 11, Ref. 110). This graphical presentation illustrates the relative performance of dosimeters, such as ion chambers, film, TLDs and gels by considering such parameters as accuracy, volume measured, cost, three-dimensionality, resolution, energy dependence, and time required for the measurement. Oldham has shown that gels compare favorably with the other detectors in most characteristics, including their relative accuracy, volumetric nature, inherent three-dimensionality, high resolution and lack of energy dependence over much of the important energy range (110). Methods for characterizing the response of gels have been found, and in particular, a technique for characterizing the dose resolution has been described (89,139,140).

However, today gels are still time-consuming and relatively expensive. Several dosimetric aspects have not yet been realized, including the absolute accuracy of measurement, and the ability to render a 3D dose distribution as opposed to multiple planes of data, although progress is being made rapidly on both aspects. In addition, the issues of cost and time required are being addressed. The availability of optical CT scanning and other imaging techniques are likely to drive down the cost of gel analysis, and improve the penetration of this modality into the clinic. At the same time, newer optical CT scanners equipped with more powerful computers are faster and can perform comprehensive imaging of gels in the time previously required for a single slice.

APPLICATIONS OF GEL DOSIMETRY

Potential applications of gel dosimetry have been summarized on several occasions in the recent past (97,138,141–143) although the field is developing rapidly. Today it is considered by many that gel dosimetry has useful characteristics that can facilitate radiation therapy dosimetry, especially in situations that are not handled well by conventional dosimeters. These characteristics include the ability to measure complex 3D dose distributions; to integrate dose accurately without dependence on dose rate, at least over a fairly wide range; tissue-equivalence; high spatial resolution; and lack of energy dependence over most of the kilovoltage and megavoltage range. With most gels, data are stored permanently, making gels suitable for performance of dosimetry at remote locations (144). They also are relatively safe to manufacture and handle, although some components such as acrylamide are toxic and must be handled with appropriate protection until mixed.

Demonstrated applications of gel dosimetry to date include basic dosimetry (depth dose, penumbra, wedge profiles) in photon, electron, neutron, and proton beams; dose distributions from imaging procedures; conformal therapy, stereotactic radiosurgery, and intensity-modulated radiation therapy (IMRT); dose distributions around brachytherapy sources (low and high dose rate, and intravascular sources); internal dosimetry (^{131}I doses); and evaluation of tissue heterogeneities. The advances made recently in these areas will be discussed.

Basic Dosimetry

Gel dosimeters have the capability to record and display the dose distribution throughout a 3D volume. This ability affords advantages over conventional dosimeters, even for basic dosimetry parameters such as percent depth dose in photon and electron beams (54,92,145). Gel dosimetry has been shown to be useful to validate simple multiple-field arrangements (146) and more complex anatomical situations including tangential breast treatment (147,148), conformal therapy (149) and scalp treatment with electron beams (150). Dynamic functions, such as a programmable wedge filter are difficult to measure with ionization chambers or diodes, and film is often used to provide data in a single plane. Gels have proven useful for capturing the dose distributions from programmable wedge filters, and allow distributions in multiple planes to be demonstrated from a single exposure (151).

Dose from Imaging Procedures

More recently, the use of gels to demonstrate dose distributions from imaging procedures has been explored (152,153). In a novel experiment, a high sensitivity gel was used to determine the dose from CT imaging. The benefit of this measurement is that the dose distribution throughout a patient volume can be estimated without requiring the use of numerous point dosimeters (e.g., TLD) and without averaging the dose along a line or throughout a volume (e.g., a pencil ionization chamber). These benefits may be most apparent in evaluating the dose distribution from helical CT scanners.

Figure 12. A BANG gel irradiated with a highly conformal dose distribution produced by a Gammaknife treatment unit. The distribution can be appreciated qualitatively without the need of imaging systems or processing. (Photograph by the author. See also Ref. 161.)

Evaluation of Conformal Dose Distributions

Stereotactic Radiosurgery. Gels have been used to demonstrate the dose distributions from stereotactic treatments both from dedicated multisource cobalt units and from linear accelerators (154–161). A clear benefit of gel dosimeters is that they can display a dose distribution, especially a highly conformal one as is produced by stereotactic radiosurgery techniques, so that it can be appreciated qualitatively in three dimensions without need of imaging systems or processing (see Fig. 12, Ref. 161).

In one series of measurements, gels were prepared in glass flasks chosen for their size and shape, which was comparable to that of a human head. Additional polymer gel material from the same batch was prepared in glass test tubes, for irradiation to selected doses, to generate a dose-response curve. The gels were prepared in Guilford, CT, and were shipped to Lexington, Kentucky for irradiation and analysis (161).

A gel prepared in a 16 cm diameter flask was fitted with a radiosurgical head frame (Leksell, Elekta Corporation, Atlanta, GA), as shown in Fig. 13. This flask was also equipped with a glass rod extending to near the center of the flask, to be used as a target. The MR images were obtained and were transferred to a Gammaknife treatment planning computer (Gammaplan; Elekta Corporation), where a complicated dose distribution was planned using multiple target points. Once the plan was completed, the coordinates of the individual target points were determined, and the gel was moved to the Gammaknife irradiation unit. Treatments were delivered to each of the target points, in accordance with the treatment plan. A dose of 10 Gy was delivered to the 100% isodose line.

Dosimetric imaging of the flask and test tubes containing gel was performed between 25 and 36 h after irradiation. The flask was placed in the head coil of the imager and the test tubes irradiated for calibration purposes were placed around the flask. The images were transferred via network to a Macintosh computer, and the DoseMap program was used to compute the maps of transverse relaxation rate (R_2).

Figure 13. Photograph of a glass flask filled with the BANG Polymer Gel dosimeter. A glass rod was inserted into the gel to provide a target around which to localize the dose distribution. The flask was fitted with a Leksell stereotactic head frame. The gel is shown as it appeared following irradiation. (Photograph by the author).

A dose-response calibration curve was obtained as described earlier. Images of the gel-filled test tubes were obtained, and R_2 determined as a function of dose.

The calibration curve was then applied to R_2 maps of the flask irradiated with the Gammaknife unit. The result yielded an image of the dose distribution, as shown in Fig. 14a and 14b. As all scans were performed with the head ring and localizer box in place, the coordinates of the image plane could be determined. These image planes were located 1 mm from each of the corresponding treatment plans shown in Fig. 14a and 14b. Finally, isodose curves were drawn (by the DoseMap program) by interpolating within the measured dose distribution.

The measured dose distributions were compared with the treatment plans prepared prior to irradiation by superimposing the two data sets. The superimposed data are shown in Fig. 15a and 15b. The calculated and measured dose distributions were registered by aligning the point representing the tip of the glass rod.

The measured dose distributions compare favorably with the calculated dose distributions. In fact, the dose

Figure 14. The R_2 maps obtained from the irradiated gel (a) Distribution in the axial plane. (b) Distribution in the sagittal plane. (Reproduced with permission from Ref. 161.)

Figure 15. Composite figures showing both the treatment plan prepared using a Gammaplan treatment planning computer (drawn in black, labeled in percent of maximum dose) and isodose curves measured by the technique described in the text (drawn in gray, labeled in Gy). map taken in the plane of the target points (Fig. 14a) indicates regions of overlap not demonstrated by the treatment planning system. As shown in Fig. 15a and 15b, the measured isodose lines conform in shape quite well with the calculated data, but seem to show a shift away from the glass target rod. The dose images were obtained in planes that were shifted 1 mm from the planes of dose calculation, and this shift might account partially for the difference in size and shape of the isodose curves. However, Fig. 15a shows a shift in the lateral (X) direction away from the glass target rod, which cannot be explained by a difference in the axial (Z) coordinates of the planes of calculation and measurement. Instead, it appears more likely that the dose distribution was placed ~ 1 mm further from the glass target rod than intended.

Evaluation of Repeat-Fixation Stereotactic Radiotherapy.

In recent years, fractionated stereotactic radiation therapy has been seen as a desirable method of delivering high dose radiation therapy to malignancies of the brain. Techniques developed for immobilizing the patient have also been applied more recently to intensity-modulated radiation therapy, in which conformal dose distributions are delivered through multiple fractions to one or more target volumes. In both techniques, reproducible positioning of the patient is critical, to ensure that the target volume receives the intended dose, and normal tissues are spared to the extent determined by treatment planning techniques. The BANG gel dosimeter has been used in a fractionated regimen to demonstrate the reproducibility of multiple setups under stereotactic position methods (158).

Intensity-Modulated Radiation Therapy (IMRT). Gels

dosimeters have proven themselves to be valuable for evaluating and confirming IMRT dose distributions (146,162–169). Most investigations have been conducted in simple geometric phantoms (Fig. 16), but others have employed anthropomorphic phantoms in arrangements that allowed direct comparison with measurements using other techniques such as film and TLD (163,165,166).

Figure 16. A cylindrical flask containing a normoxic gel shortly after irradiation with an IMRT treatment. The dose distribution is clearly visible, demonstrating the change in optical density with dose. (Reproduced from Ref. 167, with permission.)

Beach developed a gel insert for an existing anthropomorphic phantom that had been developed with film and TLD dosimeters (170). The phantom design revision included converting the existing imaging/dosimetry insert from a block-style design to a cylindrical design (Fig. 17). This insert contained embedded structures that simulated a primary and secondary target volume as well as an organ at risk (OAR). An additional insert was then constructed to house the polymer gel dosimeter. This insert was specially designed using Borex plastic. Both the imaging insert and the gel insert had an image registration system incorporated into their construction.

Figure 17. An anthropomorphic head-and-neck phantom developed by the Radiological Physics Center (170) showing the modifications made to accommodate a gel dosimeter.

Figure 18. (a) A calculated dose distribution for an IMRT treatment, shown in a gray-scale format. (b) The measured dose distribution obtained from optical CT of a polymer gel, following irradiation with the treatment plan shown in (a). (From Ref. 165, with permission.)

X-ray CT images were obtained of the phantom with the imaging insert in place, and an IMRT treatment plan was developed. The phantom was then taken to the linear accelerator, the imaging insert was replaced with the gel insert, and the IMRT treatment was delivered.

A commercially available optical computed tomography (OCT) scanner (107) was commissioned for this project and future work with polymer gel dosimetry. The OCT scanner was used to image polymer gels before and after being irradiated. The preirradiation images were subtracted from the postirradiation images using a pixel-by-pixel subtraction method. The resultant images had net OD values that were directly proportional to the dose received by each given pixel. A comparison of the calculated dose distribution and the measured distribution is shown in Fig. 18.

Repeated measurements showed that a polymer gel imaged with optical CT was reproducible to within 1% (171). Repeated OCT imaging was shown to be consistent to within 1%. However, the results also showed that the techniques used to calibrate the gel (irradiation of a similar gel container with small-diameter beams delivering doses spanning the expected range) did not provide absolute dose measurements offering better agreement than 10% with the calculated data.

Duthoy compared the dose distribution measured with gels to the calculated distribution, for complex intensity-modulated arc therapy (IMAT) treatments in the abdomen (172). Vergote also examined IMAT with gels and observed a reproducible difference between calculations and measurements in low dose regions near steep dose gradients; a phenomenon also observed by Cadman et. al. and attributed to the failure of treatment planning systems to model the transmission of radiation through the rounded ends of multileaf collimator leaves (169,173).

Brachytherapy. Determining dose distributions and confirming the results of planning for brachytherapy treatment is historically difficult. No suitable methods of dosimetry have existed in the past to enable measurement and display of these 3D and complex distributions. Measurements around single sources have been possible only in a point-by-point fashion, such as with small ionization chambers or with thermoluminescence dosimeters

(TLDs), (174) or in planar fashion with film (175). These methods are quite unsatisfactory for anything other than distributions around single sources, or very simple source arrangements. In contrast, the BANG polymer gel dosimetry system has the capability to measure and display complex dose distributions from complicated source arrangements. It is necessary to immerse the applicator containing the sources into the gel, or arrange for its introduction into a catheter already placed in the gel.

The ability of gels to record and display dose distributions around a high dose rate (HDR) source was first demonstrated over a decade ago (92,176,177). Maryanski et al. showed the dose distribution around a single catheter into which a high dose rate (HDR) remote afterloader source had been positioned (178). The HDR unit was programmed to dwell the source at several locations in the catheter, to deliver an elliptical dose distribution. After irradiation, the gel was imaged with MR, and a map of the dose distribution was computed. The map is shown in Fig. 19, where the color intensity is proportional to dose. Isodose lines, determined from the dose map data, are superimposed on the intensity map. Points at which the dose was computed by the treatment planning system also are shown. Excellent agreement between the position of the calculated dose points and the corresponding measured isodose lines indicates the agreement between doses measured by the gel and computed by the treatment planning system.

More recently, measurements have been made in close proximity to HDR ^{192}Ir sources (117,179) (see also Fig. 9). These measurements have shown that complications occur when measurements are made in the steep dose gradients close to an HDR source. Polymerization of the gel causes an increase in the gel density and a corresponding decrease in the volume filled by the gel. The change in density causes shrinkage of the gel in the vicinity of the source, distorting the resulting measured distribution. Changes to the composition of the gel to increase the concentration of gelatin

Figure 19. Use of the BANG gel to measure the dose distribution around an HDR source. The source was positioned in a catheter implanted in a BANG polymer gel. The figure illustrates a comparison between the dose distribution determined from an MRI image of the gel and the calculated dose distribution. (From Ref. 178.)

can mitigate the amount and effects of the density changes. Furthermore, there are suggestions that the high dose rates found near brachytherapy sources, particularly those of HDR afterloaders, can introduce temperature gradients that influences the polymerization of acrylamide monomer gels (87,93,180,181).

Efforts also have been made to characterize low dose rate (LDR) sources, such as prostate seeds (182–184), eye plaques (185), ^{137}Cs afterloading sources (186,187) and intravascular sources (188). Studies have indicated that the diffusion of monomers (or ferrous and ferric ions in Fricke gels) across steep dose gradients can introduce errors in measurement (92,189). As the use of gels to measure dose distributions from LDR sources requires long exposure times, diffusion of monomers or ions could introduce significant errors, and gels exhibiting high diffusion rates should be avoided for these measurements.

A further problem with gel dosimetry for LDR brachytherapy has been demonstrated by recent studies indicating energy dependence at lower energies. Data show that a polymer gel dosimeter under responds to radiation in the 20–60 keV range (190). Others have shown differences in gel response from one formulation to another, and suggest that the MAGAT gel is most water-equivalent over a wide range of energies (191). Changes in mass attenuation coefficient of polymer gels during irradiation can also introduce errors in the dose distributions measured around low energy sources.

Internal Dosimetry

Gel dosimetry has shown promise in the determination of dose distributions from administrations of unsealed radioactive sources (192). The authors embedded a vial of ^{131}I into a flask of polymer gel and observed a distance-dependent change in the T_2 signal. They also mixed ^{131}I into the gel and demonstrated a change in T_2 signal that was dependent on distance from the concentration of activity. No more recent investigations have been located.

Measurement of Neutron Dose Distributions

Some developments have been reported in characterizing fast and epithermal neutron beams with gel dosimetry (193–195). Thin layers of Fricke-xylene orange gels have been irradiated in phantoms composed of insensitive gel. Adding ^{10}B or other nuclides with large cross-sections has increased the sensitivity of the gel dosimeter to neutrons. This technique has been used to determine the profiles of neutron beams used for boron neutron capture therapy. Some benefits of the use of gel dosimetry are the tissue-equivalence of the dosimeter to these energies, and the ability to separate the components of dose.

Measurement of Particle Dose Distributions

Several investigators have demonstrated the use of polymer gel dosimeters to record the dose distributions produced by proton beams (88,137,196–198). However, several authors have noticed disagreements between measurements with gels and conventional dosimeters such as diodes in the peak region of the distribution. Gustavsson has suggested that the response of gels, as they are based

Figure 20. The variation in LET as a function of depth for a monoenergetic proton beam (dashed curve, left-hand scale) and the measured relative sensitivity for the gel dosimeter (full curve, right-hand scale). Also shown is the depth dose curve for the proton beam (dotted curve), normalized to 100% at the Bragg peak. (Reproduced with permission from Ref. 198.)

on the formation of free radicals, is dependent on the LET of the radiation (197,198). As the LET of the beam increases in the peak region, the local ionization density increases. As the distance between the radicals formed in the gel decreases, the likelihood of recombination of radicals increases. A decrease in the production of radicals with increasing LET has been described previously (199). Consequently, significant differences appear between depth dose measurements with gels and those with detectors such as diodes (see Fig. 20, Ref. 198).

Jirasek et al. performed track energy-deposition calculations and raman spectroscopy and reported agreement between these techniques and gel measurements (137). Their conclusion also was that the high density of delta-ray interactions close to the track of a proton resulted in high doses being delivered to the gel. These doses saturated the response of the gel by consuming the available monomer. This effect was greater near the end of the proton range, consistent with the results of other authors.

Gels have been used also to demonstrate the dose distribution produced by ^{12}C ions (200). Similar effects associated with decreased radical formation at high LET were observed in the carbon beam.

Evaluation of Tissue Heterogeneities

A valuable feature of gel dosimeters is that they are very nearly tissue-equivalent, particularly at photon beam energies above ~ 100 keV. Previous investigations have shown that the BANG gel, the MAGIC and MAGAS normoxic gels, as well as gels based on Fricke or vinyl solutions have electron densities within 1% of soft tissue, and effective atomic numbers in the range of 7.4 (190). However, several investigators have attempted to measure the effects of nonunit density tissues on external beam dose distributions. Early measurements were performed to estimate the dose distribution behind high atomic number heterogeneities, to simulate the presence of bone (201–204). More recently, measurements have been made behind or adjacent to cavities filled with air or with lung-equivalent plastic (168). To attempt a measurement

in lung-equivalent gel, Olberg produced a foam of gel with the approximate density of lung tissue (205). Other investigators have evaluated the promise of gel dosimeters to simulate lung tissue, by introducing polystyrene foam beads into a gel mixture (206). While these measurements showed promise, there were several sources of error. First, the introduction of air, or air-containing polystyrene beads introduced the possibility of oxygen contamination. Purging the polystyrene beads with nitrogen, or using nitrogen rather than air to foam the gel addressed this problem. The introduction of air or polystyrene eliminated the possibility of evaluating the measured dose distribution by optical scanning, and MR imaging must be used. The presence of air may lead to partial volume imaging effects that could introduce errors into the measurement.

COMPLICATIONS TO BE ADDRESSED

As was suggested earlier in this article, there are a number of complications associated with gel dosimetry that remain to be addressed, and that are inhibiting the routine use of gels in the clinic. Some of these are listed below, with short descriptions of the causes of the problems, and possibilities for correcting them.

Imaging Artifacts

This article has discussed several methods of generating images of dose distributions using gels. Principal methods are MRI, OCT, and X-ray CT. Each of these imaging methods is prone to imaging artifacts, although the type of artifact and its causes are different with the different modalities. In MRI, for example, susceptibility artifacts can result from variations in the conductivity of the volume being imaged, and interference is likely when multiplanar imaging of adjacent planes is attempted. The presence of air or low-density structures can lead to partial volume effects or susceptibility artifacts.

In OCT, any structure that blocks the light beam is likely to cause a streak artifact, similar to those produced by high densities in X-ray CT images. In addition, the refraction of the light at interfaces between the gel and other materials can cause ring artifacts or distortion of the image. The artifacts found in OCT images have been described (110). An example of the artifact caused by high optical densities is shown in Fig. 21.

When X-ray CT is used, artifacts can result from the low signal to noise ratio that occurs because of the very small density differences present in the gel. These artifacts have been investigated in some detail previously (121).

Temperature Dependence

The existence of a dependence on temperature during irradiation of polymer gels was not recognized immediately, but it has since been shown that this dependence exists. Furthermore, the temperature dependence can be more pronounced for some polymer gel formulations than others. The polymerization that occurs as a result of irradiation of the gel is exothermic, and consequently can lead to a temperature rise that influences further polymeriza-

Figure 21. An optical CT scan of a normoxic gel irradiated with a low dose rate ^{125}I brachytherapy source. The high optical densities close to the source completely attenuate the laser, resulting in a streak artifact.

tion of gel in response to continuing exposure. In extreme cases, this temperature rise can exceed several degrees Celsius (207).

Oxygen Sensitivity

The sensitivity of polymer gels to oxygen has been discussed extensively, and several investigators have responded by developing gels that contain oxygen scavengers, such as the MAGIC gel (86). The oxygen scavenger removes oxygen present in the gel at the time of manufacture, even if this is done in normoxic conditions. It can remove additional small amounts of oxygen, but ultimately will be overwhelmed if exposure to normal atmosphere is ongoing. While this problem has been addressed, it still creates minor inconvenience that might limit the successful introduction of gels into routine clinical use. The characteristics of several normoxic gel dosimeters have been investigated in detail (90,208).

Tissue Equivalence and Energy Dependence

Gels, both Fricke and polymer types, compete well when compared to other dosimeters in terms of their tissue equivalence and energy dependence. In comparison to thermoluminescence dosimeters (TLD), radiographic film, and even ionization chambers, for example, gels are considerably less energy dependent and are much more tissue equivalent (209). However, under extreme conditions of photon energies below 60 keV, and LET values greater than $\sim 2.5 \text{ keV}\cdot\mu^{-1}$, gels show a dependence that remains to be fully characterized (190).

Simulation of Nonunit Densities

The benefits of gels discussed in the previous paragraph lead to the inability of gels to easily simulate nonunit density tissues. To date, limited efforts have been described to create low density gel mixtures, to simulate lung tissue. No attempts have been described to date to create high density mixtures and are unlikely to be with today's emphasis on the use of gelatin-based formulations.

Diffusion of Monomer in Steep Gradients

The diffusion of monomer, and the shrinkage of gel proportional to the creation of long polymer chains, can be addressed through the development of better gel mixtures. Avoiding small monomers such as acrylamide can reduce the rate of diffusion in regions of steep dose gradient, such as the penumbra of radiation beams (210). Employing different concentrations of gelatin might reduce or eliminate problems associated with shrinkage of gels in high dose regions. Some normoxic gels may demonstrate decreased diffusion in regions of steep dose gradient (90,208).

SUMMARY AND CONCLUSIONS

The importance of quality assurance in radiation therapy is well documented. High quality, safe, and effective radiation therapy is dependent upon the proper operation of equipment, the accuracy of alignment devices, and the dependability of dosimetry procedures. The accurate delivery of the prescribed dose depends on procedures involving dosimetry systems. Properly functioning dosimeters are necessary to assure that the equipment is properly calibrated and that treatment planning procedures are conducted correctly.

A wide variety of dosimetry systems are available to medical physicists today. Choosing the correct dosimetry system for any given application requires an understanding of the operation of the device and its appropriateness for the intended circumstances. This presentation has reviewed a number of dosimetry systems presently available, their design and operation, and some of the uses for which they are valuable.

Gel dosimetry offers the promise of accurate and convenient dosimetry under a variety of circumstances. In most of the examples discussed above, gel dosimeters offer a number of advantages over conventional dosimeters. Chief among these is the ability to measure a complex dose distribution throughout a volume with a single radiation exposure. Additional advantages include tissue equivalence, high spatial accuracy, good dose precision, and reasonable convenience.

However, gel dosimetry continues to experience little acceptance in the clinic, largely because some aspects of promise have not been achieved, and because of a perceived lack of convenience. Members of the radiation physics community are apparently not convinced that the benefits of gels sufficiently outweigh conventional dosimeters such as film and TLD. It is incumbent on those of us working with gels to encourage more widespread use, by taking every opportunity to display the results of measurements with gels.

RADIATION PROTECTION INSTRUMENTATION

Radioactive materials and equipment that generate radiation are prevalent in industry, military, education, science and medical facilities, and even in the home. Many scientific instruments perform dedicated radiation measurement tasks; the nuclear power industry employs possibly the greatest number of instruments of different designs and degrees of sophistication. This article describes similar instruments commonly used for radiation protection in medicine. Instruments used for radiation dosimetry for medical treatments (e.g., radiotherapy ionization chambers,) and those used for medical treatments (e.g., nuclear medicine well-ionization chambers) are excluded. Included are instruments used for the general tasks of detecting radiation, determining the types of radiation or species of radionuclides present, determining quantities of radionuclides, and measuring radiation levels around materials and equipment. The focus is how instruments detect radiation, not their electronic circuitry, which is described only briefly in a few instances. Before choosing an instrument, the user must know about the availability and choice of instruments, types and sources of radiation, special terms that describe quantities of radiation, and measures of biological dose equivalency that individuals receives in the presence of radiation. A science discipline, *Health Physics*, and a scientific society, the *Health Physics Society*, are devoted to these topics (1). Since the 1988 first edition of this article, major changes in medical radiation protection instrumentation include the development of the Internet for dissemination, by manufacturers and vendors, of information about instrument designs, operating parameters, and performances; improved performance and electronic circuitry using chips with complementary metal oxide semiconductors (CMOS) microprocessor technology of various types; miniaturization of computer components that reduce the weight and size of instruments; and new

definitions and terms used to describe radiation quantities and units [Note: In addition to the common prefixes of kilo- (k), mega- (M), giga- (G), milli- (m), micro- (μ), nano- (n), pico- (p), note the use of the somewhat less familiar femto- (f; 10^{-15}), atto- (a; 10^{-18}), zepto- (z; 10^{-21}), and yocto- (y; 10^{-24})] (2). Manufacturers market smaller, compact survey meters, personnel dosimeters, and specialized detectors and monitors with improved performance. We review common features of instruments, such as ionization chambers, gas-proportional counters, Geiger-Müller (GM) tubes, scintillation and solid-state detectors, other less-common detectors, and photographic films.

AVAILABILITY OF INSTRUMENTS AND INFORMATION

Table 1 lists some major companies and manufacturers of radiation protection instruments, their worldwide web Internet addresses, and their electronic mail addresses. Commercial product catalogues, usually now available on the Internet, contain a wealth of specific information on the theory and operation of instruments. This company list represents no endorsement by the author; these companies were selected because their worldwide web Internet sites provide details about common radiation protection instruments advertised for research, laboratory, environmental, security, medical, and health physics (safety and protection) applications. Basic instruments require only modest modifications for specific field applications. Table 2 contains a typical product list of medical radiation protection instruments. Instruments are regularly reviewed in Technology Monitor articles in *Health Physics* (3). One general interest group shares information regarding procedures, selection, testing, and standardization of instruments (4). Basic radiation detection principles and instrument designs are described in university level science textbooks in Health Physics curricula; comprehensive descriptions appear in Knoll (5), Shapiro (6), Turner (7), and Gollnick (8).

CHOICE OF INSTRUMENTS

A radiation field often consists of multiple types of radiation. Instruments usually must have the capability to detect particular types of radiation and produce relative or absolute measures of their magnitudes, while discriminating against other types of radiation. Often the radiation energies must be measured. Common medical uses, Table 3, include equipment radiation surveys, area monitoring, area and personnel contamination surveys, personnel dosimetry, finding misplaced radioactive materials (radioactive seeds or sources), surveying radioactive packages, air sampling, and emergency response tasks. Individuals choosing radiation protection instruments for measurements preferably should know about the radiation environment under investigation. Is it predominantly photon

Table 2. A List of Some Medical Radiation Protection Products

Air Monitors	Neutron Meters
Alarm Ratemeters	Package Monitors
Alpha Detectors	Pocket Dosimeters
Alpha/Beta/Gamma Detectors	Pocket Survey Meters
Alpha/Beta Detectors	Portable Accessories
Area Monitors	Portable Scaler/Ratemeters
Beta Detectors	Proportional Probes
Beta/Gamma Detectors	Response Kits
Connectors	Sample Counters
Counters	Sample Holders
Detector Accessories	Scalers and Accessories
Dosimeters	Scintillation Well Counting and Detection Systems
Gamma Detectors	Specialized Monitors
Geiger Counters	Specialized Portable Meters
Geiger-Müller Probes	Survey Meters
Ion Chambers	Test Equipment
MicroR Meters	Wipe Counters
Neutron Detectors	X-ray Monitors

Table 3. Some Typical Radiation Protection Instruments and Their Major Features

Type	Generic Name	Characteristics	Uses
Portable Survey Meters			
Alpha, Beta, Gamma	Ion Chamber	Air ionization chambers to detect alpha, beta, gamma, and X rays from 50 nSv·h ⁻¹ to 20 Sv·h ⁻¹ ; sliding alpha and beta shield	General purpose survey meters with large range features
Beta, gamma	Geiger Counter Rate Meters	Multiple ranges up to 60 kcpm and 5 nSv·h ⁻¹ ; uses halogen quenched GM tube; multiple attachable probes	General purpose survey meters for lower level (5 nSv·h ⁻¹) surveys
Gamma	Gamma Survey Meters	Multiple ranges to 10 μSv·h ⁻¹ ; halogen quenched GM tube with energy compensation to 40 keV	General purpose survey meter for gamma ray surveys
Alpha, (H-3), beta	Gas Proportional Survey Meter	Measures alphas, low energy beta to 500 kcpm	For measurements in presence of volatile vapor, high γ-ray fields, and for surface contamination
Gamma	Micro "R" Meter	Uses 1 × 1 in. NaI(Tl) scintillator to measure 0.1 μSv·h ⁻¹	For sensitive low level surveys of μSv·h ⁻¹ levels
Alpha, gamma	Alpha-Gamma Scintillation Counter	Measures alpha to 2 × 10 ⁶ cpm using scintillator; measures gammas to 20 mSv·h ⁻¹ using GM tubes	For simultaneous measurements of alpha-gamma contamination
Alpha, beta, gamma, neutrons, X rays	Scaler, Ratemeter, Single Channel Analyzer	Multiple ranges (1 nSv·h ⁻¹ –10 Sv·h ⁻¹ ; 1 cpm–500 kcpm) with single-channel analyzer with selected windows	For use with multiple probes of many types; measures identifies type of radiation or radionuclide
Neutrons	Neutron rem Meter	Measures equivalent dose neutrons using BF ₃ tube in a cadmium loaded polyethylene moderator	General purpose neutron detection for thermal to high energy neutrons
Personnel Electronic Dosimeters			
Gamma	Alarming Dose Rate Meter	Scintillation detector sensitive to 0.1 μSv·h ⁻¹ to 20 μSv·h ⁻¹ with multiple preset alarm levels	Medical personnel monitoring
Gamma, beta, neutron	Alarming Dose Rate Meter	Silicon semiconductor detectors; 10 μSv–1 Sv	Medical personnel monitoring
Area Monitors			
Gamma	Area Radiation Monitors	Alarming counter rate meters with adjustable alarm that sounds when exposure rates exceed preset levels. Usually have GM tube detectors	Used to monitor areas where personnel prepare and use sources; used to determine that remote control sources have retracted to a safe.
Air Monitors and Samplers			
Beta, Gamma	Beta-Gamma Air Particulate Monitor	Measure airborne particulate beta emitting particles using pancake-type GM tubes; ¹³³ Xe monitors	Alarm monitor for laboratories using radioactive gasses emitting beta particles
Well Counting Systems			
Gamma, beta	Liquid Scintillation Counting system	Counting of wipe tests from labs, sources to identify type and amount of radionuclide	General radiation control and containment
Spectroscopy			
Gamma, beta	Multichannel Analyzer with NaI(Tl) or Ge detector	Identification of radonucleides by characteristic spectral analysis	General radiation control and containment, nuclear medicine labs, research labs, and so on.

(X ray or γ ray) radiation, charged particle (proton, beta particle) radiation, neutron radiation, or mixtures thereof? Spectroscopy measurements can determine the types and energy distributions, but often measurements require simpler detection or measurement devices. The radiation environment may be characterized by the maximum energy of radiation, whether the radiation source is continuous, as with an X-ray unit, rapidly pulsed as with some

linear accelerators, or is random decay from a radioisotope. Is the measurement made in the primary direct beam, or in scattered radiation beam filtered by radiation barriers? Choice of instruments depends on why the radiation is being measured. It is desirable to know the approximate magnitude of radiation, expressed in some appropriate units, and the approximate energy of the radiation. It is then possible to estimate personnel equivalent dose rates

in the radiation field. Multiple instruments with different features may be required to properly characterize and measure a radiation environment.

TYPES OF RADIATION

Radiation is a general term used to describe the emission and propagation of energy through space or a material. Texts describing instruments describe types of radiation (5–8). Mohr and Taylor, on behalf of The Committee on Data for Science and Technology, updated, through 2002, the numerical (*Note: In the interest of better science, we present exact values as they are not widely published nor readily available!*) parameters of common radiation types (9). Radiation may be classified as directly ionizing, indirectly ionizing, or nonionizing (e.g., microwaves, laser lights, ultrasound, not further discussed here). Particulate forms of radiation (protons, electrons) possess one unit of electrical charge (160.217653 zC is the unit of electrical charge of an electron) and directly ionize atoms and molecules, as do particulate radiations with multiple charges, such as alpha particles.

Indirectly ionizing forms of radiation (X rays, γ rays, neutrons) lack electrical charge, but interact with matter and produce secondary charged particles (electrons, positrons) that ionize atoms. The magnitude of the energy possessed by the radiation, frequently expressed in millions of electron volts (MeV) and the mass of particulate radiation, expressed in atomic mass units (1 amu is defined as 1/12 of the mass of the carbon atom, and equals 0.00166053886 ykg) are important physical parameters that arise in describing the properties of radiation.

Protons have a mass of 1.007276446 amu, possess one unit of positive charge and are one of the core particles of the nucleus. Protons are heavy charged particles, that lose energy mostly by ionization and excitation of atoms as they exert electromagnetic forces on the orbital electrons surrounding the nucleus. Loosing only a small fraction of energy during each interaction, protons move through matter mostly in a straight-line path leaving in their wake ionized or excited atoms. Heavy charged particles require great energy to penetrate tissue. A 10 MeV proton has a range of ~ 0.11 cm, while a 100 MeV proton has a range of ~ 7.5 cm. Protons with several tens of million electronvolts of energy are used at research facilities with particle accelerators as probes to study nuclear structure. Neutrons with a mass of 1.008664915 amu are slightly more massive than protons, but lack charge and interact in matter primarily by collisions with protons to which they impart a portion of their energy during the collision. Neutrons are generally classified as thermal if their energies are < 0.5 eV, intermediate if their energies are > 0.5 eV, but < 0.2 MeV, and fast if it is > 0.2 MeV, but < 20 MeV. Lacking charge, neutrons are generally more penetrating in tissue than protons of the same energy and interact with atoms by elastic and inelastic collisions. Numerous radioactive sources serve as neutron generators; an alpha particle source, such as ^{241}Am , may be mixed with a light metal, such as beryllium to produce neutrons by a (α , n) reaction. Nuclear reactors are prolific neutron generators and

numerous research facilities have accelerators capable of producing neutrons. Alpha particles, usually with several million electronvolts of energy, consist of two protons and two neutrons, and appear when certain nuclides decay into more stable nuclides, such as the decay of ^{238}U to ^{234}Th or the decay of ^{226}Ra and certain daughters. While large mass and double charge prevents even the most energetic alpha particles from penetrating much beyond the most superficial layer of external tissue, alpha particles are hazardous when ingested into the sensitive epithelium of the lungs.

Electrons have a mass of 0.00054857990945 amu, a small fraction of the mass of a proton, but carry an equal quantity of negative charge. Electrons with several tens of million electronvolts of energy can be generated with electron linear accelerators and many other pieces of equipment are capable of generating less energetic, but still hazardous electrons. Electrons interacting in a material can also produce a spectrum of bremsstrahlung X rays with the maximum X-ray energy identical to the maximum energy of the electrons. These X rays are far more penetrating than the electrons. Beta particles with several million electronvolts of energy arise from the nucleus during certain radioactive decay processes. Negative beta particles, negatrons, or ordinary electrons, possess a spectrum of energies below their maximum energy. Many nuclear transformations yield multiple beta particles; a few, for example, the decay of ^{32}P to ^{32}S , yield a single negative beta particle. Positrons have the same mass as electrons, but carrying a positive charge and arise in certain radionuclide transformations, such as the decay of ^{22}Na to ^{22}Ne . Beta particles and positrons with several million electronvolts of energy are more penetrating than alpha particles and even minute quantities of radioisotopes producing these particles, such as ^{32}P , can potentially produce damaging skin burns if spilled on the skin and left unattended.

Gamma rays frequently arise when a daughter radioactive nuclide in an excited state, decays by beta particle decay, or by other modes of decay to form a more stable nuclide, such as the decay of ^{60}Co to ^{60}Ni , yielding 1.17 and 1.33 MeV γ rays. These electromagnetic rays can possess several million electronvolts of energy and, lacking charge and mass, the more energetic γ rays can penetrate deeply into tissue and other materials. Following their interaction in a medium, such as tissue, they generate ionizing secondary electrons that actually produce the damage to cells.

X rays are a form of electromagnetic radiation arising from changes in the arrangements in the orbital electrons surrounding the nucleus, yielding characteristic X rays of several tens of kiloelectronvolts (keV) of energy. Another form of X rays, bremsstrahlung, are produced when energetic electrons with energy of several million electronvolts strike high Z targets yielding X rays with very high energies. Hence, X rays can span a broad energy range, from a few fractions of million electronvolts to several tens of million electronvolts depending on how they are produced. Like γ rays, the most energetic X rays have great potential to deeply penetrate matter. The term photon is used to describe X rays, γ rays, or other form of electromagnetic energy without referring to the method of production or source of the radiation.

Nuclei of atoms, such as a deuterium, ²H, may be accelerated in highly energetic linear accelerators as a probe to study the properties of the nucleus of various elements. Because of the great mass and charge, heavy charged particles must possess several tens of million electronvolts of energy to penetrate tissue.

In addition to this limited list of types of radiation, numerous radioactive isotopes of the elements, such as ⁶⁰Co, ¹³⁷Cs, ¹³¹I, and ¹²⁵I, and many more are widely used in medicine for a host of applications. Radioisotopes, through decay, can produce alpha particles, γ rays, beta particles, positrons, and X rays and each radioisotope has a unique spectrum of radiation that allows it to be identified even in the presence of other radioisotopes. While many forms of radioactive materials are encapsulated solids, others are unsealed and as liquids or as gases, are more readily dispersed during accidental releases. Hence, radiation is a term used to refer to many different forms of particulate and nonparticulate radiations with energies from fractions of a million electronvolt to tens and hundreds of million electronvolts. Obviously, the means of detecting radiation must be specific for the types of radiations present in a specific locale.

SOURCES OF RADIATION

The most energetic X rays, γ rays, and heavily charged particles are found almost exclusively in government or

university sponsored scientific accelerator research facilities. Photons (X and γ rays) with energies as high as several million electronvolts are the most prevalent forms of radiation as equipment yielding X and γ ray are widely used in medical facilities. X-ray imaging in hospitals is probably the single most common medical use of radiation, with diagnostic use of radiopharmaceuticals next in importance. Beta particle sources and electron producing equipment are the next most prevalent sources of radiation. Neutron producing sources and equipment are frequently found in university research laboratories but are less common in medical facilities.

RADIATION QUANTITIES AND UNITS

Radiation protection definitions and terms often lack clear meanings, as noted by Storm and Watson (10). International commissions make recommendations, but national councils and regulatory bodies in different countries (or even within the same country) adopt or apply the recommendations differently (11). As radiation quantities and units, Table 4, are used on instrument displays, users must understand both historical and newly adopted radiation units. Gollnick offers a useful review (8). We limit this discussion to popular historical quantities and units and provided brief, albeit, limited descriptions of current quantities and units recommended by the International Commission on Radiological Protection, Systeme International

Table 4. International Radiation Concepts and Units^a

Concept	Quantity	Symbol	SI unit	Numerical Value	Relationship to Other Concepts
Ionization of air by X and γ rays	Exposure	<i>X</i>	None	1 R = 0.000258 C of charge released per kilogram of air	
Kinetic energy released per unit mass of material	kerma (collisional)	<i>K</i> _{air} ^{col}	Sv	1 Gy of energy transferred per kilogram of material	<i>K</i> _{air} ^{col} = <i>XW</i> / <i>e</i>
Absorption of energy in a material	Absorbed dose	<i>D</i>	Gy	1 Gy = 1 J of energy absorbed per kilogram of material	<i>D</i> = <i>X f</i> _{med}
Risk of biological energy for different forms of radiation	Radiation weighting factor ^{b,c}	<i>W</i> _R	None	X rays, γ rays, beta particles = 1; Thermal neutrons, high energy particles = 5; Alpha particles, fast neutrons = 20	
Equivalent biological effect in humans	Equivalent dose ^d	<i>H</i> _T	Sv		<i>H</i> _T = $\Sigma W_R D$
Total (50 y) cumulative dose to an organ for internal radiation	Committed ^d equivalent dose	<i>H</i> _T (50)	Sv		
Reduced risk of partial body exposure to radiation	Tissue weighting factor ^c	<i>W</i> _T	None	Skin, bone surface = 0.01; bladder, liver = 0.05 colon; stomach = 0.12 gonads = 0.20	
Sum of weighted equivalent doses of partial body exposures	Effective dose ^d	<i>E</i>	Sv		<i>E</i> = $\Sigma W_T H_T$
Sum of weighted total (50 y) cumulative doses to organs from internal radiation	Equivalent dose	<i>E</i> (50)	Sv		<i>E</i> (50) = $\Sigma W_T H_T$ (50)

^aFor complete concepts, definitions, and descriptions, see Refs. 11, 13 and 14.

^bThe equivalent concept, Q, albeit with different values, is used in the United States by the National Council on Radiation Protection Units and the Nuclear Regulatory Commission.

^cFor complete list of *W*_R, *W*_T, see Refs. 11–13.

^dSimilar, but different nomenclature is used in the United States by the National Council on Radiation Protection and Units and The Nuclear Regulatory Commission.

d' Unites, and the International Commission on Radiological Units and Measurements (11–13).

Counts (events) or count rates (events per unit time) are denoted on instruments that detect the presence and relative magnitudes of radiation. Count rates of a few counts per minute (cpm) to millions of cpm are possible, depending on the radiation field intensity.

Exposure, denoted by the symbol, X , is the measure of the ability of X and γ rays of energies 10 keV to < 3 MeV to ionize air and is the quotient of $\Delta Q/\Delta m$, where ΔQ is the sum of all charges of one sign produced in air when all of the electrons liberated by photons in a mass Δm of air are completely stopped. Exposure is expressed in a special unit, the Roentgen (R), equal to 258 μC of charge per kilogram of air at standard temperature and pressure. As with count rates, exposure rates generally vary from $\sim 5 \mu\text{R}\cdot\text{h}^{-1}$ associated with natural background radiation to nearly $1 \text{ MR}\cdot\text{h}^{-1}$ in a linear accelerator X-ray beam. Because of its historical use in science and medicine, exposure remains popular even though its continued use is not recommended in the Systeme International d' Unites (14).

Kinetic energy released per unit mass of material, denoted in lower case, by the acronym, kerma, is a measure for indirectly ionizing radiations (photon, neutron) interacting in a material, of the total kinetic energy of all charged particles released per unit mass of material. Kerma possesses a collision component from the kinetic energy imparted by inelastic collisions with electrons and a radiation component (usually much smaller) from interactions with nuclei. For X rays absorbed in air, collision kerma in air is the product of exposure and the average energy, \bar{W} , required to produce an ion pair per unit electrical charge. Kerma is measured in gray (Gy), which is one joule (J) of energy released per kilogram (kg) of the medium. Turner offers a complete description of kerma and its relationship to other quantities (7).

Absorbed dose, denoted by the symbol D , is a measure of the amount of the released energy that is absorbed in the medium per unit mass of the medium. Under conditions of charged-particle equilibrium, with negligible energy loss, absorbed dose equals kerma. One joule of energy absorbed per kilogram of the medium, the gray, is widely used in medicine as a measure of absorbed dose, as is the submultiple, the centigray (cGy), 1/100th of a gray. The older special unit (now abandoned) of absorbed dose, rad, an acronym for roentgen absorbed dose, represents 0.01 J of energy absorbed per kilogram of the medium ($1 \text{ Gy} = 100 \text{ rad}$).

The absorbed dose in a medium may be determined from the exposure in air at the same point in the medium by multiplying the exposure by a conversion factor, f_{med} that converts the exposure in air to dose in the medium. The factor, f_{med} , is slightly < 1 for most biological materials, except bone, where values as high as 3 occur for the soft X rays in the diagnostic energy range.

Different types of radiation produce different degrees of biological damage when the same amount of energy per unit mass is deposited in the biological system. The radiation weighting factor, w_R , which replaced an older similar concept, quality factor, Q (now abandoned) is a measure of this phenomena (11). Radiation weighting factors of unity, Table 4, are assigned to most electrons, X and γ rays, while

factors as high as 20 are assigned to alpha particles and fast neutrons. Hence, the biologically equivalent effect in tissue of the absorption of 1 Gy of alpha particles is 20 times more severe than the absorption of 1 Gy of 1 MeV γ rays.

Equivalent dose, usually denoted by the symbol H_T , is the term used in radiation control programs to monitor and record the biological equivalency of exposure to amounts of radiations of different energies that an individual has received. The equivalent dose in sievert (Sv), the product of the absorbed dose, D , in gray and the radiation weighting factor, w_R , is commonly used to express the biological equivalency of absorbed doses of particular types and energies of radiation. Historically, this equivalency was expressed in the special unit, rem (now abandoned) an acronym for roentgen equivalent human. As the f_{med} factor and radiation weighting factors, w_R , ~ 1 for most photon energies commonly encountered in many situations, the units for kerma (Gy), absorbed dose (Gy), and equivalent dose (Sv) are nearly numerically equivalent and are often used interchangeably, as were the older abandoned special units, R, rad, and rem. Table 4 summarizes these relationships.

Committed equivalent dose, usually denoted by the symbol $H_T(50)$, in sieverts, is employed to consider exposure within the body from internally deposited radioactivity. It represents the total cumulative dose delivered over 50 years to an organ system by ingested radioactivity.

Effective dose, usually denoted by the symbol E , considers the consequences of partial body radiation exposure (11). Tissue weighting factors, w_T , account for the reduced effects that occur when only a portion (or organ system) of the body is irradiated. Values for w_T (Table 4) range from 0.01 for bone surfaces to 0.2 for the gonads. The effective dose, E , in sieverts, is the sum, over the body, of the products, $w_T H_T$ for each partially irradiated portion of the body.

Committed effective dose, usually denoted by the symbol, $E(50)$, in sieverts, is employed to consider exposure from internally deposited radioactivity. The committed effective dose, $E(50)$, is the sum, over the body of the products, $w_T H_T(50)$, for each partially irradiated portion of the body > 50 years.

For individuals experiencing both external and internal radiation exposure, methodologies exist (omitted here) to combine effective dose and committed effective dose to estimate cumulative risks from both types of exposures (8).

Activity, denoted by the symbol A , describes an amount of radioactivity, expressed in decays per second (dps). One becquerel (Bq) equals one decay per second. The curie (Ci), the original term used to describe an amount of activity, equals 37 Gdps. Trace amounts of radioactivity are generally expressed in the microcuries (μCi) quantities and laboratory cleanliness standards are often expressed in picocuries (pCi) or smaller amounts. One becquerel equals $\sim 27 \text{ pCi}$. Activities of millions of curies are commonly found in power reactors while curie and millicurie (mCi) quantities of materials are commonly used in medical applications.

COMMON FEATURES OF INSTRUMENTS

Radiation protection instruments in a facility can be broadly categorized as those (e.g., area monitors, personnel

scanners) used in fixed locations and those (e.g., GM detectors, survey meters) moved for use in multiple locations. Fixed instruments usually are large, heavy, and use permanent electrical power. By design, they may have more features and offer more sensitive detection or measurement features than their portable counterparts. Portable instruments generally are small, lighter, and battery powered. Some feature tripod stands for temporary uses of long duration. Instruments may be categorized as those that detect or measure a quantity of radiation and those that grossly or specifically identify types of radiation or radionuclides. Instruments of all types usually feature multiple signal ranges because of the wide variations in the signal (counts, exposure, dose, etc.) monitored. The number of photons or particulate forms of radiation from a sizable radioactive source or large piece of equipment frequently varies inversely (or approximately so) as the square of the distance of the finite size detector from the radiation source and multiple signal ranges, usually in multiples of 3 or 10, are required to map the spatial variation of the radiation around the source or equipment that will vary from the highest signals measured very near the source to the smallest signal measured at distances far from the source of radiation. Current devices often feature auto-zeroing and auto-ranging of scales. Instrument scales indicate the magnitude or measure of the radiation detected. Often, more than one unit will appear on the scales, or users may electronically select from multiple choices of units. Some instruments feature a rate mode, usually per second, minute, or hour or integrate mode that sums the signals over some predetermined time periods. Instrument scales may only be correct for specific radiation conditions under which the instrument was calibrated. Instruments can yield incorrect readings when used under noncalibrated radiation conditions.

Efficiency of a device is a measure of the number of output parameters (counts, pulses, etc.) produced relative to the number of input parameters (γ rays, particles, etc.) producing the output. Efficiencies (absolute, intrinsic, relative, etc.) have technical definitions beyond the scope of this article. Different applications require instruments with different degrees of efficiency, but, generally, high efficiency is desirable.

Signal accuracy is highly variable and depends on the type of radiation monitored and the design of the instrument. The more intense and hazardous the radiation field the greater the necessity for more accurate measurements. Conversely, measurements in very low level radiation fields need not be as accurate as the risk presented to personnel is roughly proportionately less. For example, ionization chambers used as survey meters will be calibrated to be accurate to 10% at the one-third and two-thirds of full-scale deflection while GM counters may only be 50% accurate over their full-scale range. An instrument should provide precise reproducible readings. Instruments need to reproducibly repeat measurements at the same locations when used repeatedly in the same radiation fields. Portable instruments often feature rugged weather-proof designs with lightweight features, such as ergonomic antifatigue handles to facilitate outdoor use for long times. Individuals with various skill levels frequently use

instruments; some personnel use instruments infrequently. In both situations, instruments subsequently suffer some misuse and abuse. Hence, simplicity of use is a highly desirable feature. Instruments should be designed with a minimum of controls or knobs to be adjusted, On, Off, and Battery Check switch positions must be clearly indicated and any scale selection switches should be labeled in an unambiguous manner. Some instruments feature audible signals whose intensity is proportional to the magnitude of the radiation signals. Such a feature often is useful on the most sensitive scale, but may be undesirable on the higher ranges; hence, usually the audible signal is switch selectable and may be turned off when desired. Potentiometer controls necessary during calibration adjustments and voltage setting control should not be so accessible that they can be easily changed. Such controls often are recessed or located on a rear panel so that they can only be changed in a deliberate manner. While every instrument will not possess all of the features discussed here, this discussion has included those found most commonly.

Compact, lightweight designs are easily achieved using microprocessors, liquid-crystal displays, modern CMOS electronics, and phenol, or acrylonitrile-butadiene-styrene (ABS) plastic cases. Some devices feature automatically backlit displays in low ambient light conditions. Current instruments frequently are available with either digital scales or analog scales; some offer both displaying a digital reading and an analogue bar graph emulating analogue meter movement. While digital scales are usually easily read in a constant radiation environment, they are inappropriate in rapidly changing radiation fields as the signal changes rapidly and rapidly changing digital readouts are difficult to read and interpret. For these situations, a freeze mode indicates a peak reading.

The radiation detector may physically be in the instrument with the associated electronics necessary to process the signals, connected to the counting electronics by a cable, or feature a remote reading capability, allowing the observer to stay in an area where radiation exposure is minimal. A cable connection is common in applications where the observer is physically in the radiation field monitored. Cable connectors, with instrument displays of the probe connected, allow the use of multiple probes or detectors (GM tubes, neutron probes, proportional counters, scintillation probes) with different features with a single count rate meter. Instruments with built-in detectors are free of cable problems, such as the loss of charge by poor cable insulation. Many devices feature an RS-232 interface or a universal serial bus (USB) cable that can connect to a computer; data software packages allow data retrieval, time-date stamps, or use parameter selections, such as programmable flashing displays and audible alarms, or measurements for specific applications. Some instruments feature data logging, the sequential capturing of hundreds or thousands of data points under different measurement conditions. Data captured by the instrument can be downloaded, by cable connection or by via infrared (IR) communication, to a personal computer for processing with a numerical spreadsheet (3).

Generally, instruments feature a battery check (a known scale deflection on an analog device or a brief

audible tone or indicator lamp on a digital device) that allows the user to determine that the battery possesses enough charge to operate the instrument successfully. Voltage stability is important; many instruments feature two power supplies, one for the counting electronics and another for the constant voltage required across the detecting volume. Currently, multiple 9 V alkaline batteries are widely used, providing 100–500 h of operation. The voltage across the detecting volume is usually required to be the most stable. A small variation in this voltage can lead to large changes in the observed signal, depending on the design and mode of operation of the instrument. Voltage stability of 0.1% is usually required for the voltage across the detector in most radiation detection instruments.

A zero check allows the zero point on the scale, previously set to zero in a radiation free environment, to be checked in the presence of radiation. Some devices feature auto-zeroing scales. Some instruments have an attached constancy source, a minute quantity of radioactive material, such as 0.06 μCi of ^{238}U or 10 μCi of ^{137}Cs , which, when placed on or near the detector in a predetermined geometry, yields a predetermined signal on the most sensitive range. Proper instrument use requires all three items, battery function, zero point, and known response, to be checked prior to each use. A reduced signal or complete loss of signal from the radiation protection instruments is particularly dangerous because the user falsely concludes that little or no radiation is present.

Radiation detectors generally are designed either to monitor individual events (counts) or pulses or to integrate (sum) counts or pulses that occur in such a short time interval that they cannot be electrically separated. In pulse mode, individual events or signals are resolved in 1 μs , 1 ns, or even smaller time intervals. In integrate mode, the quantity measured is the average of many individual events in some very short time period. Some devices feature signal integration when the device is used in a rate mode.

Response time of an instrument measures how rapidly an instrument responds to the radiation detected. The response time is short (fractions of a second) on the higher multiple scales and becomes longer (several seconds) as the scale multiple decreases with the longest resolving times occurring on the most sensitive scale. The response time (T) is called the time constant, and is proportional to the product of the resistance (R) of the electronic counting circuitry and its capacitance (C). (Fig. 1). Many instruments feature a slow response switch that allows electronic averaging of a rapidly varying scale signals.

Energy independence is desired for most radiation survey instruments, such as ionization chambers and GM counters; the signal is independent of the energy of radiation detected, but is proportional to the magnitude (counts, exposure, etc.) of the radiation field being monitored. However, many instruments exhibited a marked energy dependency at lower X or γ ray energies; the signal varies as the energy of the radiation varies even a constant magnitude radiation field (Fig. 2). Knowledge of the energy dependency of an instrument and of the approximate energy of the radiation field to be monitored is essential in properly using a radiation detector. Whether the signal from the

Figure 1. Simple schematic of a gas-filled ion chamber. A voltage (V) is maintained across the central wire anode (An) and chamber wall cathode (Ct). An incident (γ -ray (G)) produces ion pairs; they move to the anode and cathode producing a pulse in the circuit containing a resistor (R) and capacitor (C).

instrument is higher or lower than it should be relative to the signal observed at its calibration energy depends on many parameters. Calibration of radiation detectors is required annually for some regulatory agencies; instruments usually display a calibration sticker indicating the most recent calibration date, the calibration source, or sources if several were used to obtain energy response of the instrument, the scale readings obtained (often in $\text{mSv}\cdot\text{h}^{-1}$, $\text{mR}\cdot\text{h}^{-1}$, or other multiples, or cpm), and the accuracy and precision of those readings, expressed as a percentage of the scale reading, any necessary scale correction factors to be used specific scales, and instrument response to a reference source containing a minute quantity of radioactive material. By performing a battery check

Figure 2. Typical relative response versus incident photon energy (keV): (A) is the ionization chamber; (B_1) is a Geiger counter with thin window shield closed. (B_2) is a Geiger counter with thin window shield open.

or by observing that the battery condition is acceptable by the absence of a low battery indicator, a zero-scale reading check, and meter response check using a reference source, the user can determine that the instrument is operating correctly before use. Moreover, the average energy of radiation at a particular location in an area is highly dependent on the relative amounts of primary and scattered radiation present and frequently varies within an area. Energy dependency is, of course, advantageous when it is desirable to measure the energy spectrum in addition to determine the intensity of radiation.

Some instruments are environmentally sensitive; graphs or tables providing correction factors as a function of temperature, pressure, and humidity indicate the degree to which the signal is altered by environmental conditions. For instruments with the detector volume open to the air, corrections based on thermodynamic gas laws for the mass of air present in the detector are employed.

Excessive humidity can cause incorrect instrument readings. Humidity can cause leakage of current in cables, at electrical contacts, and at other locations in the electronic circuitry. Usually, an instrument will require a warm-up time of 1–2 min or longer. Proper warm-up allows electronic circuitry to stabilize and yields more stable and reproducible signal readings.

Strong radio frequency (RF) fields associated with some equipment generating radiation can cause improper signals in some radiation measurement instruments. The susceptibility of the instrument to strong rf fields will usually be discussed in the user's manual.

Many radiation protection instruments exhibit geotropism, orientation (gravitational) dependency, or angular dependency because radiation incident from the sides and rear of the instrument are attenuated more by metal casing surrounding the counting electronics than radiation incident on the sensitive detecting volume. The proper orientation of the instrument for measurement in a radiation field and the degree of angular response will be indicated in the users manual or on the calibration certificate.

As previously noted, some devices are designed to identify different types of radiation or to identify species of radionuclides. Many detectors will feature a thin detection window of only a few milligrams per square centimeters of thickness protected by a thicker filter, a sliding, or rotating shield, that allows the least energetic forms of radiation, such as soft X rays and alpha and beta particles to be detected through the thin window when the thicker filter is removed. Conversely, with the shield in place alpha and beta particles are discriminated against and only higher energy radiations are detected. Other windowless detectors are designed to detect the low energy radiation by flowing a radioactive gas through the detector.

Radionuclide identification requires spectroscopy, the identification of the characteristic radiation spectra of multiple radionuclides each in the presence of others. Resolution is the measure of the abilities of devices to distinguish a single energy in multiple energy radiation spectra. Different applications require instruments with different degrees of resolution. Spectroscopy formerly was limited to using heavy fixed laboratory-based NaI(Tl)

detectors or Ge(Li) detectors often with a multichannel analyzer to quantify and identify radionuclides in test samples. Currently, in-field spectroscopy can be performed with small handheld or portable NaI(Tl)-based detectors or with portable high purity germanium (HPGe) detectors that allow radionuclide identification of the most common radionuclides.

IONIZATION CHAMBERS

The ionization chamber (Fig. 1) consists of a cavity, frequently cylindrical, with a positively charged central electrode (anode) insulated from the chamber walls (cathode) at negative potential. The direct reading pocket dosimeter, with an external dosimeter charger (Fig. 3) is a simple ionization chamber. When fully charged, an internal quartz fiber, visible under a magnification lens, is deflected to a "zero" reading. As the dosimeter is irradiated, the charge is reduced proportionally to the amount of radiation received. Older pocket chambers are being replaced with personnel detectors or monitors with more electronic versatility. As a survey meter, an external power source (Fig. 1) provides the voltage potential; a resistor and capacitor in parallel (or equivalent electronic circuitry) are used to collect the charge produced when ionization occurs in the chamber. The ionization chamber electrode polarity may be reversed for special applications. Incident X or γ rays interact in air or a tissue equivalent gas, producing positive and negative ions in the chamber. If the voltage is sufficiently high to prevent recombination, that is, the positive and negative ions rejoining before they reach the charged surfaces, the negative ions will be attracted to the central electrode and the positive ions will be collected on the chamber wall. The collected charge flows to the capacitor and one electronic pulse is detected in the counting circuitry. In open air chambers, the filling gas is air at ambient temperature and pressure and appropriate corrections to the charge collected may be required as previously discussed.

Historically, ionization chambers were designed to measure exposure (R); newer instruments may offer equivalent dose readings (Sv or their submultiples) (Fig. 4). The walls of the chamber must be sufficiently thick for electronic equilibrium to be established, that is, the number of electrons entering and leaving the cavity is the same and the chamber walls are sufficiently thick to stop any electrons arising from the interaction of the radiations with the gas or in the chamber walls. Moreover, the chamber walls are usually designed of air equivalent materials. Sealed ionization chambers may be filled with a tissue equivalent gas and usually are designed to measure collision air kerma. The chamber size must be small relative to the dimensions of the irradiating beam so the chamber is uniformly irradiated. Typical ionizing voltages required across the sensitive detecting volume are ~ 150 – 300 V (Fig. 5), sufficiently high to prevent recombination of the positive and negative ions, but not high enough to cause additional ionizations that amplify the signal. Ion chamber currents are low, usually 1 pA or 1 fA. A $10 \text{ mSv}\cdot\text{h}^{-1}$ γ ray field yields ~ 1 pA; extraneous currents must be minimized in order to

Figure 3. Personnel dosimeters. measure such a small current. Electrical leakages can occur across lint, dust, or loose conductive materials between interior conducting surfaces. Cable connections can exhibit greater leakage current in high humidity. A guard ring design in some chambers minimizes leakage and polarization currents that arise after the collection

potential is initially turned on. The insulator between the outer and inner electrodes is divided into two segments with the conductive guard ring in between; any leakage current through the insulator is collected and prevented from contributing to the true current. The currents from ionization chambers are normally measured using a potential drop across a high resistor or a rate of charge method. The small currents from the ion chamber are amplified by a vibrating reed electrometer. The amplified

Figure 4. A portable ionization chamber survey meter (Cardinal Health; Invision, Model 451). The display shows the features during the initial check phase immediately after turning on the instrument.

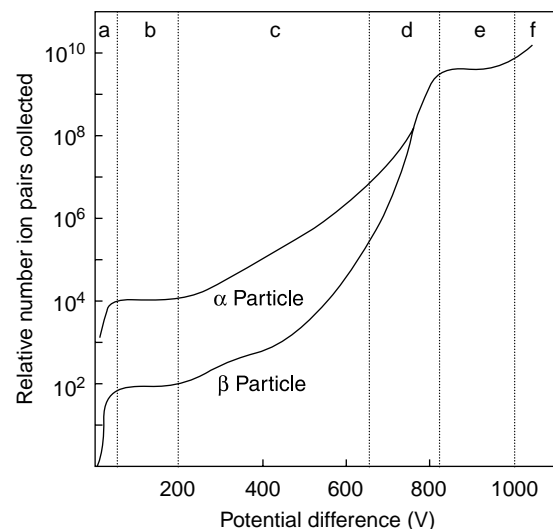

Figure 5. Voltage dependence of a gas-filled cylindrical ionization chamber: (a) Voltage is insufficient to prevent ion recombination. (b) Ionization chamber voltages are sufficient to prevent recombination. (c) Proportional counter voltages, the number of secondary ion pairs is proportional to the number of primary ion pairs. current passes through a precision resistor and the voltage drop across the resistor is proportional to the current. If collected on a capacitor, the rate of charge collected on the capacitor is proportional to the current. This latter method is used for smaller current measurements while the former is used in ionization chambers designed for more rugged use.

Ionization chambers normally exhibit good energy independence (Fig. 2) over a large energy range, and this makes them useful for measurement of X or γ rays with energies from ~ 7 –1000 keV and for measuring low ($1 \mu\text{Sv}\cdot\text{h}^{-1}$) to high ($10 \text{ mSv}\cdot\text{h}^{-1}$ or higher multiples) dose rates. Open-air ionization chambers are less useful for low dose rates of $< 1 \mu\text{Sv}\cdot\text{h}^{-1}$. Pressurized (up to 8 atm) ionization chambers allow accurate measurements $< 1 \mu\text{Sv}\cdot\text{h}^{-1}$. Properly modified ionization chambers, with sliding shields, may be used to monitor alpha, beta, and neutron radiation. For example, an ion chamber with boron on its interior chamber wall or containing boron gas may utilize the high cross-section of boron for neutrons and the subsequent ^{10}B , ^7Li reaction, and the chamber will detect neutrons using the subsequent alpha particles from this reaction.

GAS PROPORTIONAL COUNTERS

Gas proportional counters (Fig. 6) have similar design features as ionization chambers, but employ higher voltages between the central electrode and the chamber walls. The typical operating voltages of 300 up to 1000 V (Fig. 5) are sufficiently high that, following an ionizing event in the chamber, the positive and negative ions generate additional ionizations so that the number of ions from the initial ionizing events are multiplied ~ 1 thousand to 1 million times. The resulting signal is proportional to the energy deposited by the initial number of ionizing events. Propor-

tional chambers can be used in either the pulse or integrate mode, but the pulse mode is used most commonly. They are capable of detecting individual ionizing events. Because of amplification, the current from proportional chambers is much higher than those from ionization chambers. As the signal from a proportional current is dependent on the operating voltage, a highly stable power supply is required. The choice of detector gas in thin-window proportional counters depends on the type of radiation to be detected. For counting alpha particles, helium or argon gas frequently is used. For counting beta particles, a high multiplication gas is required, such as methane (CH_4) or a mixture of a polyatomic gas and a rare gas, such as argon. The gasses also help make the proportionality of the chamber more independent of operating voltage. Proportional counters are generally cylindrical in shape and the central electrode is a very fine wire of uniform diameter as any variation in the electrode's diameter causes small variations in the resulting signal. Gas (often a mixture of 90% argon and 10% methane) flow proportional counters usually have a sample of the radioactive material flow through the chamber. Either 2π (180°) or 4π (360°) solid geometries are used, and these systems are very useful for counting low energy beta particles, alpha particles, or very low energy photons. Proportional counters are useful for spectroscopy (energy determination) measurements.

Proportional counters have the ability to discriminate between alpha and beta particles by discriminating between the magnitudes of the signals produced. Gas proportional counters may be used to measure fluence or absorbed dose.

When neutron spectra are poorly known, neutron rem meters are used to estimate the equivalent dose for fast neutrons. Older style neutron detectors consisted of a proportional counter either lined with boron or filled with boron trifluoride gas; the boron has a high capture cross-section thermal neutron detector. The subsequent charged

Figure 6. Portable gas proportional counter with alpha probe (Technical Associates, Model PUG-7A).

Figure 7. Portable neutron survey meter (Cardinal Health, Inovision, Model190N). (Courtesy Cardinal Health.)

particles (alpha particles) from this reaction are readily counted. Current neutron detectors use ^3He as the fill gas and detect both the proton and tritium, ^3H , from the subsequent reaction (Fig. 7). Fast neutrons can be moderated in several centimeters of high density polyethylene to thermalize the neutrons for detection by the methods described. Olsher et al. (15) described recent improvements in neutron rem meter instrumentation.

GEIGER-MÜELLER COUNTERS

If the voltage on an ion chamber is increased to ~ 900 – 1000 V (Fig. 5), the proportionately exhibited at lower voltages is lost. Each initial radiation interaction in the walls or gas of the detector results in complete ionization of the gas in the detector. Interactions in the detector are spatially dependent, but generally, the following sequence occurs. Electrons produced following the initial ionizing event lose energy as they drift toward the anode. They lack enough energy to produce secondary ionization until they approach the anode when secondary ionization begins to occur. This secondary ionization builds up rapidly producing an avalanche of electrical charge in the detector. These processes reduce the potential difference between the central electrode and the chamber walls and the avalanche terminates. Once the necessary ionizing potential is reestablished, the detector is ready again. One undesirable aspect of the movement of the positive ions to the cathode and their resulting collisions with the cathode causes additional electrons to be ejected from the cathode. These additional electrons are undesired and may be controlled by manufacturing a tube containing a quenching and a filling gas. Organic quenching gases, such as ethanol or ethyl formate, are depleted by this process. An inorganic filling gas, such as chlorine,

recombines to provide a continuous supply (8). The energy of the undesired electrons dissociates these organic molecules rather than starting new avalanches in the tube. The number of organic molecules available for quenching limits this method of quenching. An alternative method uses halogen gases, usually bromide or chlorine. The extra energy of these electrons is used to disassociate these halogen molecules. As opposed to the organic molecules, halogen reassociates so that the same atoms are available again to continue the process.

Geiger-Müller tubes generally are used as pulse-type detectors of radiation. Their response is a function of the intensity of the radiation field. The movement of the positive ions to the cathode, previously described, requires from 100 to 200 μs and during this time interval the GM tube is unable to respond to other radiation interactions, have not recovered (reassociated) and are unable to resolve additional events (7). In very intense radiation fields, the relative long resolving times of GM tubes creates periods in which the tube is insensitive to radiation events; the GM tube may not respond to radiation, giving a false zero or low reading when an intense field is present. However, GM tubes are excellent as very sensitive detectors of X and γ rays in low level radiation fields. Commercial manufacturers offer at least three different GM tubes designs (Figs. 8,9) for specific applications. Pancake probes, with covers only a few milligrams per centimeter squared thick, allow the detection of alpha particles > 3.5 MeV, beta particles > 35 keV, and γ -rays > 6 keV, while thin end window probes detect alpha particles > 4 MeV, beta particles > 70 keV, and γ rays > 6 keV (Fig. 8). Some pancake-type probes (Fig. 9) feature removable tin and copper filters ~ 3 mm thick that allow energy compensated exposure rates measurements. Energy-compensated GM probes feature a design that reduces response energy dependency so that it responds more like an ionization chamber (Fig. 5). Geiger-Müller instruments are basically count rate meters, but may be calibrated in exposure rate for a specified energy of photons. Use of the meter in other energy spectrums different from the calibration spectrum invalidates the meter reading in $\mu\text{Sv/h}$ and mSv/h , but still the instrument allows the detection of radiation in the count rate mode.

SCINTILLATION DETECTORS

Luminescence is a physical process in which a substance, a scintillator, absorbs energy and then reemits the energy in the visible or near visible energy range. Prompt scintillators that deexcite in 10 ns following luminescence exhibit many useful properties as radiation detectors. For every photon or particle detected, a single pulse is normally counted and the size of the pulse generated is related to the energy deposited by the radiation interacting in the scintillator. Scintillators exhibit great sensitivity and yield high count rates. They can measure fluence, exposure, or absorbed dose if calibrated for the energy range of interest. Moreover, their exceptional sensitivity allows measurement of radiation rates at or near background levels, such as $1 \text{ nSv}\cdot\text{h}^{-1}$. Solid inorganic scintillators includes sodium

Figure 8. Portable GM counter (top; Ludlum Measurements, Inc. Model 14C) with an open side-window probe (left; Ludlum Measurements, Inc. Model 44-38), an end thin-window probe (center; Ludlum Measurements, Inc., Model 44-7), and a pancake probe (right; Ludlum Measurements, Inc., Model 44-9).

iodide crystals with trace amounts of thallium, NaI(Tl); cesium iodide with thallium, CsI(Tl); cesium fluoride, CsF; zinc sulfide with silver, ZnS(Ag); and bismuth germanium oxide, BiGeO, also known as BGO. The trace amounts of impurities in these inorganic salt crystals serves as luminescent process activators that promote the efficient conversion of the incident radiation energy into light. The scintillator crystal is connected to a photomultiplier by direct contact or through a light pipe. The crystal and photomultiplier must be encased in a light tight case to prevent light leaks. Typical crystals are cylindrical, ~ 1 in. (2.54 cm) diameter by 1 in. (2.54 cm) thick, but larger sizes (Fig. 10) are available for more sensitive measurements. The resulting photomultiplier signal is amplified by the

associated counting electronics. Detectors with thin windows are available for the detection of low energy X rays and energetic beta particles. Inorganic solid crystals are relatively dense and reasonably efficient for detecting higher energy photons (Fig. 11). However, they are also hydroscopic and to protect them from absorbing moisture are encased in light reflecting cases that promote good efficiency. Organic crystal scintillators produce their light by a molecular process. Anthracene and transiblene are the most widely used organic crystal scintillators. Incoming radiation excites electrons to higher energy levels of vibrational states; the electrons subsequently decay with a release of energy. Organic liquid scintillators are formed by dissolving organic scintillators in liquid organic

Figure 9. A counter (center; Cardinal Health; Victoreen, Model 190) with an energy-compensated sliding window GM probe (left; Cardinal Health; Inovision, Model 90-12), a pancake detector with filters (center; Cardinal Health; Inovision, Model 489-118FS), and a 1 × 1 in. NaI(Tl) detector (right; Cardinal Health; Inovision, Model 425-110).

Figure 11. A γ -counter system with a 1 × 1 in. (2.54 cm) NaI(Tl) detector to identify and measure γ rays. (Canberra; Packard, Model Cobra II Auto-Gamma.)

solvents, such as xylene, toluene, and phenylcyclohexane. A wave shifter fluorescent material shifts the wavelength of the light from the main solute to a longer wavelength and lower energy, so that the wavelength more closely matches the spectral response of the photocathode. Liquid organic scintillators are widely used because the sources of ionizing radiation can be dissolved into the solvent and made a part of the scintillator solution. Low energy beta emitters' tritium, ^3H (19 keV), and ^{14}C (156 keV), are counted with high efficiency by these methods (Fig. 12). Modern pulse processing methods allow separation of alpha and beta events.

Plastic scintillators consist of organic scintillators that have been dissolved in a solvent and the existing solvent polymerized to form plastic scintillators. As plastics can be made ultrathin, they can be useful for detecting low energy particles of radiation in the presence of gamma rays or for

Figure 12. A liquid scintillation counter system for beta particles (Canberra; Packard, Model B1500 Tri-Carb).

detecting heavy particles. Plastic scintillators are available in many physical configurations. Neutrons can be detected by incorporating a neutron sensitive material, such as lithium, into the solvent and the subsequent plastic scintillator. Nobel gas scintillators consist of high purity concentration of helium or xenon, which have the property that, following radiation interaction in the gas, both visible and ultraviolet (UV) light is emitted. While these materials exhibit a very short deexcitation time of 1 ns, they yield little light and the conversion of light is reasonably inefficient; nevertheless, they do have numerous applications when a fast response time is required.

As with GM probes, scintillation detectors are available as rectangular pancake probes to detect beta particles > 100 keV and γ rays > 25 keV, thin scintillators to detect γ and X rays > 10 keV, flashlight-like probes to detect alpha particles > 350 keV and beta particles > 14 keV, and conventional thick-crystal cylindrical probes for γ and X rays > 60 keV.

Photocathodes have many applications in devices that measure or detect radiation, such as image intensifiers, vidicon tubes, and other detectors. Usually, the electronics required to amplify the initial signal does not have as short a resolving time as the detector proper, but with modern solid-state electronics, the resolving times have been shortened to less than microseconds. Because of their extreme sensitivity, scintillator detectors are useful when detection and subsequent identification, by spectral analysis, of a type of radioactivity is required (Fig. 13). While the spectral peaks associated with scintillators are reasonably broad, their energy resolution is sufficient to allow rapid identification of minute quantities of various radioisotopes

Figure 13. A multiple component NaI(Tl) spectroscopy system. Detector shield (lower left; Ortec) with a NaI(Tl) detector (not shown); amplifier/bias supply (upper center; Ortec, Model Acemate); spectral analyzer (lower center; Ortec, Model 92X Spectrum Master), and computer display (left).

Figure 14. A spectrum measured with a 1×1 in. (2.54 cm) NaI(Tl) detector: (a) ^{137}Cs full-energy (0.66 MeV) peak; (b) Compton edge (0.48 MeV); (c) Compton distribution; (d) backscatter peak (0.18 MeV).

(Fig. 14). Formerly limited to laboratory analysis, NaI(Tl) spectroscopy is now available in portable handheld units (Fig. 15) that, using quadratic compression conversion (QCC), can identify 128 radionuclides in real-time (1 s intervals). Quadratic compression conversion creates spectral energy peaks whose widths vary proportionally to the NaI(Tl) crystal's energy resolution. All energy peaks are displays with the same peak width that allows radionuclides' distinct spectra to be more readily identified. The electronics associated with scintillators must be extremely stable, but often variations are introduced by environmental factors. High permeability magnetic shielding materials, for example, Mu-metal, often are used to shield against stray magnetic fields. Temperature and humidity variation can produce undesirable electronic noise. As previously noted, some crystals are hygroscopic and the moisture absorbed can reduce the efficiency of the process. Pulse discrimination techniques are often used to distinguish one type of radiation from another.

SOLID-STATE RADIATION DETECTORS

Thermoluminescence (TL) is the emission of visible light released by heating previously irradiated solid-state crystals. The light emitted from a thermoluminescent crystal is proportional to the amount of radiation to which the crystal has been exposed, and this proportionality holds over a large range (10^2 – 10^5) of exposures. At very high exposures, nonlinearity is exhibited and the amount of visible light released is no longer proportional to the amount of radiation detected. Thermoluminescent dosimetry (TLD) materials (Table 5) commonly used in medicine, include lithium fluoride (LiF), available in three forms (TLD-100, -600, -700), and lithium borate manganese ($\text{Li}_2\text{B}_4\text{O}_7:\text{Mn}$) (TLD-800).

Figure 15. A portable NaI(Tl) surveillance and measurement (spectroscopy) system. (Berkeley Nucleonics Corp., SAM Model 935).

Other TLDs used in environmental dosimetry applications, calcium fluoride manganese ($\text{CaF}_2\text{:Mn}$) (TLD-400), calcium fluoride dysprosium ($\text{CaF}_2\text{:Dy}$) (TLD-200), calcium sulfate dysprosium ($\text{CaSO}_4\text{:Dy}$) (TLD-900), and aluminum oxide ($\text{Al}_2\text{O}_3\text{:C}$) (TLD-500), are not further described here. X rays, γ rays, and neutrons are easily detected with different TLD materials; the detection of higher energy beta particles is possible, but quantification of the amount of beta radiation and calibration of the solid-state detectors for beta radiation

is often more difficult than for X and γ rays. The TL materials exhibit an enhanced response to lower energy (< 200 keV) X or γ rays as compared to higher energy (1 MeV) X or γ rays. For LiF, the over response is only a factor of 1.2, but for lithium borate manganese ($\text{Li}_2\text{B}_4\text{O}_7\text{:Mn}$) (TLD-800), there is an under response of ~ 0.9 . By adding filters, the energy response of a given type of crystal can be made more uniform and this is commonly done with TLD detectors used as personnel radiation monitors (Table 5).

Table 5. Properties of Some Thermoluminescent Materials

Property/type	LiF:Mg, Ti (TLD-100)	$^6\text{LiF:Mg, Ti}$ (TLD-600)	$^7\text{LiF:Mg, Ti}$ (TLD-700)	$\text{Li}_2\text{B}_4\text{O}_7\text{:Mn}$ (TLD-800)

Figure 16. Glow curves for TLD-100 (natural LiF) rods exposed to 10 R. (a) Without proper preparation annealing, multiple natural peaks occur; (b) Using a 1 h annealing at 400 °C and a 2 h annealing at 100 °C a smoother curve is obtained.

Physically, TLD materials consist of loose powder contained or embedded in plastic holders, compressed crystals (chips), extruded rods, and chips on a card in a configuration that allows reproducible heating of the detector materials to selected temperatures. The TL materials exhibit some undesirable features as radiation detectors. At room temperature, fading or loss of signals occurs, from < 0.5% per month for LiF to 5% in 3 months for $\text{Li}_2\text{B}_4\text{O}_7\text{:Mn}$. The degree of fading can be controlled, to some extent, by proper preparation (annealing) procedures.

The optical readers generally consist of a heating pan or device that allows the TL material to be uniformly heated in a controlled manner, at a specified temperature for a given period of time. The heating device and material holder are directly below a photomultiplier tube that usually has some filters to remove any IR radiations and transmits light in the blue-green region of the visible spectrum. The signal from the photomultiplier is amplified and used to prepare a glow curve (Fig. 16) a plot of the intensity of light versus the heating cycle of heating elements. Different TL materials exhibit different glow peaks. Numerous peaks occur in the curve and either the area under the curve or the height of the major peak is chosen to be proportional to the amount of radiation to which the material was exposed. Proper preannealing (extended heating at a controlled temperature) and post-annealing of the material will remove some smaller undesirable peaks (Fig. 16) leaving the main peak that is used for measurement purposes.

Current TL readers offer automatic features for glow curve analysis and processing of large numbers of samples (chips, rods, or cards).

Lithium fluoride is the most commonly used TL material for personnel dosimetry and consists of natural lithium. Lithium-6 is preferentially sensitive to thermal neutrons and ^7Li is insensitive to thermal neutrons, but sensitive to

γ -rays. Hence, by using paired ^6Li and ^7Li materials, it is possible to measure thermal neutrons in the presence of γ rays. Use of natural LiF detectors in radiation environments that contain low levels of thermal neutrons will yield incorrect dose equivalents for personnel, as the thermal neutrons will cause an apparent over response of LiF calibrated only to detect and measure γ rays (16).

Optically stimulated luminescence (OSL) is the release of light by a phosphor following its irradiation by a laser. Aluminum oxide (Al_2O_3) containing carbon impurities exhibit OSL releasing a blue light when excited by a green laser light. Some personnel radiation monitors employ OSL technology that offers some improvement over TLD-based personnel radiation dosimeters (17). The OSL dosimeter offers greater sensitivity, stability, and accuracy than TLD dosimeters. Aluminum oxide is highly linear from 1 mSv to 10 Sv; there is little signal fading > 1 year. It does exhibit an energy dependency below ~ 100 keV. However, unlike TLD chips, the aluminum oxide element can be reread multiple times to confirm an initial reading, an advantage for personnel dosimeter applications. The Luxel badge (Fig. 17; Table 6) contains the Al_2O_3 phosphor element, with 20 $\text{mg}\cdot\text{cm}^{-2}$ open filter (paper wrapper), 182 $\text{mg}\cdot\text{cm}^{-2}$ copper filter, and 372 $\text{mg}\cdot\text{cm}^{-2}$ tin filter in a heat-sealed, light-tight hexagonal plastic badge (18). The combination allows detection of beta particles > 150 keV with a 100 μSv threshold and X and γ rays > 5 keV with a 10 μSv threshold.

Photoluminescence (PL) occurs when the irradiated crystal emits visible light when exposed to UV light instead of heat. Silver activated glass encapsulated PL detectors are available in numerous shapes, sizes, and radiation levels as low as 100 μSv are detectable, but the detectors are commonly used to detect higher exposures. Appropriate filters can be used to make the energy response more linear, but at exposures of 0.1 Sv or higher the response of these detectors is nonlinear. These materials exhibit some signal fading that depends on the composition of the glass. Heating the glass detectors post irradiation for 30–60 min at 150 °C yields maximum luminescence. Reannealing requires 40 °C for 1 h, which restores the material to its preirradiation state. For low level exposure measurements, care is required to keep glass detectors free of dirt, dust, and other materials that would reduce the amount of light transmitted through the detector.

Semiconductor materials used for radiation detection, Si, Ge, CdTe, HgI_2 , and GaAs, have band gaps, the region between the valence and conducting band, of < 2.2 eV. Electrons migrate from the valence to the conduction band, leaving holes, that act like positively charged electrons, in the valence band. In a p-type semiconductor, the current is carried by the positively charged holes; in an n-type semiconductor, current is carried by the electrons. Usually, a potential difference is maintained across the solid-state semiconductor such that the depletion layer is devoid of electrons and holes. The interaction of X rays, γ rays, alpha particles, or beta particles generates additional electrons in the depletion layer; these are then swept away by the potential difference across the material, yielding a small current whose magnitude is proportional to the intensity of the incident radiation. Energy required to generate

Figure 17. The Luxel Dosimeter: Holder (top left); front view (top center); rear view (top right); rear view with attached Neutron 144 detector (bottom left); detector element showing Cu filter (right), the Al filter (left), and plastic filter (circle, lower center). (Courtesy Landauer, Inc.)

electron–hole pairs range from ~ 3 to 6.5 eV. Semiconductors exhibit excellent linear response over a large energy range and greater efficiency than gas detectors. (For a full description of semiconductor physics, see Refs. 7 and 8.)

Surface-barrier detectors essentially consist of an n-type and p-type layers that function as anode and cathode, with an intrinsic I layer (depletion region), without electrons, in between, in which radiation interactions occur. Depletion regions range from 0.1 to 1 mm. The composite is commonly called P-I-N structure. With a moderate reverse bias applied, radiation interactions create electron–hole pairs with each electron and hole leaving, or depleting, the intrinsic layer, and, with appropriate circuitry, creating a detection and counting system.

Silicon surface-barrier diode counters are used for charged-particle (alpha and beta particle) detectors. Alpha resolution ranges from 12 to 35 keV; beta resolution ranges from 6 to 30 keV. Passivated Implanted Planar Silicon (PIPS) detectors use implanted contacts more rugged

than conventional surface-barrier contacts. They can be customized-designed for specific applications.

Germanium (Ge) detectors are used for γ -X-ray spectroscopy to identify not only the amount of radiation present, but also to identify the type of radioactivity present. These detectors have excellent energy resolution and are used to identify the individual X and γ rays from a radioisotope, and with peak fitting programs have the ability to resolve closely lying peaks (Fig. 18). Lithium drifted germanium, Ge(Li), detectors have been replaced by high purity pure germanium (HPGe) detectors that only required liquid-nitrogen cooling (Fig. 19) or electrically refrigerated cryostats during measurements or use; otherwise they are kept at room temperature. Lithium drifted silicon, Si(Li), detectors are still used. With microprocessors, these instruments are now used for on-site identification of samples that may contain several different radioisotopes, a process previously limited to the laboratory. They are important tools in research facilities where minute quantities of many

Figure 18. A γ -ray spectrum measured with a 35 cm Ge(Li) detector with good energy resolution.

different radioisotopes may potentially accumulate and radioisotope identification is required.

Cadmium telluride (CdTe) detectors are popular as they are hygroscopic, do not require a photomultiplier, require only a 50 V bias, and operate at room temperatures. They exhibit high sensitivity, but their energy resolution is intermediate between that of NaI(Tl) and Ge detectors. They are available in a multitude of small sizes for special applications.

OTHER DETECTORS

Other physical changes that arise in materials as a result of irradiation include coloration and nuclear activation. Color changes occurs in some materials following their irradiation. Thin films with a cyanide emulsion (GAF-CHROMIC EBT) will exhibit a deep orange color following their irradiation by γ rays to a dose of 10–100 Gy (19). These materials exhibit excellent linearity > 1–800 cGy of radiation dose. While developed for high dose radiation dosimetry studies on linear accelerators, they can be used for high dose radiation protection studies.

Neutrons may be detected by numerous nuclear reactions or by the process of counting the number of recoil proton tracks produced in certain neutron sensitive mate-

rials, materials, such as boron (20). A polycarbonate material CR-39 (allyl diglycol carbonate) is insensitive to X rays, γ rays, and beta particles. However, incident neutrons collide with the protons, which produced changed particle tracks; the tracks are enhanced by chemically etching the polycarbonate, so they will be more visible under a microscope. This technology is used as one component in a composite personnel dosimeter used to monitor radiation therapy personnel working around linear accelerators with X-ray energies > 10 MeV (Table 6) (18).

Superheated Drop Detectors (SDD) consists of a small container of gel holding superheated drops ~ 0.1 mm diameter. Neutrons produce recoil protons that strike the drops, causing them to vaporize, generating an audible pop or sound that can be counted. The detector is insensitive to γ -rays, and is independent of neutron energy to ~ 14 MeV. Sensitivity is ~ 80 bubbles per 10 μ Sv, with a minimum threshold of ~ 1 μ Sv; there is a linear relationship between the number of bubbles and the neutron dose. The SDD technology has been incorporated into equivalent dose neutron survey meters with replaceable SSD cartridges that must be changed after exposure to certain maximum doses. Alternately, bubbles in samples can be visually counted to determine neutron dose (8).

PHOTOGRAPHIC DETECTORS

Photographic emulsions that darken in proportion to the amount of radiation they receive represent one of the earliest methods of detecting radiation. Most films consist of a thin plastic sheet with ~ 0.2 mm emulsions one or both sides; the emulsion, usually silver halide granules in a gelatin mixture is covered with a thin protective plastic coat. Modern films have emulsions specific for optimal detection of certain energy and intensity of radiation. Radiation incident on the emulsion changes the clear silver halide ions, forming a latent image. During processing additional silver is deposited, the darkness of the film is determined by where silver ions are deposited on the film and the amount of silver deposited. While most films are limited to dynamic ranges of $\sim 10^3$, multiple film packets can be used in combination to extend the dynamic ranges to 10^5 or higher. Fast films are sensitive to the lowest levels of radiation, while slow films require greater exposure to darken the films. Usually, the film is used in a protective cover, which can be a cassette, commonly used for imaging and including metal screens to enhance the image. Rapid processing film is wrapped in a thin light tight paper wrapping that prevent light leaks and may be used without a cassette.

Personnel monitors frequently use film as the radiation detector (Table 6). The small film packet in its light wrapper is carried in a plastic holder, but the film wrapping is sufficiently thin to allow the transmission of the low energies X rays, γ rays, or beta particles. Films usually exhibit an enhanced sensitivity of several factors of 10, to lowest energies of radiation, below ~ 100 –150 keV, relative to their response to γ rays with energies of 150–1.5 MeV. By using filters of copper, aluminum, and lead of varying thickness in the plastic holder in front of the film, estimates

Figure 19. Left Panel: liquid nitrogen dewar (left; Ortec, Model unknown) for cooling a germanium detector (right; Princeton Gamma Tech, Model RG-11B/C); Right Panel: The assembled detector ready for use.

of the energies of the radiations darkening the film can be made. One distinct advantage of film dosimeters is the permanent record generated. A disadvantage is that radiation incidence at an angle to the filter appears to have passed through a thicker filter than actually available. Film badges or monitors are available in numerous configurations for the body, head, wrist, hand, and fingers. Normally film badges are exchanged monthly if radiation levels are low; individuals working in a higher level radiation environment may be monitored more frequently.

Numerous environmental factors can fog photographic film producing erroneous personnel exposure readings. While films are free of electromagnetic interference, excessive humidity can influence results, as can excessive heat. Images in films can fade with time so prompt collection and processing of personnel monitors is important in obtaining accurate results. Special metal filters, such as cadmium, may be used in a film holder to produce a neutron sensitive film by the (n, α) reaction in cadmium. Film dosimeter are widely used as personnel monitors and the overall accuracy of a film dosimetry system is usually at least 50% or better depending on the energy range of use. Lower energy radiation present in small amounts yields the greater uncertainty in the accuracy of monitor readings. With film dosimeters,

the method of film processing is very important, as inconsistent methods of developing film will lead to substantial errors in the final results. Generally, film processors have their developer chemistry optimized for a particular type of film. Monitoring the temperature of the developing chemistry is very important and frequent use of calibration films, films previously given known exposures to radiation, is required to maintain the integrity of a film dosimetry system. Proper care and maintenance and rigorously scheduling of chemical developer replenishers are necessary.

RADIATION THERAPY, INTENSITY MODULATED

WALTER GRANT III
Baylor College of Medicine
Houston, Texas

INTRODUCTION

The past 10 years has seen the rapid emergence of a new radiation therapy process that has become known as

intensity modulated radiotherapy, or IMRT. This new process has expanded so rapidly that there are many misconceptions of its origin as well as its identity. The concept of modifying the standard radiation pattern emitted from an external radiotherapy unit has been employed for decades, for example, in the form of physical wedges or compensators. To begin to understand this new technology, it is important to recognize what differentiates the non-uniform intensity patterns associated with IMRT from those accomplished with other methods. For example, The National Cancer Institute Collaborative Working Group for IMRT stated that IMRT is, "An advanced form of image-guided 3dCRT that utilizes variable beam intensities across the irradiated volume that have been determined using computer optimization techniques". (1). While this definition is correct, it is a generalization that adds to the lack of clarity regarding IMRT and a review of the literature should allow a better understanding of the basic technologies required to produce an IMRT treatment.

In 1982, Brahme, Roos, and Lax (the BRL paper) published an article (2) describing the exact solution for the beam intensities required for a new nonlinear wedge shape that could be used to create improved dose uniformity for targets in a cylindrical phantom that were on or near the axes of symmetry and rotation of a problem in arc therapy. The authors also discussed the similarities to the imaging processes used in computed tomography (CT). This technique was used to treat 25 patients.

In 1987, Cormack (3) extended the BRL concept to noncircular symmetry. These results have nonexact solutions, but the author discussed logical approaches to selecting the best intensities.

The major step came just a year later in 1988 when Brahme published an article (4) that proposed the use of inverse treatment planning using filtered backprojections to solve both stationary and rotational problems. He believed that this approach would have a large impact and stated that it, "...largely avoids the trial and error approach often applied in treatment planning of today". His planning scheme was to have the physician place constraints on the doses to tumors and normal tissues and allow a computer to determine the location and intensities for the beams that achieved these results, as opposed to the traditional method where the planner places the beams and then evaluates the resulting dose distribution.

In diagnostic CT, one uses filtered backprojections to eliminate the artifacts that occur during image reconstruction. These filters mathematically convert a uniform beam from an X-ray tube into a nonuniform beam in order to achieve the proper images. They can have fine spatial resolution as well as negative values. It is this reality that creates the fingerprints of the process that is known as IMRT. In order to perform the reverse process in radiation therapy, we would have to use small beams and be able to produce a negative radiation source. This means that we likely will not be able to produce an exact solution, but only a "best" solution based on the clinical constraints of the patient and the source of radiation. For this reason, an optimization algorithm must be employed. We now have the unique markers for IMRT, the ability to plan and

delivery small beamlets of varying intensities that have been determined by computer optimization.

This article also cleared the path for the two delivery approaches used today in IMRT, multiple stationary gantry positions (fixed field) with dynamic intensity map creation and arc therapy delivery (tomotherapy) of dynamic intensity maps. Each of these techniques used different technologies for delivery of the dose pattern and had unique problems to overcome. In order to appreciate the complexities of the technologies, each will be addressed separately, beginning with the fixed field technique.

The limit for the effectiveness of radiation therapy as a treatment modality always has been the volume of normal tissue being irradiated. While early patients had this volume reduced by the use a library of lead blocks that were hand placed, the introduction of low melting point alloys (5) to create patient specific blocking introduced a major improvement in accomplishing the goal of the reduction of dose to normal tissue. The disadvantages of this system include the time to create the blocking as well as the weight of the finished product. To overcome these problems, multileaf collimators (MLC) were introduced (6). These devices were not created to increase blocking effectiveness, but to provide a more efficient blocking system. It took over a decade for these systems to mature to their potential, but today they are a common feature on linear accelerators. Figure 1 shows the exit port of an accelerator with the MLC leaves fully retracted. This would deliver a square radiation field. Using the MLC, one can shape the radiation field easily and Fig. 2 shows a field in the shape of a diamond. This, and any other shape, are set quickly by computer control.

The designs of the commercial MLCs have similar characteristics and some differences. The best place to find particular information is in the American Association of Physicists in Medicine (AAPM) Report No. 72 (7). There are some distinctions that will be made here as they affect the ability of these devices to create the required intensity maps for IMRT, but one should read Report No. 72 for more detail.

Figure 1. The exit port of a linear accelerator with the MLC parked completely under the primary collimating jaws.

Figure 2. The MLC positioned to deliver a radiation pattern in the shape of a diamond.

Most vendors now have leaves that project to a 1.0 cm width at the treatment distance for the machine, although there are recent advances to 0.5 cm for a general MLC and 0.3 cm for a special purpose MLC. The MLC will either replace one set of primary collimators in the head of the machine or be attached to the machine as a tertiary collimator. The former allows for more clearance between the patient and the exit port of the linear accelerator, but will have greater accuracy requirement for leaf position as inaccuracy is magnified by distance increased distance from the patient. An additional advantage is that these leaves can be double focused, allowing for a beam penumbra that is constant as a leaf moves across the field. Tertiary collimators of today have directly opposite characteristics.

There are additional characteristics that one needs to evaluate for the use of MLCs in general and IMRT in particular. One characteristic is the maximum distance a leaf may travel across the center of the field. This will determine the maximum field that can be treated with IMRT unless some additional facility of the collimator is introduced.

Another is the capability for a leaf moving from one side to pass its two neighboring leaves from the opposite side. The capacity to interdigitate leaves is important for some intensity modulation segmentation techniques, as well as create stand alone or "island" blocks in the central portion of a treatment field. Figure 3 shows an interdigitated set of leaves. The leaves on the edges of the pattern are set to the centerline of the radiation field and one can see alternating leaves extending over the center line from each side.

A final characteristic is that no MLC has adjacent leaves with smooth surfaces. In order to prevent leakage radiation from streaming through the interface of two leaves, leaves are keyed or notched to eliminate a direct path for the radiation. During the creation of an intensity map, adjacent leaves may get far enough apart that there can be a significant increase in unwanted leakage radiation because the leaf edge is not as thick as the leaf center. This is called the tongue and groove effect and will be part

Figure 3. An example of leaves that are interdigitated. The closed leaves are set at the middle of the field.

of a latter discussion regarding the creation of the intensity maps for IMRT.

Although there was a decade of development for the MLC, it was obvious that these devices could be used to create intensity maps and investigators worked on two methods, both of which are clinically available today although not from every vendor. The first involves the creation of a final intensity map by the accumulation of multiple static fields, or segments. This technique was investigated theoretically by Bortfeld et al. (8) and Webb (9) while Bortfeld et al. (10) conducted the first experiment of such delivery in 1994. As a single segment is completed, the beam is turned off and the MLC instructed to change to the next position. Then the beam is turned on and the next segment is delivered. The NCI-CWG-IMRT defines this process as Static MLC IMRT or sMLC. As an example, the MLC in Fig. 4 has the leaves positioned at the boundaries of

Figure 4. A MLC with the leaves positioned at the boundary of a shaped radiation field. The leaves on the right will move to meet the leaves on the left and then all leaves will move across the radiation field to create a nonuniform intensity map.

Figure 5. The planar intensity map created by the field from Fig. 4 (black is the highest radiation exposure).

a radiation field to be treated. If one begins by positioning all the leaves to the left-side boundary and moves them independently across the field at specified dose intervals, one can deliver a non-uniform dose pattern as shown in Fig. 5 with the darker colors indicating higher dose.

All vendors currently deliver this methodology although with some meaningful differences. As mentioned earlier, the location of the MLC plays a major role in the positional accuracy of any leaf at the treatment distance and there are differences in the time each vendor requires to assure accuracy before initiating the beam on sequence of the accelerator. This time ranges from milliseconds to multiple seconds and will discourage the use of intensity maps with many segments in order to achieve clinically realistic delivery times. The use of this technique may result in segments that have the beam on for a fraction of a second, thereby requiring the accelerator to reach its steady-state performance in that same short time. The accelerator manufacturers have developed this capability on newer accelerators, but one should be careful when attempting IMRT on older accelerators. The second method involves the creation of intensity maps by varying the dose rate while leaves are in motion. The NCI-CWG-IMRT defines this process as Dynamic MLC IMRT or dMLC. Currently, it is available from only one vendor. The technique was postulated by Kallman et al. (11) and the optimal trajectory equations developed by Stein et al. (12), Sverinsson et al. (13), and Spirou and Chui (14). To successfully deliver such a treatment, the accelerator needs to monitor leaf positions and alter the dose rate as required to allow leaves

to reach the next positions at the proper time. While this is the faster means of creating an intensity map, it also has the potential for more discrepancies in leaf position and dose than the static approach. These discrepancies are likely to be small and, with many ports being delivered, are likely to produce small degradation in the desired pattern. It is also possible to identify potential large errors and modify them to be small. This process is usually done with software programs that optimize the segment delivery. By using this segmental optimization, one can control the magnitude of such things as the number of segments, the tongue and groove effect, and minimize the potential for one beamlet to have a much higher intensity than any of the others,

Delivery of IMRT with fixed field techniques is the most common method used because there are so many MLCs in use and the MLC can be used for conventional beam shaping without intensity modulation of the beam. However, the methodology has some drawbacks. Linear accelerators are expensive ($\sim \$1.8\text{M}$) and it is important economically to treat large numbers of patients on each accelerator. For this reason, the number of ports to be treated must be limited to a few, optimal orientations. For some disease sites, such as prostate, these orientations can be predetermined and applied to all patients. In other disease sites, such as head and neck tumors, the disease presentation may have unique problems that require additional planning time to seek a satisfactory number of ports and orientations. There is no single answer to this problem as situations at each institution vary. For example, a small center might only have one or two machines while large institutions are likely to have more and can identify one that can treat fewer patients.

The alternative to fixed field IMRT is to deliver the treatment with arc therapy or tomotherapy. Since IMRT has such a strong similarity to CT, this is a logical approach. However, with the proliferation of high energy accelerators over the past 20 years, the use of arc therapy has diminished dramatically and is employed mainly in special procedures such as stereotactic radiosurgery (SRS). There are three implementations of tomotherapy and each has an analogy to current CT technology. In 1992 a neurosurgeon, Dr. Mark P. Carol, introduced a commercial system called Peacock (15) to be used as a SRS tool. The system consisted of a unique multileaf collimator (MIMiC) that consisted of two rows of 20 vanes each, with each vane projecting to a nominal $1 \times 1\text{ cm}^2$ beam at the normal isocenter of an accelerator (100 cm). The MIMiC is operated pneumatically and is a binary collimator meaning that the vane is either open (and permitting radiation to pass) or closed (blocking radiation). Figure 6 shows a patient's view of the MIMiC vanes in an alternating open/close pattern. One can see the two independent rows. The MIMiC is a removable tertiary collimator, so the accelerator could also be used for traditional clinical treatments. Figure 7 shows the MIMiC and its associated hardware in place on an accelerator. Either a 5° or 10° sector of the arc delivery is considered a fixed field and a beamlet's intensity is based around the center of the arc sector. For a 10° sector, that means a beam with 100% intensity is open for the entire 10° , while a beam with 50% intensity is closed the first 2.5° of the sector, open for the next 5° and closed the last 2.5° .

Figure 6. The MIMiC collimator as viewed by the patient. Alternating leaves are open and closed.

Because of the MIMiC's design, one treats a 2 cm length of the patient in one arc. It is then necessary to index the patient precisely and deliver another arc. The process is repeated until the total length of the tumor is treated. A CT analogy is a dual slice axial scanner and has the NCI-CWG-IMRT designation as Sequential Tomotherapy. This system also has historical importance as it was used to treat the first patient with IMRT (16) as defined by the NCI-CWG-IMRT and is still popular in 2004.

In 1995, Yu (17) introduced the concept of intensity modulated arc therapy (IMAT) that uses a traditional MLC to deliver tomotherapy. It basically is a combination of Dynamic Arc, a conformal delivery where the MLC changes its borders as a function of gantry angle but does not modulate the beam in the field, and the creation of intensity maps by using arcs with different shapes multiple times. This technique has limitations in that there are no planning systems that automatically create the fields, so the planner has to develop the skills to do this and that

Figure 7. A sequential tomotherapy system mounted on a linear accelerator.

Figure 8. A helical tomotherapy machine at installation. One can see the gantry ring holding the accelerator components.

introduces a problem because, given N possible intensities, there are $(N!)^2$ combinations that can produce that pattern. As an example, an intensity map with only 3 intensities can be created using 36 possible patterns. However, with the use of multiple gantry angles, one can create clinically acceptable plans for many simple disease presentations. This technique is extremely useful on machines that would require seconds to verify leaf positions if one were doing sMLC. Since it treats the entire volume in each arc, a CT analogy would be a multislice axial scan. More information on using this technique is found in a more recent article by Yu and Shepard (18).

In 1993, Mackie et al. (19) described a novel machine designed to treat IMRT only with a helical delivery system just like a helical CT scanner. For this reason, the system has been defined as Helical Tomotherapy by the NCI-CWG-IMRT. This machine has the physical appearance of a CT scanner, with a 6 MV waveguide and associated electronics mounted on a rotating annulus. A unit at the time of installation is shown in Fig. 8. The patient is treated with 6 MV X-rays by having the treatment couch moving at a constant speed through the bore of the rotating system. In order to modulate the beam, this machine has a pneumatically driven binary collimator. In addition, this machine had a series of Xenon detectors mounted on the rotating annulus opposite the waveguide so that the radiation exiting from the patient can be captured and analyzed. This machine became available commercially in 2001, with the first clinical installations occurring in 2003. Figure 9 shows a helical tomotherapy machine ready for patient treatment. Because it is the first new design of an external beam treatment machine since the linear accelerator was introduced at Stanford in 1955, it deserves some additional scrutiny.

As with helical CT, the operator can control the pitch (the distance the table travels per revolution) as well as the slice width (the machine has moveable jaws that can be set from 0.5 to 5.0 cm prior to the initiation of treatment). Using a pitch >1 and a large slice width, one can create a megavoltage CT image (the waveguide is tuned for 3.5 MV

Figure 9. A helical tomotherapy machine in an operational configuration and looking much like a diagnostic CT scanner.

X-rays) that can be used to verify or correct patient position prior to treatment. During treatment the exit dose can be collected in the xenon detectors and mapped back into the patient to determine the magnitude of any discrepancies between planned and actual delivery, whether they be caused by mechanical errors or patient-organ motion. These types of tools have long been desired to help insure the accuracy of these more conformal dose distributions.

Similar tools are finding their way into conventional linear accelerators as vendors are adding kilovoltage X-ray tubes as well as megavoltage cone CT to their equipment. There are questions as to how one facilitates the use of fixed-field delivery with the need to do arc rotations to gather the necessary information to create the images that are part of the desired schema.

The last issue to address is the use of optimized treatment planning as a necessary part of the IMRT concept. It was stated earlier that perfect shapes in CT often require the application of mathematical filters with negative values and, since we cannot deliver negative radiation, optimization tools are required to achieve the best result possible given the planning constraints. The evaluation of optimization techniques continues today but the application of optimization techniques in use today is very straightforward. They are either a gradient descent or stochastic algorithm. In the late 1980s, Webb (20) as well as Mohan et al. (21) investigated the stochastic algorithm, Simulated Annealing, as a possible algorithm. This was appropriate because the algorithm was powerful and no one was sure just how complicated the optimization need be to create a clinically useful plan. Because of this, Carol designed his system based on Webb's work with this stochastic optimization algorithm.

By their nature, stochastic optimizations are slower than gradient descent algorithms because they permit the solution to get worse for a number of iterations as an attempt to avoid being trapped in a local minimum. Over time, it became clear that gradient descent algorithms are useable and today all planning systems now use gradient descent algorithms and some use both. There is a product that uses no optimization at all and was given

an IMRT moniker by the vendor, but this product does not meet the NCI-CWG-IMRT definition of IMRT. Research interest in the subject continues to grow. A literature search of "inverse treatment planning" found 39 publications in 1998, 48 in 2000, and 108 in 2002, so we can expect optimization algorithms to continue to be tested and improved.

The rapid acceptance of IMRT as a delivery technique is unprecedented in radiation therapy. A mere 6 years after Brahme postulated the concept in 1988, Carol had produced a commercial system that was used clinically. Within a decade after that event, not only do vendors supply additional technology for their accelerators to treat IMRT, but also a new vendor has emerged with a dramatically new machine to treat only IMRT. Image guided systems are being adapted to take advantage of the power to shape radiation fields easily and precisely with IMRT. This technology should continue to expand.

RADIATION THERAPY SIMULATOR

DANIEL A. LOW
SASA MUTIC

Medicine
St. Louis, Missouri

INTRODUCTION

Radiation therapy, or radiation oncology, is one of the primary modalities (along with surgery and chemotherapy) for the treatment of cancer patients. Its origins can be traced to the early 1900s and today radiation therapy facilities can be found in most major medical centers and many free standing practices. This medical specialty and its success depend strongly on the technology used for cancer diagnosis and planning, delivery, and verification of patient treatments. Therefore, the amount of efforts and resources invested in the improvement of radiation therapy related technologies is significant. One of the cornerstones of modern radiation therapy practices are volumetric patient images, computed tomography (CT), magnetic resonance (MR) imaging, nuclear medicine imaging (positron emission tomography (PET) and single positron emission tomography (SPECT)), and ultrasound (US). Medical images are used for cancer detection, disease staging, treatment planning, for verification of treatment delivery, and for evaluation of treatment outcomes and patient follow up. Imaging devices that are used to image cancer patients for radiation therapy treatment planning are called Radiation Therapy Simulators. The distinguishing characteristics of radiation therapy simulators, in addition to their basic imaging properties, are that these devices need to have the following characteristics; (1) the modality allows patients to be imaged in their treatment position, (2) that the acquired images have high spatial accuracy, and (3) that the dataset be able to provide image datasets that are of sufficient quality to be used for validating the radiation beam shape and anatomic location. While these may seem like relatively straightforward

requirements, the design and implementation of radiation therapy simulators can be technically challenging. The main source of technical difficulties stems from the fact that the design of the medical imaging devices on which the simulators are based has historically been driven by the needs of diagnostic radiology that have less concern for patient positioning or for the spatial accuracy of the image datasets. For diagnostic scanning, patients often assume a comfortable position with their arms on the side or on abdomen–chest. Diagnostic physicians typically need to determine the presence of anatomic or functional anomalies, so a quantified determination of the size, shape, or location of internal organs or tumors relative to the imaging modality hardware is not a primary consideration.

For radiation therapy imaging, the patient extremities (arms and legs) are often positioned away from the torso to provide access by the radiation treatment beams. Patients are also imaged in immobilization devices that are subsequently used during treatment. Additionally, image spatial accuracy and the geometry of images is extremely important in order to precisely deliver the radiation to the tumors while avoiding radiation sensitive organs. Radiation therapy simulator design is based on an imaging device that was originally developed for diagnostic imaging, and then the device is modified to accommodate patient imaging in the radiotherapy treatment position and to improve image spatial accuracy and geometry to satisfy the needs of radiation therapy treatment planning. This approach is slowly changing and more devices are being designed exclusively for radiation therapy or major features of diagnostic imaging equipment are designed with radiation therapy in mind. This change in manufacturer attitude is reflected in description of radiation therapy simulators in the rest of this article.

The majority of simulation history in radiation therapy is based on conventional simulators (1–6). However, the modern practice of radiation therapy is dominated by CT simulators. Shortly after the introduction of clinical

CT scanners in the early 1970s, it was realized that this imaging modality has much to offer in a radiation oncology setting. The CT images provide volumetric information not only about target volumes, but about critical structures as well. Using CT images for radiation therapy treatment, planning has improved dose delivery to target volumes while reducing dose to critical organs. The CT images also provide relative electron density information for heterogeneity-based dose calculations. A major weakness of CT imaging is a relatively limited soft-tissue contrast. This limitation can be overcome by using CT images in conjunction with MR studies for treatment planning. The PET images can be used to add physiological information. Ultrasound has also been useful for imaging in brachytherapy. Multimodality imaging-based treatment planning and target and normal structure delineation offer an opportunity to better define the anatomic extent of target volumes and to define their biologic properties.

Tatcher (7) proposed treatment simulation with CT scanners. This short article described the feasibility of CT simulator and indicated potential economical benefits. In 1983, Goitein and Abrams (8,9) further described multi-dimensional treatment planning based on CT images. Sherouse et al. (10,11) went on to describe a CT image based virtual simulation process that they referred to as a “software analog to a conventional simulation”. This series of manuscripts described software tools and addressed technical issues that affect today’s CT-simulation process. The manuscripts pointed out the need for fast computers, specialized software, but also for improved patient immobilization and setup reproducibility.

The radiation oncology community eagerly embraced the concept of virtual simulation and in early 1990s commercial software packages became available. These systems consisted of a diagnostic CT scanner, external laser positioning system, and a virtual simulation software workstation. One of the early commercial CT simulation packages is shown in Fig. 1.

Figure 1. The CT-simulator room layout. (Image courtesy of Philips Medical Systems, Cleveland, Ohio.)

Figure 2. Place of CT simulation in radiotherapy treatment planning process. (Reprinted with permission from Ref. 12.)

The CT simulators have matured to a point where they are one of the cornerstones of modern radiation oncology facilities. Today's systems incorporate specially designed large bore CT scanners, multislice CT scanners, high quality laser positioning systems, and sophisticated virtual simulation packages. Many systems incorporate dose calculation capabilities and treatment plan analysis and evaluation tools.

Additional virtual simulation software features and functions along with increased efficiency and flexibility have enabled CT simulators to replace conventional simulators in many facilities. This trend seems to be further fueled by the increased demand for imaging studies for conformal three-dimensional (3D) and intensity modulated radiation therapy (IMRT) treatment planning where conventional simulators are of limited value. Figure 2 shows the place of CT simulation in the treatment planning process.

Both MR and PET-CT simulators are recent developments in radiation therapy simulation and are designed to complement CT simulation process and shortcomings of CT imaging. Magnetic resonance imaging offers superior soft tissue contrast and PET provides information about biological tissue properties. Computed tomography has relatively poor soft tissue contrast and provides rather limited information about functional tissue characteristics. Both MR and PET imaging in radiation therapy imaging greatly enhance our ability to accurately define anatomical and biological properties of tumors and normal tissues.

The implementation of simulation and treatment planning process varies greatly between radiation oncology departments. This diversity is in part driven by significant technical differences between simulation and treatment planning systems offered by different manufacturers. The discussion of radiotherapy simulators provided here describes general characteristic of processes and technology used for radiation therapy treatment planning. For more specific details, readers are referred to suggested readings list.

TECHNOLOGY OVERVIEW

In the late 1990s, the imaging equipment manufacturers began designing major devices (CT, MR, and PET scanners) specifically for radiation therapy or with radiation therapy needs in mind. This paradigm change resulted in a multitude of imaging devices available for radiation

therapy simulation. Not only are there new devices (CT, MR, PET), but conventional simulators are being improved as well in order to be able to compete with other imaging modalities.

CONVENTIONAL SIMULATOR

The radiation therapy simulator has been an integral component of the treatment planning process for > 30 years. Conventional simulators are a combination of diagnostic X-ray machine and certain components of a radiation therapy linear accelerator (1–6). A conventional simulator, as seen in Fig. 3, consists of a diagnostic X-ray unit and fluoroscopic imaging system (X-ray tube, filters, collimation, image intensifier, video camera, generator, etc. (13), patient support assembly (a model of the treatment table), laser patient positioning and marking system, and simulation and connectivity software. The treatment table and the gantry are designed to mimic the geometric functions of a linear accelerator. The gantry head is designed to accommodate the common beam modification devices (blocks, wedges, compensating filters), in a geometry that mimics the linear accelerator. The simulator provides transmission radiographs with radiation portal-defining collimator settings outlined by delineator wires. By using primarily bony landmarks, the physician delineates the radiation portal outlines.

Imaging chain: One of the major improvements in conventional simulator design was the replacement of image intensifiers and video camera systems by amorphous silicon detectors. The new imagers produce high spatial and contrast resolution images which approach film quality, Fig. 4. More importantly, these images are distortion-free, a feature that is important for accurate geometric representation of patient anatomy. The introduction of high quality digital imagers in conventional simulation further facilitates the concept of film-less radiation oncology departments.

Simulation software: Conventional simulation software has also undergone many improvements. Modern simulators use the Digital Image Communications in Medicine (DICOM) standard (14) for data import capabilities. Treatment field parameters can be imported directly from the treatment planning computer for verification on the simulator. The software can then automatically set the simulator parameters according to the treatment plan. This facilitates efficient and accurate verification of patient

Figure 3. Modern version of a conventional simulator. (Image courtesy of Varian Medical Systems, Palo Alto, California, copyright © 2002.)

treatment setup on the conventional simulator. These simulators also have DICOM export capabilities that improves the reliability of treatment setup parameter transfer directly to a record and verify system or to a treatment planning computer. The ability to import and capture digital images enables conventional simulators to have tools for automatic correlation of treatment planning and verification fields.

Another potential improvement for conventional simulators is the capability of providing cone-beam CT (15,16). Because newer simulators are equipped with digital imaging hardware, two-dimensional (2D) projection image datasets

are acquired while the gantry is rotating. The projection data is used to reconstruct a high spatial resolution CT image dataset. This capability will significantly improve imaging capabilities and usefulness of these devices. Figure 5 shows a cone beam CT image from a conventional simulator.

Figure 4. Digital image of a head from a modern conventional simulator equipped with an amorphous silicon imager. (Image courtesy of Varian Medical Systems, Palo Alto, California, copyright © 2002.)

Figure 5. Cone beam CT image of a head acquired on a conventional simulator. (Image courtesy of Varian Medical Systems, Palo Alto, California, copyright © 2002.)

While it is often mentioned that conventional simulators can be completely replaced with CT simulators, new features and usefulness of conventional simulators are slowing down this process. Conventional simulator continues to be an important component of radiotherapy process even though its use for treatment planning of many tumor sites has been significantly reduced.

CT Simulator

Computed tomography simulator (10,11,17–26) consists of a CT scanner, laser patient positioning–marking system, virtual simulation–3D treatment planning software, and different hardcopy output devices, Fig. 1.

The CT scanner is used to acquire volumetric CT scan of a patient that represents the virtual patient and the simulation software recreates the functions of a conventional simulator. In recent years, the three most significant changes in CT-simulation technology have been the introduction of a larger gantry bore opening (Large Bore CT) (27), multislice image acquisition (Multislice CT) (28), and addition of CT-simulation software directly on the CT scanner control console. These innovations improve the efficiency and accuracy of the CT-simulation process. They also improve the patient experience by allowing patients to be positioned in more comfortable positions while reducing the simulation procedure time.

Large Bore CT: Large bore CT scanners (defined here as having > 70 cm diameter bores) were specifically designed with radiation therapy needs in mind. One of the requirements in treatment of several cancer sites (breast, lung, vulva, etc.) is for extremities to be positioned away from the torso. When acquiring a CT scan with a patient in such treatment position, extremities often cannot fit through a conventional 70 cm diameter scanner bore opening. In such situations, patient positioning needs to be modified to acquire the scan. This can result in less than optimal treatment position (patient may be less comfortable and therefore the daily setup reproducibility may be compromised) or in a mismatch between the imaging and treatment positions. The first large bore CT simulator was introduced in 2000, and several additional models with enlarged bore opening have been introduced since then.

Large bore scanners also have increased the available scan field of view (SFOV), which determines the largest dimension of an object that can be fully included in the CT image. It is typically 48–50 cm in diameter on most conventional 70 cm bore opening scanners. For treatment planning purposes it is necessary to have the full extent of the patient's skin on the CT image. Lateral patient separation can often be > 48–50 cm and the skin is then not visible on CT images. Increased SFOV available on large bore scanners solves this problem. There are, however, differences in implementation of extended SFOV and validity of quantitative CT values (quantitative CT) at larger image sizes. The CT numbers for some scanners are accurate only for smaller SFOVs and the values toward the periphery of large SFOV images are not reliable. This can be a concern for some dose calculation algorithms because inaccurate CT numbers can lead to dose calculation errors. The impact of CT number accuracy for increased SFOV

images on dose calculation accuracy should be evaluated during scanner commissioning.

Multislice CT: In 1992, Elscint introduced a scanner that had a dual row of detectors and could simultaneously acquire two images (slices). Since then, multislice CT has gained wide spread acceptance and scanners that can acquire up to 64 slices are now available from all major vendors. The basic design behind the multislice CT technology is that multiple rows of detectors are used to create several images for one rotation of the X-ray tube around the patient.

One of the obstacles for radiation therapy scanning with single-slice scanners is the limited tube heat loading capability. Often, fewer images are taken, slice thickness is increased, the image quality is decreased (reduced mAs), or scan pitch is increased to reduce the amount of heat produced during the scan and to allow for the entire scan to be acquired in a single acquisition. Due to the longer length of imaged volume per tube rotation (multiple slices acquired simultaneously), the tube heat loading for a particular patient volume is reduced when using a multislice scanner relative to a single-slice scanner and multislice scanners are generally not associated with tube heat loading concerns. Faster acquisition times and decreased tube loading of multislice scanners, which allow longer volumes to be scanned in a single acquisition, can provide an advantage over single-slice systems for treatment planning purposes. Multislice technology can be especially beneficial for imaging of the thorax where breathing artifacts can be minimized with faster scanning. Multislice technology also facilitates dynamic CT scanning, often referred to as 4D CT (29,30). This application of multislice CT in radiation therapy is yet to be fully explored.

Multislice scanners are also capable of acquiring thinner slices that can result in better quality digitally reconstructed radiographs, used for treatment portal validation, and more accurate target delineation because of the improved spatial resolution with thinner slices, (Fig. 6).

CT simulator tabletop: This section and discussion about simulator tabletops applies equally to all simulators used in radiation therapy (conventional, MRI, CT, and PET) and treatment machines. Tabletops used for patient support in radiation therapy during imaging or treatment should facilitate easy, efficient, reproducible, and accurate patient. It is not only important that a tabletop improves patient positioning on a single device (i.e., treatment machine), but the repositioning of a patient from one imaging or treatment device to another also has to be considered. A great improvement in this process is if all tabletops involved in patient simulation and treatment have a common design. They do not have to be identical, but they should have the same dimensions (primarily width), flex and sag under patient weight, and they should allow registration (indexing) of patient immobilization devices to the tabletop. Figure 7 demonstrates this concept. The CT simulator tabletop has the same width as the linear accelerator used for patient treatment and both allow registration of patient immobilization system to the treatment couch. The ability to register the immobilization device and the patient to a treatment table is extremely important and improves immobilization, set-up

Figure 6. The CT slice thickness DRRs are 5, 3, and 0.8 mm. Thinner slice thickness images reveal much more relevant anatomical detail.

reproducibility, accuracy, and efficiency. The patient is always positioned in the same place on the treatment machine and patient daily setup can be facilitated using the treatment couch positions. If the patient is registered to the treatment couch, the coordinates of the couch used for patient treatment can become a part of parameters that are set and tracked in the linear accelerator record and verify system.

Patient marking lasers: A laser system is necessary to provide reference marks on patient skin or on the immobilization device. Figure 1 shows a laser system for a CT simulator:

Wall lasers: Vertical and horizontal, mounted to the side of the gantry. These lasers can be fixed or movable.

Sagittal laser: Ceiling or wall mounted single laser, preferably movable. Scanner couch can move up/down and in/out, but cannot move left/right, therefore the sagittal laser should move left–right to allow marking away from patient mid line.

Scanner lasers: Internally mounted, vertical and horizontal lasers on either side of the gantry and an overhead sagittal laser.

MR Simulator

The MR images for radiotherapy treatment planning are usually acquired in diagnostic radiology departments

because few radiation oncology departments have a dedicated MR scanner. Furthermore, currently the majority of radiotherapy MR studies are limited to brain imaging. The MR scanner has a superior soft tissue contrast compared to CT imaging and there are several benefits that MR can offer for target delineation based on this advantage. There have been several reports describing use of MR scanners for imaging and treatment simulation in radiotherapy (31–35). Some of these reports have suggested that MR studies can be used without a corresponding CT scan for radiotherapy treatment planning. Indeed, if spatial distortions (the geometry of imaged objects is not always reproduced correctly), which is the largest concern with MR imaging, can be removed or minimized MR studies can be used as the primary imaging modality for several treatment sites. Superior soft tissue contrast provided by MR can also be an advantage for treatment planning of certain extracranial tumor sites like prostate, for example (36,37).

Conventional MR scanners are not well suited for extracranial imaging for treatment planning. The main difficulty is placement of patient in treatment position with immobilization device in the scanner. The small diameter and long length of conventional MR scanner openings significantly limits patient positioning options for imaging. Open MR scanners do not share these difficulties and patients can be scanned in conventional

treatment positions. At least one manufacturer offers an open MR scanner that has been modified to serve as a radiotherapy simulator, Fig. 8. The scanner table is equipped with a flat top and external patient alignment lasers. The geometry of the scanner is then similar to the CT simulator. Another manufacturer offers a 70 cm diameter gantry opening conventional MRI scanner. The depth of the scanner opening is 125 cm. The dimensions of this scanner are very similar to a conventional CT scanner and in fact the scanner could be mistaken for a CT scanner. The ergonomics of this scanner are also well suited for radiotherapy simulation.

One of the major challenges with MR imaging for radiotherapy treatment planning are geometric distortions in acquired images. The MR scanners are often equipped with correction algorithms that will minimize geometrical distortions. These corrections do not affect the entire image and only the center portion of the image (center 20–35 cm diameter) is adequately correct (within 2 mm). Therefore, the representation of patient's skin and peripheral anatomy for larger body sections may be inaccurate. The effect of these inaccuracies must be evaluated if dose distributions will be calculated directly on MR images.

PET–CT Simulator

The PET images for radiotherapy planning can come from a standalone PET scanner or a combined PET–CT unit. Combined PET–CT scanners are being installed in radiation oncology departments and are used for PET scanning, but also these machines can be used for CT scanning only without PET acquisition. Due to this purpose, these scanners can be classified as CT simulators, though PET–CT simulator term may be more appropriate. Combined PET–CT scanners offer several advantages for radiotherapy

imaging and are generally preferred over stand-alone units.

The first combined PET–CT prototype was introduced in 1998 at the University of Pittsburgh (38), since then all major manufacturers have produced several commercial models. The key description of PET–CT scanners is that a PET and a CT scanner are *combined* in the same housing. Meaning that there are two gantries (PET and CT) combined in one housing sharing a common couch. Image reconstruction and scanner operation is increasingly performed from one control console.

Combined PET–CT scanner design varies among different vendors with respect to PET detectors, image quality and resolution, speed, image field of view; number of CT slices, scanner couch design, gantry bore opening, and other considerations. Currently, the commercially available scanners have a 70 cm gantry opening for the CT portion, though large bore CT scanners will likely become part of PET–CT scanners in the future. The PET gantry opening ranges in diameter from 60 to 70 cm, meaning that some of the commercial scanners have a nonuniform gantry opening as the patient travels from the CT portion of the scanner to the PET side. More importantly, the scanners with the smaller gantry opening on the PET side will pose the same difficulties for radiotherapy scanning as stand-alone PET scanners. Again, the size of patient immobilization devices and patient scan–treatment position will have to be adapted to the size of the gantry opening.

The combined PET/CT technology offers two major benefits for radiotherapy planning. First, because the images are acquired on the same scanner, providing that the patient does not move between the two studies, the patient anatomy will have the same coordinates in both studies. These images have been registered using hardware rather than software registration. The second benefit of the

combined PET–CT units is that CT images are used to measure attenuation correction factors (ACFs) for the PET emission data, obviating the need for a time-consuming PET transmission scan (39,40). The use of CT images to generate PET ACFs reduces the scan time up to 40% and also provides essentially noiseless ACFs compared with those from standard PET transmission measurements (41). Shorter scan times can benefit radiotherapy patients who are scanned in treatment position that often can be uncomfortable and difficult to tolerate for prolonged amounts of time. One of the concerns with ACFs generated from CT images is mismatch or misalignment between CT and PET images due to respiration motion. The PET images are acquired during many cycles of free breathing and CT images are acquired as a snapshot in time at full inspiration, partial inspiration, or some form of shallow breathing. The breathing motion will cause mismatch in anatomy between PET and CT images in the base of lung and through the diaphragm region. This mismatch can result in artifacts in these areas that may influence diagnosis and radiotherapy target definition in this region. There are various gating methods that can be used during image acquisition to minimize the motion component and essentially acquire true, motionless, images of patient anatomy. Gated or 4D CT (with time being the fourth dimension) can be used to generate more reliable ACFs and also for radiotherapy treatment planning where gated delivery methods are being used.

Virtual Simulation Software

As with all software programs, user-friendly, fast, and well functioning virtual (CT) simulation software with useful features and tools will be a determining factor for success of a virtual simulation program. Commercially available programs far surpass in-house written software and are the most efficient approach to virtual simulation. Several features are very important when considering virtual simulation/3D treatment planning software:

Contouring and localization of structures: Contouring and localization of structures is often mentioned as one of the most time consuming tasks in the treatment planning process. The virtual simulation software should allow fast user-friendly contouring process with help of semiautomatic or automatic contouring tools. An array of editing tools (erase, rotate, translate, stretch, undo) should be available. An ability to add margins in three dimensions and to automatically draw treatment portals around target volumes should be available. An underlining emphasis should be functionality and efficiency.

Image processing and display: Virtual simulation workstation must be capable of processing large volumetric sets of images and displaying them in different views as quickly as possible (near real-time image manipulation and display is desired). The quality of reconstructed images is just as important as the quality of the original study set. The reconstructed images (DRRs and multiplanar reconstruction) are used for target volume definition and treatment verification and have a direct impact on accuracy of patient treatments.

Simulator geometry: A prerequisite of virtual simulation software is the ability to mimic functions of a conventional simulator and of a medical linear accelerator. The software has to be able to show gantry, couch, collimator, and jaw motion, SSD changes, beam divergence, and so on. The software should facilitate design of treatment portals with blocks and multileaf collimators.

DISCUSSION

As radiotherapy treatment planning and delivery technology and techniques change, so does the treatment simulation. The most significant change in the recent past has been the wide adoption of CT simulation to support conformal radiotherapy and 3D treatment planning. A CT simulation has gone from a concept practiced at few academic centers to several available sophisticated commercial systems located in hundreds of radiation oncology departments around the world. The concept has been embraced by the radiation community as a whole. The acceptance of virtual simulation comes from improved outcomes and increased efficiency associated with conformal radiation therapy. Image-based treatment planning is necessary to properly treat a multitude of cancers and CT simulation is a key component in this process. Due to demand for CT images, CT scanners are commonly found in radiation oncology departments. As CT technology and computer power continue to improve so will the simulation process, and it may no longer be based on CT alone. The PET–CT combined units are commercially available and could prove to be very useful for radiation oncology needs. Several authors have described MR simulators where the MR scanner has taken the place of the CT scanner. It is difficult to predict what will happen over the next 10 years, but it is safe to say that image based treatment planning will continue to evolve.

One great opportunity for an overall improvement of radiation oncology is the better understanding of tumors through biological imaging. Biological imaging has been shown to better characterize the extent of disease than anatomical imaging and also to better characterize individual tumor properties. Enhanced understanding of individual tumors can improve selection of the most appropriate therapy and better definition of target volumes. Improved target volumes can utilize the full potential of IMRT delivery. Biological imaging can also allow evaluation of tumor response and possibly modifications in therapy plan if the initial therapy is deemed not effective.

Future developments in radiotherapy treatment planning simulation process will involve the integration of biological imaging. It is likely that this process will be similar to the way that CT scanning was implemented in radiotherapy. The imaging equipment is initially located in diagnostic radiology facilities and as the demand increases the imaging is gradually moved directly to radiation oncology.

INTRODUCTION

Boltzmann Transport Equation

The distribution of radiation in a three-dimensional (3D) heterogeneous medium is governed by the Boltzmann transport equation, which is a partial differential integral equation in six dimensions [3D for position, two (2D) for direction, and one (1D) for energy].

Due to the complex nature of the Boltzmann transport equation, analytic solutions are generally not available except for very simple, idealized cases. For realistic problems, numerical methods are needed. The Monte Carlo method is probably the most accurate and widely used method for solving radiation transport problems in 3D, heterogeneous geometry.

Random Sampling, Law of Large Numbers, Central Limit Theorem

The basic idea of the Monte Carlo method is to simulate physical events by random sampling from known probability distributions. For example, the step size a photon particle travels before the next interaction is sampled from the exponential distribution. The particular interaction event is sampled from the relative probabilities of competing interaction types. If a Compton event occurs, the energy and direction of the outgoing photon and electron are sampled from the Klein–Nishina distribution.

There are two mathematical principles underlying the Monte Carlo method: (1) The law of large numbers, and (2) the central limit theorem. The law of large numbers says that as the sample size increases to infinity, the sample average approaches the mean of the probability distribution from which the samples were drawn. Since in practice the sample size is finite, the error of the sample average needs to be estimated. For this, we make use of the central limit theorem, which states that the distribution of the sample averages approaches a normal distribution if the sample size is sufficiently large. Moreover, the standard deviation of the mean is inversely proportional to the square root of the total number of histories. Thus, in order to reduce the standard deviation of the mean by a factor of 2, the number of histories needs to be increased by a factor of 4. To estimate the statistical uncertainty, it is common practice to divide the total number of histories into separate groups, with each group containing sufficiently large number of histories. The sample average of each group, according to the central limit theorem, is normally distributed. The standard deviation of the mean is then calculated from these group averages. Alternatively, a history-by-history method can be used to estimate the standard

deviation of the mean. In this method, both the quantity of interest and its square are tallied on the fly for each history. After the simulation is completed, the standard deviation of the mean is then calculated using the sum and the sum of squares of all histories. This method tends to have smaller uncertainty in the uncertainty estimate than the multiple group method.

Applications of Monte Carlo Method in Medical Physics

The Monte Carlo method has been applied to a variety of medical physics problems (1). For radiation therapy, these include the simulation of the machine head (2–22); dose calculation for external photon beams (23–38); electron beams (39–49); proton beams (50–54); and brachytherapy (55–86). For nuclear medicine, it has been used to calculate organ doses due to internal emitters (87–97). For diagnostic radiology, it is used for calculating beam characteristics and dosimetry (98–111). For radiation measurement, various correction factors for ion chambers have been calculated with Monte Carlo (112–129).

A number of Monte Carlo codes have been developed and applied to problems in medical physics (39,43,130–141). For the purpose of radiation therapy treatment planning, the EGS4 system and its user codes (43,130,133,135) are probably the most widely used in North America.

MONTE CARLO SIMULATION

Overview

A Monte Carlo simulation consists of two major components: transport and interaction. Transport moves a particle from one position to another while interaction determines the outcome of a particular interaction event. If an interaction results in multiple outgoing particles, as in the case of Compton scattering or pair production, then each outgoing particle forms its own transport-and-interaction track. This repetitive transport-and-interaction continues until either the particle travels out of the geometry, for example, exiting the patient body, or its energy falls below a cutoff energy.

Geometry Specification

For a given Monte Carlo simulation, the 3D geometry needs to be described by a collection of mathematical objects. One such package, called combinatorial geometry (142) has been used by a number of Monte Carlo codes. The combinatorial geometry package provides a set of primitive objects, such as sphere, cylinder, box, cone, and so on. An object in question is then modeled by logical combinations of these primitives. For example, a hemisphere can be formed as an intersection of a sphere and a box. The physical properties of the object are also assigned, including the material composition and the physical density. The combinatorial geometry package is a powerful tool that can be used to define very complex geometric objects such as the treatment machine head.

If a 3D image set, such as computed tomography (CT), is used for dose calculation, then the entire 3D voxel array defines the geometry. Since the CT image is typically

acquired with kilovoltage X rays, when it is used for dose calculation for megavoltage photons or electrons, the CT Hounsfield number needs to be converted into electron density ratios relative to water. For radiation therapy dose calculations, the typical energy range is up to 20 MeV and the physical properties of the voxel can often be considered as water equivalent but with varying densities. If, however, consideration of material composition is important, such as a metal implant, then different materials can be assigned to the corresponding voxels. This can be done by creating a lookup table for material (air, lung, fat, muscle, water, bone, soft bone, metal) as a function of Hounsfield number and then subdividing each material as a function of density.

Transport

During particle transport, the step size is sampled from the exponential distribution. The exponent in the exponential distribution is related to the mean free path that depends on the particle energy and the material in which the particle travels. For neutral particles (photons or neutrons), the step size is relatively large. For example, the mean free path of a ^{60}Co photon in water is ~ 16 cm. For charged particles (electrons, positrons, protons), the step size is very short due to the Coulomb force. As a result, direct simulation would be very inefficient. To overcome this problem, multiple steps are condensed into a single step, called the condensed-history step (143). Energy deposition due to continuous slowing down is calculated along this step and angular deflection is sampled at the end of the step based on multiple scattering theory.

When transporting a particle, it may cross the boundary of one geometric object to another. When this happens, the original step has to be truncated at the boundary. This is because the next geometric object may have different physical properties from the current one. The remaining step size will have to be adjusted based on the new object and resampled if necessary.

For charged particles, there is continuous energy loss due to ionization and excitation. The energy can be deposited uniformly along the step or at a point randomly selected within the step. For neutral particles, there is no energy deposition during a step. However, if the KERMA (Kinetic Energy Released per unit Mass) approximation is made, then energy can also be deposited using the energy absorption coefficient and the step length, which is an estimate of the photon fluence.

Interaction Types

For radiation therapy dose calculation, we are mostly interested in photons and electrons, so the discussion of interaction types here is limited to these radiation particles only.

For photons, the interaction types are photoelectric, Compton scattering, and pair production. Coherent scattering is relatively unimportant as it involves no energy loss and only small angular deflection. In a photoelectric interaction, the incoming photon collides with an atom and ejects one of the bound electrons (typically K shell). The accompanying fluorescent X rays are low energy photons

and are usually ignored in radiation therapy dose calculations. In a Compton scattering event, the incoming photon knocks off a loosely bound electron, considered as a free electron, from the atom. The photon itself is deflected with a lower energy. This is the dominant event for interaction of megavoltage photons with matter. The angular distribution of the outgoing particle is governed by the Klein-Nishina formula, and the angle of the outgoing particle uniquely defines its energy. In a pair production, the incoming photon is absorbed in the field of the nucleus and a positron-electron pair is produced. For this interaction to occur, the photon energy must be > 1.022 MeV, the sum of the rest mass energies of the positron-electron pair.

For electrons and positrons, the discrete interaction types are bremsstrahlung production, delta-ray production, and positron annihilation. Bremsstrahlung production is caused by the deceleration of charged particles (electrons and positrons) passing by the atomic nuclei. This is the mechanism by which photon beams are produced in a linear accelerator. The bremsstrahlung energy spectrum is continuous with the maximum energy equal to the kinetic energy of the incoming electron. The angular distribution is largely forward. A delta-ray is the secondary electron ejected from the atom resulting from a large energy transfer from the incoming electron or positron. If the incident particle is an electron, then the energy of the delta-ray cannot exceed one-half of the incident electron energy, for by definition, the outgoing electron with the lesser energy is the delta-ray. If the incident particle is a positron, then it can give up all its energy to the delta-ray. Positron annihilation is the process that occurs when a positron and an electron collide. If they are approximately at rest relative to each other, they destroy each other upon contact, and produce two photons of 511 keV each that are emitted in opposite directions. If they are moving at different relative speeds, the energies of the photons emitted will be higher.

APPLICATIONS IN RADIATION THERAPY DOSE CALCULATION

Beam Characteristics

In order to perform dose calculation using the Monte Carlo method, it is necessary to have accurate information about the radiation field incident upon the patient, that is, the phase-space data. This data is difficult to obtain by empirical means, therefore in practice it is obtained by Monte Carlo simulation of the machine head. Figure 1 shows a typical configuration of the machine head for a medical linear accelerator that produces clinical photon beams. The components directly in the beam are the target, the flattening filter, and the monitor chamber. The components that collimate the beam are the primary collimator, and the upper and lower collimating jaws. The phase space data can be collected on two scoring planes above and below the collimating jaws, respectively. For clinical electron beams, the machine head is similar to that of photon beams except that the target is removed, the flattening filter is replaced by a scattering foil system, and an additional applicator is used for further collimation of the electron beam (Fig. 2).

Figure 1. Production of a clinical photon beam (drawing not to scale).

Figure 2. Production of a clinical electron beam (drawing not to scale).

Figure 3 shows the energy spectra of a 15 MV photon beam. Note that the low energy photons have been filtered out by the flattening filter. Moreover, the spectrum near the center of the beam, say, within 3 cm of the central axis, is harder than that away from the axis, say, 10–15 cm from

Figure 3. Energy spectra of a 15 MV photon beam.

Figure 4. The energy spectrum of a clinical 9 MeV electron beam.

the center. The reason is that the flattening filter is thicker in the middle, thus absorbing more low energy photons. Figure 4 shows the energy spectrum of a clinical 9 MeV electron beam. It is clear there are two peaks corresponding to the thin part and the thick part of the scattering foil system. Figure 5 shows the angular distribution of the electrons at the isocenter plane (~100 cm from the entrance to the primary collimator). Due to the significant scattering of electrons in the scattering foils as well as in the air space above the isocenter, the angular spread is diffused and approximates a normal distribution.

This information about beam characteristics such as the energy and angular distributions is difficult to measure, but can be calculated by Monte Carlo with relative ease.

Figure 5. The angular distribution of a clinical 9 MeV electron beam.

Treatment Planning Dose Calculation

Many modern dose calculation algorithms other than Monte Carlo are quite accurate for megavoltage (^{60}Co –20 MV) external photon beam radiation therapy for sites that are composed of soft tissue (density $\sim 1 \text{ g}\cdot\text{mL}^{-1}$) and bone (brain, pelvis, limbs) (144). However, these algorithms are less accurate when electronic equilibrium is lost due to more severe tissue inhomogeneities. This may be a clinical concern in the lung, where soft tissue tumors are surrounded by low density (~ 0.2 – $0.3 \text{ g}\cdot\text{mL}^{-1}$) lung and in the head and neck (H&N) due to the presence of air cavities. Although Monte Carlo is currently impractical for routine clinical use, Monte Carlo calculations based on patient CT scans and inhomogeneous phantoms provide clinically valuable information, especially when combined with high resolution phantom measurements (film and/or TLD). For a summary of the status of the field (145).

Lung Cancer

Since lung has lower electron density than soft tissue, there is reduced attenuation of the primary photons of a beam traversing lung compared with the same path length in soft tissue. Most inhomogeneity correction algorithms can account for this effect (144). However, other, more subtle effects are described with reasonable approximation only by superposition-convolution algorithms (146,147) and most accurately by Monte Carlo. The cause of these effects is the long range of the secondary electrons in lung compared to soft tissue (the range is approximately inversely proportional to the ratio of lung to soft tissue density). Energy is thus transported outside the beam's geometric edge, resulting in a broader beam penumbra and reduced dose within the beam. Also, especially for a small soft tissue target embedded in a very low density medium and irradiated with a tight, high energy beam, there is a build-down (low dose region) at the entrance surface and sides of the target. All these effects are more pronounced for higher energy beams and lower density lungs (longer electron ranges) and smaller fields. The clinical concern is that treatment plans developed with algorithms that do not account for these effects can result in target underdose and/or overdose to normal tissues in penumbral regions. Figure 6 shows characteristic differences between the dose distribution of a single 6 MV photon beam predicted by a measurement-based pencil beam calculation that accounts only for changes in primary attenuation and that predicted by a Monte Carlo calculation. Lung radiation treatments usually consist of two or more beams, incident on the tumor in a cross-fire technique. Figure 7 shows that even in this patient's full four-field plan, these characteristic differences between the Monte Carlo and pencil beam calculations persist.

The degree to which the target underdose and broader penumbra in lung may compromise complications-free tumor control has been addressed in several studies (24,33,34,148–155). References 148–151 used measurements only to investigate penumbra broadening and build-down effects. A recent study (154) combined film dosimetry and EGSnrc and DOSXYZnrc Monte Carlo calculations to study the dose distribution in a $2 \times 2 \times 2 \text{ cm}$

Figure 6. Dose distribution of a single 6 MV photon beam (a) predicted by a measurement-based pencil beam calculation that accounts only for changes in primary attenuation and (b) that predicted by a Monte Carlo calculation. The red contour indicates the target. Please use online version for color figure.

acrylic (\sim tissue density) cube embedded in cork, simulating a small lesion in lung irradiated with a single and with parallel opposed photon beams from 4 to 18 MV. The parallel opposed geometry is a common field arrangement for treatment of lung tumors. Cork density, field size, and depth of the lesion in cork were varied. For the entire target cube to receive at least 95% of the dose to its center required field edges of the parallel opposed fields to be at least 2 cm from the cube even for the most favorable case (4 MV photons).

Other recent studies from different institutions have compared more complex treatment plans designed on anatomical phantoms or patient CT image sets and calculated with Monte Carlo versus the local treatment planning system calculation algorithm (24,34,152,153,155). In these studies, as in routine clinical practice, the beam is shaped to cover the planning target volume (PTV), which is larger than the grossly visible tumor gross target volume (GTV). The margin is intended to account for microscopic disease, setup error and breathing motion. Based on these studies, it is expected that (a) Results depend on the treatment planning system algorithm (34,153,155); (b) For the same planning system, results are patient (phantom geometry)

Figure 7. Dose distributions of a four-field plan in the lung. Figure (a) and (b) show dose distributions on a transverse plane predicted by a measurement-based pencil beam calculation and by a Monte Carlo calculation, respectively. The red contour indicates the target. Please see online version for color figure.

dependent as well as dependent on beam energy (24,33,34,153,155); (c) Changes quoted depend on the dosimetric coverage factor being evaluated. Mean target dose and dose encompassing 95% of the target volume are relatively insensitive indices; minimum dose (a single point) and dose-volume points on rapidly changing portions of the dose-volume histogram are more sensitive; (d) The PTV is usually underdosed relative to expectations from the treatment planning system. The degree of underdose varies from 1 to 20%, for 6 MV photons, depending on the dosimetric coverage factor, the lung density and the tumor location. For most of the cases reported, the underdosage is < 10%; (e) The planning system results for coverage of the GTV are more similar to Monte Carlo, as is expected because the margin results in a larger distance from geometric beam edge to the GTV border than to the PTV border; (f) The greatest differences are for tumors surrounded by very low density lungs (33,34); (g) There are greater differences for high (e.g., 15 MV) than low (6 MV) energy beams (153); (h) Normal organ doses (primarily lung and spinal cord) are only slightly affected.

Head and Neck Cancer

H&N cancer radiation therapy usually includes photon irradiation with low megavoltage beams (^{60}Co —6 MV). Target tissue often borders on naturally occurring or sur-

gical air cavities. Experiments demonstrate that build-down accompanying the loss of electronic equilibrium in air cavities in tissue-equivalent phantoms can cause up to a 25% underdose within the first millimeter of tissue (156–159), with particularly pronounced effects for small ($\leq 5 \times 5 \text{ cm}^2$) fields, such as are used for treatment of larynx cancer. Whether this impacts on local control of larynx cancers treated with 6 MV beams versus ^{60}Co has not been resolved (160). The penumbra broadening and loss of dose within the beam that are noted in lung also occur in air cavities but the small size of these cavities, compared to the size of a lung, prevent these effects from posing a serious clinical problem.

Monte Carlo calculations compared well with parallel plate ion chamber measurements for single field and parallel opposed field irradiation (4, 6, and 8 MV photons) of a $4 \times 4 \times 4 \text{ cm}^3$ cavity centered in a $30 \times 30 \times 16 \text{ cm}^3$ phantom (161) though neither method had the spatial resolution to probe the build-down region in detail. A few studies have compared dose distributions on patient CT image sets for clinical beam arrangements as calculated with the local planning system and with Monte Carlo calculations for the same beams (31,33,162). Differences between the two calculation methods are more noticeable for individual beams than when all the beams (from two to seven, depending on the plan) are combined for the overall treatment plan. Monte Carlo predicts inferior target coverage compared to the planning system, but the differences, which depend on dosimetric index and tumor geometry, are less than in lung. Spinal cord maximum dose differences of < 1 Gy were reported in (31) (with the Monte Carlo calculation sometimes higher, sometimes lower) and 3 Gy higher as calculated by Monte Carlo in (162).

DISCUSSION

For treatment planning dose calculations, Monte Carlo is potentially the most accurate method. Monte Carlo dose calculation for electron beams has recently become available on a commercial treatment planning system (48). For photon beams, however, it has not been practical for routine clinical use due to its long running time. To improve the computation efficiency, there are variance reduction techniques available. The most common techniques are splitting and Russian roulette (136). In splitting, a particle is artificially split into multiple particles in important regions to produce more histories. In Russian roulette, particles are artificially terminated in relatively unimportant regions to reduce the number of histories. In both techniques, the particle weight, of course, needs to be adjusted to reflect the artificial increase or decrease of histories.

In addition to dose calculation, perhaps a more important application of Monte Carlo is to provide information that cannot be easily obtained by measurement. For example, in the simulation of the machine head, the phase-space data provide information on the primary and scattered radiation from various components in the machine head. These data provide important information in understanding the beam characteristics and may be used for other dose calculation methods.

RADIATION THERAPY, QUALITY ASSURANCE IN

GLEN GEJERMAN
JOSEPH HANLEY
Hackensack University Medical
Hackensack, New Jersey

INTRODUCTION

The curative goal in radiation therapy is to deliver sufficient doses of tumoricidal radiation to a target volume while protecting the contiguous normal tissues. As radiation dose and accuracy of treatment delivery correlate with improved disease-free survival and avoidance of toxicity, quality control must be maintained throughout the planning and delivery of radiotherapy. The International Commission on Radiation Units and Measurements (ICRU) has recommended that treatment should be delivered to within 5% of the prescribed dose. Treatment planning and delivery is a multistep process that includes clinical decision making, patient immobilization, simulation, delineation of target and avoidance structures, determination of beam number and orientation, dose calculation, dosimetric scrutiny, patient set up, and treatment administration. In order to meet the ICRU's stringent recommendation, each of these steps must achieve better than 3% accuracy, and yet several studies have shown that geometric uncertainty

and dosimetric inaccuracy impact the clinical reality of radiotherapy. Patient misidentification, set-up variability, organ motion, block or multileaf collimation placement errors, and dosimetric miscalculation can lead to underdosing or overdosing the target volume and unintentional irradiation of normal surrounding tissue. Studies have shown that these types of errors occur at various stages in the treatment planning and delivery process, are often due to inadequate communication and mistakes in data transfer, and quality assurance procedures facilitate early detection of and reduction in their occurrence (1,2). A recent review of radiation therapy errors over a 5 year period at a major tertiary cancer center found that 44% of errors were due to field deviations, 38% due to incorrect use of beam modifiers, and 18% due to deviations from the prescribed dose. Once a quality improvement intervention that addressed several technological issues such as electronic charting was initiated, a significant impact in error reduction was noted (3). The numerous important quality assurance duties coupled with the increasing sophistication of radiation treatment planning and delivery systems, calls for an integrated comprehensive program that validates, verifies, and maintains accuracy throughout the entire process of radiation therapy delivery (4).

Treatment inaccuracies can be divided into systematic or treatment preparation variations (which include positioning errors, organ motion during treatment planning simulation, contouring errors, field shaping errors, and machine calibration errors) and random or execution variations (which include day-to-day patient misalignment and organ motion during treatment). A comprehensive quality assurance program must encompass both systematic and random uncertainty in treatment planning and delivery in order to minimize their occurrence. Although both types of errors lead to geometrical deviations of the target volume, they have different effects on the delivered dose. Systematic errors cause a displacement of the dose distribution away from the intended target and random errors lead to blurring of the dose distribution. The impact of systematic errors on target dose and the tumor control probability is therefore much greater than the impact of random execution variations (5,6). Identifying and correcting planning preparation errors early in the treatment process is critical in order to mitigate their impact on the treatment outcome.

To minimize treatment inaccuracies, it is essential that each radiation oncology department establish a "quality system" or quality assurance program to provide the organizational structure, responsibilities, procedures, processes, and resources for assuring the quality of patient management. A series of checklists to monitor compliance with the objectives of the program should be developed and applied. Due to the ever-changing nature of radiation oncology, this quality assurance program should be reviewed annually.

SIMULATION QA

The foundation of treatment planning is the simulation process. After the radiation prescription has been filled out to include the intended target, the organs to avoid, and the

total and fractional doses, the patient undergoes treatment planning simulation, during which anatomical data is acquired, patient topography is measured, and the target volume and avoidance structures are delineated. Radiation therapy simulators use fluoroscopic, X-ray and computed tomography (CT) techniques to visualize internal anatomy in relation to external landmarks and can be divided into two broad categories: conventional or fluoroscopic simulators and CT simulators. These simulators can replicate the treatment machine geometry either physically, in the case of a conventional simulator, or virtually on a computer for CT simulation. The quality assurance program for the physical simulators must be parallel to that of the treatment machines, so that the geometric relationship between the treatment unit and the target volume can be accurately and consistently reproduced. To ensure the same accuracy in the case of virtual simulation, the treatment unit must be precisely modeled in the simulation computer.

To minimize intratreatment movement, and to ensure accurate daily positioning, patients are simulated (conventional or CT) in the treatment position with the use of special immobilization devices. These devices extend beyond the treatment site and rigidly immobilize the patient while providing them with support to enhance relaxation and minimize movement. Studies comparing set-up variations in immobilized versus free set up of patients note a significant reduction in positioning errors. In patients without custom immobilization, the percentage of fractions with set-up errors greater than 5 mm ranged from 17–57% and errors greater than 10 mm occurred in 15% of fractions (7,8). A randomized trial analyzing patients in the prone position receiving pelvic radiotherapy found a statistically significant benefit when using rigid immobilization. In the group treated without immobilization, 31% of port films had isocenter deviations greater than 10 mm compared with 11% in the immobilized patients. Average set-up deviations in the anteroposterior, right-left, and superior-inferior directions were 5.2 mm, 3.2 mm, and 4.3 mm in the patients treated without immobilization versus 2.9 mm, 2.1 mm, and 3.9 mm in those treated with rigid immobilization, respectively (9). Patient-related uncertainties also include organ motion. The patient's treatment position can impact the extent of both inter- and intrafractional movement. A randomized trial analyzing organ motion during treatment demonstrated less prostate motion in the supine treatment position. The mean anterior-posterior organ motion was 0.1 mm for patients treated in the supine position as opposed to 0.7 mm in those treated prone (10). These data demonstrate why proper immobilization is such a vital part of the quality assurance program. It should be noted that the integrity of immobilization devices should be checked on a daily basis during the treatment course.

Quality assurance of the conventional simulator is necessary to avoid inaccuracies that could lead to target-beam misalignment. After installation, and prior to clinical use, a detailed customer acceptance procedure is often performed and can act as a baseline for ongoing testing. A complete QA program for a simulator should follow the guidelines detailed in the American Association of Medical Physicists (AAPM) Task Group 40 (TG40) report (4) and be

gantry and collimator rotation, and the ability to accurately shift the isocenter. In addition to standard QA procedures for conventional CT scanners, CT simulators require interval testing of the laser system and of the data link to the virtual simulation computer system that allows tumor contouring, isocenter and field size definition, transfer of coordinates to the patient's skin, as well as construction of the DRR (13). Upon completion of virtual simulation, the patient's images, contours, and treatment beams are electronically sent to the treatment planning system.

TREATMENT PLANNING QA

Modern treatment planning systems consist of complex software run on sophisticated platforms with multiple peripheral devices. Recognizing the challenge of ensuring proper maintenance and use of these increasingly complicated systems, the AAPM Task group 53 (TG53) published a comprehensive set of quality assurance guidelines that can be applied to clinical radiotherapy planning (14). Acceptance testing and commissioning of a treatment planning system provides the benchmark by which the system will be evaluated during the periodic quality assurance testing. Acceptance testing is performed after installation but prior to clinical use of the system. The process entails testing that the system's hardware, software, and peripheral devices function according to manufacturer's specifications. These tests ensure that the system can properly acquire patient data, process anatomical contouring, orient beam direction, perform dose calculation, display the resultant isodose plots, and print hard copies of the approved treatment plan's parameters. The ability to properly transfer imaging data is confirmed by scanning phantoms of known geometry with internal markers and transferring the imaging data to the treatment planning system. The transferred data is then compared with film images to validate orientation, measurement, and fiducial positioning. System commissioning involves extensive testing of the dosimetric algorithms for a variety of clinical scenarios. The physical properties of each treatment unit have to be entered into the system and checked for consistency with manufacturer's specifications. Data such as percent depth-dose tables, off-axis profiles, and output factors are acquired using a computer-controlled water phantom for each treatment beam on each treatment unit to be used in the planning system. Phantoms with known geometric target volumes are used to simulate common clinical scenarios and treatment plans are evaluated to verify calculated dose distributions. Although anthropomorphic phantoms (that are shaped like the human body) are well-suited to test clinical treatment techniques, geometric phantoms (that are cylindrical or cubic) have more reliable ionization chamber positioning (15). If dosimetric calculations that account for inhomogeneities within the patient are to be performed, a CT number to electron density calibration curve must be established, which is performed for each CT acquisition unit that sends images to the treatment planning system. A phantom containing plugs of known electron density is scanned on the CT and

the corresponding CT number is determined. These numbers are plotted versus electron density to derive the calibration curve for that scanner. As an incorrect conversion of CT number to electron density can lead to significant dosimetric miscalculations, the American College of Radiology (ACR) recommends testing this calibration curve monthly. Although the most accurate form of dose calculations are Monte-Carlo-based, these calculations are computationally intensive and cannot currently be used for routine planning. All other dose calculation algorithms used in treatment planning systems have limitations, and it is essential to understand where these limitations manifest, for example, in areas where electronic equilibrium does not exist, such as lung-tissue interfaces. Routine periodic quality assurance testing of the planning system consists of daily, monthly, and annual tests. Daily tests validate the performance of input devices such as point digitizers and the accuracy of output devices such as printers. Monthly tests can involve calculating computer checksums for the treatment planning software executables and machine data, to ensure the program and data has not been modified. Annual tests are more involved and should include a subset of standard treatment plans that cover a wide range of clinical scenarios ranging from point-dose calculations, 2D, 3D conformal radiation therapy (3DCRT), and intensity-modulated radiation therapy (IMRT) plans. This set of standard plans are used for testing whenever software upgrades, either patches or version changes, are applied.

Once the imaging data has been transferred to the treatment planning system, the target volume and avoidance structures must be delineated if not already defined at the CT simulation. This delineation can be the major contributor to overall uncertainty in the treatment planning chain, as many factors exist that contribute to this uncertainty. It is imperative that the treating physician and the radiation treatment planner share a common vocabulary regarding the tumor volume and the additional margins necessary to account for organ motion and set-up inaccuracies. Prescribing and designing a treatment plan to a target without correcting for geometric uncertainties will result in a substantially different delivered dose than the intended one. In order to address these issues, the ICRU Report 50 (16) recommended using specific definitions regarding margins and volumes. The gross tumor volume (GTV) represents the visible tumor. The clinical target volume (CTV) denotes the GTV with an additional region encompassing suspected microscopic spread. The planning target volume (PTV) contains the CTV with margins added to account for geometric uncertainties. These margins are determined based on the extent of uncertainty caused by patient and tumor movement as well as the inaccuracies in beam and patient setup. Several margin recipes based on geometrical uncertainties and coverage probabilities have been published; however, their clinical impact remains to be proven (17). The organs at risk (OAR) are the normal tissues that are contiguous with the CTV (such as small bowel, rectum, and spinal cord) whose radiation tolerance can affect the maximum deliverable dose and treatment technique. The ICRU report 62 (18) refined the definition of the PTV with the concepts of

internal margin and set-up margin. Internal margin uncertainty that is caused by physiological changes such as respiratory movement cannot be easily modified without using respiratory gating techniques. In contrast, set-up margin uncertainty can be more readily minimized by proper immobilization and improved machine accuracy. The report also addressed the issue of OAR mobility by introducing the planning organ at risk volume (PRV) in which additional margins are added to account for the geometric uncertainty of these organs. In order to avoid significant radiation toxicity and to maintain post treatment quality of life, the planning physician must be vigilant when considering avoidance structures. In a Radiation Therapy and Oncology Group (RTOG) analysis of the impact of dose escalation in prostate cancer, a lack of physician awareness leading to unnecessary exposure of the penile bulb to high radiation doses lead to treatment-induced impotence (19).

Even with a common terminology and attention to detail when delineating the anatomical structures, several uncertainties exist that are related to the imaging modality used for data acquisition. Proper acquisition of CT data is challenging in that numerous factors, including slice thickness, slice spacing, CT number scale, and organ motion, can affect this information resulting in dosimetric and anatomic inaccuracies. A CT image artifact known as partial volume averaging occurs when two structures of different tissue density occupy the same voxel resulting in an averaging of their CT numbers. Unless the appropriate CT slice thickness is used, accurate target delineation can be compromised, as details of contiguous anatomic structures may not be appreciated. CT imaging of a moving organ can lead to significant distortions, particularly when the organ is small compared with the extent of its displacement. When the scan time is protracted, the artifact can be significant enough to render the reconstructed images unrecognizable in relation to its stationary counterpart (20). TG 53 recommends the use of imaging protocols that standardize scan parameters such as patient position and immobilization, CT slice spacing and thickness, the extent of the patient's anatomy to be scanned, breathing techniques for patients with abdominal or thoracic tumors, and the use of contrast agents (14). Some anatomical structures are better visualized using alternate imaging modalities such as Magnetic Resonance Imaging (MRI) or functional imaging such as Positron Emission Tomography (PET) scans. For example, to improve the accuracy of thoracic GTV recognition, PET scans have been used in conjunction with CT-based simulation. Although in some circumstances, the ability to distinguish between thoracic tumor and atelectasis can result in a smaller GTV (21); at other times subclinical mediastinal adenopathy appreciated on PET will require enlarging the treatment field to encompass all active disease (22). When multiple images sets, acquired with different imaging modalities, are used in the planning process, the images must be accurately correlated in a common frame of reference. Typically, the images sets are "fused" onto the CT frame of reference. In visual fusion, the independent images are studied side by side and are visually fused using data from both to outline the GTV. In software fusion, the independent studies are geometrically

registered with each other using an overlay of anatomic reference locations. A recent review found that software fusion reduced intra- and interobserver variability and resulted in a more consistent delineation of tumor volume when compared with visual fusion (23). It is imperative to perform QA on the fusion software. Acquiring datasets of a phantom with known geometrical landmarks on all modalities to be tested and performing the fusion process can accomplish this goal. PET/CT scanners that obtain both images simultaneously allowing for self-registration are becoming more widely available and will further facilitate accuracy in contouring.

In addition to uncertainties associated with various imaging modalities, it is well documented that inter- and intraobserver reproducibility exists in GTV delineation, and significant differences in the size of the GTV are noted depending on the imaging modality used (24,25). When contouring CT images, the correct window level settings must be used to appreciate the extent of the tumor shape and its relation to contiguous organs at risk. The treatment planning CT must be carefully reviewed to assess for positional or anatomic anomalies. For example, data acquired in the thoracic or abdominal region should be carefully examined for any sharp discontinuities in the outer contour that might indicate a change in breathing pattern or physical shift of the patient due to coughing, for example. A retrospective review of prostate cancer patients treated with conformal radiotherapy found an association between rectal distension on the planning CT and decreased probability of biochemical cure. Planning with a distended rectum can result in a systematic error in prostate location and was found to have a greater impact on outcome than disease risk group (26).

Once all the relevant organs have been contoured and the target dose and dose constraints have been unambiguously communicated to the dosimetry team, the appropriate combination of beam number, beam direction, energy, and intensity is determined. These parameters are optimized to deliver maximum dose to the CTV and minimum dose to the OAR. Conventional dosimetric calculations known as forward planning involves an experienced planner choosing multiple beams aimed at the isocenter and altering beam orientation and weighting to achieve an acceptable plan. The dose delivered with the chosen beam arrangement will be affected by the interaction of the radiation beam with the patient's tissue density and is calculated by the planning computer. 3D conformal radiotherapy planning uses CT data to generate tumor and normal organ 3D images and displays them from the perspective of different angles using a BEV technique. Optimization of the treatment plan is performed by iteratively adjusting the beam number and direction, selectively adjusting the field aperture, and applying compensators such as wedges. In contrast, IMRT uses inverse planning to deliver a desired dose to the GTV and PTV with constraints to the OAR. Instead of choosing beam directions and then evaluating the resultant dosimetry, the desired dose distribution is stipulated using dose-volume constraints to the PTV and OAR and then the computer algorithm alters the various beam intensities in an attempt to achieve these planning goals.

After the dosimetry team completes their calculations, the proposed treatment plan must be carefully evaluated to confirm the prescription fractional and total doses and to determine whether it satisfies the prescription goal. For conventional treatments, this determination is performed by inspecting 2D isodose displays through one or more cross sections of the anatomy. For 3DCRT and IMRT, BEV data and dose volume histogram (DVH) analysis is used in addition to the isodose displays to evaluate dose minima, maxima, and means of both target and avoidance structures. The DVH that graphically depicts the percentage of a volume of interest that receives a particular dose does not give spatial information regarding dose distribution. If the DVH indicates underdosing, only by reviewing the plan's isodose display can one locate the area of inadequate coverage. Mathematical models that use DVH statistics to estimate the normal tissue complication probability (NTCP) have been developed. These NTCP models have been found to more accurately predict the likelihood of radiation-induced toxicity than point-dose radiation tolerance data. An important task in a quality assurance program is to calculate the fractional and total doses to the OAR in order to estimate the risk of radiation injury. These doses can be described in terms of minimum, maximum, and mean doses to an entire organ or as the volume of an organ receiving greater than a particular dose. In situations where the PTV anatomically overlaps the OAR, clinical judgment must be used to assign a priority to each goal. The location and volume of dosimetric inhomogeneity (both hot spots and cold spots) must be evaluated, which is particularly true for IMRT where dose homogeneity is often sacrificed for dose conformality.

When the plan has been approved by the dosimetrist and the physician, all documented parameters including patient setup, beam configuration, beam intensity, and monitor units are sent to a R&V system either manually or, preferably, electronically. All the data from the plan, printouts, treatment chart, and R&V undergoes an independent review by a qualified medical physicist. This second check entails review of the prescription, the plan's calculation algorithm, wedge placement, dose distribution, DVH, and beam apertures. Hand calculations of a point dose in each field are analyzed to verify the dosimetry. The patient then undergoes a verification simulation to confirm the accuracy and reproducibility of the proposed plan. During this confirmatory simulation, the isocenter position is radiographically confirmed, block geometry is checked, and measurements such as SSD are validated. Finally, a pretreatment port film verification is obtained on the treatment machine to verify reproducibility of set up and to confirm measurements such as the SSD and distance to tabletop.

The verification of patient-specific dose distributions with water phantoms, ionization chambers, diodes, or film dosimetry is an essential component of the QA process. The standard method of evaluation consists of overlaying hard-copy plots of measured and calculated isodose distributions and qualitatively assessing concordance. As a result of the nonuniform intensity inherent in IMRT and the resulting steep dose gradients throughout the treatment field, IMRT plan verification is more challenging. Radiographic film

dosimetry can be used to verify the IMRT leaf sequences and monitor units; however, as film sensitivity varies with beam energy, field size, film positioning, and film processing, great care must be taken to normalize the calculated and measured dose. Computer-assisted registration techniques are now available to determine the relative difference between the planned and delivered individual beam fluence or combined dose distributions on a pixel-by-pixel basis in order to score the plan using a predetermined criterion of acceptability (27).

LINEAR ACCELERATOR QA

The quality assurance protocol for linear accelerators is designed to monitor and correct performance of the equipment so that the physical and dosimetric parameters established during commissioning and acceptance testing can be maintained. TG40 (4) described a thorough QA program for linear accelerators with recommended test frequency. The daily tests include checking the safety features such as the door interlock and audiovisual intercom systems. Mechanical performance such as the localizing lasers and the machine's optical distance indicator and dosimetric output such as the X-ray and electron constancy is also checked daily. Monthly checks of the linear accelerator's mechanical accuracy include light-field coincidence; cross hair centering; gantry, collimator, field size, and couch position indicators; latching of the electron cone, wedge, and blocking trays; electron cone interlocks; and the emergency off switch. An example of a monthly mechanical and safety checklist for a linear accelerator is shown in Fig. 2. Monthly checks of the dosimetric accuracy include constancy of the X-ray and electron output, central axis parameters, and X-ray and electron beam flatness. Annual mechanical tests include checks of the safety locks; the tabletop sag; vertical travel of the treatment couch; the collimator's, gantry's, and couch's rotation isocenter; the coincidence of the radiation and mechanical isocenter; and the coincidence of the collimator gantry and couch axes with the isocenter. The annual dosimetry tests check for monitor chamber linearity; wedge transmission factor constancy; off-axis factor constancy; and X-ray and electron output and off-axis constancy dependence on gantry angle. In addition, a subset of the depth-dose and off-axis profile scans acquired at commissioning are performed and compared with the baseline.

The use of multileaf collimators (MLC) in 3D conformal and intensity-modulated radiotherapy requires additional QA measures. When using MLC for 3DCRT, leaf position inaccuracies will have an effect on the resultant dosimetry; however, because of the PTV margins, the effect is minimal. In contrast, when using MLCs for IMRT, a miscalibration of 0.5 mm causing a 1 mm error in radiation portal size can cause a 10% dose error when delivering IMRT with an average field size of 1 cm (15). As MLC function is critical to dosimetric accuracy, rigorous QA protocols are required. The accuracy of the multileaf collimator (MLC) is verified by using radiographic film to measure radiation dose patterns and by checking for a gap between the leaves when they are programmed to be in the closed position.

RADIOLOGY INFORMATION SYSTEMS

JANICE C. HONEYMAN-BUCK
University of Florida
Gainesville, Florida

INTRODUCTION

If asked to define the functionality of a radiology information systems (RIS) 5–10 years ago, one may have listed order entry, film management, charge capture, billing, patient and examination tracking, and possibly inventory management. These systems were in place long before Picture Archiving and Communication Systems (PACS) and the Electronic Medical Record (EMR) were in widespread use. Although PACS, and especially the EMR, are not globally implemented, it is an accepted premise that they will be globally implemented sometime in the future. Now, people often refer to radiology information systems as a suite of computers serving the myriad of functions required for an electronic radiology practice that might include the classic RIS, PACS, speech recognition, modality workflow, and the radiology portion of the EMR and the Hospital Information System (HIS). Generally, in this article RIS will be defined in the more classic sense, it is the computer that manages all

aspects of radiology orders. The RIS must now additionally perform the functions required to automate the workflow in a radiology department including examination ordering and management, modality scheduling, examination tracking, capturing charges, inventory management, electronic signatures, report distribution, and management reporting. Every transaction and interaction with the system must be recorded for auditing purposes and must help maintain the privacy and security of Protected Health Information (PHI) for a patient. Furthermore, the RIS must interface seamlessly with a PACS, a speech recognition system, an HIS and an EMR. This is a nontrivial task in a multivendor installation.

This article focuses on the RIS as the center of the radiology department workflow management with the interfaces to other systems. Interface standards are introduced with examples and some developing concepts in healthcare as they pertain to radiology are discussed.

INFORMATION SYSTEMS IN RADIOLOGY

Figure 1 shows the typical workflow associated with a radiology study. The referring physician orders the study, typically through the HIS, but often in smaller institutions, through the RIS. The order is then sent to PACS and to the speech recognition system. It is available for the technologists as a virtual worklist and on PACS modalities through DICOM modality worklist. In this case, the modality worklist is supplied by a broker or translation system that creates the correct format from the order. After the examination is completed, it is sent to archives and PACS displays where it is interpreted by the radiologist. The radiologist is working from their own worklist of studies that are available according to their role in the department and which have not been dictated. A role may be defined as a radiologist who interprets chest studies or perhaps a radiologist who interprets

CT studies. The radiologist dictates into a speech recognition system that appends the report to the data about the examination that exists in the system. The reports are sent to the RIS, closing the loop, and then are sent to the EMR. The dashed line from the PACS Archive to the EMR indicates that the images may be stored in the PACS archive with links to them in the EMR, so it is unnecessary to store the images in both systems. The PACS displays and databases and the speech recognition system are frequently from different vendors, so an interface between the two must be accomplished to be certain that the radiologist is dictating the report on the study they are viewing. This loose coupling of the report and imaging exam must be carefully developed and tested to be sure the reports are permanently attached to the correct exam. Of course when all the systems are purchased from a single vendor, a tighter coupling of data and images may be easier to accomplish. The magic number in a radiology system that ties all the information, images and reports for a specific study together is the accession number. This number should be unique for a study and should identify the patient, exam, date, time, report, images, contrast used and anything else that goes with that study. An accession number query should only get one accurate result.

THE RIS AND ITS ROLE IN RADIOLOGY WORKFLOW

Although the RIS appears to be a very small actor in radiology workflow, this is far from the truth. Note the number of interfaces, indicated by arrows, with the RIS as opposed to the other systems in Fig. 1. The RIS is the integral part of the total electronic radiology practice and without it there would be no connection with the rest of the healthcare enterprise (1,2).

The other systems in Fig. 1 are also important and must be interfaced carefully. Although at times the lines between the functionality of the various systems blur, each

Figure 1. Interactions among information systems during the workflow associated with a radiology study.

system has its purpose in the overall electronic health system. The HIS is generally a system used to capture information about a patient, including but not limited to, their demographics, address, and insurance information (very important). The HIS captures charge information, alerts users when communications with a third-party payer is necessary, and generates bills. Frequently, the HIS is the centralized location for ordering various studies including radiology, lab, speech pathology, physical therapy, and so on. In addition, the HIS can be the center for reporting hospital issues, such as maintenance needs, network failures, and so on. The HIS usually provides extensive administrative reporting tools. The EMR is a patient-centric system containing the electronic record of all a patient's encounters at the institution. The HIS can be used to generate numbers of radiology orders generated in a certain time frame, but when a physician needs to see the total record for his patient with all associated orders, reports, and images to form a diagnosis and treatment plan, the EMR is a better model. The EMR will be discussed with more detail later in the article. The main purpose of PACS is to manage radiology images efficiently. These very large datasets have special needs when it comes to archiving, display, and networks and it makes sense to keep the PACS functionality a little apart from the rest of the usually text-based information systems. Speech recognition is generally developed for specific specialties, such as radiology. The radiology lexicon known by the recognition engine is unique to radiology. Of course, parallel systems exist in other specialties, but the focus here is on radiology. In general the radiologist dictates a report; the speech recognition transforms the voice file into a text file and displays it for confirmation of correctness or for editing.

RIS BASIC FUNCTIONALITY

Most RIS vendors offer a core feature set that captures the information items regarding a patient study in radiology and provides tools for those involved to manage the study. Table 1 is based on the list generated by Aunt Minnie (3) in the section on Radiology Information Systems in their buyer's guide. These functions are probably the minimum required for an RIS purchase. Anyone seeking to purchase an RIS should be aware of the resources available to help them with their decision and should follow a structured Request for Proposal (RFP) or bid format. Buyers should specify how these functions should work in their institution. For example, if the feature "interaction checking between exams" is included, the buyer should write a requirement that matches their workflow. An example of part of the requirement might be, "automatically check patient history for previous exam and warn user at the time of order". If you go back to Fig. 1, it is quite common for the physician or their agent to enter the order on the HIS, then this is transmitted electronically to the RIS, so the RIS would need to alert the HIS, which in turn would alert the physician or their agent. A requirement specification document tells vendors what the buyer expects and forces them to respond to the buyer with respect to their specific workflow. Buyers should be sure to include any special requirements for the institution. Some examples include the length and format of the medical record number or accession number or the requirement that it must be possible to enter a report directly on the RIS in the case of an HIS downtime. The buyer may want to specify their requirements for performance; "a query for a patient record should return results in < 2 s".

Table 1. Core Feature Set for the Typical Current RIS

Function	Comment
Patient registration	This may be performed at an HIS level and transferred to the RIS
Patient tracking	This allows a user to track the patient through the procedure (started, ended)
Order entry	This may be through the HIS, but in the case of HIS downtime, users must be able to enter an order
Merge or reconcile patient information	This is important after a downtime when temporary Medical Record Number (MRN) or accession numbers may have been used or in a trauma situation where a temporary name was used.
Interaction checking between exams	Does a previous exam interfere with the one being ordered?
Single exam code for combined orders	Can you combine Chest/Abd/Pelvis on one exam code with individual accession numbers?
Generate future orders	
Generate recurring orders	Can this also remind the ordering physician that the patient is receiving recurring orders, for example, recurring portable chest exams?
Document imaging	Can you scan paper and include it in the record?
Alerts for pregnancy, diabetes, allergy, and so on	This information will probably be sent from the HIS.
Attaches Prep information to ordered procedures	
Generates an online worklist for technologists	
Supports DICOM modality worklist	This could be a native feature in the RIS or an interface to PACS.
Charge capture	Including examination, supply items
Links CPT and ICD-9 codes to an examination	
Supports distribution of reports	This may be an interface to an HIS or an EHR.
Generates requisitions, labels, and so on	For those still using paper
HIPAA audit capabilities	
Graphic User Interface	

Although an institution may have an HIS and/or an EMR, the RIS will probably also keep an archive of diagnostic reports. From an information sciences storage perspective, a single data repository for specific information is more desirable than multiple, different repositories that have to be synchronized and managed. Since the RIS is rarely the system that is used by the ordering or referring physicians, it serves as an additional archive of diagnostic reports and can be used to track trends, search for diagnoses and impressions, and is used as a backup should other archives fail.

Table 2 contains a (noncomprehensive) list of advanced features for an RIS. Many of these features have become more important since hospitals have added PACS and required integration of all their systems. Bar code support may not be as important in a paperless world, but most of us are not there yet. Bar codes offer a quick and painless way to choose accurate information from a database. One or two bar code entries can locate the right information without the frustration most people experience trying to enter a long string of numbers and letters.

More institutions have merged into one larger entity or have splintered out clinics and imaging centers to locations with easier access. Since it is frequently the case that patients can be seen in various locations in a healthcare system, the RIS needs to support multifacility scheduling, as well as patient tracking. If a group of institutions form an enterprise and each institution can create individual medical record numbers (MRN) identifying patients, it is possible that more than one person will have the same medical record number: from different institutions. The RIS, as well as the EMR and HIS and PACS, must be able to differentiate individuals and track them throughout all the institutions in an enterprise. This can be a difficult and frustrating problem and should be managed carefully. All the interfaces need to be specified in detail. A more comprehensive discussion on the required interfaces is included later in this article. Electronic signatures and addenda need to match the workflow for an institution. In a large teaching hospital, it is common for a resident to

dictate a report and for a faculty member to approve and verify it. At this point, two signatures are required. Then, if an addendum is entered on the report, which could happen when comparison studies are received from an outside source, a different resident–faculty member combination could dictate it, resulting in up to four signatures on a report. If multiple addenda are allowed, multiple signatures must also be allowed.

It is important for report distribution, and especially in the case where critical results have been found, that referring physician information is stored somewhere. When an RIS is in a stand-alone installation or the RIS is the distribution entity for reports, then each ordering physician and ordering service must have a unique profile and protocol rules for the communication of reports and especially for critical results. When the RIS is part of a larger enterprise system, the HIS or EMR will distribute the reports, but some triggering mechanism must alert the physician if a critical result or unusual finding is present. This will usually be a function of the RIS. The system must keep an audit of the successful communication with the ordering physician or service as part of the Joint Commission on the Accreditation of Health Care Organizations (JCAHO) recommendations for taking specific steps to improve communications among caregivers (4). This organization requires that each accredited institution have a method for rapid communication of results for both critical results and critical tests in place. In addition, each institution must have a way to monitor and report the efficiency and effectiveness of the communication for a subset of the results considered critical. For radiology, this will most likely be a function of the RIS.

The RIS should be able to generate administrative reports on the numbers of studies performed by date, the modalities used for studies, performance figures for technologists, costs of examinations, and reimbursement trends. In addition, the system should have a query interface so custom reports can be generated. It is very common for this query interface to use the Structured Query Language (SQL) that may have a steep learning curve. Some

Table 2. Advanced Feature Set for the Typical Current RIS

RIS Options	Comments
Bar code support	For quickly entering data in the environment where paper is still used
Supports multifacility scheduling	Can a single person be tracked through multifacility visits?
Interface to PACS	This needs careful specification and configuration
PACS included	
Appointment confirmation / reminders	
Information about referring physicians available	This may be better in the HIS, but will require close coordination
Technologist comments stored	Are they available in the speech recognition system or in PACS? How will the radiologist see them?
Electronic signature	
Proxy signature	
Dual signature	
Different signature on an addendum	
Multiple addenda	
Web based user interface	
Integration with speech recognition	
Interface to HIS	
DICOM modality worklist	This may be provided by the RIS instead of the broker in PACS

Figure 2. Current standards used as interfaces among information systems associated with a radiology study.

vendors offer a graphical user interface for custom queries that may make queries and reports easier to generate. Many of the RIS systems on the market today have a web-based interface that seems to be intuitive to the current internet-literate generation.

It is increasingly common to find RIS vendors storing images and providing PACS services, such as study display. For some users, this may be a good solution to an electronic radiology practice, for others, the RIS vendors may not have the sophisticated tools for image manipulation that PACS vendors have traditionally supplied. In addition, to complicate matters, PACS vendors are now offering more RIS functionality and once again the borders between the two systems are becoming blurred. It will be up to the institution to decide whether to use one of these hybrid systems or to interface two dedicated systems.

INTERFACING SYSTEMS

In radiology, there are two main interface standards, Health Level 7 (HL7) (5) and Digital Imaging Communications in Medicine (DICOM) (6). The HL7 is a formatted text-based standard that typically specifies the content of messages that are communicated among information systems in a healthcare institution, such as admission information, radiology results, and operating room notes. An RIS typically contains information about radiology schedules, orders, billing and reports, mostly text values. A complete EMR needs reports and images from radiology. Reports can be sent using HL7, but there is no way to encode image data in the current versions of HL7. Because of this limitation, DICOM was developed as the standard to handle transfer of images between systems that acquire, store, and display them.

Figure 2 illustrates the usual standards used for communication in the electronic medical practice first introduced in Fig. 1. Following the information flow,

the attending physician places their order for a radiology study on the HIS, which is sent to the RIS via HL7. The order information is sent to PACS and the study is scheduled. The HL7 information is converted to DICOM in PACS using a translation program or broker and the patient demographics are attached to a study produced by PACS acquisition units (CT scanners, MRIs, computed radiology units, etc.). The radiologist using the DICOM viewer views the images and a report is generated using speech recognition. Note that the speech recognition system also receives the ordering information from the RIS, so at this point, there should be a single pointer or index to match the images with the report. The output from speech recognition could be in an HL7 format or a DICOM structured report. The report is usually sent to the RIS and then to the EMR.

The HL7 offers a rich data definition and is widely used to communicate information about the status of the patient in the form of an Admission Discharge Transfer (ADT) packet that informs all relevant systems about the location and identity of a patient, an order packet (ORU), and a report packet (ORP). There are of course many other types of packets that are part of normal transactions of an institution, but these are the ones most often used in the transfer of information between the RIS, PACS, and the speech recognition system. An example of an HL7 message is shown in Table 3. The field entries have been created for this example and this does not reflect an actual patient, referring physician, or radiologist. However, if this were an actual patient, the medical record number would be 0000123456, and the patient's name would Robert Richards, who was born on September 1, 1991 (19910901). The patient's ordering and attending physician is Forest Wood whose phone number is listed in the order. The accession number for this patient is 4445555 and the examination ordered is a bone age radiograph. The reason for the study is included in the text. For this institution, the procedure number for the routine bone age is 3000 and the location where the study will

be performed is AUXR. When two or more vertical lines appear in the message, they represent fields that contain no data. Each field of an HL7 message is carefully specified and each system using HL7 understands that the PID-3 field will contain a medical record number. A report message in HL7 also contains specified fields that include many of those in this order packet as well as the diagnostic report, the reporting radiologist, and the verifying or signing radiologist. The accession number, 4445555 will be the key for connecting the order to the report to the images, and also to identify that this study was performed on Robert Richards. Much more information on HL7 and the standards committee may be found on the HL7 home page (5) and on numerous other web sites.

Since HL7 had no current capacity for images, the American College of Radiology (ACR) and the National Electrical Manufacturer's Association (NEMA) developed a standard for image communication among PACS devices. The earliest incarnations of this standard were hardware based with point-to-point connections between a modality and a computer. Originally named the ACR-NEMA standard, it has evolved to become DICOM and is still evolving to meet the ever-changing demands of radiology. The standard not only specified the content of the messages passed, it specified the communication pathways for carrying these messages. A full description of the DICOM standard is beyond the scope of this article. More information may be found on the DICOM home page (6), where DICOM specifies the transfer of images among devices, printing to film and paper, and the creation of a modality worklist, among many other things. Radiology modalities typically do not have HL7 interfaces, they are strictly DICOM enabled computers, and in order for them to have knowledge of an order placed by the RIS, the HL7 order needs to be translated into DICOM. For historical reasons, this translation device or software is often called a broker. The broker receives the HL7 and builds a DICOM modality worklist that may be queried by modalities, such as computed tomography (CT) or magnetic resonance imaging (MRI) units. The modality then compiles a list of studies that have been ordered and the technologist may pick a study from the list as they are setting up the console for the examination. This alleviates the need to reenter informa-

tion about the patient and assures accurate and complete information that can be tracked back to the original order. The all-important accession number is thus associated with the study being performed. Table 4 shows a partial DICOM message attached to the image produced for the study ordered previously. This message is a series of groups, elements, element sizes, and element contents that are again very specific. The accession number is always located in group 8, element 50; the patient's name is always in group 10, element 10; and the patient's medical record number is always in group 10, element 20. The groups contain common elements. Group 8, for example, is information about the examination while group 10 contains information about the patient.

When the diagnostic report is generated on the speech recognition system, the accession number is attached and when the study is completed, the image (Fig. 3) and report (Table 5) are matched correctly. An archive query returns the basic information for the study so a correct selection can be made (Fig. 4).

The basis for PACS and speech recognition working together correctly is the RIS acting as an order entry and management system along with the HL7 and DICOM standards. Without the RIS and the standards, there would be no accurate way to capture all the patient information and to attach the report to the image. The PACS images should never be available without accurate and complete information (7). Every PACS must have a way to link pertinent patient information and the diagnostic report with the image. Although the example presented was fairly simple and straightforward with only one image, consider the case where a patient in an intensive care unit has multiple chest radiographs every day. Without a way to associate a report accurately with an image, an ordering physician could read a report for the wrong time. With accurate and complete information everyone can be assured that the report is attached to the correct study.

OPTIONS FOR THE INTEGRATION OF SYSTEMS

Although the standards are crucial to the success of an integration project, there are usually still issues among

vendors. The DICOM can be interpreted in different ways: HL7 fields may be required by one vendor and ignored by another, and problems will arise. Buyers have several options to consider. The easiest way to assure that integration will be successful is to purchase all information systems from the same vendor. Of course, that will not completely assure success because not all vendors can supply all the required systems. Most noticeably, they may not all supply the imaging modalities needed. As soon as another vendor's modality is introduced, an integration project is needed.

Another decision that must be made is the actual storage of the images from PACS and the diagnostic reports associated with these images. The RIS or EMR can supply the storage for both, or the PACS can supply the storage for both, or some combination of storage options can be designed. Neither the RIS nor the PACS would be the preferred method for storing and delivering studies and reports to referring and ordering physicians because the information is all radiography-centric and it is far more desirable to see a total picture of the patient with laboratory results, history and physical notes, nursing documentation, and all other information regarding the health record for a patient.

The Health Insurance Portability and Accountability Act (HIPAA), a landmark law that was passed in 1996, specifies mandates in the transactions between health-care companies, providers, and carriers (8). This act was

originally designed to make the healthcare records for a patient available to healthcare institutions and physicians and to insurance companies using standards. Individuals should be able to give a physician permission to access their healthcare record at any location, quickly and efficiently. The law also protects the privacy of the patient and provides security guidelines to assure the information could not be accessed inappropriately. Only an EMR system build on well-accepted standards can meet these requirements (9–12). The radiology information should be either stored in an EMR or the EMR should have pointers to the information and should be able to communicate that information in a standard format.

The Radiological Society of North America (RSNA), the Healthcare Information and Management Systems Society (HIMSS), and the American College of Cardiology (ACC) are working together to coordinate the use of established standards, such as DICOM and HL7, to improve the way computer systems in healthcare share information. The initiative is called "Integrating the Healthcare Enterprise" or IHE (13). Integrating the Healthcare Enterprises promotes the coordinated use of established standards, such as DICOM and HL7, to address specific clinical needs in support of patient care. Healthcare providers envision a day when vital information can be passed seamlessly from system to system within and across departments (10,11,14). In addition, with IHE, the EMR

Figure 3. An image associated with the simulated order shown in Table 3. Note the inclusion of the accession number on this image that is required to associate the image with the report.

will be a standard and will facilitate information communication among healthcare venues. Recent research suggests that the United States could realize a savings potential of \$78 billion annually if a seamless, fully interoperable healthcare information exchange could be established among key stakeholders in the healthcare delivery system (9).

SELECTING AN RIS

The KLAS company, founded in 1996, is a research and consulting firm specializing in monitoring and reporting the performance of Healthcare's Information Technology's (HIT) vendors. The comprehensive reports they produced are valuable for comparing the vendors they review. Buyers should be aware that not all vendors are included in the reports, but the major ones are represented. The Comprehensive Radiology Information Systems Report, Serving Large, Community, and Ambulatory Facilities was released in January, 2005 by KLAS (15). In the report, eight RIS vendor products were represented and were reviewed by interviewing users of the systems. In an addendum, seven other vendors were presented whose products did not yet meet the KLAS standards for statistical confidence in order to be compared with other ven-

dors in the main body of the report. Vendors were all allowed to prepare overviews and their perceptions of their products. Of course, these overviews stress the strengths of a vendor's product. Performance measurements of the KLAS traditional 40 indicators (Table 6), technology overviews, client win/loss and pricing provide the bases of the provider experience. The KLAS report should be part of an institution's decision-making process when a report is available, and in this case the report is available and very timely.

This report focused on large (> 200 bed) and ambulatory (free standing clinics and imaging centers) facilities. The large facilities were asked additional questions. The larger institutions were asked why a vendor was selected and why a vendor was NOT selected based on the following six criteria: Functionality, Cost, Relationship with Vendor, References/Site Visits/Technology, and Integration/Interfacing. The most cited reason as to why a vendor was selected was their ability to integrate or interface. The most cited reason as to why a vendor was not selected was their perceived limited functionality.

Survey participants from the large institutions were asked questions regarding their RIS and its: (1) benefits; (2) functional strength of the reporting module; and (3) the RIS-PACS integration. The top benefit, reported by > 50% of the survey respondents, was that of More Efficient/Better Workflow. The number two and three benefits identified were Interface-Integration and Manage Department Better. The functional strength of the reporting module on a scale of 1-5 (1 = weak and 5 = strong) was rated with an average of 3.5, with the highest score of 4, which indicates that there are a lot of users who are not totally satisfied with their reporting module. Forty-seven percent of the survey respondents indicated that they have plans to move to an integrated RIS/PACS solution and 81% of these reported that Radiologists and Clinicians were mostly driving this integration. This indicates that there are a large number of institutions without an integrated solution.

THE RIS OF THE FUTURE

In the future, it is likely that speech recognition systems will be incorporated into an RIS solution. Throughout this article, the two systems have been shown as separate entities and indeed, that is the most common incarnation at this time. Speech recognition has become a more important part of the radiology workflow as researchers demonstrate the potential for improving report turnaround time and decreasing costs when compared to systems with manual transcriptionists (16-19). Unfortunately, the increase in report turnaround time does not guarantee efficient personnel utilization. Although the report can be available for the physician immediately after the radiologist verified the dictation, the responsibility for editing the report falls on the radiologist and may make the time required for the process longer than with a transcriptionist performing the typing and editing. Because of this, speech recognition is not eagerly embraced by many radiologists, and therefore

Imaging Integration Special Interest Group (IISIG) are working on harmonizing the existing standards (20,21). Future RIS implementations will most certainly support the DICOM structured report or its HL7 CDA translation.

In addition to supporting the traditional terminal or remote computer, the RIS of the future will be required to support a web interface as well as supporting handheld devices. A radiologist with a handheld Personal Digital Assistant (PDA) can currently access e-mail, the internet, digital media, and documents. With wireless networking available in many hospitals, these devices can support the exchange of information between ordering physician and radiologist including results, they can

support exchange of information between radiologist and technologist including protocol selection, they can access history and lab reports for the patient, they can provide a worklist of current studies, and can even display low resolution images. The ability of the PDA to support these functions is only limited by the ability of the RIS to provide PDA support (22).

The RIS of the future may store PACS images, must be able to interface with the EMR, and should provide structured reporting and support for PDAs. As institutions plan for purchasing new systems or updating the old ones, future functionality of the systems must be considered and be part of the request for proposal or bid process. In the past, institutions were able to select an RIS based on individual preferences without consideration of interface issues. As the national health records structure evolves, all institutions must be in a position to interface to an EMR using well developed standards.

RADIONUCLIDE PRODUCTION AND RADIOACTIVE DECAY

SILVIA S. JURISSON
WILLIAM MILLER
J. DAVID ROBERTSON
University of Missouri
Columbia, Missouri

INTRODUCTION

Radiopharmaceuticals, drugs containing radioactive atoms, are used for diagnostic imaging or therapeutic applications in nuclear medicine, depending on their radioactive emissions. Penetrating radiations (gamma rays or annihilation photons from positron emission) are used for diagnostic applications with gamma cameras, single photon emission computed tomography (SPECT), or positron emission tomography (PET) instrumentation. Diagnostic imaging with gamma emitters became a mainstay of nuclear medicine with the advent of the molybdenum-99/technetium-99m ($^{99}\text{Mo}/^{99\text{m}}\text{Tc}$) generator (the Brookhaven generator), which was developed by Richards in ~1961 at Brookhaven National Laboratory (1). This generator made the short half-lived $^{99\text{m}}\text{Tc}$ (6.01 h; 140 keV γ -ray) readily available to nuclear medicine departments around the world, and not just at the site of $^{99\text{m}}\text{Tc}$ production. Today, $^{99\text{m}}\text{Tc}$ accounts for >80% of the diagnostic scans performed in nuclear medicine departments in the United States, with a variety of U.S. Food and Drug Administration (FDA) approved agents for functional imaging of the heart, liver, gallbladder, kidneys, brain, and so on (2). Particle emitters, such as alpha, beta, and Auger electron emitters, are used for targeted radiotherapy since their decay energy is deposited over a very short range in tissue. Radiotherapeutic applications in humans began in the late 1930s with the beta emitters radioiodine (^{128}I , ^{131}I), radiophosphorus (^{32}P) and

radiostrontium (^{89}Sr) for cancer treatment (3). Radioiodine (^{131}I iodide) was the first, and continues to be the only, true “magic bullet” through its specific and selective uptake in thyroid. It is used to treat hyperthyroidism and thyroid cancer.

Radionuclides for medical applications are produced either at nuclear reactors or accelerators. The “Availability of Radioactive Isotopes” was first announced from the headquarters of the Manhattan Project (Washington, DC) in Science in 1946 (4), and today medical isotope availability remains an important issue for the nuclear medicine community. The selection of radionuclides for use in radiopharmaceuticals is dependent on their decay properties (half-life, emissions, energies of emissions, dose rates) and their availability (production and cost).

Radionuclides suitable for diagnostic imaging are gamma emitters (with no or minimal accompanying particle emissions) such as $^{99\text{m}}\text{Tc}$ and positron emitters (annihilation photons) such as ^{18}F . The half-lives should be as short as possible and still allow preparation (synthesis and purification) of the radiopharmaceutical, administration of the agent to the patient, and the diagnostic imaging procedure. Typically, half-lives on the order of minutes to a week are used, with hours to a day considered optimal for most applications. Gamma energies in the range of 80–300 keV are considered good, although higher energy (e.g., ^{131}I at 364.5 keV) are used, and 100–200 keV is considered optimal. The PET instrumentation is designed for the two 511 keV annihilation photons.

The radionuclides used or under investigation for radiotherapeutic applications are particle emitters, with most of the efforts focusing on the beta emitters (e.g., ^{153}Sm , ^{90}Y , ^{186}Re , ^{188}Re , ^{177}Lu , ^{149}Pm , ^{166}Ho , ^{105}Rh , ^{199}Au) and some on alpha emitters (e.g., ^{212}Bi , ^{213}Bi , ^{225}Ac). In the case of radiotherapy, the half-life of the radionuclide should match the biological half-life for the radiopharmaceutical delivery to its *in vivo* target site (i.e., tumor), typically < 1 day – 1 week. The optimum particle and particle energy remains under investigation, and it is not clear that a higher particle energy translates into a more successful treatment (i.e., radiation dose to nontarget organs will limit the dose allowed for administration). Suitable accompanying gamma emissions will allow the *in vivo* tracking of the radiotherapeutic dose.

Two important factors for the use of radionuclides in nuclear medicine are thus radioactive decay and radionuclide production, both of which are discussed in detail below. Radionuclides used in nuclear medicine applications are used as examples in discussing these topics. Radioactive decay includes the types of decay (e.g., alpha, beta, electron capture, positron, gamma) with focus on those modes with nuclear medicine applications and rates of radioactive decay (e.g., units of radioactivity, exponential decay, activity–mass relationships, parent–daughter equilibria, medical generators).

TYPES OF RADIOACTIVE DECAY

A nuclide is considered to be radioactive if its nuclear configuration (number of neutrons and protons in the

nucleus) is unstable. Radioactive decay is then a means for the unstable nucleus to achieve a more stable nuclear configuration although it may or may not form a stable nuclide following a single decay. There are several modes of decay possible for a radioactive nuclide including alpha emission, beta emission, positron emission, electron capture decay and/or gamma emission. An alpha (α) particle is a helium nucleus (${}^4_2\text{He}^{2+}$) and is generally a mode of decay available in heavy nuclei (i.e., $Z \geq 83$). Some lanthanides can show α -decay and heavy nuclides can also undergo decay by β^- , EC, and spontaneous fission. The following equation gives an example of alpha decay:

where Q is the energy released during the decay process and γ is the 727 keV gamma photon emitted in 11.8% of the decays. Most of the decay energy in this process is in the form of the kinetic energy of the α -particle, which is rapidly deposited in matter (e.g., tissue) because of its relatively high charge and mass.

Beta (β^-) decay occurs when the nucleus has a proton/neutron ratio that is too low relative to the proton/neutron ratio in the stable nuclei of that element, and during this process a neutron is converted into a proton resulting in a nuclide that is one atomic number (Z) higher than its parent. An example of beta decay is shown below,

where Q is the energy released, $\bar{\nu}_e$ is an antineutrino, and γ is the 155 keV gamma photon emitted in 15% of the decays. These neutron-rich radionuclides are produced in nuclear reactors as will be discussed in the section Radionuclear Production.

When a radioactive nucleus has a proton/neutron ratio that is too high relative to that of the stable nuclei of the same element, two modes of decay are possible (positron emission and/or electron capture decay), with both converting a proton into a neutron resulting in a nuclide that is one atomic number lower than its parent. Electron capture decay arises from the overlap of nucleon orbitals with electron orbitals. It is a result of the “weak force”, which is very short ranged. During electron capture decay (ϵ), essentially an inner-shell electron (usually K -shell) is incorporated into the nucleus converting a proton into a neutron. This process creates an orbital vacancy and results in a cascade of outer-shell electrons filling the lower energy inner-shell vacancies, with the excess energy released as X-rays and/or Auger electrons. The following equation shows the electron capture process:

where Q is the energy released and ν_e is a neutrino. The 80 keV X rays emitted are used for myocardial imaging in stress–rest tests performed in nuclear medicine departments. Positron emission is only possible when Q is > 1.022 MeV, the energy equivalent of the mass of two electrons. During positron decay, a proton is converted into

a neutron with simultaneous emission of a positron (β^+), which is a positive electron. Since a neutron has greater mass than a proton, the energy equivalent of two electrons (one to convert a proton to a neutron in the nucleus, and one emitted as a positron) must be available for this decay mode to be possible. Practically, positron emission does not occur unless Q is ≥ 2 MeV. An example of the positron decay process is shown below.

where Q is the decay energy (including the maximum positron energy plus 1.022 MeV), ν_e is a neutrino, and the two 0.511 MeV photons result from positron annihilation (often called annihilation photons) and are emitted 180° opposite each other. They are the basis of PET imaging. The ${}^{18}\text{F}$ radiolabeled fluorodeoxyglucose (${}^{18}\text{F}$ -FDG) is used in nuclear medicine departments for imaging glucose metabolism, such as found in growing tumors. In some cases, both electron capture and positron emission can occur. These proton-rich radionuclides are produced by accelerators which is discussed below.

Gamma (γ) emission can accompany any other decay process (i.e., alpha, beta, electron capture, positron decay) or it can occur without any particle emission. In the latter case, it is called isomeric transition (IT) and occurs when a metastable radioisotope [higher energy excited state of a nucleus with a measurable lifetime ($\geq \text{ns}$)] decays to the ground state (lower energy state of the nucleus). Isomeric transition is accompanied by energy release without any other change occurring in the nucleus (i.e., the number of protons and neutrons in the nucleus does not change during IT). The decay of ${}^{99\text{m}}\text{Tc}$ is an example of an isomeric transition.

where Q is the decay energy and γ is the 140 keV photon released from the nucleus. The ${}^{99\text{m}}\text{Tc}$ in various chemical formulations is used routinely for diagnostic imaging of a variety of diseases and/or organ functions.

Whenever a gamma photon is released from the nucleus, the emission of conversion electrons is also possible. A conversion electron is the emission of an electron that has the energy of the gamma photon minus the electronic atomic binding energy, and it is emitted in place of the gamma photon. The probability of conversion electron emission rather than gamma emission increases as the energy of the gamma photon decreases and it increases with increasing nuclear charge. For example, the 140 keV gamma photon of ${}^{99\text{m}}\text{Tc}$ is emitted with 89% abundance; conversion electrons, rather than gamma photons, are emitted 11% of the time when ${}^{99\text{m}}\text{Tc}$ decays to ${}^{99}\text{Tc}$.

There are radionuclides in which more than one type of radioactive decay occurs. An example is the decay of ${}^{64}\text{Cu}$, which undergoes beta decay (39% of the time), positron emission decay (19% of the time), and electron capture decay (42% of the time) with a weighted average half-life of 12.7 h (the specific half-lives are shown below). This radionuclide has both diagnostic imaging (β^+ emission via the

annihilation photons) and radiotherapy ($\beta^{-/+}$ and Auger electrons) applications.

All of the above modes of radioactive decay have been utilized or are under investigation for utilization in the development of radiopharmaceuticals for nuclear medicine applications (either diagnostic imaging or radiotherapy).

RATES OF RADIOACTIVE DECAY

Radioactive decay is a random process where the number of nuclei in an isotopically pure sample that decay during a given time period is proportional to the number of nuclei (N) present in the sample. If radioactivity is defined as a measure of the rate at which the radioactive nuclei disintegrate, then the number of disintegrations per unit time (dN/dt) from a sample is given by the following expression where λ is the decay constant (the probability of decay per unit time) and negative sign indicates the loss of the radionuclide through the disintegration. This results in a radioactive decay process that follows a first-order rate law:

$$\frac{dN}{dt} = -\lambda N$$

From this definition, the number of disintegrations per unit time (dN/dt) is also known as the activity. For an isotopically pure sample, the number of nuclei N can be calculated knowing Avogadro’s number (N_A), the mass number of the isotope (A) in daltons or grams per mole and the sample’s weight (wt) in grams:

$$\text{Activity} = \lambda N = \lambda \frac{N_A}{A} \text{wt}$$

As with all measurements, several systems of units can be used to define the amount of radioactivity in a particular sample. And, as with many measuring systems, there are both “traditional” units and new SI units (International System of Units). The original units are referenced to the curie (Ci), named in honor of Madam Curie. A curie is 3.7×10^{10} (37 billion) radioactive disintegrations per second, or approximately the amount of radioactivity in a gram of radium, one of the natural radioactive elements with which Madam Curie did her research. For many applications of radiation in medicine or industry, the curie is a relatively large quantity, and so the units of mCi (1/1000th) and microcurie (μCi) (1/1,000,000th) are utilized. On the other hand, a nuclear reactor contains millions of curies of radioactivity and units of kilocurie (kCi) (1000) and megacurie (MCi) (1,000,000) are sometimes used. Although the unit of the curie is being supplemented with the newer SI unit, it is still very much in common use.

The SI unit of radioactivity, the becquerel (Bq), is named after Henri Becquerel, the discoverer of radioactivity. It is defined as one disintegration per second. Thus it is much smaller than the Ci. Multiples of becquerel

Table 1. Units of Activity

Curies	Becquerels or disintegrations s^{-1}	Becquerels or disintegrations s^{-1}	Curies
1 MCi	3.7×10^{16}	1 Bq	2.7×10^{-11}
1 kCi	3.7×10^{13}	1 kBq	2.7×10^{-8}
1 Ci	3.7×10^{10}	1 MBq	2.7×10^{-5}
1 mCi	3.7×10^7	1 GBq	0.027
1 μCi	3.7×10^4		

are the kilobecquerel (kBq) (1000), megabecquerels (MBq) (1,000,000), and so on. These units are summarized in Table 1.

The rate at which radioactive decay occurs can be defined as the half-life, or the amount of time that it takes for one-half of the radiation to decay. Unfortunately, two half-lives do not eliminate it (i.e., one-half decaying in one half-life and then the second one-half decaying in a second half-life), but rather the half-life is always referring to how much is left at any given point in time. Thus, one half-life reduces the radioactivity to one-half or 50%; two half-lives to one-half of one-half, one-fourth or 25%; three half-lives to one-eighth or 12.5%; and so on This leads to a kinetic model that is described by an exponential function (see Fig. 1), which is the solution to the previous equation:

$$N(t) = N_0 e^{-\lambda t}$$

The half-life is related to the physical decay constant (λ) by the simple expression:

$$t_{1/2} = \frac{0.693}{\lambda}$$

As a radionuclide decays, the number of nuclei (N) changes, and the amount of radioactivity present at any given time “ t ” remaining from an initial amount A_0 (expressed in either Bq or Ci) can be given by any of the following:

$$A(t) = A_0 e^{-\lambda t}$$

$$A(t) = A_0 e^{-(0.693/t_{1/2})t}$$

$$A(t) = A_0 \left(\frac{1}{2}\right)^{t/t_{1/2}}$$

Figure 1. Relative number of radioactive nuclei remaining after various half-lives of decay.

Radioactive nuclei have half-lives that range from fractions of a second to billions of years. The radioactive material introduced into the body for medical purposes would typically have half-lives on the order of a few hours to a few days, so that it decays away to negligible levels in a relatively short amount of time. At the other extreme, some of the naturally radioactive nuclei in our environment have half-lives of billions of years and the reason they are still present is that they have not had enough time to decay to negligible levels since the earth was formed. An example of such a radionuclide is ^{40}K , which makes up 0.0117% of naturally occurring potassium and has a half-life of 1.27×10^9 years.

Another interesting case of radioactive decay involves parent–daughter relationships in which a radioactive parent decays to a radioactive daughter. This process is utilized extensively in the medical profession to provide a long-lived source for a short-lived radioisotope in what is known as a generator. The daughter can be obtained from the generator by “milking” it, taking advantage of the differences in chemistry between the parent and daughter elements to extract the daughter off of an ion column, which holds the parent.

The use of $^{99\text{m}}\text{Tc}$, which has a 6 h half-life, is a case in point. Within a 24 h period it has decayed through four half-lives and is only one-sixteenth of its original value. Thus, $^{99\text{m}}\text{Tc}$ would have to be made in a nuclear facility and shipped daily to meet hospital needs. Fortunately, the daughter $^{99\text{m}}\text{Tc}$ is produced by the decay of a parent isotope ^{99}Mo , which has a 2.75 day half-life. A supply of $^{99\text{m}}\text{Tc}$ can thus be obtained over a period of ~ 1 week from the more slowly decaying ^{99}Mo .

The kinetics of the quantity of a daughter isotope (d) available from a parent isotope (p) can be readily solved using a first-order differential equation resulting in a straightforward algebraic expression:

$$\frac{A_{\text{daughter}}}{A_{\text{parent}}} = \frac{\lambda_d}{\lambda_d - \lambda_p} \left(1 - e^{-(\lambda_d - \lambda_p)t} \right)$$

For most practical cases where the parent is longer lived than the daughter, the daughter activity reaches a value close to the activity of the parent after approximately four half-lives. Thus, in an undisturbed generator that has been allowed to reach equilibrium, the quantity of daughter present (in Ci or Bq) is approximately equal to the activity of the parent at that time. Once the daughter has been extracted (or milked), it immediately begins building up again to a new equilibrium value as shown in Fig. 2.

Also of importance is the time it takes for the daughter to reach its maximum value, which is determined by the decay constants of the two isotopes involved:

$$t_{\text{max}} = \frac{\ln\left(\frac{\lambda_d}{\lambda_p}\right)}{\lambda_d - \lambda_p}$$

Again assuming a typical case where the parent is longer lived than the daughter, this is largely deter-

Figure 2. Shows build-up of $^{99\text{m}}\text{Tc}$ activity from ^{99}Mo initially and following elution.

mined by the half-life of the daughter. Thus, the daughter will reach $\sim 50\%$ of the equilibrium value in one half-life, 75% of the equilibrium value in two half-lives, and so on. The time between subsequent extractions of a daughter from a generator is set by this regeneration time. For the $^{99}\text{Mo} \rightarrow ^{99\text{m}}\text{Tc}$ system, the regeneration time needed to reach the maximum amount of daughter $^{99\text{m}}\text{Tc}$ is very close to 24 h, a very convenient amount of time for routine hospital procedures and is just a fortuitous consequence of the half-lives of the two isotopes involved.

Other examples of parent–daughter generators that are currently used or are under development for future use are $^{188}\text{W}/^{188}\text{Re}$ generators, $^{90}\text{Sr}/^{90}\text{Y}$ generators, $^{82}\text{Sr}/^{82}\text{Rb}$ direct infusion generators, $^{62}\text{Zn}/^{62}\text{Cu}$ generators, $^{224}\text{Ra}/^{212}\text{Bi}$ or $^{224}\text{Ra}/^{212}\text{Pb}$ generators, which also are a source of ^{212}Bi , the daughter product of ^{212}Pb , $^{225}\text{Ac}/^{213}\text{Bi}$ generators and $^{68}\text{Ge}/^{68}\text{Ga}$ generators. (For more information on generators see Ref. 5 and references cited therein.)

Specifically,

are two generators that can produce short lived PET isotopes, with ^{82}Rb being used for PET studies of myocardial function (rubidium acts as a potassium ion mimic).

The following three are examples of generators for beta or alpha emitting radioisotopes as possible therapeutic agents:

RADIONUCLIDE PRODUCTION

The radionuclides used in medicine and the life sciences are produced through neutron and charged particle

induced nuclear reactions. As with chemical reactions, the yield of the product (radioisotope) of interest will depend on the nuclear reaction employed, the energetics of the reaction, the probability of competing reaction pathways, and the ability to separate the desired product from the reactants (target) and any additional nuclear reaction products. For a complete overview of the practice and theory of nuclear reactions, the interested reader is referred to an introductory text on nuclear and radiochemistry (6–9).

Proton-rich radionuclides that decay by positron emission and/or electron capture are produced at cyclotrons and accelerators through charged particle induced nuclear reactions. For example, the production of the commonly used PET radionuclide ^{18}F through the bombardment of a target of ^{18}O -enriched water with high energy protons is produced by the following nuclear reaction:

that is written in a short-hand notation as $^{18}\text{O}(\text{p},\text{n})^{18}\text{F}$. Note that, as in radioactive decay, charge (number of protons), mass number, and total energy are conserved in the nuclear reaction. The Q value for the reaction is the difference in energy (mass) between the reactants and products and is readily calculated from the measured mass excess (Δ) values for the reactants and products

$$Q = \sum \Delta_{\text{reactants}} - \sum \Delta_{\text{products}}$$

If Q is < 0 , then the reaction is endoergic and energy must be supplied to the reaction (through the kinetic energy of the projectile) and if Q is > 0 , the reaction is exoergic and energy is released in the nuclear reaction. For the $^{18}\text{O}(\text{p},\text{n})^{18}\text{F}$ reaction,

$$\begin{aligned} Q &= \Delta_1^1\text{p} + \Delta_8^{18}\text{O} - (\Delta_0^1\text{n} + \Delta_9^{18}\text{F}) \\ &= -0.782 + 7.289 - (8.071 + 0.873) \\ &= -2.44 \text{ MeV} \end{aligned}$$

and the proton must supply 2.44 MeV of energy to the reaction. In practice, the actual proton bombarding energy is higher than the Q value because (1) not all of the kinetic energy of the proton is available for the nuclear reaction because of momentum conservation in the collision and (2) the probability of the reaction is typically very low at the threshold energy (Q). Typical conditions for the $^{18}\text{O}(\text{p},\text{n})^{18}\text{F}$ reaction on a water target with an in-house cyclotron are 16.5 MeV at 100 μA yielding 3–4 Ci/h. Even in those cases when the Q value for the reaction is > 0 , the incoming charged particle must have sufficient kinetic energy to overcome the coulomb or charge barrier between the projectile and the target nucleus and any angular momentum barrier that might exist for the reaction.

The probability that the projectile will strike the target nucleus and produce the radioisotope of interest is quantified with the reaction cross-section (σ) that has the dimensions of area. While quite sophisticated models exist for predicting reaction cross-sections based upon the underlying nuclear physics, the simple physical

analogy for the cross-section is the area that the target nucleus presents to the incoming beam of projectiles. The SI unit for cross-section is m^2 , but the more common unit is a barn (b); one barn is equal to 10^{-24} cm^2 (or 10^{-28} m^2). The magnitude of a barn can be understood from the fact that a target nucleus with mass number 100 has a radius on the order of $6.5 \times 10^{-15} \text{ m}$ and a “cross-sectional area” of $1.3 \times 10^{-28} \text{ m}^2$ or 1.3 b. In the simplest case when a charged particle beam is bombarding a target that is “thin” enough so that the beam does not lose any appreciable energy in passing through the target, then the production rate (R) for the radioisotope of interest is equal to

$$R = n \times I \times t \times \sigma$$

where n is the target nuclei density (nuclei cm^{-3}), I is the number of incident particles per unit time (particles s^{-1}), t is the target thickness (cm), and σ is the reaction cross-section (cm^2). In most cases, radioisotope production is performed using a thick target and an estimate of the reaction production rate takes into account the variation in the reaction cross-section with projectile energy, since the charged-particle beam loses energy as it passes through or stops in the thick target. Charged particle induced reactions used to produce medical radioisotopes have maximum cross-sections on the order of millibarns.

Neutron-rich radioisotopes that decay by negatron or β^- emission are produced primarily through neutron-induced nuclear reactions at nuclear reactors. The most commonly used reactions are direct production through single or double neutron capture, direct production through neutron induced fission, and indirect production through neutron capture followed by radioactive decay. An example of direct neutron capture is the production of the ^{166}Ho through the irradiation of ^{165}Ho in a nuclear reactor by the following reaction:

Like all neutron capture reactions used to produce medical radioisotopes, this reaction is exoergic with a reaction Q value 6.24 MeV. In contrast to charged-particle induced reactions, there is no coulomb or charge barrier for neutron induced reactions and the cross-section for the neutron capture reaction increases as the energy of the neutron decreases. This increase in cross-section can be understood in that the wavelength of the neutron, and hence its probability of interacting with the target nucleus, increases as the kinetic energy or velocity of the neutron decreases. The maximum yield for most neutron capture reactions is obtained by irradiating the target material in a region of the nuclear reactor where the high energy neutrons produced by fission have been slowed down or moderated so that they have an average kinetic energy of 0.025 eV. One advantage of producing radioisotopes through neutron capture reactions is that the cross-sections are, at 0.025 eV, on the order of barns, whereas charged particle induced cross-sections have peak values on the order of millibarns. A second advantage is that many different targets can be irradiated at the same time in a nuclear reactor, while most accelerator

facilities can only irradiate one or two targets at a time. The obvious disadvantage of neutron induced reactions is that the isotope production must be performed off-site at a nuclear reactor, whereas compact cyclotrons can be sited at or near the medical facility making it possible to work with quite short-lived proton-rich isotopes.

The production rate (R) of a radionuclide during irradiation with the moderated or "thermal" neutrons in a nuclear reactor is given by

$$R = N \times \Phi \times \sigma$$

where N is the number of nuclei of the target isotopes in the sample, Φ is the flux of thermal neutrons ($\text{n}\cdot\text{cm}^{-2}\cdot\text{s}^{-1}$), and σ is the thermal neutron reaction cross-section (cm^2). Because those radionuclides created during irradiation can decay during the production process, the activity (A) in Bq of a radionuclide with decay constant λ produced by irradiating a sample either in a reactor or with a charged particle beam is given by

$$A = R(1 - e^{-\lambda t_i})e^{-\lambda t_d}$$

where R is the production rate for the reaction, t_i is the irradiation time, and t_d is the amount of time the sample has been allowed to decay following the irradiation. Using again the example of $^{165}\text{Ho}(\text{n},\gamma)^{166}\text{Ho}$ reaction, ^{166}Ho has a half-life of 1.12 days, ^{165}Ho has a thermal cross-section of 58 b and an isotopic abundance of 100%. Irradiation of 87 mg of ^{165}Ho [100 mg target of holmium oxide (Ho_2O_3)] for 5 days in a thermal neutron flux of $1 \times 10^{14} \text{ n}\cdot\text{cm}^{-2}\cdot\text{s}^{-1}$ will produce $\sim 1.8 \times 10^{12}$ Bq or 48 Ci of ^{166}Ho with a specific activity of 0.55 Ci of ^{166}Ho mg^{-1} of Ho in the target. The specific activity that can be achieved in the overall (nuclear and chemical) production process is a critical consideration when the radionuclide is used for therapy because it represents the fraction of the atoms in the sample that will have radio-therapeutic activity. In the example of ^{166}Ho , a specific activity of 0.55 Ci· mg^{-1} means that only 1 out of every 1300 Ho atoms in the sample that will be incorporated into the therapeutic agent are radioactive. A disadvantage of using direct neutron capture reactions is that the specific activity of the product radioisotope cannot be improved through chemical means (the product is an isotope of the target).

The parent material of the most commonly used medical radionuclide ($^{99\text{m}}\text{Tc}$) is produced in high specific activity through the neutron induced fission of ^{235}U . On average, every 100 thermal neutron induced fissions of ^{235}U produce six ^{99}Mo atoms. Because the molybdenum produced in the uranium target can be chemically separated from the uranium and other fission products, and because all of the other molybdenum isotopes have much shorter half-lives than ^{99}Mo , the process results in a sample in which nearly every molybdenum atom is ^{99}Mo . While there are a number of advantages from using this "carrier free" (i.e., 100% of the Mo is radioactive ^{99}Mo) ^{99}Mo to create the commercial $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generators, the process does create significant amounts of waste that must be appropriately disposed. Neutron-rich radionuclides can also be produced in high specific activity through an indirect method that utilizes neutron capture followed by radioactive decay.

Consider for example the production of ^{105}Rh from the irradiation of ruthenium target. Neutron capture on ^{104}Ru produces ^{105}Ru through the following reaction:

^{105}Ru is radioactive ($t_{1/2} = 4.44$ h) and beta decays into ^{105}Rh , which has a half-life of 35.4 h. As in the fission case, the rhodium in the target can be chemically separated from the ruthenium target to produce a sample that is essentially carrier free.

SUMMARY

The use of radionuclides in medicine has been, and continues to be, important to diagnosis of disease and radiotherapy. Many diagnostic agents based on $^{99\text{m}}\text{Tc}$ are part of the arsenal of radiopharmaceuticals available to the physician. The last 10 years has seen the FDA approval of three new radiotherapeutic agents, namely, Quadramet (a bone pain palliation agent containing ^{153}Sm) and the first two FDA approved radioimmunoconjugates, Zevalin [a ^{90}Y labeled monoclonal antibody that specifically targets the CD20 antigen expressed on >90% of non-Hodgkin's lymphomas (NHL), and Bexxar (an ^{131}I labeled monoclonal antibody that specifically targets the CD20 antigen expressed on >90% of non-Hodgkin's lymphomas)]. The development of new radiodiagnostic and radiotherapeutic agents will continue and will undoubtedly take advantage of the advances occurring in molecular biology and genomics. Radioactive decay and radionuclide production are two important aspects in the design of new radiopharmaceuticals. For more detailed discussions on these topics, the reader is referred to general textbooks on nuclear and radiochemistry (6–8).

RADIOPHARMACEUTICAL DOSIMETRY

HUBERT M.A. THIENS
University of Ghent
Ghent, Belgium

INTRODUCTION

In nuclear medicine, radiopharmaceuticals are administered to patients for diagnosis or treatment purposes. Each pharmaceutical compound has its specific biodistribution over organs and tissues in the body with related retention times. One method of calculating absorbed dose values delivered internally was developed in the 1960s by the medical internal radiation dose (MIRD) committee of the American Society of Nuclear Medicine (1,2). The original aim was to develop a dosimetry methodology for diagnostic nuclear medicine, but the method can be applied to dosimetry for radionuclide therapy, where the need for an accurate dosimetry is more imperative in view of the high activity levels administered to the patient. The MIRD dosimetry protocol is applied by different international organizations. The International Commission on Radiological Protection (ICRP) has published catalogs of absorbed doses to organs and tissues per unit activity administered, calculated using this dosimetric approach, for most diagnostic radiopharmaceuticals commonly applied (3,4). These tables are established for patients with standard biokinetics of the radiopharmaceutical. For application of the MIRD protocol in the nuclear medicine department when taking into account patient-specific biokinetics a user-friendly computer program called MIRDOSE was developed by Stabin (5). This software has been replaced recently by the authors by an U. S. Food and Drug Administration (FDA) approved program OLINDA (Organ Level Internal Dose Assessment) (6).

By combining well-selected β -emitting radionuclides with disease-specific pharmaceuticals, administration of radiolabeled drugs can provide efficient internal radiotherapy for localized disease as well as for metastatic cancer. As a result, an increasing number of radioactive therapeutic agents are being used in nuclear medicine for the treatment of a large variety of diseases (7–12). For these medical applications of radioactive compounds accurate patient-specific internal dosimetry is a prerequisite. Indeed, the basic goal of the majority of these types of metabolic radiotherapy is to ensure a high absorbed dose to the tumoral tissue without causing adverse effects in healthy tissues. In a curative setting an optimized activity has to be calculated and administered to the patient to ensure the delivery of a predetermined absorbed dose to the tumor resulting in complete tumor control, while minimizing the risk of normal tissue complications. The determination of latter activity necessitates a patient specific dosimetry with respect to drug pharmacokinetics and if possible patient-specific anatomical data.

Nowadays, for most applications patient-specific biokinetics are derived from sequential images after administration of a tracer activity and combined with the MIRD methodology to calculate absorbed doses to target and critical tissues (13). For a more complete dosimetric ana-

lysis as in the case of clinical trials, the information from imaging is completed by data obtained from blood sampling and urinalysis. In general, patient anatomy is represented by a standard anthropomorphic phantom (14). However, in a complete patient-specific dosimetry approach the individual patient anatomy is also taken into account and derived from computed tomography (CT) or magnetic resonance imaging (MRI). Three dimensional (3D) absorbed dose estimates are then determined from single-photon emission computed tomography (SPECT) or positron emission tomography (PET) activity data using dose-point kernel convolution methods (15,16), or by direct Monte Carlo calculation (17–20). Dose point kernels describe the pattern of energy deposited by the radiation at various radial distances from a point source. Convolution of the dose point kernel of the considered radionuclide with the activity distribution in the patient results in the absorbed dose distribution in the patient. The general idea of Monte Carlo analysis is to create a model as similar as possible to the real physical system and to create interactions within that system based on known probabilities of occurrence, with random sampling of the probability density functions. For dosimetric applications, differential cross-section data of the interactions of the ionizing particles with matter are used and the path of each particle emitted by the radioactive material is simulated until it is completely stopped. The energy deposited in the medium along the path of the ionizing particles results in the absorbed dose distribution. The advantage of direct calculation by Monte Carlo techniques is that this method allows media of inhomogeneous density to be considered. More information on the application of Monte Carlo techniques in dosimetry can be found in Ref. 21. Several software packages have been devised and validated by different groups for patient specific dose calculations. Typical examples are the 3D-ID code from the Memorial Sloan-Kettering Cancer Center (22), the RMDP-MC code from the Royal Marsden hospital (UK) (23) and the VOXEL-DOSE code from Rouen (France) (24). These programs are based on general Monte Carlo codes also used in other medical applications of ionizing radiation as external beam radiotherapy: EGSnrc (25) and GEANT (26).

Radiolabeled pharmaceuticals are also used in the development of new drugs. Before a drug can be applied to patients in phase I and II clinical trials, different steps have to be taken in the investigation of the toxic effects of the new (radio)pharmaceutical compound. This involves firstly a number of animal studies followed by the administration of the pharmaceutical to a restricted number of volunteers. In general, for these animal and volunteer studies, a radiolabeled formulation of the newly elaborated drug is used with ^3H or ^{14}C as radionuclide. Sacrifice of the animals at different time points postadministration and quantitative whole-body autoradiography allow the determination of the biodistribution with metabolite profiling, the retention in the different organs and tissues, and the study of excretion pathways of the pharmaceutical in the animals. In the development of radiopharmaceuticals specifically for nuclear medicine imaging purposes, the new compound can be labeled with gamma-emitting radionuclides and the biokinetics are derived from serial

imaging of animals. To this end, dedicated (micro)SPECT and (micro)PET systems were constructed (27–29). The animal activity data are extrapolated to humans to determine the maximal activity of the radiolabeled compound allowed to be administered to healthy volunteers. Criterion is here that the effective dose may not exceed the limits for the considered risk category of the volunteers following the ICRP Publication 62 categories (30). In general, the risk category IIa (risk $\sim 10^{-5}$) with a maximal effective dose of 1 mSv is appropriate for volunteers in testing new drugs. This corresponds to an intermediate-to-moderate level of social benefit for a minor to intermediate risk level for the volunteers. This evaluation procedure necessitates a reliable dosimetry estimate based on the extrapolation of animal activity data to humans. To obtain this dose estimate generally the MIRD formalism is applied.

THE MIRD SCHEMA

Basic Principles and Equations

For patient dosimetry in nuclear medicine diagnostic procedures, the MIRD schema is applied. This formalism is also used systematically for dose calculations in administration of radiolabeled drugs of volunteers in the framework of drugs development.

In the MIRD protocol, organs and tissues in the body with a significant uptake of the radiopharmaceutical are considered as source organs. On the other hand all organs and tissues receiving an absorbed dose are considered as target organs. This is illustrated in Fig. 1 for iodine isotopes as ^{131}I with the thyroid as source organ and the lungs as the target organ on the anthropomorphic phantom developed by Snyder et al. (31). The absorbed dose to a

Figure 1. Illustration of the MIRD method for the γ rays emitted in the decay of iodine isotopes as ^{131}I with the thyroid as source organ and the lungs as target organ in the anthropomorphic phantom developed by Snyder et al. (31).

particular target organ t from a source organ s , $D_{t \leftarrow s}$, can be obtained using the following equation (1,2) :

$$D_{t \leftarrow s} = \tilde{A}_s S_{t \leftarrow s}$$

with \tilde{A}_s is the cumulated activity in the source organ and $S_{t \leftarrow s}$ is the mean dose to the target organ per unit cumulated activity in the source organ.

The cumulated activity \tilde{A}_s is the total number of disintegrations of the radioactivity present in the source organ integrated over time and expressed in units Bq.s. It depends on the activity administered, the uptake, retention and excretion from the source organ, and the physical decay of the radionuclide. The $S_{t \leftarrow s}$ values depend on the decay modes of the considered radionuclide and the source-target geometry. The $S_{t \leftarrow s}$ values are tabulated for standard men and children anthropomorphic phantoms (14).

The cumulated activity \tilde{A}_s is the time integral of the activity in the source organ $A_s(t)$:

$$\tilde{A}_s = \int_0^{\infty} A_s(t) dt$$

The biological retention in the source organ is generally derived from sequential scintigraphies with a gamma camera. For this, opposing planar views or SPECT are used with a calibrated source in the field of view. Corrections are needed for patient attenuation and scatter of the γ radiation. The cumulated activity in the different source organs \tilde{A}_s allows to calculate the residence time τ being the average time the administered activity A_0 spends in the considered source organ:

$$\tau = \frac{\tilde{A}_s}{A_0}$$

In the MIRDOSE software, the cumulated activity in the different source organs is introduced by the values of the residence time (5).

The mean dose to the target organ per unit cumulated activity in the source organ, $S_{t \leftarrow s}$, is given by the expression:

$$S_{t \leftarrow s} = \frac{1}{m_t} \sum_i \Delta_i \phi_i(t \leftarrow s)$$

with m_t mass of the target organ, Δ_i the mean energy emitted per disintegration for radiation of type and energy i , and $\phi_i(t \leftarrow s)$ the absorbed fraction for radiation of type and energy i . The absorbed fraction $\phi_i(t \leftarrow s)$ is defined as the fraction of the radiation of type i emitted by the source organ s absorbed in the considered target organ t . The Δ_i values are obtained from the decay scheme of the considered radionuclide. The values of the specific absorbed fractions $\phi_i(t \leftarrow s)/m_t$ were calculated by Monte Carlo methods (32). The $S_{t \leftarrow s}$ values for commonly used isotopes in nuclear medicine calculated in this way for a number of standard anthropomorphic phantoms including children of different ages (14) are tabulated and included in the data base of the MIRDOSE package (5). This procedure assumes a uniform distribution of the activity over the source organs and a standard anatomy of the patient.

Table 1. Effective Dose Values Per Unit Activity Administered For A Number Of Radiopharmaceuticals Commonly Applied In Nuclear Diagnostics ^a

Radiopharmaceutical	Effective Dose Per Unit Activity Administered (mSv/MBq)				
	1 year	5 years	10 years	15 years	Adult

By using the MIRD working procedure, the absorbed doses of the different target organs for frequently used radiopharmaceuticals per unit activity administered were calculated by the ICRP for an adult and children of 1, 5, 10, and 15 years assuming standard biokinetics and were tabulated (3,4). As measure of the radiation burden patient the effective dose E is calculated by summing up the tissue equivalent doses H_T using the tissue weighting factors w_T as defined in the ICRP 60 publication (33):

$$E = \sum_T w_T H_T$$

For the types of radiation emitted by the radionuclides used in nuclear medicine the radiation weighting factor w_R is one except for alpha particles, where w_R equals 20. In Table 1 the effective dose values per unit activity administered for a number of radiopharmaceuticals commonly applied in nuclear diagnostics under the assumption of standard biokinetics is summarized. Table 1 shows that in diagnostic pediatric nuclear medicine the patient dose is strongly dependent on patient age for the same administered activity. This is mostly due to the change in patient weight. Weight dependent correction factors for the activity to be administered have been calculated to obtain weight independent effective doses (34,35). The concept of effective dose is intended to estimate the risk for late stochastic radiation effects as radioinduced cancer and leukemia in the low dose range, and by this applicable to nuclear medicine investigations for diagnosis. Its value is not representative for the risk for direct deterministic effects as bone marrow depletion in case of therapeutic applications of radiopharmaceuticals.

Microdosimetric Considerations

The S-values commonly applied at the macroscopic level are calculated assuming a uniform distribution of the activity over the source organ and the target being the whole volume of the target tissue. The use of S-values based on these assumptions can lead to erroneous results at the microscopic level in case of self-dose calculation in an organ (target = source) when the isotope distribution is nonuni-

form at the cellular level and particles with range of the order of cellular dimensions are emitted in the decay. This is particularly the case when the radionuclide used is an Auger electron or an alpha emitter. A typical example is the dosimetry of lymphocytes labeled with ^{99m}Tc. In Fig. 2, the therapeutic range in soft tissue of the low energy electron groups in the decay of ^{99m}Tc is represented and compared to the dimensions of the DNA helix (2 nm) and a lymphocyte (10 μm). Taking into account the range of the large intensity Auger electron groups (2–100 nm) the dose to the DNA in the cell nucleus, which is the biological radiation target in the cell, is strongly dependent if we consider intra- or extracellular distribution of a ^{99m}Tc radiopharmaceutical. In most radiopharmaceuticals, ^{99m}Tc is located extracellularly and the radiation burden from the Auger electrons to the nucleus is very low. In those cases, the cellular dose is due to the 140 keV γ-emission and the macroscopic S-values assuming a uniform distribution of the ^{99m}Tc activity can be used for the dose calculation. However, in case of intracellular labeling as in the case of labeling of lymphocytes with ^{99m}Tc-HMPAO the dose to the lymphocytes due to the Auger electrons is very high, which leads to radiotoxic effects in these cells (36).

For dose assessment in case of intracellular labeling or labeling of the membrane with an Auger electron emitter a microdosimetric approach based on Monte Carlo calculation methods is indicated. In those cases, the MIRD method can be applied at the cellular level for the calculation of the cell nucleus dose from activity uniformly present in the nucleus, the cell cytoplasm or the cell surface using appropriate microscopic S_{t-s} values tabulated for all radionuclides (37). To cope with nonuniform activity distributions in source organs, determined by PET and SPECT imaging, radionuclide voxel S-values are tabulated for five radionuclides for cubical voxels of 3 and 6 mm (38).

DOSIMETRY FOR RADIONUCLIDE THERAPY

Methodology

In external beam radiotherapy, there is a long tradition in performing treatment planning calculations for each

Figure 2. The range in soft tissue of the low energy electron groups in the decay of ^{99m}Tc , compared to the dimensions of the DNA helix and a lymphocyte. The latter comparison is relevant for dosimetry in the intracellular labeling of lymphocytes with ^{99m}Tc -HMPAO.

individual patient. The dosimetry protocols necessary for metabolic radiotherapy, however, are far more complex than those used in external beam therapy. In fact, the *in vivo* activity distribution initially is patient-specific and unknown in both space and time. For the determination of the patient specific drug pharmacokinetics, a tracer activity of the radiopharmaceutical is administered to the patient and quantitative imaging at multiple time points is employed to establish patient-specific biokinetics (13). Here, nuclear medicine imaging with proper correction for photon attenuation, scatter, and collimator resolution is needed to obtain the most accurate activity maps possible. The patient-specific biokinetics can then be combined with the MIRD methodology, described above, to calculate absorbed doses to organs and tissues. The MIRDOSE software allows to calculate the self-absorbed dose to a sphere representing the tumor in case of oncological applications. From these dosimetric calculations, the activity of the radiopharmaceutical to be administered to deliver the prescribed absorbed dose level to the considered tissues is then calculated by extrapolation. This approach does not take into account the patient anatomy. Instead, anatomical data of the average male, female, and children of different ages are introduced by anthropomorphic phantoms (14).

More accurate dosimetric calculations require that the individual patient anatomy derived from CT or MRI images is converted into a 3D voxel representation as in external beam radiotherapy. The 3D absorbed dose estimates from the tracer activity administration are then determined from SPECT or PET activity imaging using dose-point kernel convolution methods, or by direct Monte Carlo calculation (15–24). This approach necessitates image fusion between the different imaging modalities used. The advent of combined SPECT–CT and PET–CT equipment allows a more general application of this complete patient-specific dosimetry (39–43). In this setting, the CT data may be used as an attenuation map, which is an important improvement for accurate quantification (39).

A dosimetry calculation can be useful not only for assessment of the amount of activity to be administered

before radionuclide therapy, but also after the performed radionuclide therapy. First, it is important to verify the predicted absorbed dose distribution. Second, the dosimetry results of a patient population can be combined with the outcome of the therapy to analyse the dose-response of the radionuclide therapy and to make changes in the therapy protocol when necessary (e.g., the predetermined target dose level). As was the case for the pretherapy calculation of the administered activity, posttherapy dosimetry can be performed at different levels of sophistication.

Dosimetry is not only important in the framework of therapy prediction, but also in the dose assessment of organs at risk. In radiopeptide therapy, the kidneys are the dose-limiting organ (44,45). Radiopeptides are cleared physiologically via the kidneys. Most peptides are cleaved to amino acids as metabolites in the kidneys with a high and residualizing uptake in the tubular cells. Damage to the kidneys induced by the radiolabeled metabolites can cause nephropathy after therapeutic application of radiopeptides (46). Application of basic amino acids can reduce the renal accretion of radiolabeled metabolites and the kidney dose (47).

Dosimetry of Radioiodine Therapy for Thyrotoxicosis

The most common application of radionuclide therapy is treatment of hyperthyroidism as observed in Graves' disease or Plummer's disease (toxic nodular goiter) by oral administration of ^{131}I . The rationale behind dosimetry for this kind of treatment is that at long-term hypothyroidism may be the outcome for patients treated with radioiodine and that the incidence of this inverse effect is higher with an earlier onset for patients treated with higher activities (48). A large variation exists in the literature on the value of target dose to be delivered to the hyperthyroid tissue to become euthyroid. Howarth et al. (49) reported that doses of 60 and 90 Gy cured 41 and 59 % of patients after 6 months. Guhlmann et al. (50) cured hyperthyroidism in 83 % of patients at 1 year post-treatment with a dose of 150 Gy. According to Willemsen et al. (51) hyperthyroidism is

eliminated in all patients 1 year post-treatment with a dose of 300 Gy, but at this high dose level 93% of patients became hypothyroid.

For dose calculation in general an adapted version of the Quimby-Marinelli formula (52) has to be used

$$A(\mu\text{Ci}) = \frac{6.67 \times \text{Dose (cGy)} \text{ mass (g)}}{T_{1/2\text{eff}}(\text{days}) \times \% \text{ uptake}(24 \text{ h})}$$

Application of this protocol for individual patient dosimetry necessitates the determination of the following important variables: percentage uptake 24 h after administration, effective half-life of the radioiodine, and mass of the thyroid gland. For uptake and kinetics assessment, serial scintigraphies or probe measurements of the patient's thyroid after administration of a tracer dose have to be performed. This approach assumes that the kinetics of a tracer and a therapeutical amount of administered activity are the same. According to some authors, a pretherapeutic tracer dose may induce a stunning effect limiting the uptake of the therapeutic activity in the thyroid afterward (53). The thyroid mass is generally determined by the pretherapeutic scintigraphy, by ultrasonography or by MRI (54). A ^{124}I PET image also allows measurement of the functioning mass of the thyroid (55). Dosimetry protocols exist based on only a late uptake measurement at 96 or 192 h after tracer activity administration (56). A thorough discussion of the activity to be administered and the dosimetry protocol to follow can be found in Refs. 57,58.

Dosimetry of Radioiodine Therapy for Differentiated Thyroid Cancer

Radioiodine is also administered frequently to patients for differentiated thyroid cancer to ablate remnant thyroid tissue in the early postoperative period, for locoregional recurrences, and for distant metastases. Although most centers administer standard activities, typically 2.8–7.4 GBq (75–200 mCi), because of the practical difficulties to determine the target absorbed dose, absorbed dose-based protocols are also applied (59). For the calculation of the activity to be administered to give a predetermined tumor absorbed dose protocols as for thyrotoxicosis treatment described earlier are used. As predetermined absorbed dose-to-remnant thyroid tissue a value of 300 Gy is considered to be sufficient (60). For treatment of metastases lower doses giving a complete response have been reported: 85 Gy (61) and 100–150 Gy (62). This approach necessitates determination of the remnant mass of thyroid tissue or metastases by the methods described earlier, which is now more difficult in practice. This introduces in general a large uncertainty on the activity to be administered to ensure the desired dose to the target tissue. Also, the radioiodine kinetics with the 24 h uptake and the effective half-life has to be determined for the patient by administration of a tracer dose. Because of the relatively high activities necessary for quantitative imaging of the target thyroid tissue for this application (at least 37 MBq-1 mCi ^{131}I) complication of the therapy by stunning introduced by the tracer activity mentioned earlier, is more critical here. Because of this and the inaccuracy in the target mass

determination, dosimetry protocols based on target dose levels remain difficult for treatment of differentiated thyroid cancer. The ^{124}I PET imaging allows a more exact *in vivo* determination of iodine concentration and volume determination. By using this method, radiation doses to metastases ranging between 70 and 170 Gy were delivered to the lesions (63).

Instead of target absorbed dose-based protocols, dosimetry protocols based on the largest safe approach are also applied. This approach based on the dose to the critical tissues allows the administration of the maximum possible activity to achieve the maximum therapeutic efficacy. Application of this method necessitates serial total body scintigraphy after the administration of a tracer dose. The dose to the bone marrow, the lungs, and the thyroid tissue or metastases is then calculated by the MIRD formalism. From the absorbed doses obtained by the tracer activity imaging the amount of activity giving the maximal tolerable absorbed dose to the critical tissues is calculated. It has been generally accepted that the activity that delivers 2 Gy whole body dose as a surrogate for the bone marrow dose with a whole body retention < 4.44 GBq (120 mCi) at 48 h postadministration is safe with respect to bone marrow suppression (64). In some departments, the tolerable dose level of the bone marrow in radioiodine treatment of patients with metastatic differentiated thyroid cancer is even increased to 3 Gy based on the $\text{LD}_{5/5}$ data of external beam radiotherapy with $\text{LD}_{5/5}$ being the dose for the red marrow giving a 5% risk of severe damage to the blood-forming system within 5 years after administration (62). Very high activities of ^{131}I in the range 7.4–37.9 GBq (200–1040 mCi) are then administered for treatment of metastases. In a retrospective study of patients treated with this protocol over a period of 15 years, transient bone marrow depression with thrombopenia and leukopenia was observed recovering after a few weeks (62). No permanent damage was observed. In ~ 10% of the patients the dose-limiting organ were the lungs for which a limit of 30 Gy was adopted from $\text{LD}_{5/5}$ data.

A recent review of the evolving role of ^{131}I for the treatment of differentiated thyroid carcinoma can be found in Ref. 9. Preparation of patients by administration of recombinant human thyroid-stimulating hormone (rhTSH) may allow an increase in the therapeutic radioiodine activity while preserving safety and tolerability (65). As side effects of the ^{131}I therapy, impairment of the spermatogenesis in males (66) and earlier onset of menopause in older premenopausal women (67) are reported. With respect to pregnancy, it is recommended that conception be delayed for 1 year after therapeutic administrations of ^{131}I and until control of thyroid hormonal status has been achieved. After this period there is no reason for patients exposed to radioiodine to avoid pregnancy (68).

Dosimetry of ^{131}I -MIBG Therapy

Another radionuclide therapy application for which the importance of patient-specific dosimetry is generally accepted is treatment of pediatric neuroblastoma patients with ^{131}I -MIBG. Neuroblastoma is the most common

extracranial solid tumor of childhood with an incidence of 1/70000 children under the age of 15 (69). Neuroblastoma cells actively take up nor-adrenalin via an uptake-1 system. The molecule *meta*-iodo benzyl guanidine (MIBG), radiolabeled with ^{131}I , has a similar molecular structure, uptake, and storage in the cell as nor-adrenalin. Since 1984, ^{131}I -MIBG has been used therapeutically in neuroblastoma patients (70,71). Aside from the tumor, ^{131}I -MIBG is also taken up in the liver, heart, lungs, and adrenal glands. The bladder is irradiated by the metabolites of ^{131}I -MIBG. For patient dosimetry the largest safe dose approach is applied in ^{131}I -MIBG therapy with bone marrow as dose limiting organ. In practice, the whole body absorbed dose is also used in this setting as an adequate representation or index of bone marrow toxicity. Most treatment regimens consider the maximal activity to be administered limited by rendering a bone marrow dose of 2 Gy. Prediction of whole body doses is based on a pretherapeutic administration of ^{123}I -MIBG. In Fig. 3, predicted whole body doses based on pretherapeutic ^{123}I -MIBG scintigraphies are compared to doses received by patients after ^{131}I -MIBG therapy (72). The received dose values were derived from post-therapy scans. This figure shows also that in the case of repeated therapies pre-therapy scans do not need to be repeated before each therapy except when the biodistribution of ^{131}I -MIBG is expected to change rapidly (e.g., for patients where bone marrow invasion is present). It has also been shown that the accuracy of whole body dosimetry improves when half-life values of tracer and therapy radionuclides are matched (73).

In ^{131}I -MIBG therapy, protocols with administration based on fixed activity per unit mass protocols are also applied. Matthay et al. (74) reported on dosimetry performed in a dose escalation study of patients treated with ^{131}I -MIBG for refractory neuroblastoma with a fixed activity per unit mass ranging from 111 to 666 $\text{MBq}\cdot\text{kg}^{-1}$ (3–18 $\text{mCi}\cdot\text{kg}^{-1}$). Patients treated with a specific activity $< 555 \text{ MBq}\cdot\text{kg}^{-1}$ did not require hematopoietic stem cell support, while this was necessary for one-half of the patients treated with a higher specific activity. The median

whole body dose of the group of patients requiring hematopoietic stem cell support was 3.23 Gy (range 1.81–6.50 Gy) while for the other patients the median dose was 2.17 Gy (range 0.57–5.40 Gy).

In order to improve the results of ^{131}I -MIBG therapy for patients refractive of extensive chemotherapy treatment, a high activity ^{131}I -MIBG schedule is now being used in combination with topotecan as radiosensitizer for the therapy of neuroblastoma in a controlled ESIOP (European International Society of Pediatric Oncology for Neuroblastoma) study protocol (75). The aim here is to administer in two fractions the amount of activity needed to reach a combined total body dose of 4 Gy. These kinds of high doses will inevitably invoke severe side effects, thus frequently necessitating hematopoietic stem cell support and even bone marrow transplantation. However, a contemporary oncological department is well equipped to deal with this kind of treatments. The first amount of ^{131}I -MIBG activity is administered based on a fixed activity per unit body mass ($444 \text{ MBq}\cdot\text{kg}^{-1}$ – $12 \text{ mCi}\cdot\text{kg}^{-1}$) protocol. Total body dosimetry is carried out using serial whole body scintigraphies after the first administration. Radionuclide kinetics are followed by a whole body counter system mounted on the ceiling of the patient's isolation room. These dosimetry results are then used to calculate the activity of the second administration of ^{131}I -MIBG giving a total body dose of 4 Gy over the two administrations. The first results of this study indicate that *in vivo* dosimetry allows for an accurate delivery of the specified total whole body dose and that the treatment schedule is safe and practicable (75). The approach has now to be tested for efficacy in a phase II clinical trial.

Dosimetry in Radioimmunotherapy

In general, red marrow is the dose-limiting tissue in non-myeloablative and lung for myeloablative radioimmunotherapy (RIT). Administration protocols are applied based on absorbed-dose values of the dose-limiting tissue and on an activity per body weight basis. Typical examples

Figure 3. Correlation between the whole body dose estimate based on ^{123}I -MIBG pretherapy scans and the dose derived from ^{131}I -MIBG posttherapy scans in patients treated for neuroendocrine tumors. The triangles represent the data of the first therapies, the crosses the data of retreatments. The straight line is the result of a linear regression to all data ($R^2 = 0.73$).

of these protocols are the ^{131}I -labeled anti-CD20 antibody, tositumomab (Bexxar; Glaxo-SmithKline) (76) and the ^{90}Y -labeled anti-CD20 ibritumomab tiuxetan (Zevalin; Biogen Idec) (77), respectively. These radiolabeled antibodies are used for treatment of non-Hodgkin's lymphoma. The choice for an activity-based protocol for the ^{90}Y -labeled antibody is based on the lack of correlation between absorbed dose and toxicity in the early studies. The explanation for the absence of a dose-response relationship can be found in different sources. In contrast to ^{131}I , ^{90}Y is a pure β -emitter, and ^{90}Y kinetics have to be derived from surrogate ^{111}In imaging. Another point is that prior treatment of these patients and the bone marrow reserve have a strong effect on the bone marrow toxicity in this case. As patients undergoing RIT have been treated previously by chemotherapy, the impact of such prior therapy on the hematopoietic response to the RIT is important.

Although the necessity of patient-specific dosimetry is questionable in some applications of RIT where the dose-response observations for toxicity are poor, there is a general agreement that complete radiation dosimetry is necessary for each new application of a radiolabeled antibody in phase I and most probably also in phase II studies especially for safety reasons (78). An important argument for absorbed dose driven protocols in clinical phase I trials is that many patients are treated below the biologically active level due to the interpatient variability in activity based administration protocols. This implies data difficult to interpret in antitumor response and toxicity.

In view of the central role of red marrow toxicity in RIT methodologies, bone marrow dosimetry got already a lot of attention in the literature (79–85). In general, methods based on imaging as described in the section on ^{131}I -MIBG therapy are used. Also, approaches to calculate the bone marrow dose based on blood activity measurements have been described, but these methods yield only reliable results when the activity does not bind specifically to blood or marrow components including tumor metastases in the marrow (79). By assuming rapid equilibrium of radiolabeled antibodies in the plasma and the extracellular fluid of the red marrow, a red marrow/blood concentration ratio of 0.3–0.4 can be derived. All red marrow dosimetry performed up to now uses a highly stylized representation of the red marrow over the body. More detailed representations are being generated especially for Monte Carlo calculations enhancing accuracy and reliability of the bone marrow doses (86).

Several studies have investigated the relation between the tumor dose and response especially in RIT of non-Hodgkin's lymphoma (87–89) but the results are negative. Possible explanations are the therapeutic effect of the antibody, different confounding biological factors and the accuracy of tumor dosimetry. Here, standardization of data acquisition as presented in MIRDO pamphlet No. 16 (13) may help in dose-response investigations. As discussed earlier in the section on ^{131}I -MIBG therapy, a full patient-specific 3D dosimetric approach with imaging data from the combined SPECT–CT systems will improve substantially the accuracy of the tumor dosimetry results.

DOSIMETRY IN THE DEVELOPMENT OF NEW DRUGS

For the study of the absorption, metabolism, and excretion pathways of new drugs a ^3H - or ^{14}C -radiolabeled formulation of the drug is administered to healthy volunteers. A dosimetric evaluation of the radiation burden of the volunteers based on animal biodistribution, retention, and excretion data is necessary and presented to an ethical committee before the radiolabeled drug can be administered. This procedure has to ensure that the effective dose will not exceed the limits for the considered risk category of the volunteers according to the ICRP publication 62 categories (30). For testing new drugs mostly a risk category IIa (risk $\sim 10^{-5}$) is adopted corresponding to a maximal effective dose of 1 mSv. Based on this criterion, the activity to be administered is calculated from the dosimetric evaluation.

For the calculation of the dose estimate of the volunteers the MIRDO formalism for an administration of a standard activity (37 kBq/1 μCi) of the radiolabeled pharmaceutical is applied. Animal biodistribution data are used to calculate the residence time in the source organs and tissues based on the maximum uptake f and biological half-life. In general a rat strain is used as animal model. As the organ weights in the rat and man are different an important correction of the animal data is necessary to estimate the f -values in humans. For each organ, dosimetric calculations are performed assuming (1) the same fraction of activity is absorbed by the organs in rat and humans irrespective of the difference in relative weight or (2) the fraction of activity absorbed by each organ is proportional to the relative organ weight in rat and humans. The latter assumption means that the uptake per kilogram of organ weight normalized to the whole body weight is the same for both species. Table 2 gives an overview of the organ and tissue weights in a male Wistar rat of 250 g reported in the literature (90) and in the standard human of 70 kg (32). For each organ or tissue two dose values are obtained by assuming a species independent organ uptake and an uptake proportional to the relative organ weight in different species. The highest dose estimate of both is restrained for each organ. If the retention for the individual organs is not known the whole body retention is adopted.

As model for the liver and biliary excretion it is generally assumed that a fraction of the radiopharmaceutical is taken up by the liver. Part of this activity goes directly to the small intestine while the resting part goes to the gallbladder, from where it is cleared to the small intestine. For the total fraction of activity excreted in this way by the gastrointestinal tract, the fraction of the activity retrieved in the feces is adopted from animal data. In general, data are available for different species and the maximal value is retained. For the dose calculation of the sections of the gastrointestinal tract, the kinetic model of the ICRP publication 53 is adopted (3). The kidney–bladder model described in this publication is also used to calculate the dose to the urinary bladder. Urine activity measurements in animals are used to estimate the fraction of the activity eliminated through the kidneys and again the maximal value is adopted if data are available for different species.

The dose estimates to organs and tissues of humans extrapolated in this way from animal data are combined

Table 2. Organ Weights of a Male Wistar Rat of 250 g^a and Human of 70 kg^b

Organ	RAT Weight, g	RAT Rel. Weight, %	Humans Weight, kg	Humans Rel. Weight, %

with the tissue weighting factors to obtain the effective dose after the administration of the standard activity (37 kBq/1 μ Ci) as described earlier (33). Based on the effective dose estimate obtained in this way and the dose limits proposed in the ICRP 62 publication (30) the activity of the radiolabeled drug to be administered to the volunteers is obtained.

CONCLUSIONS

To estimate the risk for late radiation effects as cancer and leukemia in patients after administration of radiopharmaceuticals for diagnosis the MIRDOSE formalism with standard human anatomy and biokinetics is generally applied. This holds also for the estimation of the same risk of volunteers after the administration of a radiolabeled formulation of newly developed drugs. However, therapeutic applications of radiopharmaceuticals necessitate a reliable patient specific approach at least with respect to the biokinetics and if possible also for the patient-specific anatomical data. For curative treatment of malignant diseases there is now a tendency to use the largest safe dose approach with administration of the maximum possible activity based on the dose to the critical tissues. On the other hand, the advent of combined SPECT-CT or PET-CT imaging means an essential step forward toward an accurate 3D tumor dosimetry, the basic need for the administration protocols with the calculated activity based on a tumor dose prescription as used in external beam radiotherapy.

INTRODUCTION

Conventional external beam radiotherapy, or teletherapy, involves the administration of radiation absorbed dose to

cure disease. The general teletherapy paradigm is to irradiate the gross lesion plus an additional volume suspected of containing microscopic disease not visible through physical examination or imaging, to a uniform dose level. External photon beams with peak photon energy in excess of 1 MeV are targeted upon the lesion site by registering external anatomy and internal radiographic anatomy to the radiation (beam) source.

Due to uncertainty and errors in positioning the patient, the radiation beam, which is directed at the lesion, may need to be enlarged to ensure that errors and uncertainty in patient positioning do not cause the radiation beam to miss some or all of the target. Unfortunately, enlarging the radiation beam results in a relatively large volume of nondiseased tissue receiving a significant radiation dose in addition to the target. For example, expansion of a 24 mm diameter spherical target volume to 26 mm to ensure that the target is fully irradiated in the presence of a 2 mm positional error will increase the irradiated volume by 60% (1). As a consequence, non-cancerous (normal) tissue in the expansion region will receive the same high dose that the target will receive. To minimize the normal tissue toxicity, the total radiation dose is delivered in many small increments (fractions), a principle first discovered by Bergonie and Tribondeau in the early twentieth century (2) and used routinely for the majority of external radiotherapy treatments.

In contrast to conventional, fractionated radiotherapy, stereotactic radiosurgery (SRS) involves the spatially precise and conformal administration of a relatively large, single dose of radiation (10–20 Gy) to a small volume of disease, thereby abandoning the advantages provided by fractionation. Hence, it is imperative to minimize the amount of normal tissue irradiated to a high dose using such an approach. Radiosurgery is commonly used to treat intracranial lesions including brain metastases, arteriovenous malformations, benign brain tumors (acoustic schwannoma, meningioma), and primary malignant brain tumors (astrocytoma, glioma, glioblastoma).

Leksell, first conceived radiosurgery for intracranial targeting in 1950 (3). His initial goal was to produce a lesion similar to one created by a radiofrequency probe but without the need to physically introduce a probe into the brain. The lesion was to be created by a very concentrated single high dose of radiation. Stereotactic targeting and arc-centered stereotaxis methods were already known to Leksell. In his initial design, Leksell mounted a therapeutic X-ray tube onto an arc-centered frame with the axis of rotation positioned in the target tissues. This approach allowed many different paths of radiation to converge on the target tissues producing a highly concentrated dose at the intersection point. While this concept did provide a concentrated dose, Leksell continued to investigate alternate radiation delivery systems in hopes of finding a better system that could produce a high concentration of radiation at the target tissues while providing more normal tissue sparing. In later designs Leksell attempted to use particle beams to take advantage of the known Bragg peak effect. The physical limitations of the particle beam delivery systems as well as the expense of the device encouraged Leksell to continue his development finally arriving at a

design based on 201 pencil thin cobalt-60 gamma radiation sources arranged on a hemisphere and focused at a single point. This device, known as the Gamma Knife (Elekta Oncology Systems), was used to treat both benign and malignant intracranial targets.

In the 1980s, several groups began to develop technology that would adapt more generally available medical linear accelerators (linacs), to deliver radiosurgical style dose distributions, thereby placing radiosurgical capabilities within the reach of many radiation therapy clinics. Betti (4) and Columbo (5) both developed linear accelerator based radiosurgery systems. Although these early linac-based systems did allow the concentration of radiation dose there existed a question as to how accurately the radiation dose could be delivered to the targeted stereotactic coordinates. Winston and Lutz addressed this issue through the use of a stereotactically positioned phantom target system (6,7). It was found that linac-based systems could maintain the accuracy of radiation beam to target coordinates to within a millimeter or two (Fig. 1 and 2). While some felt that this accuracy was adequate, it fell short of the GammaKnife claim of 0.3 mm isocentric beam accuracy. In the late 1980s Friedman and Bova (8) developed an isocentric subsystem that enabled a routine linac to achieve an

Figure 1. Modified Winston–Lutz test setup, for testing the spatial alignment of the circular radiosurgery X-ray beam with a spherical target ball. The test target sphere should be precisely aligned to the center of the X-ray field defined by the circular collimator. Several film exposures at different linac gantry rotation angles are taken.

Figure 2. Image of a developed film from the modified Winston-Lutz test, showing the alignment between the circular radiosurgery X-ray beam with a spherical target ball. Analysis of this film image shows that in this case, the target sphere is misaligned from the center of the 20 mm diameter X-ray field by 1.06 mm in one direction, and by 0.97 mm in the other direction. Repeating this test with at least one pair of linac gantry angles gives an estimate of the spatial error inherent in the treatment delivery system.

isocentric beam accuracy of 0.2 mm, thereby matching the accuracy of the GammaKnife.

All early radiosurgery systems used a similar delivery method, namely multiple circular cross-section radiation beams converging to a common point, called the isocenter, located in the center of the target, volume with the directions chosen to minimize the overlap of beams outside the target and hence the normal tissue dose. This scheme worked well for spherical targets using a single isocenter. Non-spherical targets required the use multiple circular collimator diameters focused at multiple isocenters distributed throughout the target volume in an effort to “fill” the volume with dose. The ability to properly select the optimal set of sphere as well as their spacing and weighting were provided by treatment planning systems specially designed to optimize radiosurgical planning.

The next level of advance occurred in the 1990s when new computer controlled collimation devices known as multileaf collimators (MLC) were introduced that were coupled to stereotactic treatment planning software and delivery hardware designed for these new devices. While the early attempts at using MLCs had problems matching the dose conformality and steep dose gradients achieved by multiple isocentric circular collimation techniques, they nevertheless allowed complex targets to be treated more rapidly. Recently, new techniques have been developed that allow both the conformality of multiple isocenters as well as the speed of MLC delivery (9,10).

The majority of medical linear accelerators use microwave radiation in the S band to accelerate electrons and produce X rays. During the 1990s a compact medical X band linear accelerator was developed by Accuray, Inc. Adler placed this X ray source on an industrial robot gantry to create a novel stereotactic radiosurgery system called the

CyberKnife (11,12). This system based its stereotactic targeting on an integrated orthogonal X-ray system that performed real-time imaging and correction of beam orientation to compensate for patient motion during treatment. Although this method of targeting was novel in the early 1990s, targeting systems have since been introduced for use on S band medical linacs. Unlike the GammaKnife, which by design is limited to intracranial targets, the CyberKnife can be applied to targets anywhere in the body.

Although radiosurgery based on gamma and X ray sources predominate, the theoretical advantages of proton therapy beams have stimulated great interest in advancing the use of protons to treat intracranial tumors. The physics of proton beam interactions are quite different than those of a photon beam. Unlike X rays, protons have mass and charge that result in a finite range of penetration. Additionally, the density of ionization (linear energy transfer) along the track of a proton beam is greater than that of an X-ray beam, with a region of high ionization density at the end of the track known as a Bragg peak (13,14). The finite range of penetration results in zero radiation dose beyond the Bragg peak, which in theory further allows the concentration of radiation dose to a deep-seated target while sparing underlying radiosensitive structures (15–17). The theoretical advantage of the proton beam Bragg peak is somewhat tempered by practical issue that its width is usually not large enough to encompass an entire radiosurgery target, so that it becomes necessary to superimpose a multitude of proton beams of varying energies to produce a composite depth dose distribution that covers the entire target (16). Historically, proton facilities produced only stationary beams, making it very difficult to bring multiple converging beams upon the patient’s lesion. More recently rotating gantry delivery systems for protons have been introduced, which offer more flexibility in selecting beam orientations (18). Nevertheless the high cost (>\$50M) of these facilities currently limits their availability to a few large metropolitan centers.

Early stereotactic targeting systems relied upon orthogonal radiographs for target localization, however, stereotactic procedures did not gain wide acceptance until the late 1980s with the development of three-dimensional (3D) treatment planning based on the use of computerized tomography (CT) imaging to obtain a 3D model of the patient. By the 1990s CT based target definition was augmented with magnetic resonance (MR) imaging that provided superior anatomical definition of the central nervous system. Because of difficulties related to MR incompatibility of stereotactic head fixation systems, MR imaging is performed without such hardware and the image set aligned or fused with CT images obtained with head fixation.

Initially, all intracranial stereotactic procedures used a rigid stereotactic head ring, or frame, screwed into the patient’s skull to achieve a rigid, reproducible geometry for CT imaging and treatment. While frame-based procedures are still the most precise radiosurgery method they obviously are invasive to the patient and place a time limit on the completion of the procedure within hours of the frame placement. Noninvasive frameless head fixation systems were subsequently developed to address these

issues. While less precise than ring-based approaches, they can be used in certain radiosurgery procedures where extreme accuracy is not required, such as treatment of brain metastases that are not located near critical structures like the brain stem or optical apparatus. Some of these systems are based upon the fitting of patients with thermoplastic face masks (19), while other systems separate the fixation and localization processes through the use of biteplates and thermoplastic masks (20,21).

Extracranial stereotactic targeting of lesions outside of the skull has been made possible through the development of a number of new technologies. One of the first was the use of ultrasound to allow the clinician to obtain a two-dimensional (2D) or 3D image set of the patient in position for radiosurgery (22). The ultrasound probe is tracked during image acquisition and the image voxels are mapped to a reference that allows precise targeting of the radiation beam. To enhance the ability to target tissues these scans are often registered to pretreatment CT and MR scans. Other methods involving fixed stereotactic X-ray tubes with image intensifiers have been developed by Accuray (23) and BrainLab (24). These systems function by obtaining either orthogonal or stereoscopic radiographs that are registered to the projection of a previously obtained 3D CT dataset. While these planar X-ray localization methods work well for bony anatomy the poorer contrast of soft tissues makes them less useful for localizing targets that are not rigidly fixed to bone. More recently the development of large format amorphous silicon detectors has facilitated the development and integration of cone beam CT scanning systems onto medical linear accelerators allowing stereotactic localization and registration of soft tissue anatomy to the linear accelerator's reference coordinate system. These new units have promise of providing unprecedented targeting accuracy to extra cranial targets.

STEREOTACTIC IMAGING AND LOCALIZATION

The uncertainty inherent to the imaging modality used can be the largest source of uncertainty in the radiosurgery process. Poor imaging techniques increase this uncertainty and nullify the efforts to improve accuracy in treatment planning and delivery. Therefore, it is important to understand stereotactic imaging techniques, the increased quality assurance demands that are placed on the diagnostic imaging apparatus used, and the inherent limitations associated with each modality. Following are brief explanations of the three stereotactic imaging techniques used in radiosurgery: computed tomography, magnetic resonance imaging, and angiography.

Computed tomography is the primary modality used for radiosurgery treatment planning due to its spatial accuracy and electron density information that are both useful for accurate dose calculation and targeting. Stereotactic CT images can be obtained with a CT-compatible localizer attached to the stereotactic head ring such as the Brown–Roberts–Wells (BRW) (Fig. 3) or other commercially available designs (25,26). Since the geometry of the localizer is known relative to the head ring, stereotactic coordinates of any point in a volumetric CT image set may be

Figure 3. Computed tomography localizer attached to frame.

accurately calculated, using the localizer fiducial markers in each axial image (Fig. 4). For example, the characteristic N-shaped rods of the BRW localizer allow the x - y - z coordinates of any point in space to be mathematically determined relative to the head ring rather than relying on the CT coordinates. This method provides more accurate spatial localization, and minimizes the CT scanner quality assurance requirements. In order to minimize the inaccuracies associated with the stereotactic imaging, it is important to obtain all imaging studies with the best available spatial resolution. Typically this means reducing the uncertainty to < 1 mm by acquiring CT images at an

Figure 4. Axial CT image of patient with BRW stereotactic headframe and CT localizer attached. There are three sets of N-shaped rods; the location of any point in a CT image that contains all nine CT localizer rods, can be computed using the interrod distances to precisely define the plane of the image with respect to the BRW headframe and its coordinate system.

image resolution and slice spacing less than this amount. For example, a minimum 34.5 cm field of view is just large enough to image all of the stereotactic fiducials of a BRW localizer. This FOV corresponds to a pixel size of 0.67 mm for a 512×512 image matrix. In addition, current multi-slice diagnostic helical CT scanners can obtain CT images at 0.5–1 mm splice spacing.

Magnetic resonance (MR) imaging often provides superior tumor visualization, but spatial distortion inherent in the MR images due to magnetic field non-uniformities and patient-specific artifacts, and secondarily the lack of electron density information makes the use of MR images less desirable than CT images for radiotherapy dose calculations. Introducing a stereotactic frame and localizer into an MR imager will perturb the magnetic field producing image distortions on the order of 0.7–4 mm in each orthogonal plane (axial, sagittal, coronal) of a stereotactic MRI (27,28). Furthermore the size of the stereotactic head frame may be incompatible with the geometry of standard MRI head coil necessitating the use of a larger MRI coil, such as the standard body coil, with a consequent degradation in image quality due to a reduced signal/noise ratio. These problems are overcome by eliminating the head frame during the MR imaging procedure and using image fusion techniques to register the MR image volume to the CT image volume of the patient in the head frame. For frame-based radiosurgery, the 3D volumetric MR scan is acquired prior to head ring placement using a pulse sequence that allows a fast image acquisition to minimize image distortion due to patient movement. All currently available image correlation routines consider the MR images as rigid bodies, and do not remove local image distortions that can exist in the MR data, hence careful review of the coregistered MRI and CT image sets is essential. This comparison should focus on internal anatomy, such as the ventricles, tentorium, sulci, and avoid the external contour since it can be shifted 3–4 mm due to the fat shift (a distortion resulting in the difference in the resonant frequency of protons in fat relative to their resonant frequency in water).

The third imaging modality important to radiosurgery, angiography, is used for diagnosis and anatomic characterization of cerebral arteriovenous malformations (AVMs). Unlike volumetric CT and MR tomography, stereotactic planar angiography utilizes a set of orthogonal radiographs of a special localizer attached to the stereotactic head ring bearing radio-opaque fiducials. The stereotactic coordinates of any point within the localizer may be calculated very accurately since the geometry of the fiducials is known relative to the head ring. The orthogonal film pair is obtained with contrast injected rapidly at the location of the AVM nidus allowing excellent visualization of fine vasculature and fiducials.

The use of orthogonal images as the sole localization method for treatment planning is inadequate for accurately determining the shape, size and location of an arbitrarily shaped AVM nidus (29–31). Furthermore, overlapping structures, such as feeding or draining blood vessels, may obscure the view of the AVM nidus and will result in unnecessary irradiation of normal tissue if these blood vessels are included in the targeted volume. Because of

these issues a volumetric CT angiography image dataset (1 mm slice thickness; intravenous contrast infused at a rate of $1 \text{ cm}^3 \cdot \text{s}^{-1}$) is always acquired in addition to, or in replacement of, stereotactic angiography. The resultant CT images provide an accurate 3D description of the AVM nidus, along with the feeding and draining vessels.

RADIOSURGERY DELIVERY TECHNIQUES

Numerous radiosurgery techniques have been devised based noncoplanar configurations static beams or arcs. The majority of radiosurgery treatments use circular collimators to create spherical regions of high dose. The classic example of a static beam delivery system is the GammaKnife unit, which consists of 201 narrow-beam cobalt-60 sources arranged on a hemisphere. A collimation helmet containing 201 circular collimators, each of the same diameter, is placed between the hemisphere of sources and the patient's head with the collimator's focal point centered on the intracranial target. This produces a spherical dose distribution or shot in GammaKnife parlance. An irregular volume is treated with multiple shots whose diameters are selected based on the available helmet collimators (32). The CyberKnife robotic radiosurgery unit is also used in a similar manner to deliver treatments from fixed beam orientations using a circular collimator.

Alternatively, a conventional medical linear accelerator can be outfitted with a circular collimator and multiple (5–9) noncoplanar arc delivery used to achieve a spherical dose distribution. When used with linear accelerators, the circularly collimated beam is rotated around the target at isocenter by moving the gantry in arc mode while the patient and treatment couch are stationary, producing a parasagittal beam path around the target. Betti and Derichinsky developed their linac radiosurgery system with a special chair, the Betti chair, which moved the patient in a side to side arc motion under a stationary linac beam, and which produced a set of para-coronal arcs (4). With modern, computer controlled linear accelerators, more complex motions other than these simple arcs are possible. The Montreal technique, which involves synchronized motion of the patient couch and the gantry while the radiation beam is on, is an example of this, producing a baseball seam type of beam path (33). The rationale of using arcs with circular collimators is to concentrate radiation dose upon the target, while spreading the beam entrance and exit doses over a larger volume of nontarget tissue, theoretically reducing the overall dose and toxicity to nontarget tissue.

Radiosurgery based on circular collimators produces a spherical region of high dose with steep falloff, or gradient, that is adequate for spherical targets. Irregular target volumes require the use of multiple spheres, or isocenters, abutted together to conform the dose more closely to the shape of the target so as to minimize nontarget tissue dose (34). A consequence of the multiisocenter approach is that the shape of the total dose distribution is very sensitive to the abutment of the spherical dose distributions due to their steep falloff. For this reason, it is common practice to accept 30% or greater dose variation over the irregular target volumes using circular collimation.

Figure 5. Beam's eye view showing target shape. Instead of constructing a custom block for the conformal shape of the target, at left a MLC (narrow rectangles) approximates the shape of the conformal beam. Each rectangle represents a tungsten leaf which moves left and right across the field of view shown under computer control. In this example, the MLC leaves would remain stationary while the treatment beam is on, providing a dose distribution very similar to a custom block. At center, the position of the MLC (arrow) on the linac gantry is shown; X rays emerge from the MLC-shaped aperture. At right, close-up photograph of the actual MLC, whose leaves are shaped to the field shown in the left image.

The linear accelerator offers additional flexibility in that tertiary computer-controlled multileaf collimators (MLCs) may be used to produce noncircular beams and beams with nonuniform intensity profiles that conform dose distributions more closely to irregular target volumes with less dose non uniformity. The most common type of MLC consists of two banks of opposed high density metal plates, or leaves that can be moved in a plane perpendicular to the beam's direction. The MLC can be rotated with the treatment machine's collimator in order to align the leaves for the best fit to the target's projected shape. The simplest use of an MLC is simply as a functional replacement for custom made beam shaping blocks, in which the rectangular MLC edges are used to approximate a continuous target outline shape (Fig. 5) (35). This field shaping can be used for either static field treatments or for dynamic arcs in which the MLC shape is continually changed to match the beam's-eye-view projection of the target volume. Moss investigated the efficacy of performing radiosurgery treatments with a dynamically conforming MLC in arc mode, and concluded that dynamic arc MLC treatments offered target coverage and normal tissue sparing comparable to that offered by single and multiple isocenter radiosurgery (36). Nedzi (37) showed that even crude beam shaping devices offered some conformal benefit over single isocenter treatments with circular collimators. Since the mid- to late-1990s, the use of miniature multileaf collimators (MLCs with a leaf width projected to isocenter of 5 mm or less) has become increasingly common.

However, the MLC may be used in a more sophisticated fashion to form many different beam shapes of arbitrary size and intensity (by varying the amount of radiation applied through each beam aperture). In this manner, radiation fields with a similar dose profile as a shaped, wedged field may be delivered using only the computer-controlled MLC, shall can also deliver intensity modulated dose profiles similar to those achievable using custom beam compensators, but without the disadvantages of fabrication time or of needing to manually change a physically mounted beam filter between each treatment field (38).

Thus, a computer-controlled MLC and treatment machine offer the potential to deliver more sophisticated radiation treatments to each patient with the same time and cost resources available.

The MLC-based solutions are available for both static multiple beams and arc-based delivery. Radionics initially introduced the use of a mini-MLC for defining static beam shapes that conformed to the projected shape of the target volume in the beam's eye view (35,39,40). The device consisted of multiple thin plates, or MLC leaves, that were mechanically clamped together to form an irregular beam shape defined by a plastic template corresponding to the projected shape of the target. Subsequent developments by other vendors added computer-controlled motorization to the leaves so that treatments could be carried out more efficiently. While most mini-micro-MLC implementations were based on static delivery of few fixed beams, NOMOS, Inc. and 3D Line, Inc. developed specialized arc-based intensity-modulated radiosurgery (IMRS) systems. Most, if not all, tertiary MLC vendors have now developed integrated treatment planning systems designed specifically for their MLCs and treatment applications, including IMRS.

The potential for improvement presented by some of these newer and more sophisticated treatment delivery methods has spurred interest in their evaluation relative to the more traditional linac SRS methods of multiple intersecting arcs and circular collimators. These studies are usually conducted by those who have had difficulty achieving the conformality routinely published by those experienced in multiisocenter planning. These comparisons generally demonstrate that for small to medium (up to $\sim 20 \text{ cm}^3$) intracranial targets multiple static beams offer conformity with ratios of normal tissue to target tissue treatments in the range of 1.5–2.0, with target dose homogeneity on the order of 10–20%, while offering a more standard radiation therapy treatment planning interface and process (39,41–43). These studies go on to show that static beam IMRT techniques generally performed comparable to or better than static beam plans, usually increasing the dose homogeneity and possibly conformality (44,45).

Figure 6. Ideal target (a) and nontarget volume (b) direct DVHs. Note that in the ideal direct DVH of the nontarget volume (right side), the plot is empty, since there is no nontarget volume receiving any dose in the ideal case.

A potential problem with these comparison studies is that they may not equitably compare the full potential of multiple isocenter radiosurgery with circular collimators. A qualitative inspection of the multiple isocenter dosimetric results shown in these comparisons leads one to suspect that in many cases, suboptimal multiple isocenter plans are being compared with reasonably optimized static beam and dynamic MLC arcs–IMRT plans. Although the multiple isocenter treatment plans in these comparisons in the literature may represent a level of plan quality achievable by an average or unfamiliar user, they do not always represent the experience of expert users. Some expert users have reported on the use of multiple isocenter–circular collimator radiosurgery systems to plan and deliver tightly conformal dose distributions to irregularly shaped targets near radiosensitive structures, while maintaining a sharp dose gradient away from the target toward radiosensitive structures (34,46–48).

TOOLS FOR EVALUATING RADIOSURGERY TREATMENT PLANS

The clinical objective of radiosurgery is to deliver a tumoricidal radiation dose to a target volume while minimizing the dose to surrounding tissues. The following tools are available to the treatment planner to evaluate a 3D dose distribution in order to quantify the degree to which this objective is achieved: (1) 2D isodose curves and 3D isodose surfaces, (2) dose–volume histograms, and (3) physical dose–volume figures of merit. The following sections explain the use of each of these tools in radiation therapy and radiosurgery treatment planning.

It is possible to display 3D semitransparent surface renderings of constant dose levels overlaid on 3D renderings of the target volume to determine if the target adequately covered, but these can be difficult to analyze quantitatively. For this reason, 2D cross-sections of the 3D dose distribution are evaluated making it easier to quantitatively assess target coverage. The 2D dose cross-sections are displayed as isocontour plots (isodose plots) overlaid on the patient’s CT and MR images to allow visual assessment of dose coverage to an accuracy of within one image pixel. Although this implies submillimeter precision, the 1 pixel uncertainty in isodose position can result in a large uncertainty in dose coverage for small intracranial targets. In the case of a 0.67 mm pixel, a 20 mm sphere,

equal to 4.2 cm³, would apparently be equally well covered by an isodose surface ranging in volume from 3.8 to 4.6 cm³ corresponding to a 10% uncertainty in volume. Hence, although visual inspection of isodose plots on multiple images is commonly performed, it is cumbersome and there is a large uncertainty in assessing the dose coverage that is associated representing small targets using finite size pixels.

One commonly used solution to this problem is to use dose–volume histograms (DVHs). DVHs are a method of condensing 3D dose information into a more manageable form for analysis. The simplest type of DVH is a differential histogram of volume versus dose (49). This is simply a histogram showing the number of occurrences of each dose value within a 3D volume. A second more common representation is the cumulative DVH, which is the integral of the differential DVH as a function of dose. Unfortunately, in either type of DVH, the spatial information of which specific volumes are exposed to each dose level is lost in the process of constructing a DVH. For this reason, DVHs are generally used clinically in conjunction with the evaluation of multiple isodose plots as mentioned earlier.

The ideal treatment planning situation is one in which the target volume receives a uniform dose equal to the maximum dose, and the nontarget volume receives zero dose. This would correspond to ideal differential DVHs for target and nontarget volumes as shown in Fig. 6. Clinically realistic differential DVHs for target and nontarget volumes for a more typical (non-ideal) radiosurgery dose distribution are shown in Fig. 7. Figure 8 shows two differential DVHs from competing radiosurgery plans plotted on a common axes to allow a direct comparison of the plans. Note that it can be difficult to evaluate competing plans using such differential histograms (50), as demonstrated in Fig. 8. Above ~ 40 units of dose, both plans appear to be identical, but the two plans expose differing volumes of brainstem at doses less than ~ 40 units. For this reason cumulative DVH analysis is more commonplace. Transforming the differential DVHs into cumulative DVHs, by plotting the volume receiving at least a certain dose versus dose, makes it simpler to evaluate the differences in the dose distributions, as shown in Fig. 9.

Optimal cumulative DVH curves for target structures will be as far toward the upper right hand corner of the plot as possible, while the those for nontarget structures will be as close as possible to the lower left hand corner of the

Figure 7. Typical (nonideal) radiosurgery direct DVHs for target volume (a) and nontarget volume (b).

Figure 8. Direct DVHs for a radiosensitive nontarget structure in two hypothetical treatment plans.

plot as shown in Fig. 10. Considering the two completing plans shown in Fig. 9, the better plan will have its target cumulative DVH further to the upper right corner and its nontarget cumulative DVH further to the lower left corner than the poorer plan. Plan 1 is the preferred plan, since its nontarget DVH for the brainstem lies below and to the left of that for Plan 2. The relative ease of this comparison underscores the general utility of cumulative DVHs over differential DVHs (49,51). Unfortunately, it is rare for the cumulative DVHs of rival treatment plans to separate themselves from one another so cleanly. Typically, the DVHs cross one another, perhaps more than once as shown in Fig. 11. The simple rules for evaluating DVHs cannot resolve this situation, in which case other means must be used to evaluate the treatment plans by applying a score to each plan derived from a clinically relevant figure of merit.

Figure 10. Ideal cumulative DVH curve for target and nontarget volumes.

The three properties of radiosurgery dose distributions that have been correlated with clinical outcome and that lend themselves to clinical figures of merit are (1) dose conformity, (2) dose gradient, and (3) dose homogeneity (34). The conformity of the dose distribution to the target volume may be simply expressed as the ratio of the prescription isodose volume to the target volume, frequently referred to as the PITV ratio (52).

$$\text{PITV} = \text{Prescription isodose volume} / \text{target volume} \quad (1)$$

Perfect conformity of a dose distribution to the target, that is, $\text{PITV} = 1.00$, is typically not achievable, and some

Figure 9. Cumulative DVH plot of the direct DVH data shown in Fig. 8.

Figure 11. Crossing cumulative DVH curves.

Figure 12. Transaxial, sagittal, and coronal isodose distributions for five arcs of 100° each delivered with a 30 mm collimator. Isodose lines in each plane increase from 10 to 90% in 10% increments, as indicated. The isocenter is marked with cross-hairs.

volume of nontarget tissue must be irradiated to the same dose level as the target, resulting in PITV ratios greater than unity. The most conformal treatment plans are those with the lowest PITVs, if all of the plans under comparison provide equivalent target coverage. This stipulation is necessary because the definition of PITV does not specify how the prescription isodose is determined. It is possible (but undesirable) to lower, and thus improve, the PITV by selecting an isodose level that incompletely covers the target as the prescription isodose, and therefore reduces the numerator of Eq. 1. Many investigators report isodose shells that cover in the neighborhood of at least 95% of the target volume or 99% of the target volume (17,34,46,48,53–57). This ensures a more consistent basis of comparisons for all treatment plans.

A sharp dose gradient (fall off in dose with respect to distance away from the target volume) is an important characteristic of radiosurgery and stereotactic radiotherapy dose distributions. Dose gradient may be characterized by the distance required for the dose to decrease from a therapeutic (prescription) dose level to one at which no ill effects are expected (half prescription dose). For illustrative purposes, a typical dose distribution in a hemispherical water phantom for a single isocenter delivered with five converging arcs and a 30 mm collimator is depicted in Fig. 12. A quantitative measure of gradient is obtained from examining the dose profiles along orthogonal directions in the principal anatomical planes (transaxial, sagittal, and coronal), as shown by cross-plots in Fig. 13. As in this example the steepest dose gradient (4.6 mm) occurs between the 80% and 40% isodose shells, and for this reason single isocenter dose distributions are prescribed to the 80% isodose shell (34). Table 1 lists dose gradient information between the 80 and 40% isodose shells for single isocenter spherically symmetric dose distributions with 10–50 mm diameter collimators.

A method has been proposed that uses easily obtainable DVH information to generate a numerical measure, or score, of the overall dose gradient for evaluating the dose conformality of radiosurgery dose distributions. The Conformity–Gradient Index score, or CGIg, has been proposed as a metric for quantifying dose gradient of a stereotactic treatment plan (58,59). From treatment planning experience at the University of Florida, it has been observed that it is possible to achieve a dose distribution that decreases from the prescription dose level to half of prescription dose in a distance of 3–4 mm away from the target. Taking this as a guide, a gradient score CGIg

Figure 13. Dose cross-plots through the isocenter, corresponding to the isodose distributions shown in Fig. 12. The sharpest dose fall-off, from dose D to half-dose 0.5D, occurs between dose D of 80% to 0.5D = 40%, which occurs in a distance of 4.6 mm. The D to 0.5D fall-off distance is larger for 90–45% (5.1 mm) and for 70–35% (4.9 mm) doses.

may be computed as

$$CGI_g = 100 - \{100 \times [(R_{\text{eff},50\%R_x} - R_{\text{eff},R_x}) - 0.3 \text{ cm}]\} \quad (2)$$

where $R_{\text{eff},50\%R_x}$ is the effective radius of the half-prescription isodose volume, and R_{eff,R_x} is the effective radius of the prescription isodose volume. The effective radius of a

Coll.	$V_{80\%}, \text{cm}^3$	$R_{\text{eff}80\%}, \text{mm}$	$V_{40\%}, \text{cm}^3$	$R_{\text{eff}40\%}, \text{mm}$	Eff. Gradient, mm	CGI _g
10	0.3	4.2	1.2	6.7	2.4	106
20	3.9	9.8	9.7	13.2	3.5	95
30	13.9	14.9	30.8	19.4	4.5	85
50	67.4	25.2	111.6	29.9	4.6	84

volume is the radius of a sphere of the same volume, so that R_{eff} for a volume V is given by

$$R_{\text{eff}} = (3V/4\pi)^{-1/3} \quad (3)$$

The volumes of the prescription isodose shell and the half prescription isodose shell are obtained from a DVH of the total volume (or a sizeable volume that completely encompasses the target volume and a volume that includes all of the half prescription isodose shell) within the patient image dataset. The CGIg score is a dimensionless number that exceeds 100 for dose gradients < 3 mm (steeper falloff from prescription to half-prescription dose level), and which decreases < 100 as a linear function of the effective distance between the prescription and half-prescription isodose shells.

Dose conformity is another important characteristic of a radiosurgery treatment plan that should be considered in plan evaluation. The Conformity-Gradient Index (conformal), or CGIc, is defined as (58):

$$\text{CGIc} = 100 \times (\text{PITV})^{-1} \quad (4)$$

The CGIc converts PITV into a numerical score expressing the degree of conformity of a dose distribution to the target volume. The CGIg score increases as the dose gradient improves, and the CGIc score increases as dose conformity improves. Perfect conformity (assuming the target is adequately covered) of the prescription isodose volume to the target is indicated by a $\text{PITV} = 1.00$ and a $\text{CGIc} = 100$.

As dose gradient and dose conformity are both important parameters in judging a stereotactic radiosurgery or radiotherapy plan, an overall figure of merit for judging radiosurgery plans should incorporate both of these characteristics. Since clinical data to indicate the relative importance of conformity versus gradient is currently lacking, an index, the Conformity-Gradient Index (CGI) is proposed that assigns equal importance to both of these factors. The overall Conformity-Gradient Index score, or CGI, for a radiosurgery or radiotherapy plan is the average of the CGIc and CGIg scores:

$$\text{CGI} = 0.5 \times (\text{CGIc} + \text{CGIg}) \quad (5)$$

A final measure of plan quality considered by some to be an important factor in evaluating treatment plans is dose homogeneity. While a homogenous dose is desirable for conventional, fractionated radiotherapy (60), its role is less clear in radiosurgery. Several studies have associated large radiosurgical dose heterogeneity (maximum dose to peripheral dose ratio, or MDPD, > 2.0) with an increased risk of complications (61,62). However, some radiosurgeons have hypothesized that the statistically significant correlation between large dose inhomogeneities and complication risk may be associated with the relatively nonconformal multiple isocenter dose distributions with which some patients in these studies were treated, and not with dose inhomogeneity alone. One theory is that the extreme hot spots associated with large dose heterogeneities may be acceptable, if the dose distribution is very conformal to the target volume and the hot spot is contained within the target volume. Nonconformal dose distributions could easily cause the hot spots to occur outside of the

target, greatly increasing the risk of a treatment complication. The extensive successful experience of gamma unit treatments administered worldwide (almost all treatments with $\text{MDPD} \geq 2.0$) lends support to this hypothesis (63). Therefore, as a general principle, one strives for a homogeneous radiosurgery dose distribution, but this is likely not as important a factor as conformity of the high dose region to the target volume, or the dose gradient outside of the target.

SUMMARY

While the use of radiosurgery is now in its fifth decade the basic principles of dose prescription and delivery have changed very little from those first conceived by Leksell. The primary, and still most effective method to treat relatively small target tissues with a high dose and to maintain a very steep dose gradient is through the use of many beams that all converge on the target tissue and diverge along independent paths while approaching and leaving the target region. Other dose targeting and restriction techniques, such as intensity modulation, provide the ability to position beams that geometrically avoid tissue and potentially provide a more powerful tool for dose optimization. These techniques are often combined to allow for the best of both optimized dose planning and efficient dose delivery.

INTRODUCTION

The use of radiation to treat cancer is a complex process that involves many trained professionals and a variety of inter-related functions. Radiation oncologists, medical physicists, dosimetrists, and radiation therapists have for many years sought apparatus and devices that aid in this process, particularly in regard to tumor localization, treatment planning, treatment delivery, and verification (1). Precision radiation therapy is necessary as clinical and experimental results show that tumor control and normal tissue response can be a very steep function of radiation dose, and hence, small changes in the dose delivered can result in a dramatic change in the local response of the tumor and/or normal tissues. Moreover, the prescribed curative tumor doses are often, by necessity, close to the doses tolerated by the normal tissues. Thus, for optimum treatment, the radiation dose must be delivered with a high degree of accuracy; a value of $\pm 5\%$ has been recommended by the International Commission on Radiation Units and Measurements (ICRU) (2).

Since the first edition of this encyclopedia, the field of radiation oncology has undergone dramatic changes. At that time, radiation oncologists were trained to plan and treat patients using what has been labeled a two-dimensional (2D) approach. This approach emphasizes the use of a con-

ventional X-ray simulator for designing beam portals that are based on standardized beam arrangement techniques and the use of bony landmarks visualized on planar radiographs. This approach, while still used by some clinics, has been largely replaced by a three-dimensional (3D) approach in modern day radiotherapy clinics. This was made possible by the introduction of commercial 3D treatment planning systems in the early 1990s (3). In contrast to the 2D method, 3D treatment planning emphasizes an image-based virtual simulation approach for defining tumor volumes and critical organs at risk for the individual patient (4). The new 3D process puts new demands on the radiation oncologist to specify target volumes and organs at risk with far greater accuracy than before, and also on the medical physicist to provide effective quality assurance (QA) processes to ensure safe use of the new image-based planning and computer controlled treatment delivery approach (5).

This article presents a review of the devices that have been designed to help achieve the high degree of precision and accuracy needed in the radiation treatment (for both the 2D and 3D approaches) of the cancer patient. These devices have been arranged in the following general categories: tumor localization and treatment simulation devices, patient setup and restraint–repositioning devices, field-shaping devices–dose-modifying devices, and treatment verification and quality assurance devices.

TUMOR LOCALIZATION AND TREATMENT SIMULATION DEVICES

Devices and apparatus in this category are designed to aid in visualizing and determining the extent of the tumor in relation to the treatment geometry (target volume localization) and to obtain measurements of the patient’s body contours and thicknesses. In the past, target volume localization was usually accomplished by physical examination and the use of a device called an X-ray simulator, which combines radiographic and fluoroscopic capability in a single machine that mimics the actual treatment unit geometries (Fig. 1). The simulation process itself may be supplemented with other diagnostic imaging studies including computed tomography (CT), magnetic resonance images (MRI), and, more recently, positron emission tomography (PET).

Devices used to aid the conventional simulation process include a radiopaque fiducial grid (Fig. 2) projected on the patient’s anatomy, which allows one to determine dimensions of the treatment volume from the simulator plane films. Examples of other devices used in the 2D target volume localization process are magnification rings placed in the irradiated field and lead-tipped rods that can be inserted into body openings, such as the vagina for carcinoma of the cervix or into the rectum for carcinoma of the prostate. The lead tip can be visualized clearly on simulator films or treatment portal films and allows evaluation of treatment field margins.

Note that a new generation of conventional simulators (Fig. 3) has recently been developed in which the image intensifier system has been replaced with an amorphous silicon flat-panel detector. This device produces high resolution, distortion-free digital images, including cone-beam CT.

Figure 1. The basic components and motions of a radiation therapy simulator: A, gantry rotation; B, source-axis distance; C, collimator rotation; D, image intensifier (lateral); E, image intensifier (longitudinal); F, image intensifier (radial); G, patient table (vertical); H, patient table (longitudinal); I, patient table (lateral); J, patient table rotation about isocenter; K, patient table rotation about pedestal; L, film cassette; M, image intensifier. Motions not shown include field size delineation, radiation beam diaphragms, and source-tray distance. (See Ref. 6.)

Figure 2. X-ray simulator radiograph showing fiducial grid projected on patient's anatomy. The grid is used for localizing target volume and determining treatment field size.

Figure 3. New generation radiation therapy simulator, in which image intensifier system has been replaced with amorphous silicon flat-panel that produces high resolution, distortion-free images and facilitates a filmless department. (Courtesy of Varian Medical Systems.)

Once the treatment geometry has been determined and the patient is in treatment position, the patient's body thicknesses and contours are measured and recorded for purposes of computing a dose distribution and determining treatment machine settings. Manual methods using calipers, lead solder wire, plaster cast strips, flexible curves, or other devices, such as the contour plotter (see Fig. 4) are the most common methods of obtaining this type of data when using the 2D planning approach.

Fields to be treated are typically delineated in the 2D simulation process using either visible skin markings or marks on the skin visible only under an ultraviolet (UV) light. Some institutions prefer to mark only reference setup points using external tattoos. These skin markings are used to reposition the patient on the treatment machine using the treatment machine's field localization light and optical distance indicator and laser alignment lights mounted in the treatment room that project transverse, coronal, and sagittal light lines on the patient's skin surface (Fig. 5).

In the new 3D era, CT simulators have become the standard of practice; a typical CT simulator facility design is shown in Fig. 6. A volumetric set of CT images is used to define the target volume, critical organs at risk, and skin surface. The CT numbers can be correlated with the electron densities of the tissues imaged to account for heterogeneities when calculating the dose distribution. Numerous studies have documented the improvements in target volume localization and dose distributions achieved with anatomic data obtained from CT scans as compared with the conventional simulation process (7,8). The CT simulators have advanced software features for image manipulation and viewing such as beam's eye view (BEV) display, and virtual simulation tools for setting isocenter, and digital reconstructed radiographs (DRRs)

Figure 4. Contour plotter. The device is a simple, easy-to-use precision pantograph that links a drawing pen to a stylus arm and, upon contact with the body, communicates body contours to an overhead drawing board. The contour plotter is suspended on a vertical column and can easily be adjusted and locked securely. A continuous plot is drawn as the operator follows the physical contours of the patient. Marks can be made along the contour to indicate beam entry and laser light locations. (Courtesy of MEDTEC.)

(9,10). Such systems provide all the functionality of a conventional simulator, with the added benefit of increased treatment design options and the availability of software tools to facilitate the understanding and evaluation of treatment options. In addition, the simulation process is

more efficient and less traumatic to the patient. Laser alignment lights and repositioning devices registered to the treatment couch are used to facilitate repositioning the patient in the treatment machine coordinate system once the virtual simulation process is complete.

Figure 5. Laser alignment system. Patient in treatment position on treatment couch. Close-up of laser lines imaged on patient skin under typical treatment room lighting conditions. (Courtesy Gammex RMI, Inc.)

PATIENT RESTRAINT AND REPOSITIONING DEVICES

Accurate daily repositioning of the patient in the treatment position and reduction of patient movement during treatment is essential to accurately deliver the prescribed dose and achieve the planned dose distribution. As we will see in this section, modern day immobilization and repositioning systems are designed to be able to be attached to the simulation and treatment couches, so that the immobilization device and the patient are registered to the treatment machine coordinate system. Once the immobilization device has been locked into a specified position, the patient is then aligned to the immobilization system. The end result is that a set of coordinates is obtained from the CT simulator that is used in the virtual simulation process and that can be correlated to the treatment room isocenter.

The anatomic sites most often needing immobilization in radiation therapy are the head and neck, breast,

Figure 6. Typical CT simulation suite showing the scanner, flat tabletop, orthogonal laser system, virtual simulation workstation and hardcopy output device. (Courtesy of Philips Medical Systems.)

thorax–esophagus, shoulders and arms, pelvic areas (especially if obese), and limbs rotated to unusual positions. The precision achievable in the daily treatment positions of a patient depends on several factors other than the anatomic site under treatment, such as the patient’s age, general health, and weight. In general, obese patients and small children are the most difficult to reposition.

Simple patient restraint and repositioning devices can be used in treating some anatomic sites. For example, the disposable foam plastic head holder shown in Fig. 7 provides stability for the head when the patient is in the supine position. If the patient is to be treated in the prone position, a face-down stabilizer can be used as shown in Fig. 8. This device has a foam rubber lining and a disposable

Figure 7. Disposable foam plastic head holder provides stability to the head when the patient is in the supine position.

Figure 8. Face-down stabilizer. This formed plastic head holder has a foam rubber lining and disposable paper liner with an opening provided for the eyes, nose, and mouth. It allows comfort and stability as well as air access to the patient in the prone position.

Figure 9. Polyurethane body mold. The chemical mixture is poured into the foam mold under a latex sheet. The patient is positioned in the foam mold as the polyurethane mixture expands to body shape. paper lining with an opening provided for the eyes, nose, and mouth of the patient. It allows comfort and stability as well as air access for the patient during treatment in the prone position.

There are now several commercially available body mold systems that are in widespread use as immobilization and repositioning aids. Fig. 9 illustrates one such system that utilizes a foam block cutout of the general anatomic area and polyurethane chemicals, which when mixed expand and solidify to conform to the patient's shape in

a matter of minutes. Another widely used system (Fig. 10) consists of a vinyl bag filled with plastic minispheres. The bag is positioned around the patient to support the treatment position and then a vacuum is applied causing the minispheres to come together to form a firm solid support molded to the patient's shape.

Plaster casts are still used in some clinics, but have not gained widespread use in the United States, probably because they are too labor intensive and time consuming. Also, transparent form-fitting plastic shells (Fig. 11) that

Figure 10. Vacuum-form body immobilizer. The system consists of a plastic mattress filled with microspheres connected to a vacuum pump. Under vacuum, the mattress shapes itself to the body contours. (Courtesy of MEDTEC.)

Figure 11. Plastic shell. Transparent form-fitting plastic shells fabricated using a special vacuum device. (See Ref. 11.)

are fabricated using a special vacuum device are also used in some countries (e.g., Great Britain and Canada), but again are very labor intensive and have not gained acceptance in this country. Both methods are described in detail in the book by Watkins (11). In the United States, thermal plastic masks are much more commonly used (Fig. 12). The plastic sheet or mesh is placed in warm water to make it very pliable, and when draped over the patient conforms to the patient's shape and hardens upon cooling.

Fig. 13 illustrates a device called a bite block, which is used as an aid in patient repositioning in the treatment of head and neck cancer. With this device, the patient is

Figure 12. Thermoplastic cast. When placed in a warm (170°F) water bath, thermoplastic material becomes very flexible and can easily be molded to the patient's surface curvature. Immobilization using this material is less labor intensive than the conventional plaster cast or plastic shells and is therefore more readily adaptable on a routine basis for the immobilization of patients during radiation therapy. (Courtesy of MEDTEC.)

Figure 13. Bite-block system. Placement of the patient in a comfortable supine position and use of bite-block immobilization minimize patient movement for head and neck treatments. placed in the treatment position and instructed to bite into a specially prepared dental impression material layered on a fork which is attached to a supporting device. When the material hardens, the impression of the teeth is recorded. The bite-block fork is connected to a support arm that is attached to the treatment couch and may be used either with or without scales for registration.

There are many other devices used to help in the treatment setup of patients that are site specific. For example, breast patients are usually positioned supine, with the arm on the involved side raised and out of the treatment area. Fig. 14 shows a device called a breast or tilt board that is used to optimize the position of the patient's chest wall (or thorax). The device is constructed with a hinge section that can be positioned and locked into place at various angles to the horizontal treatment table top. Modern breast boards now provide options for head support, arm positioning, and breast support. Sometimes, it is more convenient to use a separate arm board that can be attached directly to the treatment couch (Fig. 15). The perpendicular support provides a hand grasp that can be adjusted to the proper height and assists the patient in holding their arm in a comfortable position away from the treatment field.

Another useful device is the breast bridge (Fig. 16), which can be placed on the patient's chest and adjusted to the skin markings, for determining separation of the tangential fields. Precise angulation of the beam portals is determined using a digital readout level. In addition, a squeeze bridge (Fig. 17) with plastic plates can be used to provide buildup when a higher surface dose is desired, or one with a wire mesh frame can be used when no additional surface dose is warranted. A beam alignment device (Fig. 18) is used to match multiple fields used in tangential breast irradiation (12). The alignment component of the device is a curved piece of aluminum with a row of nylon

Figure 14. Tilt board or adjustable breast board. The top piece is fabricated with a hinged section that allows the sloping chest wall to be more appositional to a vertical beam. (Courtesy of MEDTEC.)

Figure 15. Patient arm support used for breast irradiation assists patients in holding their arm in a comfortable position, away from the treatment field. (Courtesy of Varian Medical Systems.)

pins protruding from its surface. The pins have a thin inscribed line to which the light field is aligned.

In some instances, it may be advantageous to treat the cancer patient in an upright position. The treatment chair (Fig. 19) is a device that facilitates such treatments by allowing a patient to be accurately repositioned in a seated position each day. The chair provides means of stabilizing the patient by the use of hand grips, elbow holders, and a seatbelt. The back of the seat is constructed of carbon fiber and thus the radiation beam can penetrate with minimal effects, and the angle of the seat back is adjustable.

Another device used to optimize patient position is the shoulder retractor. It provides a means by which the patient's shoulders can be pulled down in a reproducible manner, as illustrated in Fig. 20. Such a device is often

Figure 16. A Breast Bridge is used with tangential radiation fields and consists of a pair of plastic plates that can be locked at the appropriate separation determined for the individual patient. After the treatment area has been marked, the bridge is placed on the patient's chest and adjusted to the skin markings, thus determining separation of the fields. Precise angulation of the portals is determined by the digital readout level. Once the portals are set, the bridge may be removed. (Courtesy of MEDTEC.)

used in the treatment of head and neck cancer involving lateral fields.

A standard feature on most accelerator treatment couches is a Mylar window or tennis racket-type table insert. This device consists of a thin sheet of Mylar stretched over a tennis racket-type webbing material and mounted in a frame that fits into a treatment table that has removable sections. Newer table insert devices made of carbon fiber (Fig. 21) eliminate the need to "restring" such panels and minimize the "sag" that can occur with nylon string panels. Such inserts provide excellent patient support

Figure 17. A squeeze bridge used for breast treatments with and without bolus. The wire mesh device is used where no additional surface dose is desired and the plastic frame device is used when increased surface dose is needed. (See Ref. 1.)

Figure 18. A beam alignment device used to implement field matching techniques. (a) Schematic of beam alignment device. (b) Example of use of device with three-field technique for breast treatment. Superior edges of tangential breast fields are coplanar and abutted to the vertical inferior edge of the anterior supraclavicular field. (See Ref. 12.)

with a minimum of surface buildup effect for opposing beam portals, minimum reduction of beam intensity, and good visual access to the treatment surface. In addition, most medical linacs come with clamps that can be attached to

Figure 20. Shoulder retractor. Device used to pull the patient's shoulders down in a reproducible manner for treatment of the head and neck with lateral radiation fields. (Courtesy MED-TEC, Inc.)

the treatment couch and can be used with several different accessories, such as hand grips.

The development of 3D conformal radiation therapy (3DCRT) and more recently intensity-modulated radiation therapy (IMRT) has greatly enhanced the radiation oncologist’s ability to plan and deliver very high doses that conform closely to the target volume, and falls off sharply, thus avoiding high dose to the nearby organs at risk (13,14). Both 3DCRT and IMRT invite the use of tighter margin to achieve higher dose escalation, and thus have spurred the development of new accessories and processes to better account for setup variation and organ motion that can occur during one (intra-) fraction, and between (inter-)

fractions. Efforts thus far have focused on accounting for internal movement of the prostate gland and internal motion cause by respiratory function.

For example, for prostate cancer, the use of daily ultrasound imaging (Fig. 22), or daily electronic portal imaging of implanted radiopaque markers, has now become standard practice in many clinics (15,16).

Devices—methodologies used to address the problem of breathing motion in radiation treatment include: (1) gating and/or tracking and (2) breathhold devices—strategies. In gating and tracking, the state of the treatment machine is adjusted in response to a signal that is representative of a patient’s breathing motion. With breathholding, the lung volume of the patient is directly immobilized prior to beam-on, and released after the beam is off. The basic components of a gating or tracking system consist of a respiration sensor whose signal is processed and evaluated by a computer for suitability to trigger, or gate, the radiation. An example of a respiratory gating system is the Real-time Position Management (RPM) system (Fig. 23) commercially available from Varian Medical Systems (Palo Alto, CA) (17,18). An example of a breath control device is the Elekta Inc. (Norcross, GA) Active Breathing Coordinator (ABC) (Fig. 24) (19). The ABC apparatus is used to suspend breathing at any predetermined position along the normal breathing cycle, or at active inspiration, and consists of a digital spirometer to measure the respiratory trace, which is in turn connected to a balloon valve. Another example is the ExacTrac system (BrainLAB AG) that combines X-ray imaging and infrared tracking that permits correlation of internal 3D tumor motion with the patient’s breathing cycle (Fig. 25) (20). Automatic fusion of digitally reconstructed radio-graphic (DRR) images computed from the treatment planning CT data to the live X-rays allows any set-up error or target shift and rotation to be identified and any discrepancy compensated for via robotic table movement.

Figure 22. BAT (B-mode Acquisition and Targeting) SXi system. Targeting device that provides fast ultrasound localization of a treatment target on a daily basis. (Courtesy North American Scientific)

From both simulation and virtual simulation to treatment, the RPM Respiratory Gating system allows you to accurately monitor and compensate for tumor movement.

Figure 23. Real-time Position Management system. Device used to allow respiratory gating treatment delivery. (Courtesy of Varian Medical Systems)

For stereotactic radiosurgery or fractionated stereotactic radiotherapy, a suite of accessories is now available. Most important is a head stereotactic localizer such as the Gill–Thomas–Cosman (GTC) relocatable head ring (Fig. 26), which enables precise fixation and localization and repositioning of targets in the cranium (21). Another

Figure 24. Active Breathing Coordinator™ system. Device allows the radiation oncologist to pause a patient's breathing at a precisely indicated tidal volume and coordinate delivery with this pause. (Courtesy of Elekta AB)

important device when using the newly emerging radiotherapy treatment, stereotactic body radiation therapy (SBRT), in which a high dose is delivered in either a single fraction or just a few fractions, is the frame-based body stereotactic immobilization system (22). There are several now commercially available; an example is the Elekta Stereotactic Body Frame shown in Fig. 27. This device provides a reference stereotactic coordinate system that is external to the patient's body, so that the coordinates of a target volume can be reproducibly localized during simulation and treatment. This frame has built-in reference indicators for CT or MR determination of target volume coordinates. In addition, a diaphragm control attached to the frame can be used to minimize respiratory movements. Horizontal positioning of the frame, on the CT simulator or treatment couch, is achieved using an adjustable base on the frame.

FIELD-SHAPING, SHIELDING, AND DOSE MODIFYING DEVICES

The Lipowitz metal (Cerrobend) shielding block system introduced by Powers et al. (23) is in widespread use throughout the world. The block fabrication procedure is illustrated in Fig. 28 and more details using this form of field shaping can be found in the review article by Leavitt and Gibbs (24). Lipowitz metal consists of 13.3% tin, 50.0% bismuth, 26.7% lead, and 10.0% cadmium, and has a

Figure 25. ExacTrac X-Ray 6D automated image-guided radiation therapy system. System consists of 2 kV X-ray units recessed into the linac floor and two ceiling-mounted amorphous silicon Flat Panel detectors integrated with a real-time infrared tracking device to enable imaging of internal structures or implanted markers for extremely accurate set-up of the target volume's planned isocenter position. (Courtesy Brain LAB AG.)

physical density at 20 °C of $9.4 \text{ g}\cdot\text{cm}^{-3}$ as compared with $11.3 \text{ g}\cdot\text{cm}^{-3}$ for lead. A simulation radiograph is obtained with the patient in the treatment position and the desired treatment field aperture is drawn on the radiograph by the radiation oncologist. The marked radiograph is then used as a template for cutting a foam mold with a “hot-wire” cutting device in which molten Lipowitz alloy is poured and then cooled to form a shielding block. Computer-controlled adaptations of the hot-wire cutting technique have evolved as an adjunct to 3D treatment planning in which the treatment field shape is defined based on beam's eye-view displays. The shaped field coordinates are transferred directly to the computer-controlled blockcutting system, thereby eliminating potential errors in manual tracing, magnification, or image reversal. The other steps in the block forming and verification process remain similar to the manual procedure.

(c) Proper-thickness foam block is aligned to central axis of cutter. (d) Foam mold is cut using hot-wire cutter. Courtesy of Huestis Machine Corp. (e) Foam pieces are aligned and held in place with a special clamping device. Molten alloy is poured into the mold and allowed to harden. (f) Examples of typical shielding blocks cast using this system.

Returning to accessories used for field shaping, Fig. 29 shows a Multileaf Collimator (MLC) system. The MLCs were first introduced in Japan in the 1960's (25) and have now gained widespread acceptance, and have replaced alloy blocking as the standard-of-practice for field shaping in modern radiation therapy clinics. All medical linac manufacturers now provide MLC systems. The leaves

Figure 29. Multileaf Collimation (MLC) system. Computer controlled system used to shape beam aperture and also to deliver IMRT. (Courtesy of Elekta AB.)

are typically carried on two opposed carriages that transport the leaves in unison. The leaves (under computer control) can be individually positioned to serve either as a block replacement, or as a means to provide IMRT treatment delivery.

Fig. 30 shows a commercial binary multi-leaf collimator system (called "MIMiC") designed and built by the NOMOS Corporation and incorporated into their serial tomotherapy system, known as Peacock, for planning and rotational delivery of IMRT treatments (26). This device can be attached to a conventional linac to deliver IMRT by rapidly moving leaves in or out of a slit field. Like a CT unit, the radiation source and the collimator continuously revolve around the patient.

Other more conventional devices used to achieve a desired dose distribution and to correct for perturbing influences, such as patient shape, include bolus, wedges, and compensating filters. Bolus is a tissue-equivalent material used to smooth an irregular surface, increase the dose to the patient's surface region, or sometimes to fill external air cavities, such as the ear canal or nasal passage. Bolus should have an electron density and atomic number similar to that of tissue or water. Examples of bolus materials include slabs of paraffin wax, rice bags filled with soda ash, gauze coated with Vaseline, and synthetic-based substances, such as Superflab (Fig. 31).

Wedge filters (Fig. 32) are typically made of a dense material, such as brass or steel, and are mounted on a frame that can be inserted into the beam at a specified

Figure 30. Binary multileaf collimator system (called MIMiC) designed and built by the NOMOS Corporation and incorporated into their serial tomotherapy system, known as Peacock for planning and rotational delivery of IMRT treatments. This device can be attached to a conventional linac to deliver IMRT by rapidly moving leaves in or out of a slit field. Like a CT unit, the radiation source and the collimator continuously revolve around the patient.

distance from the source and cause the dose distribution at a specified depth to be angled to a desired amount relative to the incident beam direction. Modern linacs have replaced physical wedges with software control of independent jaws that provide what is called dynamic wedging (27, 28). Currently, there are two versions of dynamic wedging, the Varian Enhanced Dynamic Wedge (EDW), and the Siemens Virtual Wedge (VW). The desired wedge angle is achieved by moving a collimating jaw while the beam is on, thereby shrinking the field during treatment.

A compensating filter (Fig. 33) is a beam modifier that is used to counteract the effect of air gaps caused by the patient's topography while still preserving the skin-sparing characteristic of megavoltage photon beams (29). To do this, the compensating filter is placed in the beam

some distance away from the patient's skin surface. This requires that the lateral dimensions of the filter be reduced and causes the scatter radiation conditions to be altered, complicating the relationship between the thickness of the compensator along a ray and the amount of tissue deficit to be compensated.

Other accessories include shields designed specifically to protect certain organs at risk. For example, in the treatment of Hodgkin's disease and other malignant lymphomas, in which the inguinal and femoral lymph nodes are frequently irradiated, a testicular shield (Fig. 34) is frequently used. This device is typically constructed with lead and is designed to reduce scatter radiation to the testicles. Another example is the eye shields shown in

Figure 33. Compensating filter. Composite photograph illustrating design and fabrication procedure: (a) Push rod device is attached to the head of the simulator directly over the patient in the treatment position. The rods are lowered one by one, until they are in contact with the patient's surface. (b) Tissue deficits are determined from measurement of each rod length. (c) Aluminum and brass blocks, which are numbered to correspond to the tissue deficits determined, are selected from storage bins. (d) Blocks are attached on the plastic tray according to the pattern specified by the calculations. (e) Completed filter. (f) Compensating filter positioned on treatment machine.

TREATMENT VERIFICATION AND QUALITY ASSURANCE DEVICES

Radiographic film (port films) using film cassettes with lead or copper filters which improve the radiographic contrast of the port films are typically used to verify patient isocenter position and for portal shape (Fig. 36). Devices to support the port film cassettes and to help insure that the film plane is orthogonal to the beam direction and close to the patient's surface from which the beam exits are also important accessories (Fig. 37). In addition, radiopaque graticules (Fig. 38) that can be inserted into the treatment beam are invaluable for the evaluation of port films (30). Typically, such devices consist of platinum or tungsten wire embedded in plastic and molded in a frame that can be attached to the treatment machine accessory mount.

Figure 36. Radiotherapy port film cassette. Copper screens are used to improve subject contrast and improve resolution as shown in the portal localization radiograph. (Courtesy Eastman Kodak Co.)

The generally poor quality of the film images and the inconveniences of the film processing and physician reviewing procedure have spurred development of computer-aided enhancement and digital imaging techniques in radiation therapy. Computed radiography (CR) systems, such as the Kodak 2000RT CR system shown in Fig. 39, is an example of such a system that allows digital DICOM images to be distributed electronically throughout the department.

In addition, electronic portal imagers (EPID) have made great strides this past decade and such devices are poised to replace film over the next few years (31,32). More recently, linac manufacturers have integrated EPID and tomographic imaging systems on their linacs (Fig. 40) for localization of bone and soft-tissue targets and have set the stage for image-guided radiation therapy to move into routine practice (33,34). Such systems will make quantitative evaluation of immobilization and repositioning of the patient much more achievable by allowing daily imaging of the patient's treatment.

In addition to imaging verification, there is sometimes a need to verify actual dose delivered to the patient. Simple point dose verification can be achieved using TLDs, diodes,

Figure 37. Port film cassette holder. Devices used to support a port film cassette behind the patient in any orientation device are especially useful for oblique treatment angles as the plane of film can be adjusted so as to produce normal incidence of the radiation field. (Courtesy of MEDTEC.)

Figure 38. Example of a port film fiducial grid. Device identifies the central axis of the radiation beam and provides a scale at the calibration distance, thus providing a magnification factor for the port film. (Courtesy of MEDTEC.)

Figure 39. Kodak 2000RT CR system. Computed radiography system that allows digital DICOM images to be distributed electronically throughout the department. (Courtesy Eastman Kodak Co.)

or MOSFET dosimeters placed on the patient's skin surface or in body cavities. The most recent development in these types of devices is the OneDose patient dosimetry system (Fig. 41) developed by Sixel Technologies, Inc. It consists of a wireless handheld reader which interacts with self-adhesive external MOSFET dosimeters placed on the patient. To use, the therapist simply places the precalibrated dosimeters on the patient's skin in the treatment field, treats the patient, and then slides the dosimeter into the reader

Figure 40. Elekta Synergy[®] system. Linac with electronic portal imager (EPID) and conebeam tomographic imaging system for localization of bone and soft-tissue targets. (Courtesy of Elekta AB.)

Figure 41. Patient dosimetry monitoring system. Semiconductor detectors are typically used and applied on the patient's surface using surgical tape. (Courtesy of MEDTEC.)

for an immediate display. The reader automatically provides a permanent record of dosage, time, and date with minimal data entry. Another dose verification device is shown in Fig. 42; because IMRT treatments presently require verification of the dose delivered and pattern for each patient, special phantoms and/or check devices have been developed to facilitate the IMRT verification measurements.

Also, there are numerous QA devices available to check the constancy of the linac's beam calibration, symmetry, and radiation-light field alignment. Generally, the QA radiation detection devices consist of several ionization chambers or semiconductors positioned in a plastic phantom that can be placed in the radiation beam (Fig. 43).

Finally, one of the latest advances is a system (still under development) that will be capable of performing continuous objective, real-time tracking of the target volume during treatment (Calypso Medical Technologies, Inc.) (35). The system is based on alternating current (ac) magnetic fields utilizing permanently implantable wireless transponders that do not require additional ionizing radiation and do not depend on subjective interpretation of

Figure 42. MapCHECK device provides 2D therapy beam measurements intended for quick and precise verification of the dose distribution resulting from an IMRT plan. (Courtesy of Sun Nuclear.)

Figure 43. DoubleCheck A matrix detector, consisting of multiple ionization chambers embedded in a plastic phantom, used to check the constancy of radiation beam output, symmetry, and flatness. (Courtesy MED-TEC, Inc.)

images. The system is currently undergoing clinical evaluation and is not yet available for clinical use.

SUMMARY

In summary, numerous radiotherapy accessories are used to aid in planning, delivering, and verifying radiation treatments. New systems continue to be developed that give the ability to more accurately position the patient and account for the internal target volume relative to the treatment machine's isocenter. Such devices enable significant reductions in the amount of normal tissue included in the irradiated volume. Finally, it should be recognized that the preferences of the individual radiation oncologist, radiation therapist, and clinical physicist still play a major role in the acceptance and use of all of the types of devices discussed in this article. The major considerations for any specific application are typically cost, speed and ease of preparation, ease of use, and effectiveness.

PREFACE

This six-volume work is an alphabetically organized compilation of almost 300 articles that describe critical aspects of medical devices and instrumentation.

It is comprehensive. The articles emphasize the contributions of engineering, physics, and computers to each of the general areas of anesthesiology, biomaterials, burns, cardiology, clinical chemistry, clinical engineering, communicative disorders, computers in medicine, critical care medicine, dermatology, dentistry, ear, nose, and throat, emergency medicine, endocrinology, gastroenterology, genetics, geriatrics, gynecology, hematology, hepatology, internal medicine, medical physics, microbiology, nephrology, neurology, nutrition, obstetrics, oncology, ophthalmology, orthopedics, pain, pediatrics, peripheral vascular disease, pharmacology, physical therapy, psychiatry, pulmonary medicine, radiology, rehabilitation, surgery, tissue engineering, transducers, and urology.

The discipline is defined through the synthesis of the core knowledge from all the fields encompassed by the application of engineering, physics, and computers to problems in medicine. The articles focus not only on what is now useful but also on what is likely to be useful in future medical applications.

These volumes answer the question, "What are the branches of medicine and how does technology assist each of them?" rather than "What are the branches of technology and how could each be used in medicine?" To keep this work to a manageable length, the practice of medicine that is unassisted by devices, such as the use of drugs to treat disease, has been excluded.

The articles are accessible to the user; each benefits from brevity of condensation instead of what could easily have been a book-length work. The articles are designed not for peers, but rather for workers from related fields who wish to take a first look at what is important in the subject.

The articles are readable. They do not presume a detailed background in the subject, but are designed for any person with a scientific background and an interest in technology. Rather than attempting to teach the basics of physiology or Ohm's law, the articles build on such basic concepts to show how the worlds of life science and physical science meld to produce improved systems. While the ideal reader might be a person with a Master's degree in biomedical engineering or medical physics or an M.D. with a physical science undergraduate degree, much of the material will be of value to others with an interest in this growing field. High school students and hospital patients can skip over more technical areas and still gain much from the descriptive presentations.

The *Encyclopedia of Medical Devices and Instrumentation* is excellent for browsing and searching for those new divergent associations that may advance work in a peripheral field. While it can be used as a reference for facts, the articles are long enough that they can serve as an educational instrument and provide genuine understanding of a subject.

One can use this work just as one would use a dictionary, since the articles are arranged alphabetically by topic. Cross references assist the reader looking for subjects listed under slightly different names. The index at the end leads the reader to all articles containing pertinent information on any subject. Listed on pages xxi to xxx are all the abbreviations and acronyms used in the *Encyclopedia*. Because of the increasing use of SI units in all branches of science, these units are provided throughout the *Encyclopedia* articles as well as on pages xxxi to xxxv in the section on conversion factors and unit symbols.

I owe a great debt to the many people who have contributed to the creation of this work. At John Wiley & Sons, Encyclopedia Editor George Telecki provided the idea and guiding influence to launch the project. Sean Pidgeon was Editorial Director of the project. Assistant Editors Roseann Zappia, Sarah Harrington, and Surlan Murrell handled the myriad details of communication between publisher, editor, authors, and reviewers and stimulated authors and reviewers to meet necessary deadlines.

My own background has been in the electrical aspects of biomedical engineering. I was delighted to have the assistance of the editorial board to develop a comprehensive encyclopedia. David J. Beebe suggested cellular topics such as microfluidics. Jerry M. Calkins assisted in defining the chemically related subjects, such as anesthesiology. Michael R. Neuman suggested subjects related to sensors, such as in his own work—neonatology. Joon B. Park has written extensively on biomaterials and suggested related subjects. Edward S. Sternick provided many suggestions from medical physics. The Editorial Board was instrumental both in defining the list of subjects and in suggesting authors.

This second edition brings the field up to date. It is available on the web at <http://www.mrw.interscience.wiley.com/emdi>, where articles can be searched simultaneously to provide rapid and comprehensive information on all aspects of medical devices and instrumentation.

JOHN G. WEBSTER
University of Wisconsin, Madison

LIST OF ARTICLES

ALLOYS, SHAPE MEMORY
AMBULATORY MONITORING
ANALYTICAL METHODS, AUTOMATED
ANESTHESIA MACHINES
ANESTHESIA, COMPUTERS IN
ANGER CAMERA
ANORECTAL MANOMETRY
ARRHYTHMIA ANALYSIS, AUTOMATED
ARTERIES, ELASTIC PROPERTIES OF
AUDIOMETRY
BIOCOMPATIBILITY OF MATERIALS
BIOELECTRODES
BIOFEEDBACK
BIOHEAT TRANSFER
BIOIMPEDANCE IN CARDIOVASCULAR MEDICINE
BIOINFORMATICS
BIOMAGNETISM
BIOMATERIALS, ABSORBABLE
BIOMATERIALS: AN OVERVIEW
BIOMATERIALS: BIOCERAMICS
BIOMATERIALS: CARBON
BIOMATERIALS, CORROSION AND WEAR OF
BIOMATERIALS FOR DENTISTRY
BIOMATERIALS: POLYMERS
BIOMATERIALS, SURFACE PROPERTIES OF
BIOMATERIALS, TESTING AND STRUCTURAL

AEA	Articulation error analysis	ASHE	American Society for Hospital Engineering
AEB	Activation energy barrier	ASTM	American Society for Testing and Materials
AEC	Automatic exposure control	AT	Adenosine-thiamide; Anaerobic threshold; Antithrombin
AED	Automatic external defibrillator	ATA	Atmosphere absolute
AEMB	Alliance for Engineering in Medicine and Biology	ATLS	Advanced trauma life support
AES	Auger electron spectroscopy	ATN	Acute tubular necrosis
AESC	American Engineering Standards Committee	ATP	Adenosine triphosphate
AET	Automatic exposure termination	ATPD	Ambient temperature pressure dry
AFO	Ankle-foot orthosis	ATPS	Ambient temperature pressure saturated
AGC	Automatic gain control	ATR	Attenuated total reflection
AHA	American Heart Association	AUC	Area under curve
AI	Arterial insufficiency	AUMC	Area under moment curve
AICD	Automatic implantable cardiac defibrillator	AV	Atrioventricular
AID	Agency for International Development	AZT	Azido thymidine
AIDS	Acquired immune deficiency syndrome	BA	Biliary atresia
AL	Anterior leaflet	BAEP	Brainstem auditory evoked potential
ALG	Antilymphocyte globulin	BAPN	Beta-amino-propionitril
		BAS	Boston anesthesia system
		BASO	Basophil
		BB	Buffer base
		BBT	Basal body temperature

BCC	Body-centered cubic	CCTV	Closed circuit television system
BCD	Binary-coded decimal	CCU	Coronary care unit; Critical care unit
BCG	Ballistocardiogram	CD	Current density
BCLS	Basic cardiac life support	CDR	Complimentary determining region
BCRU	British Committee on Radiation Units and Measurements	CDRH	Center for Devices and Radiological Health
BDI	Beck depression inventory	CEA	Carcinoembryonic antigen
BE	Base excess; Binding energy	CF	Conversion factor; Cystic fibrosis
BET	Brunauer, Emmett, and Teller methods	CFC	Continuous flow cytometer
BH	His bundle	CFR	Code of Federal Regulations
BI	Biological indicators	CFU	Colony forming units
BIH	Beth Israel Hospital	CGA	Compressed Gas Association
BIPM	International Bureau of Weights and Measurements	CGPM	General Conference on Weights and Measures
BJT	Bipolar junction transistor	CHO	Carbohydrate
BMDP	Biomedical Programs	CHO	Chinese hamster ovary
BME	Biomedical engineering	CI	Combination index
BMET	Biomedical equipment technician	CICU	Cardiac intensive care unit
BMO	Biomechanically optimized	CIF	Contrast improvement factor
BMR	Basal metabolic rate	CIN	Cervical intraepithelial neoplasia
BOL	Beginning of life	CK	Creatine kinase
BP	Bereitschafts potential; Break point	CLAV	Clavicle
BR	Polybutadiene	CLSA	Computerized language sample analysis
BRM	Biological response modifier	CM	Cardiomyopathy; Code modulation
BRS	Bibliographic retrieval services	CMAD	Computer managed articulation diagnosis
BSS	Balanced salt solution	CMi	Computer-managed instruction
BTG	Beta thromboglobulin	CMRR	Common mode rejection ratio
BTPS	Body temperature pressure saturated	CMV	Conventional mechanical ventilation; Cytomegalovirus
BUN	Blood urea nitrogen	CNS	Central nervous system
BW	Body weight	CNV	Contingent negative variation
CA	Conductive adhesives	CO	Carbon monoxide; Cardiac output
CABG	Coronary artery by-pass grafting	COBAS	Comprehensive Bio-Analysis System
CAD/CAM	Computer-aided design/computer-aided manufacturing	COPD	Chronic obstructive pulmonary disease
CAD/D	Computer-aided drafting and design	COR	Center of rotation
CADD	Central axis depth dose	CP	Cerebral palsy; Closing pressure; Creatine phosphate
CAI	Computer assisted instruction; Computer-aided instruction	CPB	Cardiopulmonary bypass
CAM	Computer-assisted management	CPET	Cardiac pacemaker electrode tips
cAMP	Cyclic AMP	CPM	Computerized probe measurements
CAPD	Continuous ambulatory peritoneal dialysis	CPP	Cerebral perfusion pressure; Cryoprecipitated plasma
CAPP	Child amputee prosthetic project	CPR	Cardiopulmonary resuscitation
CAT	Computerized axial tomography	cps	Cycles per second
CATS	Computer-assisted teaching system; Computerized aphasia treatment system	CPU	Central Processing unit
CAVH	Continuous arteriovenous hemofiltration	CR	Center of resistance; Conditioned response; Conductive rubber; Creatinine
CB	Conjugated bilirubin; Coulomb barrier	CRBB	Complete right bundle branch block
CBC	Complete blood count	CRD	Completely randomized design
CBF	Cerebral blood flow	CRL	Crown rump length
CBM	Computer-based management	CRT	Cathode ray tube
CBV	Cerebral blood volume	CS	Conditioned stimulus; Contrast scale; Crown seat
CC	Closing capacity	CSA	Compressed spectral array
CCC	Computer Curriculum Company	CSF	Cerebrospinal fluid
CCD	Charge-coupled device	CSI	Chemical shift imaging
CCE	Capacitance contact electrode	CSM	Chemically sensitive membrane
CCF	Cross-correlation function	CT	Computed tomography; Computerized tomography
CCL	Cardiac catheterization laboratory	CTI	Cumulative toxicity response index
CCM	Critical care medical services	CV	Closing volume
CCPD	Continuous cycling peritoneal dialysis		

C.V.	Coefficient of variation	EBS	Early burn scar
CVA	Cerebral vascular accident	EBV	Epstein–Barr Virus
CVP	Central venous pressure	EC	Ethyl cellulose
CVR	Cardiovascular resistance	ECC	Emergency cardiac care; Extracorporeal circulation
CW	Continuous wave	ECCE	Extracapsular cataract extinction
CWE	Coated wire electrodes	ECD	Electron capture detector
CWRU	Case Western Reserve University	ECG	Electrocardiogram
DAC	Digital-to-analog converter	ECM	Electrochemical machining
DAS	Data acquisition system	ECMO	Extracorporeal membrane oxygenation
dB	Decibel	ECOD	Extracranial cerebrovascular occlusive disease
DB	Direct body	ECRI	Emergency Care Research Institute
DBMS	Data base management system	ECS	Exner's Comprehensive System
DBS	Deep brain stimulation	ECT	Electroconvulsive shock therapy; Electroconvulsive therapy; Emission computed tomography
dc	Direct current	EDD	Estimated date of delivery
DCCT	Diabetes control and complications trial	EDP	Aortic end diastolic pressure
DCP	Distal cavity pressure	EDTA	Ethylenediaminetetraacetic acid
DCS	Dorsal column stimulation	EDX	Energy dispersive X-ray analysis
DDC	Deck decompression chamber	EEG	Electroencephalogram
DDS	Deep diving system	EEI	Electrode electrolyte interface
DE	Dispersive electrode	EELV	End-expiratory lung volume
DEN	Device experience network	EER	Electrically evoked response
DERS	Drug exception ordering system	EF	Ejection fraction
DES	Diffuse esophageal spasm	EF	Electric field; Evoked magnetic fields
d.f.	Distribution function	EFA	Estimated fetal age
DHCP	Distributed Hospital Computer Program	EGF	Epidermal growth factor
DHE	Dihematoporphyrin ether	EGG	Electrogastrogram
DHEW	Department of Health Education and Welfare	EIA	Enzyme immunoassay
DHHS	Department of Health and Human Services	EIU	Electrode impedance unbalance
DHT	Duration of hypothermia	ELF	Extra low frequency
DI	Deionized water	ELGON	Electrical goniometer
DIC	Displacement current	ELISA	Enzyme-linked immunosorbent assay
DIS	Diagnostic interview schedule	ELS	Energy loss spectroscopy
DL	Double layer	ELV	Equivalent lung volume
DLI	Difference lumen for intensity	EM	Electromagnetic
DM	Delta modulation	EMBS	Engineering in Medicine and Biology Society
DME	Dropping mercury electrode	emf	Electromotive force
DN	Donation number	EMG	Electromyogram
DNA	Deoxyribonucleic acid	EMGE	Integrated electromyogram
DOF	Degree of freedom	EMI	Electromagnetic interference
DOS	Drug ordering system	EMS	Emergency medical services
DOT-NHTSA	Department of Transportation Highway Traffic Safety Administration	EMT	Emergency medical technician
DPB	Differential pencil beam	ENT	Ear, nose, and throat
DPG	Diphosphoglycerate	EO	Elbow orthosis
DQE	Detection quantum efficiency	EOG	Electrooculography
DRESS	Depth-resolved surface coil spectroscopy	EOL	End of life
DRG	Diagnosis-related group	EOS	Eosinophil
DSA	Digital subtraction angiography	EP	Elastoplastic; Evoked potentiate
DSAR	Differential scatter-air ratio	EPA	Environmental protection agency
DSB	Double strand breaks	ER	Evoked response
DSC	Differential scanning calorimetry	ERCP	Endoscopic retrograde cholangiopancreatography
D-T	Deuterium-on-tritium	ERG	Electron radiography; Electroretinogram
DTA	Differential thermal analysis	ERMF	Event-related magnetic field
d.u.	Density unit	ERP	Event-related potential
DUR	Duration	ERV	Expiratory reserve volume
DVT	Deep venous thrombosis		
EA	Esophageal accelerometer		
EB	Electron beam		
EBCDIC	Extended binary code decimal interchange code		

ESCA	Electron spectroscopy for chemical analysis	GC	Gas chromatography; Guanine-cytosine
ESI	Electrode skin impedance	GDT	Gas discharge tube
ESRD	End-stage renal disease	GFR	Glomerular filtration rate
esu	Electrostatic unit	GHb	Glycosylated hemoglobin
ESU	Electrosurgical unit	GI	Gastrointestinal
ESWL	Extracorporeal shock wave lithotripsy	GLC	Gas-liquid chromatography
ETO, Eto	Ethylene oxide	GMV	General minimum variance
ETT	Exercise tolerance testing	GNP	Gross national product
EVA	Ethylene vinyl acetate	GPC	Giant papillary conjunctivitis
EVR	Endocardial viability ratio	GPH	Gas-permeable hard
EW	Extended wear	GPH-EW	Gas-permeable hard lens extended wear
FAD	Flavin adenine dinucleotide	GPO	Government Printing Office
FARA	Flexible automation random analysis	GSC	Gas-solid chromatography
FBD	Fetal biparietal diameter	GSR	Galvanic skin response
FBS	Fetal bovine serum	GSWD	Generalized spike-wave discharge
fcc	Face centered cubic	HA	Hydroxyapatite
FCC	Federal Communications Commission	HAM	Helical axis of motion
Fct	Fluorocrit	Hb	Hemoglobin
FDA	Food and Drug Administration	HBE	His bundle electrogram
FDCA	Food, Drug, and Cosmetic Act	HBO	Hyperbaric oxygenation
FE	Finite element	HC	Head circumference
FECG	Fetal electrocardiogram	HCA	Hypothermic circulatory arrest
FEF	Forced expiratory flow	HCFA	Health care financing administration
FEL	Free electron lasers	HCL	Harvard Cyclotron Laboratory
FEM	Finite element method	hcp	Hexagonal close-packed
FEP	Fluorinated ethylene propylene	HCP	Half cell potential
FES	Functional electrical stimulation	HDPE	High density polyethylene
FET	Field-effect transistor	HECS	Hospital Equipment Control System
FEV	Forced expiratory volume	HEMS	Hospital Engineering Management System
FFD	Focal spot to film distance	HEPA	High efficiency particulate air filter
FFT	Fast Fourier transform	HES	Hydroxyethylstarch
FGF	Fresh gas flow	HETP	Height equivalent to a theoretical plate
FHR	Fetal heart rate	HF	High-frequency; Heating factor
FIC	Forced inspiratory capacity	HFCWO	High-frequency chest wall oscillation
FID	Flame ionization detector; Free-induction decay	HFER	High-frequency electromagnetic radiation
FIFO	First-in-first-out	HFJV	High-frequency jet ventilation
FITC	Fluorescent indicator tagged polymer	HFO	High-frequency oscillator
FL	Femur length	HFOV	High-frequency oscillatory ventilation
FM	Frequency modulation	HFPPV	High-frequency positive pressure ventilation
FNS	Functional neuromuscular stimulation	HFV	High-frequency ventilation
FO	Foramen ovale	HHS	Department of Health and Human Services
FO-CRT	Fiber optics cathode ray tube	HIBC	Health industry bar code
FP	Fluorescence polarization	HIMA	Health Industry Manufacturers Association
FPA	Fibrinopeptide A	HIP	Hydrostatic indifference point
FR	Federal Register	HIS	Hospital information system
FRC	Federal Radiation Council; Functional residual capacity	HK	Hexokinase
FSD	Focus-to-surface distance	HL	Hearing level
FTD	Focal spot to tissue-plane distance	HMBA	Hexamethylene bisacetamide
FTIR	Fourier transform infrared	HMO	Health maintenance organization
FTMS	Fourier transform mass spectrometer	HMWPE	High-molecular-weight polyethylene
FU	Fluorouracil	HOL	Higher-order languages
FUDR	Floxuridine	HP	Heating factor; His-Purkinje
FVC	Forced vital capacity	HpD	Hematoporphyrin derivative
FWHM	Full width at half maximum	HPLC	High-performance liquid chromatography
FWTM	Full width at tenth maximum	HPNS	High-pressure neurological syndrome
GABA	Gamma amino buteric acid	HPS	His-Purkinje system
GAG	Glycosaminoglycan	HPX	High peroxidase activity
GBE	Gas-bearing electrodyamometer		

HR	Heart rate; High-resolution	IMIA	International Medical Informatics Association
HRNB	Halstead-Reitan Neuropsychological Battery	IMS	Information management system
H/S	Hard/soft	IMV	Intermittent mandatory ventilation
HSA	Human serum albumin	INF	Interferon
HSG	Hysterosalpingogram	IOL	Intraocular lens
HTCA	Human tumor cloning assay	IPC	Ion-pair chromatography
HTLV	Human T cell lymphotropic virus	IPD	Intermittent peritoneal dialysis
HU	Heat unit; Houndsfield units; Hydroxyurea	IPG	Impedance plethysmography
HVL	Half value layer	IPI	Interpulse interval
HVR	Hypoxic ventilatory response	IPPB	Intermittent positive pressure breathing
HVT	Half-value thickness	IPTS	International practical temperature scale
IA	Image intensifier assembly; Inominate artery	IR	Polyisoprene rubber
IABP	Intraaortic balloon pumping	IRB	Institutional Review Board
IAEA	International Atomic Energy Agency	IRBBB	Incomplete right bundle branch block
IAIMS	Integrated Academic Information Management System	IRPA	International Radiation Protection Association
IASP	International Association for the Study of Pain	IRRAS	Infrared reflection-absorption spectroscopy
IC	Inspiratory capacity; Integrated circuit	IRRS	Infrared reflection spectroscopy
ICCE	Intracapsular cataract extraction	IRS	Internal reflection spectroscopy
ICD	Intracervical device	IRV	Inspiratory reserve capacity
ICDA	International classification of diagnoses	IS	Image size; Ion-selective
ICL	Ms-clip lens	ISC	Infant skin servo control
ICP	Inductively coupled plasma; Intracranial pressure	ISDA	Instantaneous screw displacement axis
ICPA	Intracranial pressure amplitude	ISE	Ion-selective electrode
ICRP	International Commission on Radiological Protection	ISFET	Ion-sensitive field effect transistor
ICRU	International Commission on Radiological Units and Measurements	ISIT	Intensified silicon-intensified target tube
ICU	Intensive care unit	ISO	International Organization for Standardization
ID	Inside diameter	ISS	Ion scattering spectroscopy
