the ISFETs were incubated in different concentrations of anti-HSA antibodies solution ranging from 0.06 to 64 μ M. The anti-HSA antibody was able to change the inversion point of the HSA-coated membrane from 3.70 to 5.55. The above experiments clearly demonstrated that the net charge density in a protein layer deposited on an ISFET could be determined by exposing the membrane to a stepwise change in electrolyte concentration while measuring ISFET current change. The transient membrane potential observed is a result of the different mobilities of the positive and negative ions present in the protein layer. It is also observed that characteristic inversion points and slope are a function of the protein concentration and type of protein. Also isoelectric points could be detected from the membrane potentials as a function of the pH. This detection of the isoelectric point of a protein complex is the basis for the development of an IMFET. An immunological reaction results in a change of the fixed-charge density in the membrane, which can be explained by a shift of the protein isoelectric point due to the immunological reaction.

The ion-step method was originally designed to measure immunoreaction via the change in charge density, which occurs in an antibody-loaded membrane, deposited on an ISFET, upon reaction with a charged antigen. The efficacy of ion-step method for the quantification of a non-charged antigen was demonstrated using progesterone as the model analyte (53). Progesterone is an uncharged molecule, hence, it cannot be detected directly by using the ion-step method. A competitive method was devised using a charged progesterone-lysozyme conjugate. To prepare the ISFETs for ion-step measurement, a membrane support was created by depositing a 1:1 mixture of polystyrene beads and agarose on the gate. The ISFETs were then cooled to 4 °C and the solvent was slowly evaporated, leaving a porous membrane with a thickness of approximately 4 μ m. The ISFET was then heated to 55 °C for 1 h to immobilize the membrane onto the gate. The ISFET was placed in the flow-through system (see Fig. 8) and a monoclonal antibody specific to progesterone was incubated on the membrane (0.5 mg/ml, 4 °C for 20 h). A competitive assay method was used to detect progesterone levels, and the detection limit was approximately 10^{-8} M of progesterone in the sample solution. Recently, Besselink et al. (54) described an amino bead-covered ISFET technology for the immobilization of antibodies. HSA was immobilized onto the amino bead-coated ISFET, by covalent cross-linking method, and the anti-HSA antibodies were quantitated using the ion-step method. The antibody concentration was detected within 15 min, with yields up to 17 mV (Fig. 9).

Indirect-Sensing IMFET

The indirect-sensing IMFET concept emerged during the early 1990s in order to overcome the difficulties met with the direct-acting IMFET devices (55). Colapicchioni et al. (56) immobilized IgG using protein A onto the gate area of an ISFET. The efficacy of the IMFET was demonstrated using Human IgG and atrazine antibodies captured using protein A. As the atrazine is a small molecule (hapten), which does not induce an immunoresponse as such, it was linked to a carrier protein. Bovine Serum Albumin (BSA)

Figure 9. Ion-step responses of HSA-coated ISFET before (upper solid curve) and after incubation (for 15 min) with undiluted anti-HSA (lower solid curve) and anti-BSA (dashed curve). Ion stepping was performed at pH 4.02.

was conjugated to ametryn sulfoxide, which has structural similarity with atrazine, and the ametryn-BSA conjugate was injected into rabbit to raise antibodies. A sandwich assay format was used to detect Human IgG and a competitive assay format was used to quantitate atrazine concentration. The antigen-antibody reaction was monitored by the addition antihuman IgG-GOD conjugate and ametryn-GOD, respectively. Glucose was used as the substrate and the pH variation was detected by the ISFET. The sensitivity of the assay was 0.1 $\mu\text{g/ml}$ and 1 ppb for human IgG and atrazine, respectively. An ISFET-based immunosensor was demonstrated for the detection of bacterial (*Clostridium thermocellum*) cells. The analysis included the reaction of antibacterial antibodies with cells in suspension or after covalent immobilization of cells on porous photoactivated membranes and, subsequently, the revelation of bound antibodies by the conjugate of protein A and HRP and the quantitation of enzyme activity with ISFET. The sensitivity of the sensor was within a range of 10^4 – 10^7 cells per ml (57). Selvanayagam et al. (23) reported ISFET-based immunosensors for the quantitation of β -Bungarotoxin (β -BuTx), a potent presynaptic neurotoxin from the venom of *Bungarus multicinctus*. A murine monoclonal antibody (mAb 15) specific to β -BuTx was immobilized on the gate area, and the antigen-antibody reaction was monitored by the addition of urease-conjugated rabbit anti- β -BuTx antibodies. The sensor detected toxin level as low as 15.6 ng/ml. The efficacy of the sensor for the determination of β -BuTx from *B. multicinctus* venom was demonstrated in the mouse model.

An immunological *Helicobacter pylori* urease analyzer (HPUA), based on solid-phase tip coated with a monoclonal antibody specific to *H. pylori*'s urease and ISFET, was reported by Sekiguchi et al. (58). A solid-phase tip, with an inner diameter of 0.55 mm, coated with the monoclonal antibody, was incubated for 15 min at room temperature in an endoscopically collected gastric mucus sample. The activity of urease captured on the inner surface of the solid-phase tip was measured by coupling it with an ISFET in a measuring cell containing urea solution. The pH change of urea solution after 55 s of the enzymatic

reaction inside the tip was measured by withdrawing 1.1 μl of solution toward the upstream of the tip, where the measuring ISFET was installed. One cycle of measurement was completed in 17.5 s, and the sensitivity of system was 0.2 m IU/ml. The calibration curve for the quantitation of urease is shown in Fig. 10. Clinical studies were carried out with 119 patients (75 males and 44 females with an average age of 51, ranging from 13 to 79) who underwent gastroduodenoscopy and judged necessary to evaluate the infection of *H. pylori* and urea breath test (UBT) was used as a gold standard. Thirty-three of the UBT positive 36 patients were positive, and 81 of UBT negative 83 patients were negative by HPUA resulting in the 92% sensitivity and 98% specificity.

An IMFET for the detection of HIV-specific antibodies based on a combination of ELISA principle and ISFET flow injection analysis setup was presented by Aberl et al. (59). The active sensing components consist of a reaction cartridge containing a carrier with the immobilized receptor layer and an ISFET sensor mounted in a flow-through cell. A flow cell was constructed using two ISFET sensors on one in a two-channel configuration (Fig. 11). The liquid

Figure 10. A standard curve for HPUA.

Figure 11. Diagrammatic representation of a flow injection system for indirect immunosensing.

headspace on top of the ISFET sensors was reduced to about $1 \mu\text{l}$, and the dead volume of the whole sensor cell was $7 \mu\text{l}$. The detection principle was realized according to the sandwich ELISA procedure using urease as a pH shifting marker enzyme. Antigen molecules (p24 or gp120) were immobilized on cellulose nitrate membranes mounted in a special flow-by cartridge or the inner surface of Borosilicate glass capillary tubing. After blocking the unspecific binding sites, the antigen was reacted with specific serum in different dilution or nonspecific serum as a negative control. In comparison with conventional ELISA, the ISFET-FIA ELISA showed a slight lower sensitivity. The antibodies were detected in a serum diluted more than 1:12,000 in ELISA, whereas the sensitivity of the ISFET-FIA ELISA was between a 1:1000 and a 1:10,000 dilution. Glass as a support material showed highly reproducible test results when compared with cellulose nitrate membrane.

Tsuruta et al. (60) reported a fully automated ISFET-based ELISA system using a pipette tip as a solid phase and urease as a detecting enzyme. The inner wall of the end part of a pipette tip was used as a solid phase, and the urease activity of the conjugate, captured after a two-step immunoreaction, was measured by coupling the pipette tip with the ISFET in a pH measuring cell (Fig. 12). A two-step sandwich assay procedure was used for the quantitation of AFP, CEA, HBsAg, and HBsAb, and a two-step competition assay was used for HBcAb, and second-antibody configuration was used for HTLV-1 Ab. After final incubation in conjugate solution, the pipette tip was washed and it was introduced into the pH measuring cell in order to couple it with ISFET. At the same time, feeding of the substrate solution was stopped, to read the pH change for 20 s. The output (source potential) of the ISFET was read and stored in the CPU during the above-mentioned 20 s at 0.1 s intervals. The maximum changing rate of the source potential ($\Delta V/\Delta t$, mV/s) was calculated from these 200 data points. The total assay time was 21 min as the sum of 5, 10, 5 and 1 min for preheating of sample, First immunoreaction, Second immunoreaction, and pH measurements, respectively. The assay speed was 60 samples/h. Assay performance, such as within run CVs, between run CVs, detection limits, and correlation with the conventional ELISA kits, were satisfactory for all of six

Figure 12. Cross-sectional view of a pH-measuring cell.

analytes. The detection limit for CEA, $0.09 \mu\text{g/l}$ was comparable to better than those reported for the most advanced chemiluminescent ELISA system ($0.086 \mu\text{g/l}$).

Polymerase chain reaction (PCR) has proven to be of great importance in clinical diagnosis (61). Usually, the PCR products have been detected by staining with ethidium bromide in qualitative methods, and fluorescent dyes in real-time quantitation. Although electrophoresis has the advantage of giving information on the molecular size of PCR products, it is not well-suited to mass screening or automation. On the other hand, real-time monitoring is well-suited for mass screening and automation but is expensive. One of the most promising methods for automatizing the detection system of PCR products is ELISA. An ISFET-based ELISA was used to quantitate PCR products (62). Double-stranded PCR products with digoxigenin and biotin at both terminals were obtained by using digoxigenin- and biotin-labeled primers. The PCR products were detected by a two-step sandwich ELISA. One μl of the solution after PCR was introduced into the end part of the solid-phase pipette tip coated with antidigoxigenin antibody. Biotin-labeled PCR products captured at the solid phase were detected with avidin-urease conjugate, and the enzyme activity was measured by the ISFET in a pH measuring cell containing urea solution. The detection limit of the system was determined using a known amount of purified PCR product labeled with digoxigenin and biotin, and it was found that 10 amol of the labeled DNA in $1 \mu\text{l}$ sample. The assay was used to detect HTLV-1 provirus gene integrated in the genome of human MT-Cell, and it was found that 100 pg of the genomic DNA was specifically detectable after 35 cycles of PCR. The apparent dynamic range for detection of MT-1 DNA was from 100 pg to 100 ng .

One of the most important targets in molecular biology is the quantitation of mRNA related to special disease by RT-PCR. The accuracy of quantitative RT-PCR has been remarkably improved by the introduction of competitive

RT-PCR, in which a synthetic RNA is used as an internal standard (63). Tsuruta et al. (64) developed a ISFET-ELISA method for the quantitation of mRNA in clinical samples. In this method, a fixed amount of a synthetic RNA, pRSET RNA, was added as internal standard to the solution of target RNA (IL-1 β) after reverse transcription, PCR was carried out using digoxigenin-labeled sense primer and biotin-labeled antisense primer for IL-1 β , and FITC-labeled sense primer and a biotin-labeled antisense primer for pRSET. The double-stranded PCR products of IL-1 β and pRSET were captured by two solid-phase pipette tips, one coated with antidigoxigenin antibody and another with anti-FITC antibody, respectively, and sandwiched by an avidin-urease conjugate, whose activity was measured with ISFET. The ratio of the signal intensity for IL-1 β to that for pRSET was used to quantitate the concentration of IL-1 β . A calibration curve was obtained using a known amount of AW109 RNA as an external standard in place of IL-1 β mRNA. It was found that 10^2 – 10^6 copies of IL-1 β mRNA were measurable by the present method. Expression levels of IL-1 β mRNA in clinical samples, such as monocytes of peripheral blood or synovial cells from patients with RA or OA, were determined.

Practical Limitations

In this section, we shall address some practical problems that have been limiting factors in the commercial application of IMFETs. The widespread use of IMFETs for applications ranging from medical diagnosis to industrial process control or environmental monitoring has not actually happened. The underlying reasons for this situation fall into two main categories, those that are inherent to the transistor, such as material, encapsulation, and reference electrode, and those problems common to its application as an immunosensor function, such as, antibody immobilization, stability, and durability. The pH sensing properties and drift behavior of the ISFET is the main limiting factor in the commercial breakthrough of ISFET. After the invention of the ISFET, initially the only gate material used was SiO₂. Although SiO₂ showed pH sensitivity of 20 to 40 mV/pH, the thermally grown gate oxide loses its isolation property within a few hours of immersion in a solution. In order to isolate this gate oxide from the solution, another isolating layer, such as Si₃N₄, Al₂O₃, or Ta₂O₅, has to be placed on top of this gate oxide. A layer of Si₃N₄ on top of SiO₂ showed 45–50 mV/pH, and other layers, such as Al₂O₃ and Ta₂O₅, showed even higher pH sensitivity, 53–57 mV/pH and 55–59 mV/pH, respectively (65). Drift rate for Si₃N₄ is reported as 1 mV/h and for Al₂O₃ and Ta₂O₅ 0.1–0.2 mV/h after 1000 min of operation at pH 7.0. In most of the work on IMFETs published so far, these three gate materials, Si₃N₄, Al₂O₃, and Ta₂O₅, have been used. IMFETs are also sensitive to light and temperature (66).

The pH-sensitive ISFETs can be fabricated by means of standard MOS technology, except for the metallization step. However, after dicing the wafers into single chips, the substrate becomes exposed at the edges of the sensor. Encapsulation and packaging are two final processing steps that determine reliability and durability (lifetime) of the IMFETs. In order to achieve high quality sensors, all

electrical components have to be isolated from their surroundings. Several reports exist on the encapsulation and packaging of ISFET devices for pH application (21). The simplest method of isolating these sides is encapsulation with epoxy-type resins. The most important ISFET characteristics, such as stability, accuracy, and durability, also pertain to the reference electrode. One of the major hurdles in IMFETs is the lack of a solid-state reference electrode. The small IMFETs have to be combined with a conventional KCl-solution-filled reference electrode. In order to achieve miniaturized IMFET, it is important to miniaturize the reference electrode. In general, two approaches have been followed: reference FETs (REFETs), which are used in an ISFET/REFET/quasi-reference electrode setup, and miniaturized conventional reference electrodes. In the first approach, attempts have been made to cover the ISFET surface with a pH-insensitive layer or to render the surface pH insensitive by chemical modification. In the second approach, the structure of a conventional electrode (mostly Ag/AgCl type) is miniaturized partially or completely on a silicon wafer. Its potential is a function of concentration of chloride ions. They are supplied either from an internal electrolyte reservoir formed by an anisotropic etching in the silicon wafer or by adding chloride ions into the test solution.

Some of the technological factors such as pH sensitivity and drift can now be overcome with the existing technology. A hurdle peculiar to direct-acting IMFET is the need to provide a thin but fully insulating layer (membrane) between the antigen or antibody coating and the semiconductor surface. Such a membrane must be thin enough to allow a small charge redistribution occurring as a result of analyte (antigen-antibody) binding to exert a detectable change in electrical field. Conversely, it must also provide adequate insulation to prevent dissipation of the field by leakage of ions. Even assuming that the ideal insulating membrane can be developed, a further hurdle may need to be overcome. Surface charges and hydrogen binding sites of proteins cause a counter-ion shell (double-layer) and structured water shells to surround the molecules; these regions of structured charge will inevitably contribute to the electrical field affecting the FET gate. Pending these breakthroughs, the development of direct-acting IMFETs appears to be stagnant.

The immobilization methods used for immunosensors include a variety of adsorption, entrapment, cross-linking, and covalent methods. In general, a covalent immobilization method consisting of silanization step and subsequent coupling procedure via glutaraldehyde has been used to immobilize antibodies onto the gate region (67,68). However, no methodical investigation about antibody stability, storage, and lifetime exists. Reproducible regeneration of the sensing area is one of the major problems met with IMFETs that have been used for continual monitoring or repeat usage. The need for renewal of the sensing surface derives from the high affinity constants derived from the strong antigen-antibody reaction. Two different strategies have been used to achieve the renewal of the sensing surface, breakage of the antigen-antibody bond and reusing the immunologic reagent immobilized on the solid phase. A second alternative is the elimination of antigen-antibody

complex from the solid support and immobilization of fresh immunologic material. Dissociation of antigen from antibody is usually carried out in low pH and high ionic strength solutions. Protein A was chemically immobilized onto the gate surface by using a polysiloxane layer of [3-(2-aminoethyl)aminopropyl]trimethoxysilane (APTES) and cross-linking agent such as glutaraldehyde. Reversibility of the linkage between Protein A and antibodies in order to restore the device for the next measurement was studied by breaking the antibody-antigen complex formed on Protein A using a variety of reagents. Glycine buffer pH 2 and 3 and MgCl_2 3.5 M were found to be more effective when compared with other tested reagents due to high ionic strength (55). Selvanayagam et al. (23) studied the reusability of an ISFET sensor by removing the antibody membrane from the gate area. The regenerated devices tested were reported to function normally five times, although a considerable amount of time was required for the regeneration process. Recently, IMFET using magnetic particle and integrated to flow injection system has been described to overcome the problem of regeneration (69,70). The immunological material was immobilized on the surface of magnetic particles and were transported by a flow system, and were retained on the gate area of the ISFET by a magnetic field produced by a magnet (Fig. 13). The regeneration of immunologic materials was achieved by releasing the magnetic field, thus freeing those particles that were washed by the flow system, and new magnetic particles were injected and retained on the surface of transducer by reacting the magnetic field. A fresh and reproducible surface was thus produced, ready for the next analytical cycle.

The main barrier to the successful introduction of IMFETs for clinical testing is undoubtedly the high performance and automation level of the machines that already exist in centralized laboratories. They have been developed specifically for use with either immunoassay or clinical chemistry. Immunoassay performance is continually being optimized and assay times have been reduced over the past few years. Depending on the parameter, the assay time can be as low as 6 min and the majority of the larger machines could carry out between 100 to 200 testes per hour. IMFETs must be compared with these methods with respect to assay time, sensitivity, and cost. The need for in-built calibration has been frequently encountered in sophisticated quantitative IMFETs. Although feasible and acceptable in laboratory-based instrumentation, it remains

Figure 13. Schematic representation of the magnetoIMFET.

a major problem in small disposable IMFET devices. To facilitate the increased use of IMFETs, one should look for real tests and standards that prototypes can meet, based on current diagnostic needs and perceived future development. The progress of IMFET beyond the experimental laboratory level is mainly dependent on how skillfully its development and marketing are combined with parameter selection.

FUTURE DIRECTIONS

A key consideration in antibody immobilization to the gate area is to maintain, reproducibly, the highest possible binding activity after immobilization while conserving the amount of antibody used. However, many aspects, both fundamental and more applied, require in-depth study before IMFETs can become successful commercial device, including improved control of biomolecule immobilization and novel immobilization strategies; enhancement of biomolecule stability and retention of activity *in vitro*; and the ability to reproduce the high signal-to-noise ratios obtained in simple test solutions in "real" samples such as blood or water. The IMFETs tends to respond nonspecifically to any molecule bound to the surface; hence, it affects the measurement parameter to some extent. The specificity of analyte detection, therefore, relies entirely on achieving high ratios of specific to nonspecific binding, which, in the context of low concentrations of analyte in blood, can represent a formidable problem. Reduction of nonspecific binding is another area that will continue to be of major importance. The ability to immobilize ordered antibodies will maximize antigen binding to a given surface while reducing the availability of nonbinding site sections of the immobilized antibody, or uncovered surface areas, which can promote nonspecific interaction with other components in the sample. The potential advantages of using Fab fragments rather than more complex intact antibodies (such as IgG) could be explored.

IMFETs, similar to immunoassays, involve multistep procedures, including washing steps, incubation periods, and quite complex signal generation protocols. It is likely that research efforts into a novel signal amplification system, without the normally associated complications of multi-reagents or multistep protocol will be of increasing importance. The irreversibility of antigen-antibody interaction presents a major challenge in designing IMFETs for continual monitoring or repeated usage. Treatment of an antibody-antigen complex with a mildly denaturing medium for a short time interval has shown some promise in regenerating sensor surfaces. Development of enhanced denaturation conditions, which optimize dissociation of antigen while minimizing irreversible loss of antibody structural integrity, may be possible in the near future. The use of catalytic antibodies in immunosensors has been proposed. The ability of catalytic antibodies to catalyze the hydrolysis of phenyl acetate with the formation of acetic acid allows integration of pH-sensitive microelectrodes to give a potentiometric immunosensing system (71). The advantage of catalytic antibodies over normal antibodies is that reversibility of

response is readily achieved, because bound antigen reacts to form a product with a low affinity for the antibody, resulting in dissociation. As the binding event is followed immediately by a catalytic reaction and release of the reaction products, the molecular recognition site is regenerated with each molecular reaction; as a consequence, catalytic antibodies can be used to create reversible IMFETs for continuous monitoring of analyte concentrations. Improvements in sensitivity and cross-reactivity are likely to be achieved as a result of the increasing interest in this field of research.

CONCLUSION

Although the ISFET concept has existed for over 30 years, its practical applications such as the IMFETs are still emerging very slowly. The relatively slow rate of progress of IMFET technology from inception to fully functional commercial devices for these applications is a reflection of technology-related and market factors. In general, two approaches have been followed in the past to realize IMFETs. In the first approach, antigen-antibody reaction on an immobilized membrane was monitored without any addition of labels. The second approach takes the advantage of an enzyme label to indirectly monitor the antigen-antibody reaction using pH-sensitive FET. The development of IMFETs that directly detect antigen-antibody reaction is extremely challenging; only a few examples exist, the majority of which are without valid theoretical explanation. Although it shows enormous promise in the early stages of development, an effective, reliable, and analyte-selective direct-acting IMFET sensor is yet to be constructed. The ion-step method represents a novel measurement concept for potentiometric detection and quantification of an adsorbed antigen or antibody molecule in which modified ISFETs are used. Many approaches to transduction of the antibody-antigen combining event are indirect, necessarily involving the use of reagents admixed with analyte, and therefore cannot be seen as routes to development of "True" IMFETs. Nevertheless, such reagent-dependent, indirect-sensing IMFETs may offer real commercial advantages over the current generation direct-acting IMFET readout technologies. The clinical diagnostic field offers real opportunities for the exploitation of IMFET, but because it is a highly competitive and well-established market, those who wish to introduce new products must carefully target their market niche. IMFETs will have to compete with such technology on the basis of factors such as cost, ease of use, sensitivity, operational stability, robustness, and shelf-life.

INTRODUCTION

Immunotherapy of cancer, infectious disease, and autoimmune disease has opened a new area for disease management. This approach has developed very fast lately due to the advances and involvements of modern technology in molecular biology, cell biology, immunology, biochemistry, and bioengineering. Adoptive T cell immunotherapy of cancer involves passive administration of lymphoid cells from one host to another, or back to itself in order to transfer tumor immunity for cancer treatment. It was first realized >20 years ago that adoptive immunotherapy may be feasible to treat human malignancies. However, the early form of this practice was quite simple. It could be as easy as a straightforward blood cell transfer. The apparent inefficiency of antitumor immune responses, and the failure to successfully combat the disease laid the foundation for current concepts of immunotherapy. It did not take too long before it was realized that boosting the antitumor immune response by deliberate vaccination could increase the potential benefits of immune cell-based therapies. In addition, activation of lymphoid cells with monoclonal antibodies (mAb) toward the molecules involved in T cell signaling pathways has resulted in therapeutic effector T cells. The use of immune adjuvants coadministered with the cell infusion has enhanced the antitumor efficacy of the transferred cells and has made adoptive cellular immunotherapy a promising strategy for cancer treatment. Studies on the trafficking of adoptively transferred cells *in vivo* as well as the identification and characterization of T cell subsets responsible for antitumor reactivity have provided valuable insights toward the development of novel immunotherapeutic strategies. The adoptive immunotherapy of established tumors with the transfer of tumor-reactive lymphoid cells has now been shown to be highly effective against significant tumor burdens both in animal models and in clinical trials. This is, at least in part, due to recent developments in this area, such as treating cancer in special settings (e.g., in lymphopenic hosts induced by prior conditioning); redirecting the effector cells to tumor through genetic engineered chimerical T cell receptors (TCRs) or by transferred tumor antigen-specific TCRs; and the use of these strategies in combination. This article intends to review the above developments that have made adoptive T cell immunotherapy an attractive alternative for cancer treatment.

INDUCTION OF TUMOR-REACTIVE PRE-EFFECTOR T CELLS *IN VIVO*

Successful induction of tumor-reactive “pre-effector” cells in a tumor-bearing host represents the first step toward the conduct of an effective adoptive T cell immunotherapy of cancer. This procedure provides a source of “pre-effector” cells for subsequent T cell activation and expansion *in vitro*

to generate large numbers of “effector” cells to be infused back to the tumor-bearing host or cancer patient for therapy. Due to the relative lack of immunogenicity and potential immunosuppressive mechanisms of human malignancies, application of tumor T cell therapy in the clinical setting has been hampered for a long time by difficulties to reliably isolate tumor-sensitized lymphoid cells from the cancer-bearing host. Nevertheless, recent observations in animal studies and clinic trials have led to the development of strategies to induce T cell sensitization *in vivo*.

Peripheral blood lymphocytes (PBL) represents a convenient source of pre-effector cells. However, in most cases, particularly in the case of solid tumors, the frequency of tumor-specific pre-effector cells in PBL is extremely low, generally far below what is observed in response to viral infection. Experimental studies and clinical experience with adoptive immunotherapy have demonstrated that tumor-draining lymph node (TDLN) cells are potentially effective antitumor reagents. Chang et al. was the first to evaluate vaccine-primed LN (VPLN) as a source of lymphoid cells that could be secondarily sensitized by *in vitro* methods to generate effector cells capable of mediating regression of established tumors upon adoptive transfer in clinical trials (1–3). These trials included subjects with metastatic melanoma, renal cell cancer, and head and neck squamous cell cancers, and have resulted in prolonged, durable, complete responses.

In murine models, it has been observed that TDLN harbor lymphoid cells that are functionally capable of mediating rejection of immunogenic tumors in adoptive transfer after *in vitro* activation (4,5). However, both tumor-infiltrating lymphocytes (TIL) and TDLN cells were found to be incapable of mediating the regression of poorly immunogenic tumors such as the B16–BL6 melanoma, a highly invasive tumor of spontaneous origin. It was then discovered that the subcutaneous inoculation of B16–BL6 tumor cells admixed with the bacterial adjuvant, *Corynebacterium parvum*, resulted in reactive TDLN cells that differentiated into therapeutic effector T cells upon activation *in vitro* (6,7). Upon adoptive transfer, these LN cells successfully mediated the regression of established tumors. In addition to the ability to mediate regression of experimentally induced pulmonary metastases, these activated cells were effective in the treatment of spontaneous visceral metastases originating from a primary tumor, a condition that more closely approximates human malignancy. These studies thus demonstrated that vaccination of animals with irradiated tumor cells admixed with a bacterial adjuvant was capable of inducing tumor-reactive T cells in the draining LN.

We have applied these methods to generate vaccine-primed LN in patients with advanced melanoma and renal cell cancer (RCC) for therapy (3,8). Patients with RCC or melanoma received intradermal inoculation of irradiated autologous tumor cells admixed with *Bacillus Calmette–Guerin* (BCG) as a vaccine. Seven to ten days later, draining LN were removed for *in vitro* activation and expansion. Activated LN cells were then administered intravenously with the concomitant administration of IL-2 for immunotherapy with defined success (3).

Studies demonstrated that tumor cells genetically modified with immunostimulatory genes are capable of sensitizing T cells. Transfection of cytokine genes into murine tumor cells have resulted in reduced tumorigenicity following inoculation of the modified tumor cells into animals (9). In these studies, animals that rejected the inoculum of modified tumor cells also rejected a subsequent challenge of unmodified parental tumor cells, thus demonstrating the development of tumor immunity. We performed a clinical study of patients with melanoma to evaluate the immunobiological effects of GM-CSF transduced autologous tumor cells given as a vaccine to prime draining lymph nodes (10). There was an increased infiltration of dendritic cells (DCs) in the GM-CSF-secreting vaccine sites compared with the wild type (WT) vaccine sites. This resulted in a greater number of cells harvested from the GM-CSF-VPLNs compared with the WT-VPLNs. Patients received adoptively transferred GM-CSF-VPLN cells secondarily activated and expanded *in vitro*. A complete clinical response was observed in one of five patients. This work documented measurable immunobiologic differences of GM-CSF-transduced tumor cells given as a vaccine compared with WT tumor cells.

Collectively, these observations suggested that TDLN or VPLN cells may represent an ideal source of tumor-reactive T cells. They also established the rationale for developing tumor vaccines utilizing autologous tumors admixed with bacterial adjuvant or genetically modified with cytokine genes, which may prove useful in facilitating the generation of immune T cells for adoptive immunotherapy.

ACTIVATION AND POLARIZATION OF EFFECTOR T CELLS *IN VITRO*

A major challenge in T cell immunotherapy of cancer is how to activate and expand the relatively low numbers of tumor-specific T cells obtained from the tumor-bearing host. Previous studies demonstrated that freshly isolated TDLN cells had defects in TCR-mediated signal transduction and were not immediately competent in adoptive transfer models (11,12). It has therefore become a critical prerequisite in adoptive immunotherapy to expand the pre-effector cells into large numbers of effector cells while augmenting their antitumor reactivity.

In vitro T cell activation using monoclonal antibodies in the absence of antigen takes advantage of common signal transduction pathways that are ubiquitous to T cells. This principle has been used to expand tumor-primed T cells contained within TDLN or VPLN. The initial efforts involved the use of anti-CD3 mAb as a surrogate antigen to activate tumor-primed lymphoid cells, followed by expansion in IL-2 (12). This approach resulted primarily in the generation of CD8⁺ effector cells that mediated tumor regression *in vivo*. Subsequent clinical studies utilizing this method to activate VPLN cells demonstrated that this cellular therapy can result in achieving durable tumor responses in subjects with advanced cancer (1,3). We have extended these investigations in animal models and with human samples by examining other mAbs that deliver

costimulatory signals in concert with anti-CD3 to activate tumor-primed lymphoid cells. These other antibodies have involved anti-CD28 and anti-CD137 (13–16). The results of these investigations have indicated that costimulation can increase the proliferation of tumor-primed lymphoid cells and their ability to mediate tumor regression *in vivo*.

Several important principles in animal models that are relevant for the treatment of human malignancies have been identified. For example, the *in vitro* cytokine profiles released by effector T cells when cocultured with tumor cells are found to be predictive of their ability to mediate tumor regression *in vivo*. Effector cells that mediate a type 1 (i.e., IFN γ) and GM-CSF response to tumor antigen are capable of eradicating tumor upon adoptive transfer. In contrast, cells that demonstrate a type 2 profile (i.e., IL-10, IL-4) appear suppressive, and do not mediate tumor regression (16,17). We have determined the importance of IFN γ in mediating tumor regression both in animal studies (16) and in clinical trials (3). In a phase II adoptive cellular trial in patients with advanced renal cell cancer, we demonstrated that IFN γ secretion and the IFN γ : IL-10 ratio of cytokine released by effector T cells in response to tumor antigen was associated with clinical outcomes. Specifically, activated T cells that have an increased IFN γ :IL-10 ratio correlated with tumor response (3). Although effector T cells can be generated through antibody activation to mediate tumor regression in animal models, clinical responses in adoptive immunotherapy have been confined to a minority of patients. One potential reason for these limited responses is that antibody-activation procedures generally stimulate T cells broadly without discriminating between type 1 and type 2 cells, presumably due to the polyclonal expansion characteristics of antibodies directed to the TCR common chain, for example, CD3 ϵ of the TCR/CD3 complex or CD28. As a result, both type 1 cytokines, such as IL-2, IFN γ , and type 2 cytokines, for example, IL-4, IL-5, and IL-10, are modulated (13,18). Therefore, alternative protocols need to be defined that will preferentially stimulate the type 1 cytokine profile to generate more potent tumor-reactive T cells for cancer immunotherapy. Toward this end, various *in vitro* strategies have been investigated utilizing additional signaling stimuli to promote Th1/Tc1 cell proliferation and antitumor reactivity (19,20). We reported that costimulation of TDLN cells through newly induced 4-1BB and CD3/CD28 signaling can significantly increase antitumor reactivity by shifting T cell responses toward a type 1 cytokine pattern, while concomitantly decreasing type 2 response (16). Using the proinflammatory cytokines, we recently reported that IL-12 and IL-18 can be used to generate potent CD4⁺ and CD8⁺ antitumor effector cells by synergistically polarizing antibody-activated TDLN cells toward a Th1 and Tc1 phenotype, and that the polarization effect was NF- κ B dependent (21).

The recognition and use of cell polarization strategies during and/or post antibody activation of T cells represents another significant change and addition to the traditional practice of adoptive therapy. While adoptive immunotherapy of cancer requires large numbers of therapeutic T cells for transfer into cancer patients, the phenotype and cytokine profile of these cells are crucial in determining the

outcomes of the therapy. The use of polarizing reagents to modulate T cell function toward the type 1 response provides a rational strategy to enhance the efficacy of cellular therapy.

USE OF IMMUNE ADJUVANT IN CONCERT WITH T CELL ADMINISTRATION

In the course of adoptive immunotherapy of cancer, administration of T cell growth factors accompanying T cell transfer may promote T cell activation, proliferation, and tumor killing, and therefore augment clinical outcomes for the therapy. These growth factors, as well as other immune modulatory reagents used in concert with T cell transfer, function as immune adjuvants in eliciting antitumor activities *in vivo*. The most useful adjuvant to T cell transfer to date has been the exogenous administration of IL-2 (1–3,22,23).

Nearly 20 years ago, Rosenberg and colleagues performed a pilot protocol to investigate the feasibility and practicality of immunotherapy of patients with advanced cancer using TIL and recombinant IL-2 (22). The study represents an initial attempt to use TIL plus IL-2 administration with enhanced tumoricidal capacity in the adoptive immunotherapy of human malignancies. Twelve patients with melanoma, renal cell carcinoma, breast carcinoma, or colon carcinoma were treated with varying doses and combinations of TIL, IL-2, and cyclophosphamide. Three partial responses (PR) to therapy were observed. No toxic effects were directly attributable to TIL infusions. However, the toxicities of therapy were similar to those ascribed to IL-2. Indeed, the use of IL-2 has resulted in significant morbidity associated with cellular therapies (3,24). Moreover, a few recent studies showed that IL-2 may negatively regulate effector cells through activation-induced cell death (23,25), expanding the frequency of CD4⁺CD25⁺ T cells, or cause cell redistribution secondary to Ag-induced cell death (26,27). These studies suggest that novel reagents need to be identified to serve as alternative immune adjuvants for adoptive T cell therapy.

In a recent study (25), failed adoptive T cell therapy could be reversed with low dose IL-15 administration, but not IL-2. A related T cell growth factor, IL-15, protected T cells against activation-induced cell death and promoted homeostatic maintenance of memory T cells and, therefore, may be advantageous to T cell-based cancer treatment. Similarly, the role of IL-15 in early activation of memory CD8⁺ CTLs has been described (28). In this study, memory CD8⁺ T cells expressing OVA-specific TCR were transferred into IL-15-transgenic (Tg) mice, IL-15 knockout (KO) mice, or control C57BL/6 mice followed by challenge with recombinant *Listeria monocytogenes* expressing OVA (rLM-OVA). *In vivo* CTL activities were significantly higher in the IL-15 Tg mice, but lower in the IL-15 KO mice than those in control mice at the early stage after challenge with rLM-OVA. *In vivo* administration of rIL-15 conferred robust protection against reinfection via activation of the memory CD8⁺ T cells. In addition, IL-27 is a novel IL-12 family member that plays a role in the early

regulation of Th1 initiation and synergizes with IL-12 in IFN γ production (29). Mechanistic studies revealed that although a comparable proliferative response to IL-27 was observed between STAT1-deficient and wild-type CD4⁺ T cells, synergistic IFN γ production by IL-27 and IL-12 was impaired in STAT1-deficient CD4⁺ T cells. IL-27 also augmented the expression of MHC class I on CD4⁺ T cells in a STAT1-dependent manner (29).

Although the *in vivo* administration of proinflammatory cytokines has demonstrated antitumor efficacy, their potent antitumor activity is often achieved at the expense of unacceptable toxicity. For example, IL-12 and IL-18 administration was found to be associated with lethal organ damages, attributed in part to extremely high levels of host-induced IFN γ production (30). It is anticipated that administration of low doses of proinflammatory cytokines in the context of passively transferred TDLN cells will lead to increased therapeutic efficacy. To this end, the adjuvant effect of low dose cytokine administration over a long period of time can be compared with that of a high dose over a short period of time. These experiments should help to determine if prolonged administration of low dose cytokines can enhance the therapeutic efficacy by improving trafficking, survival, and proliferation of the adoptively transferred T cells.

While toxicity of traditionally used IL-2 limits its clinical utility at high doses, use of novel cytokines at tolerable low doses in conjunction with cellular therapy may provide alternative strategies that are less toxic. If the newly identified proinflammatory cytokines, such as IL-15 and IL-27 prove to be useful adjuvants to T cell therapy, they may result in more effective antitumor responses with reduced morbidity.

TRAFFICKING AND PROLIFERATION OF EFFECTOR T CELLS AFTER ADOPTIVE TRANSFER

Adoptive T cell therapy has been used for treatment of viral and malignant diseases with encouraging results. However, little is known about the fate and trafficking of the transferred effector cells. A study performed at NCI assessed the trafficking of gp100-specific pmel-1 cells to large, vascularized tumors that express or do not express the target Ag (31). It was found that approximately equal numbers of pmel-1 T cells infiltrated the Ag-positive and -negative tumors. Massive infiltration and proliferation of activated antitumor pmel-1 cells were observed in a variety of peripheral tissues, including lymph nodes, liver, spleen, and lungs, but not peripheral blood. However, T cell function, as measured by production of IFN γ , release of perforin, and activation of caspase-3 in target cells, was confined to Ag-expressing tumor. It was thus concluded that adoptively transferred CD8⁺ T cells traffic indiscriminately and ubiquitously while mediating specific tumor destruction.

We recently characterized the infiltration of adoptively transferred TDLN cells in the host bearing pulmonary metastases (21). The TDLN cells were activated with anti-CD3/anti-CD28 followed by cell culture in IL-12 + IL-18 before transfer into tumor-bearing host. The TDLN

cells were labeled with CFSE immediately before infusion. Immunohistochemical evaluation of adoptively transferred TDLN cells accumulating in pulmonary tumor nodules was performed. Infused TDLN cells were observed to (1) attach to venules, (2) mix with host leukocytes in perivenular collections, and (3) infiltrate tumor nodules. Active migration of infused cells into pulmonary tumor nodules was found to be correlated with significant tumor regression. This corroborates a previous report by Plautz et al. showing that infused TDLN cells must infiltrate pulmonary nodules to suppress tumor growth (32).

Several other reports support the hypothesis that efficient tumor regression needs the *in situ* accumulation of transferred effector cells. Another study conducted at the University of Michigan demonstrated that the infused cells must accumulate in metastatic lesions to suppress tumor growth, and that the process is dynamic (33). In studies treating murine lung metastases with adoptively transferred TDLN cells, the TDLN donor cells were initially confined to alveolar capillaries with no movement into metastases after infusion. However, within 4 h, TDLN cells began migrating across pulmonary postcapillary venules and first appeared within metastases. After 24 h, most donor cells in the lung were associated with tumor nodules. Donor cell proliferation both within the lung and in the lymphoid organs was detected. Importantly, T cells that had proliferated in the lymphoid organs trafficked back to the tumor-bearing lungs, accounting for ~50% of the donor cells recovered from these sites. These studies demonstrate that adoptively transferred TDLN cells migrate directly into tumor-bearing organs and seed the recirculating pool of lymphocytes after infusion. Cells that have differentiated in lymphoid organs eventually migrate into the tumor site. Additionally, *in vitro*-generated Melan-A-specific CTLs were found to survive intact *in vivo* for several weeks and localize preferentially to tumor (34). Over all, these studies suggest that methods to improve trafficking and recruitment of donor T cells to the tumor may improve therapeutic efficacy of cellular therapy.

The availability of congenic strains of mice bearing T cell markers that differ by epitopes that can be identified by monoclonal antibodies allows us to track adoptively transferred cells in a semisyngeneic host. In order to perform quantitative tracking studies of the infused cells, the congenic strain of B6 mouse that expresses CD45.1 can be used to generate TDLN for transfer into CD45.2 hosts. Analysis of the infiltrate can be performed by mechanical dissociation of the tumors in order to recover viable lymphoid infiltrates. By FACS analysis, the number of transferred CD4/CD8 T cells can be quantified. Proliferation of infused cells can be assessed by labeling them with CFSE. Confirmed correlation between effective tumor regression and the infiltration of infused cells to tumor should encourage further attempts to modulate T cell trafficking by biochemical controls or by genetic modification of well-identified adhesion molecules, for example, LFA, ICAM, and selectins. Furthermore, a very recent study described the regulation of T cell trafficking by sphingosine 1-phosphate (S1P) receptor 1 (S1P1) (35). Mature T cells from S1P1 transgenic mice exhibited enhanced chemotactic response toward S1P, and preferentially distributed to the blood

rather than secondary lymphoid organs, such as draining lymph nodes. This work suggests that S1P1 affects systemic trafficking of peripheral T cells, and therefore makes the S1P/S1P1 signaling pathway a novel target for T cell trafficking modulation.

IDENTIFICATION AND CHARACTERIZATION OF T CELL SUBSETS RESPONSIBLE FOR ANTITUMOR REACTIVITY

The CD8⁺ CTLs have long been recognized as the effector cells that mediate tumor regression. In addition, CD4⁺ effector T cells and NK cells have also been identified to directly or indirectly mediate tumor regression. We reported that CD28 costimulation of tumor-primed lymphoid cells promotes the generation of potent tumor-reactive effector cells, particularly CD4⁺ T cells. These anti-CD3/anti-CD28 activated CD4⁺ TDLN cells could independently mediate tumor regression in adoptive immunotherapy (13,14,21).

It has to be presumed that any source of antitumor reactive T cells derived from the tumor-bearing host, that is, TDLN, will represent a small percentage of the total population of retrieved cells. Therefore, a theoretically practical approach would be the identification, isolation, activation and expansion of subsets of T cells capable of mediating tumor regression. In this endeavor, Shu and co-workers found that the down-regulation of the homing molecule L-selectin could serve as a surrogate marker for the isolation of specific tumor-sensitized T cells (18). In adoptive immunotherapy of established intracranial MCA 205 tumors, L-selectin^{low} (CD62L^{low}) cells displayed at least 30-fold greater therapeutic efficacy than unfractionated cells. The L-selectin^{high} cells did not demonstrate any antitumor effects. These results demonstrate that the purification of L-selectin^{low} cells led to the generation of immune effector cells with unusually high therapeutic efficacy against chemically induced tumors. After that, Plautz et al. used advanced tumor models in a stringent comparison of efficacy for the L-selectin^{low} subset versus the total population of TDLN cells following culture in high dose IL-2. L-selectin^{low} subset comprised 5–7% of the TDLN cells. Adoptive transfer of activated L-selectin^{low} cells eliminated 14-day pulmonary metastases and cured 10-day subcutaneous tumors, whereas transfer of maximally tolerated numbers of unfractionated TDLN cells was not therapeutic (36). At the same time, it was identified that tumor-induced L-selectin^{high} cells were suppressor T cells that mediated potent effector T cell blockade and caused failure of otherwise curative adoptive immunotherapy (37). The treatment failure using unfractionated TDLN cells was due to cotransfer of the L-selectin^{high} suppressor T cells present in TDLN. However, the L-selectin^{high} suppressor T cells were only found in day-12 TDLN. In contrast, day-9 TDLN and normal spleens lacked L-selectin^{high} cells.

It was not long before a second surrogate marker was identified for the isolation of tumor-specific T cells. Stoolman et al. described that tumor-specific responses in TDLN were concentrated in cells expressing P-selectin ligand (Plig^{high} T cells) (38). This study found that the minor subset of TDLN T cells expressing binding sites for the

adhesion receptor P-selectin (Plig^{high} T cells) produced T lymphoblasts with the most tumor-specific IFN γ synthesis *in vitro* and antitumor activity following adoptive transfer *in vivo*. The cultured Plig^{high} TDLN cells were 10- to 20-fold more active against established pulmonary micrometastases than cultured, unfractionated TDLN, and >30-fold more active than cultured TDLN cells depleted of the Plig^{high} fraction. The Plig^{high} T cells expressed high levels of CD69 and low levels of CD62L (L-selectin^{low}), which agrees with the previous studies on L-selectin in TDLN. Further supporting these observations is a recent study indicating that recruitment of IFN γ -producing cells into the inflamed retina *in vivo* is preferentially regulated by P-selectin glycoprotein ligand (39).

In a different attempt to selectively activate tumor-sensitized T cells, superantigens were utilized *in vitro* to stimulate effector cell generation in a murine model (40). The TDLN cells stimulated with staphylococcal enterotoxins A (SEA), B (SEB) or C2 (SEC2) resulted in the selective expansion of V β 3 and 11, V β 3 and 8, or V β 8.2 T cells, respectively. Adoptive transfer studies revealed that SEB- and SEC2-, but not SEA- stimulated cells mediated tumor-specific regression. These results suggested that T cells bearing V β 8 may preferentially respond to the growing tumor than T cells bearing V β 3 or 11 elements of the T cell receptor. Similarly, stimulating TDLN cells with different anti-V β mAbs instead of the pan-T cell reagent anti-CD3 mAb enabled the selective activation of V β T cell subsets (17). Enrichment of V β subsets of TDLN cells revealed that V β 8⁺ cells released high amounts of IFN γ and GM-CSF with minimal amount of IL-10 in response to tumor, and mediated tumor regression *in vivo*. In contrast, enriched population of V β 5⁺, V β 7⁺, and V β 11⁺ cells released low amounts of IFN γ and GM-CSF with high levels of IL-10, and had no *in vivo* antitumor reactivity. *In vitro* depletion of specific V β subsets from the whole TDLN pool confirmed that the profile of cytokine released correlated with *in vivo* antitumor function. These studies indicate that functional V β subpopulations of effector cells express differential antitumor reactivity, and that selective stimulation of tumor-sensitized T cells is feasible and may represent a more efficient method of generating therapeutic T cells for therapy.

Application of cell subsets for successful T cell therapy should include two approaches: identification of T cell subsets responsible for mediating antitumor reactivity as discussed above, and simultaneously, the elimination of those subsets that are non-reactive or even suppressive. Characterization of regulatory CD4⁺CD25⁺ T cell subpopulation in terms of their potential suppressive effects on anticancer effector cells would warrant further investigations in this area. A current study showed that CD8⁺ T cell immunity against a tumor self-antigen is augmented by CD4⁺ T helper cells, but hindered by naturally occurring CD4⁺CD25⁺ T regulatory cells (Treg cells)(41). Adoptive transfer of tumor-reactive CD8⁺ T cells plus CD4⁺CD25⁻ Th cells into CD4-deficient hosts induced autoimmunity and regression of established melanoma. However, transfer of CD4⁺ T cells that contained a mixture of CD4⁺CD25⁻ and CD4⁺CD25⁺ Treg cells or Treg cells alone prevented effective adoptive immunotherapy. These findings thus

suggest that adoptive immunotherapy requires the absence of naturally occurring CD4⁺CD25⁺ Treg cells to be effective, and the optimal composition of a cellular agent should be composed of CD8⁺ cells plus CD4⁺CD25⁻ cells.

ADOPTIVE T CELL IMMUNOTHERAPY OF CANCER IN LYMPHOPENIC HOST

Studies in the late 1970s demonstrated that the induction of lymphopenia by sublethal total body irradiation can be beneficial for the treatment of tumors in mice (42). Chang et al. reported that the adoptive transfer of immune cells in the irradiated host confers improved therapeutic effects compared to the normal host (43). The role of lymphodepletion on the efficacy of T cell therapy is incompletely understood and may depend on the destruction of CD4⁺CD25⁺ regulatory cells, interruption of homeostatic T cell regulation, or abrogation of other normal tolerogenic mechanisms. A report by Dummer et al. indicated that the reconstitution of the lymphopenic, sublethally irradiated murine host with syngeneic T cells triggered an antitumor autoimmune response that required expansion within lymph nodes (44).

There are several different animal models of lymphopenia that can be utilized. These include the use of whole body irradiation (WBI), chemotherapy-induced, or genetically altered hosts (i.e., RAG1 knockout mice) that are deficient of T and B cells. The use of various chemotherapeutic agents to induce lymphopenia would simulate the clinical setting. Cyclophosphamide (CTX) is an agent that has been extensively used in murine models and is actively used in the therapy of certain human cancers. It has been described to eliminate tumor-induced suppressor cells in both animal and human settings.

A few years ago, a report described a phase I study of the adoptive transfer of cloned melanoma antigen-specific T lymphocytes for therapy of patients with advanced melanoma (45). Clones were derived from peripheral blood lymphocytes or TILs of patients. Twelve patients received two cycles of cells. Peripheral blood samples were analyzed for persistence of transferred cells by TCR-specific PCR. Transferred cells reached a maximum level at 1 h after transfer, but rapidly declined to undetectable levels by 2 weeks. The lack of clinical effectiveness of this protocol suggested that transfer of different or additional cell types, or that modulation of the recipient host environment was required for successful therapy. Relevant to these studies is the clinical experience reported by Rosenberg and co-workers who infused tumor-reactive T cells in melanoma patients after a nonmyeloablative conditioning regimen (cyclophosphamide/fludarabine) (46). Conditioning with the nonmyeloablative chemotherapy before adoptive transfer of activated tumor-reactive T cells enhanced tumor regression and increased the overall rates of objective clinical responses. Six of thirteen patients demonstrated significant clinical responses as well as autoimmune melanocyte destruction. In a follow up of this experience in 25 patients, the conditioning regimen was given prior to adoptive T cell therapy as before (47). Examination of the T cell persistence through analysis of the specific TCR demonstrated

that there was a significant correlation between tumor regression and the degree of persistence in peripheral blood of adoptively transferred T cell clones. Transferred cells persisted for as long as 2 months in the lymphopenic setting induced by the conditioning regimen. In contrast, they presented in the blood for only 2 or 3 weeks without the prior chemotherapy. These series of studies strongly suggest that the lymphopenic host induced by the non-myeloablative conditioning regimen may provide a better environment for the functioning of the transferred T cells, and hence improve their therapeutic efficacy. Examination of the mechanisms involved in the reconstitution of the lymphodepleted host after adoptive T cell transfer will be important in identifying methods to improve the efficacy of T cell therapies for cancer.

REDIRECT EFFECTOR T CELLS TO TUMOR

As mentioned earlier, the low precursor frequency of tumor-specific T cells in patients hampers routine isolation of these cells for adoptive transfer. To overcome this problem, "targeted adoptive immunotherapy" or "genetic adoptive immunotherapy" has become an attractive option for cancer treatment. This strategy can be approached in two ways: introduction of a chimeric TCR into effector cells; or introduction of a tumor-specific TCR into naïve cells.

The T-body approach uses patient-derived lymphocytes transfected with chimeric receptor genes constructed with the variable domains of monoclonal antibodies or cytokines linked to the constant regions of TCR. The rationale for this novel approach to redirect effector cells combines the effector functions of T lymphocytes with the ability of antibodies or cytokines to recognize predefined surface antigens or cytokine receptors with high specificity and in a non-MHC restricted manner.

Eshhar et al. (48) was one of the first to describe this approach by developing a chimeric receptor gene which recognized trinitrophenyl (TNP). Retroviral transduction of the anti-TNP/TCR chimeric gene into a T cell hybridoma line resulted in gene expression. These gene modified T cells were cytolytic and released IL-2 in response to TNP-labeled Daudi cells, but not unlabeled cells. Also among the pioneers in this area, Hwu et al. (49) developed a recombinant chimeric receptor against an epitope expressed on the majority of ovarian cancer cell lines. The TIL were transduced with this chimeric gene and evaluated for immunologic function. The gene modified TIL showed specific lysis of an ovarian carcinoma cell line, but not nonovarian cell lines. In a direct comparison, the gene modified TIL showed greater therapeutic efficacy *in vivo* than the nontransduced TIL (49). Pinthus et al. evaluated the therapeutic efficacy of anti-erbB2 chimeric receptor-bearing human lymphocytes on human prostate cancer xenografts in a SCID mouse model (50). Local delivery of erbB2-specific transgenic T cells to well-established subcutaneous and orthotopic tumors resulted in retardation of tumor growth and prolongation of animal survival. In a setting of metastatic cancer (51), anti-erbB2 chimeric receptor-modified T cells killed breast cancer cells and secreted IFN γ in an Ag-specific manner *in vitro*. Treatment of established metastatic dis-

ease in lung and liver with these genetically engineered T cells resulted in dramatic increases in survival of the xenografted mice. In another report, CD4⁺ cells isolated from the peripheral blood and engrafted with a recombinant immunoreceptor specific for carcinoembryonic Ag (CEA) efficiently lysed target cells in a MHC-independent fashion, and the efficiency was similar to that of grafted CD8⁺ T cells (52). In an attempt to further improve the therapeutic utility of redirected T cells, T lymphocytes were transferred with CEA-reactive chimeric receptors that incorporate both CD28 and TCR-zeta signaling domains. T cells expressing the single-chain variable fragment of Ig (scFv)-CD28-zeta chimera demonstrated a far greater capacity to control the growth of CEA⁺ xenogeneic and syngeneic colon carcinomas *in vivo* compared with scFv-CD28 or scFv-zeta transfected T cells. This study has illustrated the ability of a chimeric scFv receptor capable of harnessing the signaling machinery of both TCR-zeta and CD28 to augment T cell immunity against tumors (53).

In addition to antibodies, cytokines could also be used to reconstruct chimeric TCRs. The IL-13 receptor alpha2 (IL-13R α 2) is a glioma-restricted cell-surface epitope not otherwise detected within the central nervous system. Kahlon et al. (54) described a novel approach for targeting glioblastoma multiforme (GBM) with IL-13R α 2-specific CTLs. The chimeric TCR incorporates IL-13 for selective binding to IL-13R α 2. This represents a new class of chimeric immunoreceptors that signal through an engineered immune synapse composed of membrane-tethered cytokine (IL-13) bound to cell-surface cytokine receptors (IL-13R α 2) on tumors. Human IL-13-redirection CD8⁺ CTL transfectants display IL-13R α 2-specific antitumor effector function including tumor cell cytotoxicity and cytokine production. *In vivo*, the adoptive transfer of genetically modified CTL clones resulted in the regression of established human glioblastoma orthotopic xenografts.

The second genetic approach to redirect T cells involves the introduction of tumor-specific TCRs into naïve cells. Genes encoding tumor antigen-specific TCRs can be introduced into primary human T cells as a potential method of providing patients with a source of autologous tumor-reactive T cells. Several tumor-associated antigens have been identified and cloned from human tumors, such as melanoma, breast cancers, and RCC. The antigens have been identified by their ability to induce T cell reactivity by their binding to the TCR $\alpha\beta$ complex. The subsequent cloning of functional TCR genes capable of recognizing tumor-associated antigens offers a potential opportunity to genetically modify naïve cells that have not been previously exposed to tumor antigen and to become competent in recognizing tumor. Cole et al. (55) transfected the cDNA for the TCR α and β chains of an HLA-A2 restricted, melanoma-reactive T cell clone into the human Jurkat T cell line. The transfected line was able to mediate recognition of the melanoma antigen, MART-1, when presented by antigen-presenting cells. This represented the first report of a naïve cellular construct designed to mediate functional tumor antigen recognition. A recent study explored the simultaneous generation of CD8⁺ and CD4⁺ melanoma-reactive T cells by retroviral-mediated transfer of a TCR specific for HLA-A2-restricted epitope of the melanoma antigen tyrosinase

(56). The TCR-transduced normal human peripheral blood lymphocytes secreted various cytokines when stimulated with tyrosinase peptide-loaded antigen-presenting cells or melanoma cells in an HLA-A2-restricted manner. Rosenberg and co-worker (57) isolated the α and β chains of the TCR from a highly avid anti-gp100 CTL clone and constructed retroviral vectors to mediate gene transfer into primary human lymphocytes. The biological activity of transduced cells was confirmed by cytokine production following coculture with stimulator cells pulsed with gp100 peptides, but not with unrelated peptides. The ability of the TCR gene to transfer Ag recognition to engineered lymphocytes was confirmed by HLA class I-restricted recognition and lysis of melanoma tumor cell lines. In addition, nonmelanoma-reactive TIL cultures developed antimelanoma activity following anti-gp100 TCR gene transfer. Together, these studies suggest that lymphocytes genetically engineered to express melanoma antigen-specific TCRs may be of value in the adoptive immunotherapy of patients with melanoma.

The HPV16 (human papilloma virus type 16) infection of the genital tract is associated with the development of cervical cancer in women. The HPV16-derived oncoprotein E7 is expressed constitutively in these lesions and represents an attractive candidate for T cell mediated adoptive immunotherapy. In a recent study, Scholten et al. reported that HPV16E7 TCR gene transfer is feasible as an alternative strategy to generate human HPV16E7-specific T cells for the treatment of patients suffering from cervical cancer and other HPV16-induced malignancies (58). These TCR genes specific for HPV16E7 were isolated and transferred into peripheral blood-derived CD8⁺ T cells. Biological activity of the transgenic CTL clones was confirmed by lytic activity and IFN γ secretion upon antigen-specific stimulation. Most importantly, the endogenously processed and HLA-A2 presented HPV16E7 CTL epitope was recognized by the TCR-transgenic T cells. In a separate study, ovalbumin (OVA)-specific CD4⁺ cells were successfully generated. Chamoto et al. (59) prepared mouse antigen-specific Th1 cells from nonspecifically activated T cells after retroviral transfer of TCR genes. These Th1 cells transduced with the α and β genes of the I-A (d)-restricted OVA-specific TCR produced IFN γ in response to stimulation with OVA peptides or A20 B lymphoma cells expressing OVA as a model tumor antigen. The TCR-transduced Th1 cells also exhibited cytotoxicity against tumor cells in an antigen-specific manner. In addition, adoptive transfer of TCR-transduced Th1 cells exhibited potent antitumor activity *in vivo*.

Genetic alteration of T cells with chimeric receptor genes or antigen-specific TCR genes confers the redirection of effector cells to the tumor for its destruction. These approaches may offer novel opportunities to develop immunocompetent effector cellular reagents and improve the efficacy of adoptive immunotherapy of cancer.

COMBINED THERAPY

Cancer is a disease that involves multiple gene malfunctions and numerous biochemical and cellular event errors during its development and metastasis within an indivi-

dual. Therefore, it is difficult to achieve success utilizing adoptive T cell transfer as a monotherapy. The above-reviewed use of vaccination to induce tumor-reactive pre-effector *in vivo*; the coadministration of immune adjuvant with T cell transfer; and the gene therapy to redirect T cells to tumor are all among the strategies taken to elicit and/or strengthen the efficacy of T cell therapy. Combination therapy is a very common practice during the treatment of diseases. Active vaccine therapy, for example, can be used in concert with chemotherapy, radiotherapy, or antibody therapy. Combining a glioma tumor vaccine engineered to express the membrane form of macrophage colony-stimulating factor with a systemic antiangiogenic drug-based therapy cured rats bearing 7 day old intracranial gliomas (60). We successfully demonstrated that local radiotherapy potentiates the therapeutic efficacy of intratumoral dendritic cell (DC) administration (61), and that anti-CD137 monoclonal antibody administration augments the antitumor efficacy of DC-based vaccines (62).

In order to enhance the efficiency of T cell therapy, various strategies have been employed accompanying cell transfer. These combined therapies include cell transfer in combination with intratumoral expression of lymphotactin (63), DC vaccination (64), or blockade of certain molecules expressed in tumor cells, such as B7-H1 (65).

One of the major obstacles to successful adoptive T cell therapy is the lack of efficient T cell infiltration of tumor. Combined intratumoral lymphotactin (Lptn) gene transfer into SP2/0 myeloma tumors and adoptive immunotherapy with tumor specific T cells eradicated well-established SP2/0 tumors in six of eight mice, and dramatically slowed down tumor growth in the other two mice (63). Cell tracking using labeled T cells revealed that T cells infiltrated better into the Lptn-expressing tumors than non-Lptn-expressing ones. These data provide solid evidence of a potent synergy between adoptive T cell therapy and Lptn gene therapy as a result of facilitated T cell targeting. Dendritic cells are well-known potent antigen-presenting cells. Hwu and co-workers (64) reported that DC vaccination could improve the efficacy of adoptively transferred T cells to induce an enhanced antitumor immune response. Mice bearing B16 melanoma tumors expressing the gp100 tumor antigen were treated with activated T cells transgenic for a TCR specifically recognizing gp100, with or without concurrent peptide-pulsed DC vaccination. Antigen-specific DC vaccination induced cytokine production, enhanced cell proliferation, and increased tumor infiltration of adoptively transferred T cells. The combination of DC vaccination and adoptive T cell transfer led to a more robust antitumor response than the use of each treatment individually. This work shows that in addition to their ability to initiate cell-mediated immune responses by stimulating naive T cells, dendritic cells can strongly boost the antitumor activity of activated T cells *in vivo* during adoptive immunotherapy. Certain cell surface molecules, expressed either on tumor cells or on T cells, have demonstrated have demonstrated potential suppressive impact on the adoptive T cell immunotherapy. For example, during the last few years, new members of the B7 family molecules have been identified, for example, B7-H1, which

is constitutively expressed on 66% of freshly isolated squamous cell carcinomas of the head and neck (SCCHN) (65). When B7-H1-negative mouse SCC line, SCCVII, was transfected to express B7-H1, all of the animals succumbed to B7-H1/SCCVII tumors even after adoptive T cell immunotherapy. However, the infusion of B7-H1 blocking monoclonal antibody with activated T cells cured 60% of animals. The data support B7-H1 blockade as a new approach to enhance the efficacy of T cell immunotherapy. These findings also illuminate a new potential application for the blockade of certain "negative costimulation molecules" on T cells, for example, CTLA-4 and programmed death-1 (PD-1) molecules. This kind of blocking may augment the therapeutic efficacy mediated by the transferred T cells. The blockade can be done using specific monoclonal antibodies, soluble ligands for CTLA-4 or PD-1, or by synthesized antagonists. In addition, effector cells can be derived from the animals deficient in the relevant molecules for preclinical investigations.

Immune tolerance of tumor-bearing host represents another major obstacle for the successful use of adoptive T cell immunotherapy. A recent study examined the requirement for assistance to the low affinity tumor-specific CD8⁺ T cells transferred into tumor-bearing mice (66). The TCR transgenic mice expressing a class I-restricted hemagglutinin (HA)-specific TCR (clone 1 TCR) were generated. Upon transfer into recipient mice in which HA is expressed at high concentrations as a tumor-associated Ag, the clone 1 TCR CD8⁺ T cells exhibited very weak effector function and were soon tolerized. However, when HA-specific CD4⁺ helper cells were co-transferred with clone 1 cells and the recipients were vaccinated with influenza, clone 1 cells were found to exert a significant level of effector function and delayed tumor growth. This work shows that in order to optimize the function of low avidity tumor-specific T cells after adoptive transfer, additional measures need to be taken to help break the host tolerance.

Effective tumor therapy requires a proinflammatory microenvironment that permits T cells to extravasate and to destroy the tumor. Proinflammatory environment can be induced by various chemical, physical, and immunological protocols. Greater extent of success can be expected by combining adoptive T cell therapy with the traditional cancer treatment methods, for example, surgery, chemotherapy, and radiation therapy, as well as with different forms of immunotherapeutic strategies, such as vaccine, antibody, cytokines, gene therapy, and so on. The factors to be combined can involve two or more approaches.

In summary, adoptive immunotherapy utilizing tumor-reactive T cells offers a promising alternative approach for the management of cancer. Through the endeavors of clinical and basic research scientists during the last two decades, the process of adoptive T cell therapy of cancer has evolved from its original single-step approach into its current multiple-step procedure. Successful T cell immunotherapy of cancer is the outcome of this multi-step process that depends on successful Ag priming, numerical amplification of low frequency Ag-specific precursors, use of immune adjuvants, and efficient infiltration of tumors in all metastatic sites by effector T cells. New directions in

this field include the identification and application of tumor-reactive subpopulation of T cells, creation of a lymphopenic environment in the recipient host, and the redirection of the effector cells toward the tumor. Development of these latter techniques and the combined use of different therapeutic strategies may further improve the efficacy of the immunotherapy of human cancer employing adoptive T cell transfer. Studies and developments of immunotherapy for cancer should accelerate the application of this strategy in infectious disease, autoimmune disease and other disease managements.

IMPEDANCE PLETHYSMOGRAPHY

HELMUT HUTTEN
University of Technology
Graz, Australia

INTRODUCTION

Plethysmography is a volumetric method, that is, a method for the assessment of a volume (the Greek words *plethys* and *plethora* mean full and fullness, respectively). Impedance plethysmography is based on the measurement of passive electrical properties of biological tissues. Those passive electrical properties are parameters of the so-called bioimpedance. The first publication about impedance plethysmography by Nyboer et al. (1) dates back to 1943. Pioneering contributions to the basic understanding of the relations between the assessment of volumes by impedance plethysmography and the electrical properties of biological tissue have been provided by Schwan et al. (2) already in 1955. But already by the end of the nineteenth century Stewart had used the recording of electrical conductivity to study transit times between different sites of the body after injection of saline into the circulation (3). Blood flow record-

ing is one of the most relevant fields for the clinical application of impedance plethysmography nowadays.

Impedance plethysmography is a volumetric method that aims to assess a volume or changes of a volume. Usually, a volume is the filling volume of a space that is enclosed by geometric boundaries. In this case, volumetry means the determination of the boundaries with subsequent assessment of the volume within the boundaries. Those boundaries can be determined by the impedance method if the electrical properties of the substances on both sides of the boundaries are different.

Impedance plethysmography, however, can also be applied to the assessment of volumes that are not lumped compartments within geometric boundaries, for example, it can be used for the volumetric measurement of a certain component within a mixture. Such components may be cells (e.g., the volume of cells in blood), tissues (e.g., the volume of fat tissue in the body), spaces with different composition (e.g., intra- and extracellular spaces), or the volume of the air that is enclosed in the alveoli of lung tissue. In that case, volumetry means the estimation of the space that would be occupied by the respective component if it would be concentrated in one single lumped compartment. Usually, this volume is estimated as a percentage of the whole distribution volume, for example, the volume of cells in blood or the content of water in the whole body. The electrical properties of the respective component must be different from those of all other components. The volumetric assessment does not require a homogeneous distribution of the considered component within the given space if the actual distribution can be taken into account, for example, by a model. Under certain conditions, a tissue can be identified by specific features like morphological structure and/or chemical composition if those features are related with its electrical properties.

The typical application of plethysmography in clinical routine is the diagnosis of those diseases for which the measurement of volumes or changes of volume renders possible the interpretation of functional disorders or functional parameters. The most widely and routinely applied diagnostic examinations are concerned with:

1. Heart: Cardiac mechanical disorders by impedance cardiography (i.e., pumping insufficiency by measuring cardiac stroke volume, including heart rate and other cardiac parameters like ejection period). This application is discussed in another article.
2. Peripheral circulation: Vascular disorders by impedance rheography (i.e., deep venous thrombosis by impedance phlebography, and estimation of blood flow in the brain or other peripheral vessels).
3. Lung: Ventilatory disorders by impedance pneumography (i.e., insufficient ventilation by monitoring the tidal volume and/or respiratory rate).

METHODOLOGY

Impedance plethysmography is a noninvasive method that employs contacting, usually disposable electrodes, in most cases metal-gel electrodes, for example, with Ag/AgCl for

the metal plate. Usually, the electrodes have circular geometry; however, other geometries might be preferable, for example, band-like geometry for segmental measurement at the extremities. It must be considered that the metal plates of electrodes are areas with the same potential, and therefore may affect the electromagnetic field distribution in the considered object. Electrodes with small areas help to reduce that effect, whereas electrodes with large areas render it possible to reach a more homogenous current field in the measured object.

Contacting electrodes can easily be attached to the skin or surface of the measurement object, usually by an adhesive material that is already fixed to the electrode. Only in special cases, for example, for research purposes, does the measurement require invasive application.

Different contactless measurement modes gain increasing attention, for example,

1. Microwave-based methods with antennas as applicators and measurement of the scattered electromagnetic field.
2. Methods based on exploiting the magnetic instead of the electrical properties: inductive plethysmography that uses coils and records the changes in the inductance and magnetic susceptibility plethysmography that employs strong magnetic fields and records the changes in the magnetic flux, for example, by superconducting quantum interference devices (SQUID).

All bioimpedance-based methods are aiming at recording either the effect on the applied electromagnetic field by the measurement object or the response of the measurement object to the application of the electromagnetic field. The directly measured quantities are electrical quantities, for example, voltages or currents. Those quantities are actually imaging electrical coefficients, for example, conductivity, permittivity, or resistivity, which are material-specific parameters of the tissue impedance and monitor its morphological structure and/or chemical composition. With these material-specific parameters the geometric boundaries are determined and used for the estimation of the volume or volume changes. Relations between the measured electrical parameters and the volume are usually based on models. The employed models can be very simple, for example, described by simple geometric boundaries like cylinders, spheres, or ellipsoids. More complex 3D models may be described by the finite element method (FEM) or similar approaches, which allows simulating the distribution of the electromagnetic field in the measured object, that is, the current pathways and the iso-potential planes. Sophisticated iterative optimization procedures are employed to match the simulated values with the measured ones (4).

Electrical impedance tomography (EIT) is a direct approach for determining the 3D geometry of those compartments with the same material-specific parameters in a biological object like the human torso or an extremity. This technique uses multiple electrodes, usually arranged in a plane. Mapping (or imaging) of the impedance distribution in the examined cross-sectional layer requires the solution of the inverse or back-projection problem. Actually, the

obtained 2D image is a pseudo-3D image since the current pathways are not constrained to the examined layer. Electrical impedance tomography supplies a comparable near-anatomic cross-sectional image comparable to those of other CT-based procedures [e.g., X-ray CT, NMR, or ultrasound (US)], however, with very poor spatial resolution. Boundaries of compartments with the same material-specific coefficients are found by segmentation. Segmented areas with assumed thickness of the single layers are used for volume estimation. Changes in the volume can be assessed by comparing the volumes obtained in consecutive images.

It is a characteristic feature of all methods that record the electrical bioimpedance that the evoked response depends on the strength of the local electromagnetic field. For this reason, it has to be taken into account that the resulting current density may be inhomogeneous in the considered tissue volume. Causes for such nonhomogeneity may be geometric constraints (e.g., a nonregular shape of the considered volume); the composition of the tissue within the considered volume that may be a mixture of tissues with different electrical properties (e.g., blood with low resistivity, or bone with high resistivity, as compared with skeletal muscle). Those different tissues may electrically be switched in parallel or serial order; and the size and the location of the current-feeding electrodes. The current density is higher in regions near to the feeding electrodes than in distant regions. Consequently, the regions near to the feeding electrodes give the strongest contribution to the measured voltage.

This requires (1) careful selection of the current-feeding site. In the tetrapolar mode also the position of the voltage-sensing electrodes must be taken into account; and (2) appropriate consideration of the inhomogeneous distribution of the electrical parameters within the considered tissue volume, that is, the course of blood vessels.

Special electrode arrangements have been developed for certain applications in order to minimize the measurement errors. Concentric multielectrode arrangements with the outer electrodes on a potential different from that of the inner electrode have been proposed with the objective to optimize the current distribution in the measured volume.

The frequency that can be used for the measurement of the passive electrical properties of biological tissue ranges from very low frequencies to some gigahertz. The most popular frequency band for impedance plethysmography is between 1 kHz and 10 MHz. This frequency band encloses the so-called β -dispersion, which is actually a dielectric or structural relaxation process. The β -dispersion is also known as Maxwell–Wagner relaxation. It is characterized by a transition in the magnitude of the electrical parameters with frequency. This transition is caused by the fact that cellular membranes have high impedance below and low impedance above that β -dispersion. For frequencies distinctly below the β -dispersion, the current flow is restricted to the extracellular space. For frequencies distinctly above the β -dispersion, the current can pass through the cellular membrane. Consequently, with frequencies distinctly below the β -dispersion only the volume or volume changes of the extracellular space will be monitored, whereas with frequencies distinctly above the

^aNote that those values must not be assumed to represent exact figures since they do not consider important details like species, preparation of sample, time after excision, temperature, or the procedure and protocol for their measurement. The values are compiled from many different sources and, if necessary transformed to resistivity.

β -dispersion, the total volume (i.e., both extra- and intracellular space) or changes of this total volume can be recorded. Using at least one frequency below and another one above the β -dispersion allows determining the ratio of extra- and intracellular spaces, and hence also fluid shifts between these spaces.

Special applications of this approach are the monitoring of fluid exchange processes during hemodialysis (5) and orthostatic challenges (6), the control and management of fluid infusion therapy, the detection of lung edema, and the viability surveillance of organs after blood flow has been stopped during surgery or when the organs are preserved for transplantation (7,8). The viability surveillance is based on the fact that oxygen deficiency with the subsequent lack of energy-rich substrates causes a failure of the active transmembrane ionic transport mechanisms and, as a consequence, leads to an intracellular edema (i.e., an increase of the intracellular volume). This approach has also been investigated for graft rejection monitoring.

The passive electrical properties are specific for each tissue. They are mainly depending on the content of water, the ratio of extra- and intracellular space, the concentration of electrolytes, and the shape of the cells and their orientation in the electrical field (e.g., of the fibers of skeletal and cardiac muscle). Table 1 shows a compilation of typical values of resistivity of various body tissues. It must be taken into account, however, that these values do not represent exact figures. Exact figures need detailed information about species, preparation of the sample, time after excision, measurement temperature, the employed method, and the protocol for the measurement. Comprehensive data compilations with the supplement of those details are found in Refs. 9 and 10.

These tissue-specific properties can be used for special applications, such as the analysis of the tissue composition or for tissue characterization by Impedance Spectroscopy. Those methods are the subject of another article and will not be discussed here in detail. A very popular application is the determination of total body water (11) or of whole body composition, for example, the determination of the percentage of body fat in order to support adequate nutrition management or control of physical exercises. Such approaches aim for the estimation of the compartmental volume of a certain tissue (e.g., fat) that is mixed with

another tissue (e.g. fat-free tissue) in a common space (i.e., the body or an extremity).

FUNDAMENTALS OF BIOIMPEDANCE MEASUREMENT

The most important principle for bioimpedance measurements is the adequate modeling of the passive electrical behavior of the tissue by an equivalent electrical circuit. The validity of simple models is restricted to narrow frequency ranges (e.g., the β -dispersion) and/or to simple geometric shapes of the biological object (e.g., cylinders as a model for extremities). The most widely accepted models for the bioimpedance in the frequency range around the β -dispersion are the RC -networks shown in Fig. 1. These models represent the spatially distributed electrical properties by discrete components. Actually, they are only simplified 2D models. The network shown in Fig. 1a is mimicking the biological system and its histological structure. It represents both the extracellular and intracellular space by the resistors R_e and R_i , respectively, and the cell membrane by the capacitor C_m . Since the current passes twice the membrane when flowing through the cell, the two capacitors C_m^* in series with R_i can equivalently be expressed by one single capacitor C_m in series with R_i . This network is usually replaced by the one shown in Fig. 1b in which R_s is arranged in series with the parallel circuit of R_p and C_p . These components have no relation with real histological structures. The parameter R_s corresponds to the parallel circuitry of R_e and R_i as can be demonstrated for high frequencies. The parameter R_s can be considered to be very small as compared with R_p . In many cases, R_s may

Figure 1. RC -networks modeling tissue impedance. The model in (a) mimicks morphological structures, whereas the model in (b) shows the electrically equivalent, but, more usual circuitry.

Figure 2. Bioimpedance measurement set-up. (a) Shows the two-electrode configuration, whereas the four-electrode configuration is depicted in (b).

even be neglected for cases of simplification, that is, the electrical model is simply a parallel circuit of a resistor and a capacitor (e.g., $R_p || C_p$).

When using contacting electrodes, different approaches are possible for the measurement of the bioimpedance. The most important feature is the number of employed electrodes, usually two or four electrodes. More than 4 electrodes, up to 128 electrodes, are primarily used for CT-based impedance imaging like EIT. The two-electrode configuration is called the bipolar mode, and the four-electrode configuration is the tetrapolar mode (Fig. 2). The bipolar mode can be compared with the usual method for impedance measurement by feeding a current into the measurement object and recording the voltage or vice versa. In the tetrapolar mode, two electrodes are the feeding electrodes (usually the outer electrodes) and the other two electrodes are the sensing electrodes (usually the inner ones). In the tetrapolar mode, more than two sensing electrodes can be employed, for example, if monitoring of serial segments at the extremities are to be achieved.

The interface between the electrode with the metallic plate on the one side and the electrolyte on the other side is the boundary where a current carried by electrons is transformed into a current carried by ions. The electrolyte may either be contained in the gel of the electrodes or be the electrolytic fluid in the tissue. The basic process of the charge transfer from electrons to ions is a chemical reaction (12). The simplest model of such an interface is again an impedance consisting of a parallel circuit with a resistor R_F (the Faraday resistance) and a capacitor C_H (the Helmholtz capacitance), i.e., $R_F || C_H$ (Fig. 3b). Real electrodes show a polarization effect that is caused by a double layer of opposite charges at the interface, actually the Helmholtz capacitance (Fig. 3a). Therefore, the electrode model with $R_F || C_H$ has to be supplemented with an additional voltage source E_P . The steady-state condition is reached if the tendency of metallic ions to enter the electrolyte and leave behind free electrons is balanced by the electrostatic voltage originating from the double layer. After disturbances, for example, by charge transfer forced by an externally applied voltage, another equilibrium for the double-layer voltage is reached with a time constant depending on R_F and C_H . All these components may have poor stability with time, especially in the period immediately after attaching the electrode on the skin. For surface electrodes, it must also be taken into account that the impedance of the skin, especially the stratum corneum, which is the outmost

epidermal layer, can be much larger than the impedance of the deeper tissue (e.g., skeletal muscle), which is in a complex parallel-serial arrangement with the skin. Sweating underneath the electrode lowers the electrode-tissue transimpedance. For the measurement of the impedance of deeper tissues the adequate preparation of the skin by abrasion, stripping, or puncturing at the site of the electrodes might be necessary in order to diminish the transimpedance. This transimpedance depends on the size of the electrode (i.e., the contacting area) and the measurement frequency, and . . . additionally on the pressure with which the electrode is attached to the skin. For electrodes, a typical value for the transimpedance is $\sim 100\text{--}200 \Omega \cdot \text{cm}^2$.

In the bipolar mode, the two electrode–electrolyte interfaces are in series with the actual bioimpedance of the measured object. Therefore, the recorded impedance is always the sum of at least three impedances. The impedance of the biological sample cannot be calculated as an individual quantity from the recorded impedance value. This is the most serious shortcoming of the bipolar mode.

In the tetrapolar mode, the electrode–electrolyte interface usually can be neglected if the measurement is performed with a device with high input impedance (i.e., with very low current passing across the electrode–tissue inter-

Figure 3. Metal electrode: electrolyte interface. (a) Illustrates the steady-state condition at the boundary. Following the tendency of metallic ions (Me^+) to enter the electrolyte and to leave behind free electrons, the steady state is reached when this tendency is balanced by the electrostatic voltage originating from the double layer. (b) Shows the simplified model with only the passive electrical components, that is, the Faraday resistance R_F and the Helmholtz capacitance C_H .

face). A drawback of the tetrapolar mode, however, is that the measured impedance value cannot be exactly assigned with a certain volume of the tissue between the sensing electrodes, even if the sensing electrodes are positioned on a straight line connecting the two feeding electrodes. Band electrodes that are attached at the whole circumference (e.g., at the extremities), yield more valid results. If circular electrodes are applied and both the feeding and the sensing electrodes are placed on the circumference of a cross-section (e.g., around the thorax or the head), it is nearly impossible to assign the actually measured impedance value with a certain volume within that cross-section due to the complex current field. In those cases, the monitored volume consists of a serial-parallel circuitry of different tissue layers with different electrical properties (e.g., skin, subcutaneous soft tissue, bone, deeper tissues). For this reason, the result of ventilation measurements with electrodes, either disk or band electrodes, placed on the thorax may be affected by the higher conductivity of extra-thoracic muscles as compared with the very low conductivity of the rib cage, which prevents the entrance of current into the pulmonary tissue that is actually the object of interest. Sweating may additionally cause another low impedance parallel circuit along the skin and, thus, yield considerable measurement errors. The situation is similar for the measurement of brain parameters, for example, brain–blood flow or brain edema, with electrodes placed on the scalp. Since the conductivity of the extra-cranial soft tissue (e.g., skin, muscle) is much higher than the conductivity of the bony skull, only few current pathways will pass through the brain.

The different instrumental approaches for measuring the bioimpedance in the frequency range of the β -dispersion are the impedance bridge (e.g., an extension of the classical Wheatstone bridge); the self-balanced active bridge; the resonance method that is mainly a compensation method; the pulse method that is a time domain procedure and not widely used; the voltage-current method, based either on feeding a constant voltage (i.e., from a generator with low source impedance) and monitoring the resulting current or on feeding a constant current (i.e., from a generator with a sufficiently high source impedance, ~ 100 k Ω since the load impedance may be up to 1 k Ω) and monitoring the resulting voltage. If employing the bipolar mode, it would be more correct in this case to use the term transimpedance than impedance for the actually measured quantity between the electrodes.

For the tetrapolar configuration only the voltage-current method is applicable. Phase angle measurements employ an ohmic resistor in series with the measuring object as reference. Absolute phase angle measurements are questionable even for the bipolar configuration since the measured phase angle always includes the phase shifts that are caused by the two electrode–skin contacts and depend on the actual values of the Faraday resistance and the Helmholtz capacitance. If the Faraday resistance is small and the Helmholtz capacitance is fairly large, the phase shift by the electrode–skin interface may become negligible. This is one of the advantages of electrodes with artificially increased surfaces, for example, electrodes with porous or fractally coated surfaces that might be obtained

by sputtering or chemical processes, as compared with polished surfaces.

Usually, the measurement is performed with a constant-voltage generator for technical reasons. The applied feeding signal, whether voltage or current, should be sinusoidal with a very low distortion factor (i.e., with a low content of harmonics) and with high stability both in amplitude and frequency. Any modulation of the feeding signal may provoke an additional response for this undesired modulation frequency that has to be avoided with regard to the frequency dependence of the impedance specific variables. The voltage amplitude is in the range of some volts, the current amplitude is in the range of some microamps to milliamps (μA to mA). The changes in the impedance caused by volume changes can be very small, $<0.001\%$. This means that very small changes in the measured current or voltage have to be processed. Hence, the sensitivity and stability of the input amplifier must be very high in order to detect such small changes in the measured signal.

Independent from the measurement method, careful consideration of measurement errors is necessary. A main source of measurement errors may be parasitic components, such as stray capacitances between neighboring wires leading to the sensing electrodes, or between wires and their shielding, or stray capacitances between metallic components of the measuring system and ground, which become the more effective the higher the measuring frequency.

The risk for undesired stimulation of the heart or peripheral nerves if such electrical voltages or currents are applied for monitoring purposes, is negligible, both with regard to the high frequency and the low current density. Furthermore, heating and heat-induced secondary effects can be neglected.

However, proper attention must be paid for the selection of the equipment and its performance data for the intended application. Furthermore, the employed devices must be safe even in case of technical failure. Patient-near devices are directly connected with the patient whereby the connecting impedance is rather low.

CHARACTERISTICS OF BIOIMPEDANCE

The microscopic electrical properties that describe the interaction of an electromagnetic wave with biological tissue are the complex conductivity σ^* with the unit $\Omega^{-1}\cdot\text{m}^{-1}$, $\text{mho}\cdot\text{m}^{-1}$, $\text{S}\cdot\text{m}^{-1}$, or $1\cdot(\Omega\cdot\text{m})^{-1}$

$$\sigma^*(\omega) = \sigma'(\omega) + j\sigma''(\omega)$$

and the complex dielectric permittivity ε^* with the unit F/m

$$\varepsilon^*(\omega) = \varepsilon'(\omega) - j\varepsilon''(\omega)$$

ω is radian frequency with the unit hertz. The electrical properties are depending on the frequency with strong dependence in the range of a dispersion.

The relation between these two quantities can be described in accordance with Ref. 13 by

$$\sigma^*(\omega) = j\omega\varepsilon^*(\omega)$$

With the conduction current that is related with the basic conductivity σ_0 , that is, the current carried by the mobility of ions in the extracellular space, and the polarization current (sometimes called displacement current) that is related with permittivity, the following equations are obtained

$$\begin{aligned}\sigma' &= \sigma_0 + \omega \varepsilon''(\omega) \\ \sigma'' &= \omega \varepsilon'(\omega) = \varepsilon_0 \varepsilon_r(\omega)\end{aligned}$$

where ε_0 is the dielectric permittivity of free space with $\varepsilon_0 = 8.85 \times 10^{-12} \text{ F}\cdot\text{m}^{-1}$, and ε_r is the relative dielectric permittivity (with $\varepsilon_r = 1$ for the free space and $\varepsilon_r = 81$ for water in the low and medium frequency range).

Instead of the complex conductivity σ^* , the inverse complex resistivity ρ^* with the unit $\Omega\cdot\text{m}$ can be used. The resistivity is usually preferred in the context of impedance plethysmography:

$$\rho^*(\omega) = \rho'(\omega) + j\rho''(\omega)$$

The complexity of these quantities considers the fact that in the alternating current (ac) range the biological tissue cannot adequately be described by a simple resistance (or its inverse conductance), but needs the extension to a complex quantity, that is, impedance or admittance. Some authors prefer the term Admittance Plethysmography instead of Impedance Plethysmography (14,15). The simplest adequate model for such an impedance is represented by a resistance and a reactance. The resistance causes the loss in power, whereas the reactance causes the delay (or 18 phase shift) between voltage and current. The dominating reactance of bioimpedance in the frequency range of interest is capacitive and becomes more relevant for higher frequencies. Only for very high frequencies that usually are not employed for impedance plethysmography, can the reactance be composed by both a capacitive and an inductive component.

Bioimpedance can be described like any technical impedance in different forms, for example, by its magnitude (or modulus) Z_0 and its phase angle (or argument) φ , (i.e., the delay between voltage and current):

$$Z = Z_0 e^{j\varphi}$$

or by its real part (or resistance) $\text{Re}\{Z\}$ and its imaginary part (or reactance) $\text{Im}\{Z\}$:

$$Z = \text{Re}\{Z\} + j\text{Im}\{Z\}$$

Alternating current voltages and ac currents, too, can be expressed as complex quantities, that is, by their magnitude and phase angle, or by their real and imaginary part although this is rather unusual. The magnitude of the impedance Z_0 corresponds to the quotient of the magnitudes of voltage V_0 and current I_0 , that is,

$$Z_0 = V_0/I_0$$

Appropriate modeling of the electrical properties of biological tissue by discrete and lumped electrical components renders possible the proper consideration of multilayer or compartmentally composed tissues with different electrical properties of each layer or compartment. Such tissues can

be modeled as serial, parallel, or serial–parallel equivalent circuits in 2D presentation. More recently, the modeling has been extended to 3D models using the FEM or comparable approaches.

The impedance parameters can be depicted in different modes as a function of frequency (Fig. 4). The presentation of the magnitude (usually in logarithmic scale with regard to its wide range) and the phase angle against the frequency over several decades, and therefore in logarithmic scale is known as the Bode plot. A similar presentation is used for both the real and imaginary part versus the frequency on the x axis. This mode of presentation is sometimes called the spectrum (e.g., modulus spectrum and phase angle spectrum). A different form of presentation is in a plane with the real part along the x axis and the imaginary part along the y axis, both in linear scaling, with the frequency as parameter. This mode of presentation is frequently called the Cole–Cole-plot (but also the Nyquist plot, locus plot, or Wessel graph). The same modes of

Figure 4. Different modes for the presentation of impedance quantities. (a) Shows the magnitude (in logarithmic scaling) and the phase angle of impedance as functions of frequency in logarithmic scaling (Bode plot). (b) Shows the real and imaginary part of impedance depicted versus the frequency in logarithmic scaling. (c) Presents the Cole–Cole plot with the real part at the x axis, the imaginary part at the y axis, and the frequency as parameter along the curve. The results shown are not from biological tissue, but calculated for the circuit of Fig. 1b with $R_s = 500 \Omega$, $R_p = 5 \text{ k}\Omega$, and $C_p = 500 \text{ nF}$.

presentation are possible for the complex quantities σ^* , ρ^* , and ε^* .

Usually, impedance plethysmography is accomplished employing only a single measuring frequency or a few discrete measuring frequencies. However, impedance spectroscopy with a multitude of measuring frequencies is gaining interest, especially for the determination of spatially distributed volumes. Typical examples are the determination of body composition, tissue, or organ vitality monitoring in combination with cellular edema as a result of hypoxemia, and monitoring of infusion therapy.

Certain forms of electrotherapy are also utilizing the passive electrical properties of biological tissue. Methodology and technology for these forms of electrotherapy, however, are not discussed here.

MODEL-BASED RELATIONS FOR VOLUME DETERMINATION

Valid relations between the monitored electrical quantities and the searched volumetric parameters have to be used to calculate a quantitative result that can be expressed in units of volume (e.g., mL or cm³). Most of these relations are based on models. Possibly the first model for the interpretation of bioimpedance measurements has already been developed for a suspension of cells in a fluid by Fricke and Morse in 1925 (16).

The simplest model-based approach for establishing an impedance-volume relationship is a cylindrical volume conductor of radius r_0 , length L , and resistivity ρ^* . It is assumed that this volume conductor is surrounded by soft material with significantly higher resistivity $\rho_e^* \gg \rho^*$, so that it must not be considered as a parallel circuit and its actual radial extension has no impact. This volume conductor may be a blood vessel (e.g., an artery or vein) surrounded by tissue that has higher resistivity than blood. Furthermore, it is assumed that the inflow of the volume ΔV into that cylinder expands the radius homogeneously by Δr over the total length. It is also assumed that neither the length L nor the resistivity ρ^* are affected by the volume injected into the volume conductor. For didactic simplicity, only the real part ρ' of the complex resistivity ρ^* is considered; that is, only the real part of the impedance is taken into account. However, despite this simplification, the variable is understood as impedance Z . This simplification is generally valid for frequencies much lower than the β -dispersion, since for these frequencies the phase angle is small ($< 10^\circ$). For higher frequencies, the calculation must be performed with proper consideration of the complex quantities.

With these assumptions the following relations for Z and V are valid:

$$\begin{aligned} Z_0 &= \rho' L / [\pi r_0^2] \\ V_0 &= L \pi r_0^2 \end{aligned}$$

From these two equations the following equation can easily be calculated

$$Z_0 = \rho' L^2 / V_0$$

After the inflow of the volume ΔV and the increase of the radius by Δr , the following relations are valid:

$$\begin{aligned} Z_1 &= Z_0 - \Delta Z = \rho' L / [\pi (r_0 + \Delta r)^2] \\ V_1 &= V_0 + \Delta V = L \pi (r_0 + \Delta r)^2 \end{aligned}$$

with $Z_1 < Z_0$ and $V_1 > V_0$ for $\Delta r > 0$.

With some simple mathematical operations it can be shown that

$$\rho' L^2 Z = (\rho' L^2 + \Delta V Z) (Z - \Delta Z)$$

If the product $\Delta V \Delta Z Z$ is neglected as a product of small quantities, the result becomes:

$$\Delta V = \rho' (L/Z)^2 \Delta Z$$

This is the well-known Nyboer equation that relates the volume change ΔV with the change in impedance ΔZ as a consequence of the blood inflow into a peripheral artery, for example, into the aorta or carotid artery with each heart beat.

For proper application all included simplifications must carefully be taken into account. Only mathematical simplifications, but no methodological constraints have been mentioned here. Such a constraint may be that a part of the injected volume is already flowing out of the measured vessel segment before the inflow of the whole volume ΔV into this vessel segment has been completed. This constraint must especially be considered if the segment is short and the vessel wall rather stiff.

With regard to the surrounding tissue, a more realistic model would be an arrangement of two concentric cylinders of length L with different conductivities. The inner cylinder with radius r_1 and resistivity ρ_1' has the impedance $Z_1 = \rho_1' L / [\pi r_1^2]$, whereas the outer cylinder with radius r_2 and resistivity ρ_2' has the impedance $Z_2 = \rho_2' L / [\pi (r_2 - r_1)^2]$. Electrically both cylinders are arranged in parallel configuration. Hence, the total impedance is obtained by $Z_0 = Z_1 Z_2 / (Z_1 + Z_2)$. The inner cylinder shall be a vessel into which blood of volume ΔV is pumped, causing a homogenous dilation of the vessel radius by Δr_1 and a lowering of its impedance to $Z_1^* = Z_1 - \Delta Z_1 = \rho_1' L / [\pi (r_1 + \Delta r_1)^2]$. Since Z_2 shall not be affected, the total impedance is $Z_0^* = Z_1^* Z_2 / (Z_1^* + Z_2)$. The following steps are similar to those leading to the Nyboer equation. Since the resulting equation and its application to measurements are more complicated, they will not be discussed here in detail. Even this model is actually simplified, because in reality the tissue around the vessel will neither be a cylinder nor have a homogeneous resistivity. This last situation may become relevant with a vein or a bone in the vicinity of the artery.

With regard to the constraints of the Nyboer equation, another approach has been used that finally leads to the Kubicek equation (17). The model-based approach starts again with the single-vessel model of length L . However, in contrast to the Nyboer approach the assumption is not made that the inflow of the volume ΔV into the considered vessel segment is finished before the outflow starts. Here, the basic assumption is that the inflow is constant during the inflow time T_{inf} and that the outflow starts with some delay, however, temporal overlap of outflow with inflow

must not be excluded. With this assumption, the change in the intravascular volume and, hence, in the impedance, is maximal when there is only inflow into and no outflow from the segment. This maximal change of the impedance can be expressed by its first time derivative [i.e., by $(dZ/dt)_{\max}$]. The total inflowing volume ΔV can then be taken into account by multiplying $(dZ/dt)_{\max}$ with the inflow time T_{inf} . With regard to the aorta this inflow time is equivalent with the ejection time of the left ventricle. In many cases even the inflow time can additionally be obtained from the impedance curve. This leads finally to the Kubicek equation:

$$\Delta V = \rho'(L/Z)^2 T_{\text{inf}} (dZ/dt)_{\max}$$

Obviously, the only relevant difference in both approaches is the Nyboer assumption that the total volume change ΔV has already been injected into the measured vessel segment before the outflow starts against the Kubicek assumption that this volume ΔV is entering the measured vessel segment with constant rate during the whole inflow period. The Kubicek equation is more realistic for a short vessel segment with a rather stiff wall. For such vessels, the Nyboer equation leads to an underestimation of the real volume change. In contrast, if the inflow is decreasing at the end of the inflow period, for example, at the end of the ventricular ejection period, the Kubicek equation yields an overestimation of the volume change.

All other model-based assumptions are identical or comparable. Both approaches consider only a single vessel with homogeneous dilation over the total length within the measured tissue and neglect the surrounding tissue and its composition with regard to nonhomogeneous resistivity. Blood resistivity is taken as constant although there is some evidence that it depends on the flow velocity.

Although the Kubicek equation has primarily been proposed for the monitoring of cardiac output, both equations have also been applied to the monitoring of pulsatile peripheral blood flow. Both models, however, do not consider that in the peripheral circulation a basic or nonpulsatile blood flow may exist as well.

Different modifications have been suggested in order to overcome relevant drawbacks. Most of these modifications are optimized with regard to the monitored quantity, geometric constraints, modes of application, or positioning and shape of electrodes. They will not be discussed here.

No valid impedance–volume models have been proposed for the quantitative monitoring of ventilation by the application of impedance plethysmography. Statistical models are used for the impedance–volume relationship regarding body composition. Some first approaches have been suggested for the volume changes due to fluid shifts.

INSTRUMENTATION AND APPLICATIONS

The typical basic equipment for impedance plethysmography consists of the signal generator, either a constant voltage generator or a constant current generator; the frequency-selective measuring device, either for current or voltage, in combination with AD conversion. The equipment may be supplied with more than one signal channel

for certain applications, for example, with two channels for simultaneous and symmetric monitoring at both extremities or one channel for each frequency in multifrequency measurements; the signal processor, for example, for processing the impedance quantities; the processing unit for calculating the volumetric quantities; the monitor and/or data recorder; multiple electrodes and shielded leads; specific auxiliary equipment, for example, venous occlusion machine with cuff and pump.

Devices for impedance plethysmography are small, light, usually portable, and battery powered. The devices for patient-near application are much cheaper than competitive equipment based on nuclear magnetic resonance (NMR), X ray, or US. Also, the running costs are much lower than for the competitive technologies, usually these costs are mainly required by the single-use electrodes.

Peripheral Hemodynamics

The objective is the detection of deficiencies either in the arterial or venous peripheral circulation. The application of impedance plethysmography to peripheral vascular studies has already been in the interest of Nyboer in 1950 (18).

In the peripheral circulation, the most interesting quantity is arterial blood flow or perfusion. Impedance measurement is performed either in the bipolar or, more frequently, in the tetrapolar configuration. The tetrapolar configuration requires a longer segment for measurement in order to place the sensing electrodes in proper distance from the feeding electrodes with the nonhomogenous current field in their vicinity. Electrodes are either of the circular or disk or the band type. Disk electrodes can be placed directly above the monitored vessel and therefore provide high sensitivity, but the magnitude and the reproducibility of the measured signal in repeated measurements are strongly dependent on exact electrode placement (19–21). Band electrodes are preferred for the measurements at extremities because they can be placed around the extremities. In this case, the measured object is the whole segment between the sensing electrodes including the extravascular tissue and may include more than only one vessel. Flow can be estimated by application of the Nyboer, the Kubicek or any modified impedance–volume equation. Competitive methods are utilizing ultrasound Doppler, contrast X-ray angiography, or NMR.

Some diagnostic information about the stiffness of the arterial vessel wall can be obtained by the impedance method from the measurement of the pulse wave propagation velocity, usually executed at two different sites of the same arterial pathway. The pulse that is actually recorded with the impedance method is the intravascular volume pulse, that is, the dilation of the vessel with each heart beat (22). Simple formalistic models are used to relate the pulse wave propagation velocity with the stiffness of the vessel wall. If the intravascular blood pressure is also monitored, then it is possible to calculate the stiffness or its inverse, the compliance as ratio of the volume change and pressure change $\Delta V/\Delta p$, directly.

Another problem is the diagnosis of proximal or deep venous thrombosis and of other obstacles for the venous return flow to the heart from the extremities (23). One

approach is actually a modification of the venous occlusion plethysmography that has already been introduced in 1905 by Brodie and Russel (24). A cuff is placed around the extremity and connected with a pump. The cuff pressure is enhanced abruptly so that it occludes the vein and stops venous outflow without affecting the arterial inflow. The volume increase following venous occlusion allows estimating the arterial inflow. When the occlusion is stopped after ~ 20 s, the venous outflow starts again and thereby leads to a reduction in volume. The slope or the time constant of this postocclusion emptying process are used to assess the outflow resistance, for example, the hydrodynamically obstructive impact of deep venous thrombosis, or the venous wall tension. However, other pathological effects must be carefully considered, for example, increased central venous pressure. For this reason, the recording is frequently and simultaneously performed on both extremities, so that the results can be compared with each other. The measurement is usually executed with band electrodes. Competitive methods are ultrasound Doppler, contrast X-ray venography, or NMR.

A similar impedance-based approach is employed to test the performance of the drainage system in extremities. Changes in the hydrostatic pressure are used to shift volume between the trunk and an extremity, for example first by bringing down an arm before raising it above the head. The affected volume shifts can be recorded and render possible the assessment of the performance of the draining system. This approach is frequently used to study fluid shifts caused by tilting experiments, during microgravity experiments, or after long periods of bedrest.

Brain Perfusion and Edema

The most important objectives are monitoring of cerebral bloodflow and the detection of cerebral edema. First publications about rheoencephalography are dating back to 1965 (25,26).

The volume of the brain with its enclosed fluid spaces, for example, the intravascular volume and the cerebrospinal fluid volume, is kept constant by its encapsulation in the bony skull. The expansion of the volume of one compartment, for example, increase of the intravascular volume by augmented arterial blood pressure, the space-demanding growth of a brain tumor or intracerebral bleeding, can only be compensated by the diminution of the volume of other compartments. If the space-demanding process is of nonvascular origin, the most affected compartment will be the intravascular volume. Due to the compression of blood vessels, the cerebral bloodflow and thus metabolism will be reduced.

Impedance measurements aiming for the brain as organ are difficult because the encapsulating bony skull has a very high resistivity as compared with the soft extracranial tissue of the face and the scalp. If the tetrapolar mode is used, more than two sensing electrodes may be applied. Different electrode arrangements have been described to force the current pathways through the skull into the brain, but also the application of the feeding electrodes to the closed eyelids. However, the measurement of the transcephalic impedance has not become a routinely

applied clinical method with the exception of neonates in which the thickness of the bony skull is very small. Competitive methods based on NMR, X ray, US, and even photoplethysmography have gained more attention in the recent past. Some expectations are related to the development of contactless applications, especially for the continuous monitoring of edema (27). This might allow control treatment by hyperosmolaric infusion therapy.

Ventilation and Lung Performance

Impedance pneumography were among the first applications of impedance plethysmography and had already been described by Geddes et al. in 1962 (28,29).

The objective of impedance pneumography is to record the tidal volume under resting conditions or during exercise. Additionally, the breathing rate can be obtained by the impedance method. The principle is based on the measurement of the transthoracic impedance that increases during inspiration as a consequence of increasing alveolar air filling, and decreases during expiration (30). The conductivity of lung tissue at the end of a normal expiration is $\sim 0.10 \Omega^{-1}\cdot\text{m}^{-1}$ as compared with $0.05 \Omega^{-1}\cdot\text{m}^{-1}$ at the end of normal inspiration. The application of impedance pneumography is very simple and also applicable for critically ill patients, since it allows continuous recording without requiring a breathing tube. However, the quantitative determination of the tidal volume is difficult and needs calibration by another spirometric method. No realistic model-based interpretation of quantitative assessment is available until now. Some expectations are related with multifrequency measurement (31).

The impedance measurement can be performed with the bi- or tetrapolar configuration. It is usually performed separately for each side of the lung in order to detect differences. Even with more electrodes, however, the spatial resolution is too poor to allow detection of regional inhomogeneities of alveolar air filling. For that reason, this field is gaining growing interest for the application of EIT (4). Also, EIT has limited spatial resolution, as compared with other CT-based imaging procedures. Despite this drawback, it has some potential for the detection of regional inhomogeneities in ventilation. Such an approach would be of high relevance for diagnostic purposes and for the efficiency control of artificial ventilation. Serious drawbacks for EIT, however, are the costs of the equipment and the necessity to attach up to 64 or 128 electrodes around the thorax.

Since pulmonary edema is usually a general and not a localized phenomenon, its monitoring might be possible by utilizing the transthoracic impedance measurement. Measurement of extravascular lung water is investigated as a methodological approach to guide the fluid management of patients with noncardiogenic pulmonary edema (32). The conductivity of lung edema fluid is $\sim 1 \Omega^{-1}\cdot\text{m}^{-1}$, and therefore is distinctly different from alveolar tissue filled with more or less air.

The impedance coefficients of tumor tissue are different from normal lung tissue. Hence, cancer detection might be possible by bioimpedance measurement. But with regard to its poor spatial resolution, the bi- or tetrapolar transthor-

acic impedance measurement is not qualified, but EIT might become useful for some special applications. Other imaging procedures were superior until now, primarily due to the higher spatial resolution as compared with EIT.

Much work has been devoted to comparing impedance pneumography with inductive pneumography. There is some evidence that inductive pneumography is superior concerning ventilation monitoring in newborn infants, especially for risk surveillance with regard to SIDS. An interesting approach tries to utilize inductive pneumography in combination with the evaluation of the signal morphology for the monitoring of airway obstruction (33).

Intercompartmental Fluid Shifts

Intercompartmental fluid shifts occur during dialysis, for example, hemodialysis, but also during infusion therapy and emergence of edema. The assessment of fluid shifts, which are actually changes of volumes, by the measurement of electric variables has been an outstanding objective very early in the scientific research and medical utilization of bioimpedance and dates back to 1951 (34).

Hemodialysis is a therapeutic procedure that is employed in patients with renal insufficiency. The therapeutic objective is to remove water, electrolytes, urea, and other water-soluble substances in combination with the reestablishment of a normal acid-base status. In a simplified model, the water is first removed from the intravascular volume, (i.e., the blood plasma). This means that the hematocrit, and thereby the viscosity of blood, is increased causing the work load for the heart is enhanced. Also, the osmotic pressure of the blood is raised, whereas the hydrostatic blood pressure is lowered. Both effects contribute to the refilling of the intravascular space by a fluid shift from the interstitial space (i.e., the extravascular extracellular space). This fluid shift finally causes another fluid shift from the intracellular space into the interstitial space. The dynamics of these fluid shifts is primarily controlled by the hydrostatic and osmotic pressure differences between the different spaces, but also by the substance-specific permeability of the different barriers between the spaces including the dialysis membrane. If removal of water is too fast or changes of ions like sodium, potassium, and calcium are too large, the hemodynamics of the patient or the excitability of tissues like the heart or central nervous system may become disturbed. Impedance plethysmographic methods have some potential for the control of those fluid shifts, that is, may help to avoid critical disequilibrium syndromes like hypotension, headache, and vomiting. The best results of the plethysmographic measurement are achieved if segmental measurement is performed at the extremities instead of whole body measurements (5). Figure 5 shows a schematic presentation of such segmented body. The forearm accounts only for $\sim 1\%$ of body weight, but contributes 25% to whole body impedance.

Infusion therapy aims mainly to filling the intravascular volume by utilizing venous access. However, depending on the control variables (e.g., hydrostatic pressure, osmotic pressure, and permeability of the barriers), intercompartmental fluid shift cannot be avoided. Consequently, part of the infused volume will not remain in the intravascular

Figure 5. Schematic presentation of the whole body subdivided into 11 segments that are modeled by RC-networks.

system and help to stabilize blood pressure, but escape to the extravascular space.

A special objective of intravenous infusion therapy with hyperosmolaric fluid is the removal of fluid from the extravascular space in order to avoid the emergence of edemas. In the brain, such infusion may help to lower the intracranial pressure that is caused by edema.

Body Composition

Most frequently this method is called bioelectric impedance analysis (BIA). The interest in this methodological approach has increased with the increased interest in healthy life style in industrialized populations since the first reports at the end of the 1980s (35,36).

The body consists of different tissues, for example, muscle, fat, bones, skin, the nervous system, and connective tissue. All these tissues contain intra- and extravascular spaces. The extravascular space can be subdivided into the extracellular or interstitial space and the intracellular space. Chemically, the body consists of water, proteins, carbohydrates, lipids, ions, rare elements, and some other substances. The main objective of body composition analysis

is the assessment of total body water, of lean or fat free tissue mass, and of fat tissue. Those measurements have clinical relevance, but they are also gaining growing attention in the field of sports, physical fitness, wellness, nutrition, and for life science in aerospace research.

The methodological approaches are different, for example bipolar or tetrapolar mode, single- or multiple-frequency measurement, whole body or segmental measurement. In single-frequency measurements, a sinusoidal current with usually < 1 mA (range 0.02–10 mA) and a frequency with typically 50 kHz (range 20–100 kHz) is employed. The basic assumption is that resistivity of fat tissue is higher than that of the so-called lean tissue that has a higher content of water. In the nonclinical field, the determination of body composition is frequently combined with the measurement of body weight using a scale with two integrated electrodes in the foot platform. In that case, however, only the two legs and the lower part of the trunk will be included into the estimation. In more advanced devices, additional electrodes are available in the form of hand grips. Detailed segmental measurements are more valid since the trunk of the body may contribute $\sim 70\%$ to the total body weight and up to 90% to the total body fat, but only 5% to the measured whole body impedance. More sophisticated equipment utilize multifrequency measurement (11).

The applied statistically based predictive equations are of the linear regression type and consider individual parameters like sex, age, height, and weight. They are primarily used to assess the lean muscle mass, the body fat, the fat free mass, the water content, and the body mass index. For physically based segmental calculations, the extremities, the body trunk, and even the head are modeled by cylindrical shape with uniform cross-section over the total length.

Competitive methods include anthropometric measures like the girth, simple skin-fold measurements by mechanical calipers, but also highly advanced methods, such as NMR, X ray (dual energy X-ray absorptiometry, or nuclear imaging), and for certain purposes even the hydrostatic weighing in a water tank that is assumed to be the most accurate method.

Laboratory Applications

Blood Cell Counting. The employed methodological principle is frequently called the Coulter principle (37). Blood cells (e.g., erythrocytes, leucocytes) are passing through a capillary (diameter < 100 μm) filled with blood plasma. For frequencies below the β -dispersion the impedance of the cell is higher than that of the surrounding plasma. Consequently, the passage of each cell affects the recorded impedance. Those impedance changes are used for cell counting. In sophisticated devices the impedance changes are quantitatively measured and allow cell volume estimation, which also renders possible the determination of the cell volume distribution function (frequently called the Price–Jones distribution function with the cell diameter as variable). Since the number of leucocytes is very small compared with that of the erythrocytes (usually $< 0.1\%$), leucocytes do not really disturb the counting of erythrocytes. In contrast, however, the erythrocytes must

be destroyed before the leucocytes can be counted. This is usually achieved by chemical hemolysis of the erythrocytes. Furthermore, chemical substances are utilized to render possible the differentiation between the different populations of leucocytes (e.g., granulocytes, monocytes, lymphocytes).

Hematocrit. The objective is the estimation of the intracellular volume of blood. The hematocrit is defined as the ratio of the volume of blood cells to total blood volume, although frequently the hematocrit is taken as a measure for the ratio of only the volume of erythrocytes to total blood volume. However, since the partial volume of all other blood cells (i.e., leucocytes, platelets) is very small compared with that of the erythrocytes, the results are not distinctly different. Determination of the ratio between the extracellular volume and the total blood volume is possible by application of at least one measuring frequency below and another one above the β -dispersion. Problems that need further consideration as possible sources of error are the electrolytic conductivity of blood plasma, which is dependent on the actual concentration of ions, and the sedimentation of the cells as a consequence of their higher specific weight that may take place during the measuring period. The measurement requires the withdrawal of a sample of blood from a vein or another blood vessel. Measurement of the hematocrit can be achieved either with the impedance or the dielectric technique (38).

Several modifications of the impedance method for the noninvasive determination of the hematocrit have been proposed. In one approach, impedance measurement is performed at the finger by application of two different frequencies (i.e., 100 kHz and 10 MHz). The hematocrit is determined by an algorithm that uses both the pulsatile and the baseline component of both measuring frequencies (39). In another remarkable methodological approach, the patient puts a finger in a temperature-stabilized bath. A fluid with gradually increasing ionic concentration is pumped through the bath chamber, thus leading to a decrease in the impedance of the bath fluid. The pulsatile volume changes of the finger are recorded by impedance measurement in the bath chamber. These pulsatile impedance fluctuations disappear only if the impedance of the bath fluid is identical with that of the blood in the finger. The conclusion is made from the actual impedance of the bath fluid on the hematocrit (40).

Others

Cell Imaging. Nanotechnology-based on bioimpedance sensing, chip devices have been described that allows us to rapidly detect and image cells with a specific phenotype in a heterogeneous population of cells (41). This might be useful for screening purposes, recognition of cell irregularities, and detection of risk patients like human immunodeficiency virus (HIV)-infected individuals. Cell identification is made possible by administration of marker substances. A promising measurement procedure is electrochemical cyclic voltammetry. When a sinusoidal voltage with constant amplitude and a variable frequency in the range of some kilohertz is applied, the impedance is plotted

in the spectrographic mode. Among other effects, volume changes might be the dominating measured effect if the marker binds with a receptor in the cell membrane, and herewith affects membrane properties like its permeability for water or ions or the transmembraneous active ion transport mechanisms.

Inductive Plethysmography. Inductive plethysmography is employed for respiratory monitoring, so-called respiratory inductance plethysmography (RIP). It is based on the measurement of the thoracic crosssection that is enclosed by coils and includes both the rib cage and abdominal compartments (42–45). In the medium frequency range (30–500 kHz), changes in the volume are monitored by the influenced inductance. In the higher frequency range (~100 MHz), the inductively provoked signals (i.e., eddy currents depending on the alveolar air filling) are recorded by appropriately arranged coils.

Magnetic Susceptibility Plethysmography. Magnetic susceptibility plethysmography is a contactless method. It is based on the application of a strong magnetic field and monitors the variation of the magnetic flux. The measurement is accomplished with superconducting quantum interference device (SQUID) magnetometers. This approach may primarily be utilized for the assessment of blood volume changes in the thorax, but until now it is not employed for clinical routine (46).

SUMMARY

In comparison with biomedical engineering as a recognized discipline, the research activities in the field of bioimpedance are much older. It can be assumed that Nikola Tesla, a former student of physics in Graz (Austria) and the inventor of the ac technology, already knew about the passive electrical properties of biological tissues when he demonstrated his famous and public performances with the administration of high voltage pulses "...I demonstrated that powerful electrical discharges of several hundred thousand volts which at that time were considered absolutely deadly, could be passed through the body without inconvenience or hurtful consequences" in the 1880s. This knowledge was utilized by d'Arsonval since 1892 for therapeutic purposes, mainly aiming for heat induction in certain parts of the body. In 1913, Rudolf Hoerber, at that time a physiologist at the University of Kiel (Germany), measured the electrical conductance of frog muscle at 7 MHz and found that at this frequency the membrane resistance is short circuited.

Since its beginning, bioimpedance remained to be a challenge to physicists, medical doctors, and of course engineers. The most relevant basic research was performed in the second half of the twentieth century. The progress that has been reached has been and is still utilized both for diagnostic and therapeutic purposes in medicine. Impedance plethysmography is one of the different fields of bioimpedance application. If impedance plethysmography is correctly understood, it does not only mean the determination of a solid volume with well-defined boundaries, but also the volumetric determination of one component contained in a mixture of different components.

Progress in technology has rendered possible applications that are of great interest for medicine. The most relevant progress is in the field of signal acquisition, including advanced electrode technology, signal processing, and model-based signal interpretation. Not all attempts to utilize the passive electrical properties of biological tissue for diagnostic purposes have been successful. In many cases, other technologies have been shown to be superior. But there is no doubt that the whole potential of impedance plethysmography has not been exhausted. New challenges in the medical field are cellular imaging and possibly even molecular imaging. In all applications, however, impedance plethysmography will have to prove its validity and efficiency.

INTRODUCTION

Impedance spectroscopy (IS), also referred to as electrochemical impedance spectroscopy (EIS), is a versatile approach to investigate and characterize dielectric and conducting properties of materials or composite samples (1). The technique is based on measuring the impedance

(i.e., the opposition to current flow) of a system that is being excited with weak alternating current or voltage. The impedance spectrum is obtained by scanning the sample impedance over a broad range of frequencies, typically covering several decades.

In the 1920, researchers began to investigate the impedance of tissues and biological fluids, and it was early known that different tissues exhibit distinct dielectric properties, and that the impedance undergoes changes during pathological conditions or after excision (2,3).

The advantage of IS is that it makes use of weak amplitude current or voltage that ensures damage-free examination and a minimum disturbance of the tissue. In addition, it allows both stationary and dynamic electrical properties of internal interfaces to be determined, without adversely affecting the biological system. The noninvasive nature of the method combined with its high information potential makes it a valuable tool for biomedical research and many medical applications are currently under investigation and development; this will be reviewed at the end of the article.

This article starts with providing a general introduction to the theoretical background of IS and the methodology connected to impedance measurement. Then, the focus will be on applications of IS, particularly devised for *in vitro* monitoring of cultured cell systems that have attracted widespread interest due to demand for noninvasive, marker-free, and cost-effective methods.

THEORY

Impedance, \mathbf{Z} , is a complex-valued vector that describes the ability of a conducting medium to resist flow of alternating current (ac). In a typical IS experiment (Fig. 1), a sinusoidal current $\mathbf{I}(t)$ signal with angular frequency ω ($\omega = 2\pi f$) is passed through the sample and the resulting steady-state voltage $\mathbf{U}(t)$ from the excitation is

Figure 1. Schematic of a two-electrode setup to measure the frequency-dependent impedance of a sample that is sandwiched between two parallel plate electrodes.

measured. According to the ac equivalent of Ohm's law, the impedance is given by the ratio of these two quantities

$$\mathbf{Z} = \frac{\mathbf{U}(t)}{\mathbf{I}(t)} \quad (1)$$

The impedance measurement is conducted with use of weak excitation signals, and in this case the voltage response will be sinusoid at the same frequency ω as the applied current signal, but shifted in phase φ . Introducing complex notation, Eq. 1 translates into

$$\mathbf{Z} = \frac{U_0}{I_0} \exp(i\varphi) = |\mathbf{Z}| \exp(i\varphi) \quad (2)$$

with U_0 and I_0 being the amplitudes of the voltage and current, respectively, and $i = \sqrt{-1}$ being the imaginary unit. Thus, at each frequency of interest the impedance is described by two quantities: (1) its magnitude $|\mathbf{Z}|$, which is the ratio of the amplitudes of $\mathbf{U}(t)$ and $\mathbf{I}(t)$; and (2) the phase angle φ between them. The impedance is measured over a range of frequencies between hertz and gigahertz, dependent on the type of sample and the problem to study.

The measured impedance can be divided into its real and imaginary components, that is, the impedance contribution arising from current in-phase with the voltage and 90° out-of-phase with the voltage

$$R = \text{Re}(\mathbf{Z}) = |\mathbf{Z}| \cos(\varphi), \quad X = \text{Im}(\mathbf{Z}) = |\mathbf{Z}| \sin(\varphi) \quad (3)$$

The real part is called resistance, R , and the imaginary part is termed reactance, X . The reactive impedance is caused by presence of storage elements for electrical charges (e.g., capacitors in electrical circuit).

In some cases it is convenient to use the inverse quantities, which are termed admittance $\mathbf{Y} = 1/\mathbf{Z}$, conductance $\mathbf{G} = \text{Re}(\mathbf{Y})$, and susceptance $\mathbf{B} = \text{Im}(\mathbf{Y})$, respectively. In the linear regime (i.e., when the measured signal is proportional to the amplitude of the excitation signal), these two representation are interchangeable and contain the same information. Thus, IS is also referred to as admittance spectroscopy.

INSTRUMENTATION

The basic devices for conducting impedance measurements consist of a sinusoid signal generator, electrodes, and a phase-sensitive amplifier to record the voltage or current. Commonly, a four-electrode configuration is used, with two current injecting electrodes and two voltage recording electrodes to eliminate the electrode-electrolyte interface impedance. As discussed below, some applications of IS make use of two-electrode arrangements in which the same electrodes are used to inject current and measure the voltage.

Since the impedance is measured by a steady-state voltage during current injection, some time is needed when changing the frequency before a new measurement can be performed. Therefore, it is very time consuming if each frequency has to be applied sequentially. Instead, it is common to use swept sine wave generators, or spectrum analyzers with transfer function capabilities and a white noise source. The white noise signal consists of the

superposition of sine waves for each generated frequency, and the system is exposed to all frequencies at the same time. Fourier analysis is then used to extract the real and imaginary parts of the impedance.

The electrodes used for impedance experiments are made from biocompatible materials, such as noble metals, which in general is found not to have deleterious effect on biological tissue function. Electrode design is an important and complicated issue, which depends on several factors, including the spatial resolution required, the tissue depth, and so on. It falls beyond the scope of this article to go further into details. The interested readers are referred to the book by Grimnes and Martinsen (4) for a general discussion.

Common error sources in the measurements include impedance drift (e.g., caused by adsorption of particles on the electrodes or temperature variations). Ideally, the system being measured should be in steady-state throughout the time required to perform the measurement, but in practice this can be difficult to achieve. Another typical error source is caused by pick-up of electrical noise from the electronic equipment, and special attention must be paid to reduce the size of electric parasites arising, for example, from cables and switches.

DATA PRESENTATION AND ANALYSIS

The most common way to analyze the experimental data is by fitting an equivalent circuit model to the impedance spectrum. The model is made by a collection of electrical elements (resistors, capacitors) that represents the electrical composition in the system under study.

As a first step, it is useful to present the measured data by plotting $\log |Z|$ and ϕ versus $\log f$ in a so-called Bode-diagram (Fig. 2a), and by plotting $\text{Im}|Z|$ versus $\text{Re}|Z|$ named a Nyquist diagram or an *impedance locus* (Fig. 2b). The examples provided in Fig. 2 are made for an electrical circuit (insert Fig. 2b). While the first way of presenting the data shows the frequency-dependence explicitly, the phase angle ϕ is displayed in the latter.

The impedance spectrum gives many insights to the electrical properties of the system, and with experience it is possible to make a qualified guess of a proper model based on the features in the diagrams (cf. Fig. 4). Similar to other spectroscopic approaches like infrared (IR) or ultraviolet (UV)/visible (vis), the individual components tend to show up in certain parts of the impedance spectrum. Thus, variations in the values of individual components alter the spectrum in confined frequency windows (Fig. 3).

For a given model, the total impedance (transfer function) is calculated from the individual components with use of Ohm's and Kirchhoff's laws. The best estimates for the parameters, that is, the unknown values of the resistors and capacitors in the circuit, are then computed with use of least-square algorithms. If the frequency response of the chosen model fits the data well, the parameter values are used to characterize the electrical properties of the system.

In order to fit accurately the equivalent circuit model impedance to the impedance of biomaterials, it is often necessary to include nonideal circuit elements, that is,

Figure 2. Different representations of impedance spectra. (a and b) visualize the frequency-dependent complex impedance of the electrical circuit shown in (b) with the network components: $R_1 = 250 \Omega$; $R_2 = 1000 \Omega$; $C_1 = 10 \mu\text{F}$; $C_2 = 1 \mu\text{F}$. (a) Bode-diagram presenting frequency-dependent impedance magnitude $|Z|$ together with the phase shift ϕ of the sample under investigation. (b) Wessel diagram locus of the same electrical network. The imaginary component of the impedance (reactance) is plotted against the real component (resistance). The arrow indicates the direction along which the frequency increases.

elements with frequency dependent properties. Such elements are not physically realizable with standard technical elements. Table 1 provides a list of common circuit elements that are used to describe biomaterials with respect to their impedance and phase shift. The constant phase element (CPE) portrays a nonideal capacitor, and was originally introduced to describe the interface impedance of noble metal electrodes immersed in electrolytic solutions (5). The physical basis for the CPE in living tissue (and at electrode interfaces) is not clearly understood, and it is best treated as an empirical element. Another example is the Warburg impedance σ that accounts for the diffusion limitation of electrochemical reactions (4).

It is important to place a word of caution concerning the equivalent circuit modeling approach. Different equivalent circuit models (deviating with respect to components or in the network structure) may produce equally good fits to the experimental data, although their interpretations are very different. It may be tempting to increase the number of elements in a model to get a better agreement between experiment and model. However, it may then occur that the model becomes redundant because the components cannot be quantified independently. Thus, an overly complex

Figure 3. Calculated spectra of the impedance magnitude $|Z|$ for the electrical circuit shown in the insert of Fig. 2b when the network parameters have been varied individually. The solid line in each figure corresponds to the network parameters: $R_1 = 250 \Omega$; $R_2 = 1000 \Omega$; $C_1 = 10 \mu\text{F}$; $C_2 = 1 \mu\text{F}$. (a) Variation of C_1 : $10 \mu\text{F}$ (solid), $20 \mu\text{F}$ (dashed), $50 \mu\text{F}$ (dotted). (b) Variation of C_2 : $1 \mu\text{F}$ (solid), $0.5 \mu\text{F}$ (dashed), $0.1 \mu\text{F}$ (dotted). (c) Variation of R_1 : 1000Ω (solid), 2000Ω (dashed), 5000Ω (dotted). (d) Variation of R_2 : 250Ω (solid), 500Ω (dashed), 1000Ω (dotted).

model can provide artificially good fits to the impedance data, while at the same time highly inaccurate values for the parameters. Therefore, it is sound to use equivalent circuits with a minimum number of elements that can describe all aspects of the impedance spectrum (6).

Alternatively, the impedance data can be analyzed by deriving the current distribution in the system with use of differential equations and boundary values (e.g., the given excitation at the electrode surfaces). The parameters of the model impedances are then fitted to the data like described above. An example of this approach is presented below, where it is used to analyze the IS of a cell-covered gold film electrode.

IMPEDANCE ANALYSIS OF TISSUE AND SUSPENDED CELLS

The early and pioneering work on bioimpedance is associated with the names of Phillipson, et al. (5). In these studies blood samples or pieces of tissue were examined in an experimental setup as shown in Fig. 1, and the dielectric properties of the biological system were investigated over a broad range of frequencies from hertz to gigahertz.

To understand the origin of bioimpedance, it is necessary to look at the composition of living material. Any tissue is composed of cells that are surrounded by an extracellular fluid. The extracellular medium contains proteins and polysaccharides that are suspended in an ionic solution and the electrical properties of this fluid

are determined by the mobility and concentration of the ions, primarily Na^+ and Cl^- . The cell membrane marks the boundary between the interior and exterior environment, and consists of a 7–10 nm phospholipid bilayer. The membrane allows diffusion of water and small nonpolar molecules, while transport of ions and polar molecules requires the presence of integral transport proteins. On the inside, the cell contains a protein-rich fluid with specialized membrane-bound organelles, like the nucleus. For most purposes the fluid behaves as a pure ionic conductor. Thus, the cell membrane is basically a thin dielectric sandwiched between two conducting media and in a first approximation its impedance characteristics are mainly capacitive.

The simplest possible explanatory model for biological tissue (Fig. 4a-1) therefore consists of two membrane capa-

Table 1. Individual Impedance Contributions of Ideal and Empirical Equivalent Circuit Elements

Component of Equivalent Circuit	Parameter	Impedance, Z	Phase Shift, φ
Resistor	R	R	0
Capacitor	C	$(i\omega C)^{-1}$	$-\pi/2$
Coil	L	$i\omega L$	$+\pi/2$
Constant phase element (CPE)	$\alpha(0 \leq \alpha \leq 1)$	$1/(iC\omega)^\alpha$	$-\alpha\pi/2$
Warburg impedance, σ	σ	$\sigma(1 - i)\omega^{-0.5}$	$-\pi/4$

Figure 4. (a) Schematics of the impedance measurement on living tissue. The arrows indicate the pathway of current flow for low frequencies (solid line) and high frequencies (dashed). Only at high frequencies the current flows through the cells. The electrical structure of tissue can be directly translated into equivalent circuit 1, which can be simplified to equivalent circuit 2. (b) Bode-diagram for network 2 in Fig. 4a, using $R_{ext} = 1000 \Omega$; $R_{cyt} = 600 \Omega$; $C_m = 100 \text{ nF}$. (c) Impedance locus generated with the same values.

citors C_{m1} and C_{m2} in series with a resistor of the cytosolic medium R_{cyt} , which in turn acts in parallel with the resistance of the conducting extracellular medium R_{ext} . Since the two series capacitances of the membrane cannot be determined independently, they are combined to an overall capacitance C_m . The equivalent circuit model of this simple scenario (Fig. 4a-2) gives rise to a characteristic impedance spectrum, as shown with the Bode-diagram (Fig. 4b) and the Nyquist diagram (Fig. 4c). Impedance data for biological tissue is also often modeled by the so-called Cole–Cole equation (7)

$$Z = R_\infty + \frac{\Delta R}{1 + \Delta R(i\omega C)^\alpha} \quad \Delta R = R_0 - R_\infty \quad (4)$$

This simple empirical model is identical to the circuit of Fig. 4, except that the capacitor is replaced by a CPE element. The impedance spectrum is characterized by four parameters ($\Delta R, R_\infty, \alpha, \tau$), where R_0, R_∞ is the low- and high frequency intercepts on the x axis in the Nyquist plot (cf. Fig. 4d), τ is the time constant $\tau = \Delta R \cdot C$, and α is the CPE parameter. The impedance spectrum will be similar to Fig. 4b, c, but when $\alpha \neq 1$, the semicircle in the Nyquist diagram is centered below the real axis, and the arc will appear flattened. For macroscopically heterogeneous biological tissue, the transfer function is written as a sum of Cole–Cole equations.

The features of the impedance spectrum Fig. 4b can be intuitively understood: at low frequencies the capacitor prevents current from flowing through R_{cyt} and the measured impedance arises from R_{ext} . At high frequencies, with the capacitor having a very low impedance, the current is free to flow through both R_{cyt}, R_{ext} . Thus, there is a

transition from constant-level impedance at low frequencies to another constant level. This phenomenon is termed dispersion, and will be discussed in the following.

A homogenous conducting material is characterized by a bulk property named the resistivity ρ' having the dimensions of ohm centimeters ($\Omega \cdot \text{cm}$). Based on this intrinsic parameter, the resistance may be defined by

$$R = \frac{\rho' L}{A} \quad (5)$$

where A is the cross-sectional area and L is the length of the material. Thus, by knowing the resistivity of the material and the dimensions of the system being studied, it is possible to estimate the resistance. Similarly, a homogeneous dielectric material is characterized by an intrinsic property called the relative permittivity ϵ' , and the capacitance is defined by

$$C = \frac{\epsilon' \epsilon_0 A}{d} \quad (6)$$

where ϵ_0 is the permittivity of free space with dimension F/m, and A, d are the dimensions of the system as above. For most biological membranes, the area-specific capacitance is found to be quite similar, with a value of $\sim 1 \mu\text{F} \cdot \text{cm}^{-2}$ (8).

For historical reasons the notation of conductivity σ' with dimensions $\text{S} \cdot \text{m}^{-1}$ and conductance ($G = \sigma' A / d$) has been preferred over resistance R and resistivity ρ , but the information content is the same, it is just expressed in a different way.

It is possible to recombine ϵ' and σ' by defining a complex permittivity $\epsilon = \epsilon' + \epsilon''$, with $\text{Re}(\epsilon) = \epsilon'$ and $\text{Im}(\epsilon) = \epsilon''$. The

imaginary part accounts for nonideal capacitive behavior, for example, current within the dielectric due to bound charges giving rise to a viscous energy loss (dielectric loss). Therefore, ε'' is proportional to σ' , when adjusted for the conductivity that is due to migration σ_0 (9)

$$\varepsilon'' = \frac{\sigma' - \sigma_0}{2\pi f \varepsilon_0} \quad (7)$$

When a piece of biological material is placed between two electrodes, it is possible to measure the capacitance of the system and thereby to estimate the tissue permittivity ε' . In general, ε' quantifies the ratio of the capacitance when a dielectric substance is placed between the electrodes, relative to the situation with vacuum in between. The increase of capacitance upon insertion of a dielectric material is due to polarization in the system in response to the electric field. For direct current (dc) or low frequency situations ε' is called the dielectric constant. When the frequency is increased, ε' often shows strong frequency dependence with a sigmoid character in a log-log plot of ε' versus frequency. This step-like decrease of the permittivity is referred to as a dielectric dispersion. The frequency f_c at which the transition is half-complete is called the characteristic frequency, and is often expressed as time constant τ with

$$\tau = \frac{1}{f_c} \quad (8)$$

Going back to Fig. 4c, the characteristic frequency is found directly as the point when the phase angle is at maximum.

The origin of dielectric dispersion in a homogeneous material is due to a phenomenon termed orientation polarization. Dipolar species within the material are free to move and orient themselves along the direction of the field, and therefore they contribute to the total polarization. However, when the frequency becomes too high, the dipoles can no longer follow the oscillation of the field, and their contribution vanishes. This relaxation causes the permittivity ε' to decrease.

For heterogeneous samples like tissue additional relaxation phenomena occur, leading to more complex frequency dependence. In 1957, Schwan (10) defined three prominent dispersion regions of relevance for bioimpedance studies called α , β , and γ , which is shown in Fig. 5. The dispersions are generally found in all tissue, although the time constant and the change in permittivity $\Delta\varepsilon'$ between the different regions may differ (9).

Briefly stated, the α -dispersion originates from the cloud of counterions that are attracted by surface charges of the cell membrane. The counterions can be moved by an external electric field, thereby generating a dipole moment and relaxation. The β -dispersion, which is also called Maxwell–Wagner dispersion, is found in a window between kilohertz and megahertz (kHz and MHz). It arises due to the accumulation of charges at the interface between hydrophobic cell membranes and electrolytic solutions. Since the aqueous phase is a good conductor, whereas the membrane is not, mobile charges accumulate and charge up the membrane capacitor, thus, contributing to polarization. When the frequency gets too high, the charging is not complete, causing a loss of polarization. Finally,

Figure 5. Frequency-dependent permittivity ε' of tissue. The permittivity spectrum $\varepsilon'(f)$ is characterized by three major dispersions: α -, β -, and γ -dispersion.

the γ -dispersion is due to the orientation polarization of small molecules, predominantly water molecules.

Most IS measurements are performed at intermediate frequencies in the regime of the β -dispersion. In this frequency window, the passive electrical properties of tissue are well described with the simple circuit shown in Fig. 4 or by the Cole–Cole equation. The measurements can be used to extract information about extra- and intercellular resistance, and membrane capacitance. For example, it has been shown that cells in liver tissue swell, when the blood supply ceases off (ischemia) and that the swelling of the cells can be monitored as an increase in the resistance of the extracellular space R_{ext} (11). Cell swelling compresses the extracellular matrix around the cells, and thereby narrows the ion pathway in this region. Based on experiments like these, there is a good perspective and prognosis that IS may serve as a routine monitoring tool for tissue vitality even during the surgery.

APPLICATION: MONITORING OF ADHERENT CELLS IN VITRO

The attachment and motility of anchorage dependent cell cultures is conveniently studied using a microelectrode setup. In this technique, cells are grown directly on a surface containing two planar metal electrodes, one microelectrode and one much larger counter electrode. The cells are cultured in normal tissue culture medium that serves as the electrolyte.

When current flows between the two electrodes, the current density, and the measured voltage drop, will be much higher at the small electrode. Therefore the impedance measurement will be dominated by the electrode polarization of the small electrode Z_{el} . Instead, no significant polarization takes place at the larger counter electrode and its contribution to the measured impedance may be ignored. The electrode polarization impedance Z_{el} acts physically in series with the resistance of the solution R_{sol} . Since the current density is high in a zone (the constrictional zone) proximal to the microelectrode, the electrolytic resistance will be dominated by the constriction resistance R_c in this region (Fig. 6). The total measured impedance may therefore be approximated by $Z \sim Z_{\text{el}} + R_c$ (4). If necessary, R_c may be determined from high frequency measurements where the electrode resistance is

Figure 6. Schematic of two-electrode configuration.

infinitely small, that is, $\text{Re}(Z_{el}) \rightarrow 0$, and subtracted from the measured impedance to determine the impedance of the electrode–electrolyte interface.

When cells adhere on the small electrode, they constrain the current flow from the interface, increasing the measured impedance. The changes mainly reflect the capacitive nature of nonconducting lipid-bilayer membrane surrounding the cells. The cell membranes cause the current field to bend around the cells, much like if they were microscopic insulating particles. It is possible to follow both cell surface coverage and cell movements on the electrode, and morphological changes caused by physiological/pathological conditions and events may be detected. The technique may also be used to estimate cell membrane capacitances, and barrier resistance in epithelial cell sheets. In addition, the method is highly susceptible to vertical displacements of the cell body on the electrode with sensitivity in the nanometer range.

INSTRUMENTATION

The technique was introduced by Giaever and Keese in 1984 and referred to as Electrical Cell-Substrate Impedance Sensing (ECIS) (12,13). The ECIS electrode array consists of a microdisk electrode ($\sim 5 \times 10^{-4} \text{ cm}^2$) and a reference electrode ($\sim 0.15 \text{ cm}^2$); depending on the cell type to be studied, the recording disk electrode may contain a population of 20–200 cells. The electrodes are made from depositing gold film on a polycarbonate substrate over which an insulating layer of photoresist is deposited and delineated. A 1 V amplitude signal at fixed frequency (0.1–100 kHz) is applied to the electrodes through a large resistor to create a controlled current of $1 \mu\text{A}$, and the corresponding voltage across the cell-covered electrodes

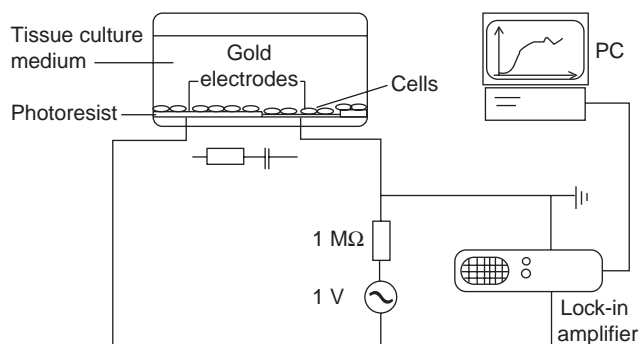

Figure 7. The ECIS measurement setup.

is measured by a lock-in amplifier, which allows amplification of the relatively small signals. The amplifier is interfaced to a PC for data storage. The impedance is calculated from the measured voltage displayed in real time on the computer screen (Fig. 7). During the measurements the sample is placed in an incubator at physiological conditions.

The ECIS system is now commercially available, and the electrode slides allow multiple experiments to be performed at the same time (14). Some modifications to the technique have been described, such as a two-chamber sample well, which permit simultaneous monitoring on a set of empty electrodes being exposed to the same solution (15), platinized single-cell electrodes (15), and inclusion of a voltage divider technique to monitor the impedance across a range of frequencies (16). More recently, impedance studies have been performed using other types of electrode design. One approach has been to insert a perforated silicon-membrane between two platinum electrodes, thereby allowing for two separate electrolytic solutions to exist on either side of the membrane (17). The results obtained with these techniques are generally identical to those obtained by the ECIS system.

MODEL OF ELECTRODE–CELL INTERFACE

To interpret ECIS-based impedance data, a model of the ECIS electrode–cell interface has been developed that allows determination of (1) the distance between the ventral cell surface and the substratum, (2) the barrier resistance, and (3) the cell membrane capacitance of confluent cell layers (18). The model treats the cells as disk shaped objects with a radius r_c that are separated an average distance h from the substratum (Fig. 8). When cells cover the electrode, the main part of the current will flow through the thin layer of medium between the cell and the electrode, and leave the cell sheet in the narrow spacing between cells. However, the cell membrane, which is modeled as a capacitor (an insulating layer separating the conducting fluids of the solution and the cytosol) allows a parallel current flow to pass through the cells. The minor resistive component of the membrane impedance due to the presence of ionic channels is ignored in the calculations. By assuming that the electrode properties are not affected by the presence of cells, a boundary-value model of the current flow across the cell layer may be used to derive a relation

Figure 8. Model of current flow paths. The impedance changes associated with the presence of cells, arise in three different regions: from current flow under the cells quantified by α , from current flow in the narrow intercellular spacings causing the barrier resistance R_b . In parallel, some current will pass through the cell membranes giving rise to capacitive reactance C_m .

between the specific impedance of a cell-covered electrode Z_{cell} and the empty electrode Z_{el}

$$\frac{1}{Z_{\text{cell}}} = \frac{1}{Z_{\text{el}}} \left(\frac{Z_{\text{el}}}{Z_{\text{el}} + Z_m} + \frac{\frac{Z_m}{Z_{\text{el}} + Z_m}}{\frac{\gamma r_c}{2} \frac{I_0(\gamma r)}{I_1(\gamma r)} + R_b \left(\frac{1}{Z_{\text{el}}} + \frac{1}{Z_m} \right)} \right)$$

$$\gamma = \sqrt{\frac{\rho}{h} \left(\frac{1}{Z_{\text{el}}} + \frac{1}{Z_m} \right)} \quad (9)$$

where I_0, I_1 are the modified Bessel functions of the first kind of order zero and one, R_b and ρ are the specific barrier resistance and resistivity of the solution, and $Z_m = -2i/(\omega C_m)$ is the specific membrane impedance of the cells. A parameter $\alpha = r_c(\rho/h)^{0.5}$ is introduced as an assessment of the constraint of current flow under the cells. The impedance spectrum of an empty electrode and a cell-covered electrode is used to fit the three adjustable parameters (R_b, α, C_m).

The model outlined above has been further refined to describe polar epithelial cell sheets, treating separately the capacitance of the apical, basal, and lateral membranes (19). Some applications of the model will be discussed in the following sections.

MONITORING ATTACHMENT AND SPREADING

As a cell comes into contact with a solid surface, it forms focal contacts, primarily mediated by transmembrane proteins that anchor structural filaments in the cell interior to proteins on the substrate. During this process, the rounded cell spreads out and flattens on the surface, greatly increasing its surface area in contact with the electrode. The cell will also establish contacts with neighboring cells through particular cell-cell junctions, such as tight junctions, where strands of transmembrane proteins sew neighboring cells together, and gap junctions formed by clusters of intercellular channels, connecting the cytosol of adjacent cells.

The attachment process is normally studied using single-frequency measurements. Figure 9a and b show Bode

Figure 9. (a, b) Bode-diagrams of an ECIS electrode with confluent MDCK cells and an empty electrode. (c) Plot showing the division of the measured resistance of an ECIS electrode with confluent MDCK cells with the corresponding values of the empty electrode plotted versus $\log f$.

plots for ECIS data of an empty electrode and an electrode with a confluent layer of epithelial MDCK cells. It is seen that the presence of cells primarily affects the impedance spectrum for intermediate frequencies between 1 and 100 kHz (Fig. 9a). At the highest frequencies, the two plots approach a horizontal plateau that represents the ohmic solution resistance between the working and the counter electrode. Within the relevant frequency window, the

phase-shift plot for the data of the cell-covered electrode displays two extrema. At frequencies ~ 200 Hz, the phase shift φ is closest to zero, indicating that the contribution of the cells on the measured impedance is mainly resistive. At higher frequencies, the effect of the cell layer becomes more capacitive, and φ starts approaching -90° . The impedance spectrum of the empty electrode displays a single dispersion related to double-layer capacitance at the electrode interface.

The ideal measurement frequencies, where the presence of cells is most pronounced, are determined by dividing the impedance spectrum of a cell-covered electrode with the spectrum of a naked electrode. The same can be done for the resistance or capacitance spectrum, respectively. The most sensitive frequency for resistance measurements is typically found between 1 and 4 kHz (Fig. 9c), where the ratio $R_{\text{cell}}(f) / R_{\text{el}}(f)$ is at maximum. The capacitive contribution peaks at much larger frequencies, typically on the order of 40 kHz, so that capacitance measurements are often performed at this higher frequency.

During the initial hours following the initial electrode-cell contact, the monitored impedance undergoes a characteristic steep increase. Once the spreading is complete, the impedance continues to fluctuate, reflecting the continuous morphological activities of living cells, for example, movements of cells on the electrode, either by local protrusions or directed movements of the entire cell body, or cell divisions (Fig. 10). The signal characteristics of the impedance during the spreading phase are generally found to be distinct for different cell cultures, both in terms of the duration of the initial gradient and its relative size in comparison to the impedance recorded from a the naked electrode (20). Also, characteristic impedance curves can be obtained by coating the electrode with different proteins (e.g., fibronectin, vitronectin) (21).

Simultaneous optical monitoring of a transparent ECIS electrode has allowed systematic comparison of cell confluence and measured impedance (22). Analysis of data from subconfluent MDCK epithelial cultures revealed a strong linear association between the two variables with cross-correlation coefficients > 0.9 ; the correlation was found to be equally strong in early and late cultures. This result indicates that $\sim 80\%$ of the variance in the measured

Figure 10. Attachment assay of BSC and NRK fibroblastic cells followed for an interval of 15 h. The graph shows the measured resistance (4 kHz) as function of time; the spreading phase is indicated with arrows.

Figure 11. Correlation between resistance and cell coverage. The normalized resistance (4 kHz) versus time (upper panel), and the electrode coverage versus time (lower panel) during the same time interval. The measurement was started 32 h after the cells had been seeded out; the cross-correlation factor was $r = 0.94$.

resistance (4 kHz) can be attributed to changes in cell coverage area (Fig. 11). Moreover, it was possible to link resistance variations to single-cell behavior during cell attachment, including cell-division (temporary impedance plateau) and membrane ruffling (impedance increase). The measured cell confluence was compared to the theoretical model (Eq. 9), neglecting the barrier resistance (i.e., $R_b = 0$), and the calculated values were found to agree well with the data (Fig. 12). Studies like these might pave the way for standardized use of ECIS to quantify attachment and spreading of cell cultures.

IMPEDANCE SPECTROSCOPY AS A TRANSDUCER IN CELL-BASED DRUG SCREENING

Another application of impedance spectroscopy with strong physiological and medical relevance is its use as transducer in ECIS-like experiments for cell-based drug screening assays. Here, the impedance readout can be used to monitor the response of cells upon exposure to a certain drug or a drug mixture. In these bioelectric hybrid assays the cells serve as the sensory elements and they determine the specificity of the screening assay while the electrodes are used as transducer to make the cell behavior observable. In the following example, endothelial cells isolated from bovine aorta (BAEC = bovine aortic endothelial cells) were grown to confluence on gold-film electrodes since they

Figure 12. Theoretical prediction of cell coverage. Theoretical curve of normalized resistance plotted as function of cell coverage on the electrode. Normalized resistance and corresponding cell density are shown for four different registrations with circles. Time points indicate when the recordings were initiated with respect to the start of the culture; each circle corresponds to average values for 15 min time intervals.

express cell-surface receptors (β -adrenoceptors) that are specific for adrenalin and derivatives (23,24). These β -adrenoceptors belong to the huge family of G-protein coupled receptors (GPCR) that are of great pharmaceutical relevance and impact. By measuring the electrical impedance of the cell-covered electrode, the stimulation of the cells by the synthetic adrenaline analogue isoproterenol (ISO) can be followed noninvasively in real time without any need to apply costly reagents or to sacrifice the culture (25). Experimentally, the most sensitive frequency for time-resolved impedance measurements is first determined from a complete impedance spectrum along an extended frequency range as depicted in Fig. 13. The figure compares the impedance spectrum of a circular gold-film electrode ($d = 2$ mm) with and without a confluent monolayer of BAECs. The contribution of the cell layer to the total impedance of the system is most pronounced at frequencies close to 10 kHz, which is, thus, the most sensitive sampling frequency for this particular system. It is noteworthy that the most sensitive frequency may

Figure 13. Frequency-dependent impedance magnitude for a planar gold-film electrode ($d = 2$ mm) with and without a confluent monolayer of BAEC directly growing on the electrode surface. The difference in impedance magnitude is maximum at a frequency of 10 kHz.

Figure 14. (a) Time course of the impedance magnitude at a sampling frequency of 10 kHz when a confluent monolayer of BAECs is exposed to 10 μ M ISO or a corresponding vehicle control. (b) Dose-response relationship between the increase of impedance magnitude ΔZ and the concentration of isoproterenol applied. Quantitative analysis reveals an EC_{50} of 0.3 μ M similar to the binding constant of ISO to β -adrenoceptors.

change with the electrode size and the individual electrical properties of the cells under study.

Figure 14a traces the time course of the impedance magnitude at a frequency of 10 kHz when confluent BAEC monolayers were either challenged with 10 μ M ISO or a vehicle control solution at the time indicated by the arrow. The exchange of fluids produces a transient rise of the impedance by 10–20 Ω that is not caused by any cellular response, but mirrors the reduced fluid height within the measuring chamber. As expected, no response of the cells is seen in the control experiment. The cell population exposed to 10 μ M of ISO shows a significant increase in electrical impedance that goes through a maximum 10 min after ISO application, and then slowly declines. The reason for the increase in impedance as observed after ISO stimulation is similar to what has been described for three-dimensional (3D) tissues above. The adrenaline derivative induces a relaxation of the cytoskeleton that in turn makes the cells flat out a bit more. As a consequence the extracellular space between adjacent cells narrows and increases the impedance of the cell layer. Note that the time resolution in these measurements is ~ 1 s so that even much faster cell responses than the one studied here can be monitored in real time. Moreover, no labeled probe had to be applied and

the sensing voltages used for the measurement ($U_0 = 10$ mV) are clearly noninvasive.

From varying the ISO concentration, a dose-response relationship (Fig. 14b) can be established which is similar to those derived from binding studies using radiolabeled ligands. Fitting a dose-response transfer function to the recorded data returns the concentration of half-maximum efficiency EC_{50} as $(0.3 \pm 0.1) \mu M$, which is in close agreement to the binding constant of ISO to β -adrenoceptors on the BAEC surface as determined from binding assays with radiolabeled analogs (23).

These kind of electrochemical impedance measurements are also used to screen for potent inhibitors of cell-surface receptors. Staying with the example discussed in the preceding paragraph, the blocking effect of Alprenolol (ALP), a competitive inhibitor of β -adrenoceptors (β -blocker), is demonstrated. Preincubation of BAEC with ALP blocks the stimulating activity of ISO, as shown in Fig. 15. The figure compares the time course of the impedance magnitude at a frequency of 10 kHz when BAEC monolayers were stimulated with $1 \mu M$ ISO either in absence of the β -blocker (a) or after preincubation (b).

Figure 15. (a) Time course of the impedance magnitude at a sampling frequency of 10 kHz, when confluent BAEC are exposed to $1 \mu M$ ISO. (b) Time course of the impedance magnitude of a confluent monolayer of BAECs upon sequential exposure to $10 \mu M$ of the β -blocker ALP and $1 \mu M$ ISO 20 min later. The β -adrenergic impedance increase is omitted by the β -blocker. Intactness of the signal transduction cascade is verified by addition of forskolin (FOR), a receptor independent activator of this signal transduction pathway.

Figure 16. Time course of the impedance magnitude at a sampling frequency of 10 kHz when a confluent BAEC monolayer is exposed to an over dose of the β -blocker alprenolol ($100 \mu M$ ALP). Addition of ALP is indicated by the arrow.

When the cell layers were incubated with $10 \mu M$ ALP prior to the addition of $1 \mu M$ ISO, the cells do not show any ISO response indicating that a 10-fold increase of ALP was sufficient to block activation of the receptors. To prove that the cells were not compromised in any way during these experiments the same signal transduction cascade was triggered via a receptor-independent way at the end of each experiment. This can be easily done by application of FOR, a membrane permeable drug that intracellularly activates the same enzyme that is triggered by ISO binding to the receptor. Forskolin stimulation of those cells that had been blocked with ALP earlier in the experiment induces a strong increase of electrical impedance indicating that the intracellular transduction pathways are functional (Fig. 15b).

Besides screening for the activity of drugs in cell-based assays, these kind of measurements are also used to check for unspecific side effects of the compounds of interest on cell physiology. Dosage of ALP and many of its fellow β -blockers has to be adjusted with great care since these lipophilic compounds are known to integrate nonspecifically into the plasma membrane. As shown in Fig. 15b, application of $10 \mu M$ ALP does not show any measurable side effects. Using ALP in concentrations of $100 \mu M$ induces a transient but very pronounced reduction of the electrical impedance (Fig. 16). This decrease in impedance may be the result of the interaction of ALP with the plasma membrane or an induced contraction of the cell bodies.

The preceding examples showed that impedance measurements of cell-covered gold electrodes in which the cells serve as sensory elements can be used in screening assays for pharmaceutical compounds, but also for cytotoxicity screening. The interested reader is referred to Ref. 26 and 27.

SUMMARY AND OUTLOOK

Impedance spectroscopy is a general technique with important applications in biomedical research and medical diagnostic practice. Many new applications are currently under investigation and development. The potential of the

technique is obviously great, since it is noninvasive, easily applied, and allows on-line monitoring, while requiring low cost instrumentation. However, there are also difficulties and obstacles related to the use of IS. Foremost, there is no separate access to the individual processes and components of the biological system, only the total impedance is measured, and this signal must be interpreted by some chosen model. There are many fundamental issues yet to be solved, both connected with understanding the origin of bioimpedance, methodological problems with finding standardized ways of comparing different samples, as well as technical issues connected with the equipment used to probe bioimpedance.

Prospective future *in vivo* applications include quantification of ischemia damage during cardiac surgery (28) and organ transplantation (29), as well as graft rejection monitoring (30). Impedance spectroscopy are also used for tissue characterization, and recently a device for breast cancer screening became commercially available. Multifrequency electrical impedance tomography (EIT) performing spatially resolved IS is a potential candidate for diagnostic imaging devices (31), but due to poor resolution power compared to conventional methods like MR, only few clinical applications are described.

The use of impedimetric biosensor techniques for *in vitro* monitoring of cell and tissue culture is promising. With these methods, high sensitivity measurements of cell reactions in response to various stimuli have been realized, and monitoring of physiological-pathological events is possible without use of marker substances. The potential applications cover pharmaceutical screening, monitoring of toxic agents, and functional monitoring of food additives. Microelectrode-based IS is interesting also for scientific reasons since it allows studying the interface between cells and technical transducers and supports the development of implants and new sensor devices (32).

Finally, affinity-based impedimetric biosensors represent an interesting and active research field (33) with many potential applications, for example, immunosensors monitoring impedance changes in response to antibody-antigen reactions taking place on electrode surfaces.

INCUBATORS, INFANTS

ROBERT WHITE
Memorial Hospital South Bend
South Bend, Indiana

INTRODUCTION

Providing newborn infants with appropriate thermal protection is known to improve their growth rates (1–3), resistance to disease (4,5) and survival (6–11). Keeping premature, sick, or otherwise high risk babies warm is particularly critical and, when their care precludes covering them with protective swaddling clothing, especially difficult. Incubators are devices used during the care of such high-risk infants and are designed with the intent of producing environmental conditions that are consistently suitable to each unique infant's particular needs. There are many different kinds of incubators that differ in detail in the way they are constructed, heated, and controlled (12–16). All provide a mattress for the infant to lie upon, surrounded by a warmed microclimate that is controlled by a logical system governing the amount of heat needed to keep the environmental temperature within a limited range. In some incubators, this microclimate is produced within a rigid walled chamber; such devices are called closed incubators. When they are heated by using a fan to force air over a metallic heating coil prior to its entry into the infant's chamber, these closed incubators are also called forced convection incubators. There also are open incubators; those have no walls and, therefore, no chamber surrounding the mattress. There is nothing delimiting the convective environment in an open device, so they need to be heated by using a radiant warmer directed to the mattress area. These devices, therefore, are commonly called open radiant incubators, radiant warmer beds, or radiant heaters.

Each of these types of incubators provides certain unique advantages. The convectively heated incubator

provides a caretaker with a far easier method for controlling the humidification of the infant's microclimate, when compared to the open radiant warmer bed. Therefore, a baby under an open radiant heater loses more body fluid than does an infant within a closed convectively heated chamber (17). But conversely, a baby in an open incubator, while more complicated to care for in terms of medical fluids administration, is physically more accessible in terms of other kinds of care that sometimes are equally important to the well being of sick babies. Current "top of the line" incubators incorporate the advantages of both types, utilizing a radiant warmer bed with a removable enclosure that allows full physical access to the infant when the incubator is operated in the radiant heater mode, and better control of humidification and noise when the enclosure is placed around the baby and operated in the convectively heated mode.

An incubator, in many respects, is just a very little house sized to fit the space and functional requirements of an infant occupant. As choices must be made when conditioning the environment in any house, different options must be considered when designing the climate control system in an incubator. In the following review, some of these considerations will be explained from the perspective of how environmental manipulators affect newborn infants who are not just little human adults, but also developing individuals with special physical, physiologic, metabolic, and neurological capabilities and limitations that make them unique. In great measure incubator manufacturers have been successful in translating present day knowledge of babies and their special needs into technical solutions that make today's incubators remarkably functional. But any infant caretaker or incubator manufacturer can attest to the limitations of today's devices which, as they are approximate to our present scientific knowledge and the existing level of technology, are flawed by our considerable remnant ignorance and the failure of existing technology to meet certain imperative needs already known.

HISTORY

It is ancient knowledge that infants who are allowed to get cold have a greater chance of dying than do infants kept warm. Prior to the nineteenth century, keeping small babies warm meant swaddling with multiple layers of cloth, providing body contact with the mother, or placement of the infant near a warm, roaring fireplace. Such classic thermal care served lusty, healthy babies well, but was inadequate to provide for the special needs of premature or otherwise enfeebled newborns. These special needs were not met because, until the last century, there was almost no recognizable major medical or social commitment toward enhancing the survival of babies born prematurely. The infant mortality rate was high and accepted. However, in response to various politico-social events that occurred in the late 1700s and early 1800s, the value of improving premature infant survival increased, stimulating the development of special incubators in which to care for these fragile, newly valued babies.

Figure 1. von Ruehl warming tub (1835). Reprinted with permission from T. E. Cone, Jr., *History of the Care and Feeding of the Premature Infant*, Boston, MA: Little, Brown, 1985.

The first serious attempt to improve on the thermal protection provided newborns was reflected in a warming tub developed in 1835 by Johann Georg von Ruehl (1769–1846) in Russia (Fig. 1). The von Ruehl tub was simply a double-walled sheet-iron open cradle that was kept warm by filling the space between the walls with warm water. Variations on von Ruehl's design were subsequently developed throughout Europe, and this type of primitive open incubator remained a standard device for care until 1878.

Although the von Ruehl device must be recognized as a developmental milestone, to be truly accurate, the developmental history of modern infant incubators must be traced back centuries to Egypt where the artificial incubation of eggs was refined and remained a closely guarded secret and uniquely Egyptian profession. Not until 1799 were these secrets introduced into Europe by members of Napoleon's expedition. Professor Stephane Tarnier (1828–1897) of the Paris Maternity Hospital in 1878 saw a chicken incubator at the Paris Zoo. The incubator, based on old Egyptian designs, had been constructed by Odile Martin. Dr. Tarnier perceived how such a device, with modifications, could be used to keep premature infants warm. Odile Martin subsequently built the first approximation of the modern enclosed infant incubator initially used at the Paris Maternity Hospital in 1880 (Fig. 2)

The Tarnier incubator was simple in its design. The infant lay in the upper chamber of a two-chambered double-walled box insulated to slow the loss of heat. The infant chamber was topped with a removable cover through which the infant could be observed while remaining protected from cooling room drafts. The heating of the upper chamber was achieved by warming a large supply of water contained in the lower chamber of the incubator. The water was heated by an alcohol or gas lamp thermosyphon that was external to the incubator chambers and connected by piping that allowed convection driven water flow between the heater and the water reservoir. Cool room air freely flowed into the lower warming chamber where the air picked up heat from the surface of the warm water reservoir and then, by natural convection, rose to enter and warm the upper chamber containing the infant.

The Tarnier incubator was neither elegant nor efficient, and even when within the device, infants needed the extra

Figure 2. Tarnier incubator (1880). Reprinted with permission from T. E. Cone, Jr., *History of the Care and Feeding of the Premature Infant*, Boston, MA: Little, Brown, 1985.

protection of swaddling blankets. It did, however, reflect the technology of its day and, in the climate of a new commitment toward the study and welfare of feeble infants, stimulated others to refine the basic Tarnier design to correct deficiencies discovered through acquired practical experience with the incubator in clinical settings. The historical progression in this development has been illuminated by Dr. Thomas Cone, and the reader is referred to Dr. Cone's excellent treatise for a more detailed description of the many design variations introduced and tested along this early path leading to today's equipment (18).

The modernization of incubators has not only led to marked improvement in the thermal protection provided infants, but it also has been pivotal in increasing our knowledge of diseases unique to newborn babies. In turn, each increment of knowledge has required manufacturers to modify incubators in order to provide solutions to problems the new scientific discovery imposed. For example, when electric fans became available and forced air convection systems were developed, incubator heating became so improved that infants for the first time could be undressed during care. This along with the use of new transparent plastics in the construction of incubator walls allowed clinicians to make observations that led to detailed descriptions of illnesses about which little was known when infants were hidden within the predominately opaque wooden and metal chambers of the past. But while the employment of clear plastic in incubator construction enhanced the ability to observe infants, its poor insulating qualities made the task of maintaining the incubator chamber in a warm and stable state more difficult. And as improved visibility led to new lifesaving therapies, such as the administration of intravenous fluids, the use of respirators in care, and the development of new diagnostic procedures and surgical interventions, the transparent plastic walls that provided caretakers with visual access to sick babies during these therapeutic processes also served as impediments. Incubators had to be modified so that catheters, tubes, and wires could be connected to an infant's body. Increasing numbers of access holes were

drilled through the walls of the incubator to provide portals of entry for these therapeutic tools, but the new fenestrations also produced new exits for life-sustaining heat. More modifications were needed and, as each problem was solved, a new dilemma emerged.

Even today, infant caretakers and incubator manufacturers continue to struggle with these and other problems contributing to the strengths and weaknesses in incubator devices. In this article, the physiologic, clinical, and technical factors leading to the design of existing incubators will be outlined further and some of the limitations of incubators explained in greater detail. Throughout, we hope that it remains clear that incubator development is an ongoing process requiring frequent and critical review of existing methods to assure that the thermal protection being provided is still appropriate during the delivery of other and especially newer forms of care also deemed necessary to a baby's well being. The ideal incubator of tomorrow is one that neither impedes care nor can itself, when providing thermal protection, be impeded by other forms of care. This has always been and remains the major challenge to health care providers and engineers committed to incubator development.

FACTORS CONSIDERED IN INCUBATOR DESIGN

Physiological Heat Balance

Even though some controversy exists concerning the exact definition of the body temperature limits within which a newborn's body functions optimally, in general, any temperature between 35.5 and 37.5 °C is probably within that normal range and can be referenced to published data available on the subject. Body temperature is determined by the balance between the heat produced within and lost from the body tissues. In order to design or even understand the design and limitations of modern incubators, a knowledge of these basic factors is required to provide the context for how infants differ from adults in their thermoregulatory capabilities.

Heat Production

All animals, including human babies, produce body heat as a by-product of the biochemical processes that sustain life. The basic amount of heat produced by a newborn infant is $\sim 1.5\text{--}2\text{ W}\cdot\text{kg}^{-1}$. During the first weeks of life, this minimal rate of heat production is both weight and age related, with smaller and younger babies capable of producing less heat than larger and older infants (19–23).

In addition to this basic capacity, most healthy babies have the capability to generate additional heat to a maximum production rate of $\sim 4.5\text{--}5\text{ W}\cdot\text{kg}^{-1}$ (21–23). This additional heat-producing capacity is often called upon for protective purposes, as, for example, when the infant is challenged to fight off infection or when stressed by situations that cause an exorbitant amount of heat to be lost from the body. The capability to increase the amount of heat produced to replace body heat losses is called homeothermy. In contrast to homeotherms, some creatures, such as lizards, reptiles, and fish, are poikilotherms that

do not produce more heat when cooled, but actually decrease their metabolic rates when exposed to cold.

When considering thermoregulatory problems associated with newborn care, both homeothermy and poikilothermy must be understood, because under some circumstances, it is possible for a homeothermic animal to behave like a poikilotherm. Sometimes during the medical care of humans this possibility is used to a patient's benefit; for example, during some heart operations patients are given drugs that prevent their nervous systems from responding to the cold. In this circumstance, it is desirable to slow the body's metabolic rate, which can be achieved by cooling the drug treated patient who, by intent, has been changed to a temporary poikilotherm.

At times, a homeotherm may revert temporarily to a poikilothermic state. This is particularly common in immature or very sick newborns, and especially those with neurologic damage (24) or with breathing problems that lead to inadequate blood and tissue oxygen levels (25,26). Poikilothermy in a newborn can also occur because of drugs administered to a mother in labor with subsequent placental transport of those drugs to the infant (27).

In spite of their occasional reversion to poikilothermy, it nonetheless is commonly advised that newborns should be thought of as homeotherms and protected from environments that would unduly stimulate homeothermic tendencies. This is because homeotherms increase heat production by increasing metabolic work which can cause excess utilization of finite fat, sugar, and protein stores needed to sustain other vital body functions and to meet growth and developmental milestones. Moreover, extra metabolic work produces more than just extra heat; acidic and other metabolic by-products produced at the same time can cause severe imbalances in the body's critical acid–base balance (4). As a consequence of the self-protective reaction to cold stress a newborn may, therefore, be faced with an equally life-threatening biochemical stress (Fig. 3).

It has been suggested that one reason cold-exposed infants have higher mortality rates is that they become metabolically exhausted and incapable, in part because of the consequent acidosis, to fight off the stresses placed on their bodies by other threatening events. But problems can arise when attempts are made to provide infants with protection from cold stress, since it is unclear how to be sure that a given environment minimizes the infant's metabolic efforts to maintain homeothermy. Theoretically, this could be achieved by measuring the infant's metabolic rate continuously and making adjustments in the environmental supports whenever the infant's rate of metabolism changed, but measurement of heat production by a newborn is very difficult in the clinical setting.

In any case, few infant caretakers would consider the infant's metabolic rate as the only measure of success when providing a baby with thermal protection. The infant's actual body temperature is also considered important (21) and it is well known that metabolic rate is only one factor contributing to the body temperature measured. Body temperature also is influenced by the rate at which heat is lost from the body and, if one wishes to produce a device that contributes to the maintenance of an infant's body temperature, it is necessary, by virtue of its balancing

Figure 3. Schematic of homeothermy in newborns. On sensing loss of body heat, the infant minimizes heat loss from the skin by vasoconstricting blood vessels, changing body positions, and increasing metabolic rate. The increase in metabolism can produce acidosis and depletion of energy substrate stores. Reproduced by permission from P. H. Perlstein, "Routine and special care—Physical environment." In A. A. Fanaroff and R. J. Martin (Eds.), *Behrman's Neonatal-Perinatal Medicine*, 3rd ed., St. Louis, MO: C. V. Mosby Co., 1983.

effect on the final body temperature achieved, to understand how heat loss occurs in newborns.

Heat Loss

In the final analysis, incubators actually protect infants only by modifying the factors that contribute to heat loss via the well-known conductive, convective, radiant, and evaporative mechanisms.

The flow of heat occurs only when there is a difference in the temperatures of adjacent structures. Heat can only be lost by a warmer object to a cooler one. Conductive heat losses occur when an infant comes in physical contact with a cooler solid surface. A baby loses heat by conduction to a cooler mattress, blanket, diaper, or other clothing. Convective losses are similar to, but independent of, conductive losses and occur when a baby is exposed to air currents that are cooler than the infant. Convective losses are influenced not only by temperature differences, but also by the wind chill factor determined by speed at which the air is flowing. In a practical sense, this means that if an incubator has a fan as part of a forced convection heating system, air movement produced by the fan can cause a cooling effect in excess that which would occur if air at the same temperature was still.

Heat loss in infants also occurs by radiation in the infrared (IR) spectrum to cooler solid objects surrounding, but not in contact with their skin. The incubator and room walls, windows, and furniture all contribute to heat loss via radiant mechanisms. Finally, evaporative heat losses occur

as infants transpire water from their skin into the surrounding environment. They can also lose heat by evaporation as residual amniotic fluid or bath water dries from their skin and hair, and they lose heat from their lungs as they exhale warm humid air.

Gross estimates of the magnitude of heat loss can be calculated by physical heat-transfer equations for each mechanism. The reader is referred to thermal transfer books for the details of these mechanisms, but examination of these equations here in a simplified form is a useful way to discover some of the special features that influence heat transfer as applied to newborn care.

All nonevaporative heat losses are quantitatively proportional to the magnitude of the temperature difference between the warmer object (T_o) losing heat and the cooler environmental feature (T_e) that will receive the heat in transfer:

$$\text{Heat loss} = \propto (T_o - T_e)$$

This equation becomes equality by adding to it an object specific constant called a thermal transfer coefficient (k):

$$\text{Heat loss} = k(T_o - T_e)$$

Different materials at the same temperature lose heat at different rates when exposed at the same thermal environment; for example, a block of wood has a lower thermal transfer coefficient than a block of steel. Newborn infants have higher thermal transfer coefficients than do adults and therefore lose body heat more rapidly than adults when exposed to any environment that is cooler than body temperature, so in a room temperature that feels comfortable to an adult, a newborn can get cold.

It must be emphasized that the heat loss equation as written above is grossly simplified and omits numerous other factors important to actual heat exchange. A more accurate equation would have to include a factor accounting for the infant's exposed surface area, which is a quantity that changes with changes in an infant's position and is modified if the infant is swaddled in blankets, wears a diaper, booties, hat, or, if in the course of surgical care, has a bandage applied. The equation as simplified particularly fails to reflect the true degree of complexity describing the thermal relationship between an infant's skin and the radiant surfaces of a room or incubator. The relationship is modified, for example, by complex factors describing the exact path and distance traveled by infrared (IR) waves in their transfer from object to object.

Radiant heat loss is also modified by the emissivities of the objects exchanging energy. Like black carbon, an infant's skin, no matter what its actual color, is presumed to have an emissivity of 1, which means it absorbs and emits IR rays perfectly and completely. The emissivities of the materials used in incubator manufacture or in nursery wall coverings also modify the amount of radiant exchange occurring with the infant's radiant surface. The emissivities of these objects become particularly important in an incubator chamber in which the surface area of the interior walls surrounds the exposed surface area of the infant's radiating skin.

The following equation, although still simplified, provides a better approximation of expected radiant losses (H_r)

from an infant in an incubator (28). In this equation, A_b is the exposed surface area of the infant, A_r is the area of the walls surrounding the infant, E_s is the emissivity of the infant's skin, and E_r is the emissivity of the walls. The symbol σ is the Stefan-Boltzmann constant, $5.67 \times 10^{-8} \text{ W}^{-1} \cdot \text{m}^{-2} \cdot \text{K}^{-4}$. When using this equation, temperatures are expressed in kelvin and the heat loss in watts.

$$H_r = A_b \left[\frac{1}{E_s} + \frac{A_b}{A_r} \left(\frac{1}{E_r} - 1 \right) \right]^{-1} \sigma (T_s^4 - T_r^4)$$

Radiant exchange relationships are so variable because of differences between infants and different incubator environments that, even using this more complex equation, only poor and static quantitative approximation of actual radiant flux can be made in clinical settings. This proves to be a practical problem when considering incubator designs, since it has been documented that in many situations radiant losses can account for >60% of the total heat loss from an infant (29).

Evaporative heat losses are not specifically related to temperature difference and occur instead because of differences that exist between the partial pressures of water in the boundary layer of air next to the infant's skin and that in the environment beyond the boundary layer limits.

$$\text{Evap loss} = K(\text{partial pressure skin} \\ - \text{partial pressure air})(\text{ares})$$

Partial pressures are not the same as relative humidities, so even in an environment at 100% relative humidity, an infant can lose water and heat if the skin surface is warmer than the environment. For each milliliter of fluid lost from the body, $\sim 580 \text{ g} \cdot \text{cal}$ (2.4 kJ) of heat are lost in the vaporization process. This route of heat loss accounts for $\sim 25\%$ of the total heat loss when an infant is dry. When lying unclothed on an open bed heated only by a radiant heater, up to $300 \text{ mL}^{-1} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ of fluid can be lost by evaporation from the skin of very immature infants in the first days of life. In an enclosed incubator that is poorly humidified, up to $150 \text{ mL}^{-1} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ of water can be lost by this mechanism in very immature infants. Following birth when the infant is wet with amniotic fluid, or following a bath, this can become the predominant route of heat loss (30–34,34).

Environmental Temperature

It should be obvious from the previous discussion that since conduction, convection, radiation, and evaporation are each relatively independent mechanisms, no single measurable quantity can be used to calculate their combined contribution to heat loss. Air temperature, for example, can be used to estimate only the convective component of heat loss from a baby, while measurements of incubator inside wall temperatures can only be helpful in determining approximate losses due to radiation. This means that if the incubator walls are cold, a baby in an incubator can lose heat even if the air temperature is warmer than the infant. The only feature necessary for this to be true is for radiant losses to be higher than convective heat gains.

Environmental temperature, although frequently used loosely to describe any ambient thermal value, must be

understood to be a specific reference to the combination of temperatures actually experienced by an infant in thermal exchange relationships via multiple mechanisms. Unfortunately, few guidelines exist at present to help caretakers know the true environmental temperature for an infant within an incubator in a clinical setting. When certain conditions are met, however, some of the guidelines seem to be useful. Dr. Hey, for example, determined that in a well-humidified enclosed convectively heated incubator with single-layer Plexiglas walls, the environmental temperature perceived by a contained infant is $\sim 1^\circ\text{C}$ lower than the measured midincubator chamber air temperature for every 7°C difference that exists between the incubator air temperature and the air temperature of the room within which the incubator stands (35).

Heat Transfer within the Body

Since the skin of the newborn is the major heat-losing surface in exchange with the environment, mechanisms by which heat transfers from interior tissues to the skin play an important part in the heat loss process. The rate at which internally produced heat is transferred from the body core temperature T_B through body tissues to the outer body skin surface at temperatures T_s is computed using the following equation:

$$\text{Heat transfer} = C(T_B - T_s)$$

Where C is an individual's specific thermal conductance coefficient, which is affected by the absolute thickness and character of the skin, subcutaneous fat, and other subcutaneous tissue, and by the blood flow rate from the body core to its surface. Obviously, babies are smaller and have thinner body coverings than do adults, and, therefore, as they lose heat more rapidly from their surfaces than do adults, they also transfer heat more rapidly to their surfaces from their internal heat-producing organs. In addition, an infant's blood vessels are relatively close to the body surface. Since the vascularity of a particular body surface determines the rate at which blood will shunt core heat around intervening insulating tissues to the skin surface, such shunting contributes heavily to the high thermal conductance of a baby.

Heat can also be lost rapidly from an infant's body core via the respiratory system. This route of loss is of relatively minor significance in a healthy and spontaneous breathing infant, but in a baby who is ill and especially one being mechanically assisted by a respirator, this can become the major route by which body heat is lost or gained. Body heat transferred by this route is dependent on the infant's temperature, breathing rate, the flow rate and temperature of gases reaching the lungs, and the water content of the gas delivered to the airway. If temperatures and humidification are not properly monitored and controlled, the heat losses from the respiratory passages can be so great that they exceed the capacity of the incubator heater.

The Concept of a Neutral Thermal Environment

Theoretically and as demonstrated by several authors (21,36,37), it is possible for a competent homeothermic baby to have a body temperature that is below the normal

range at a time when the measured metabolic rate of the infant is at a minimal unstimulated level. For example, Brück (36) documented that during a period of cooling associated with a falling environmental temperature, an infant's metabolic rate and heat production increased, but, as soon as the cooling environment was caused to reheat, the infant's metabolic rate decreased to minimal heat-producing levels, and this decrease occurred even before the infant's cooled body temperature returned to normal. This was confirmed by Adamsons et al. (21) and again in the study by Grausz (37).

The study by Adamsons et al. in particular provided some insight into why homeothermic reactions are not predicted only by examination of static body temperatures. In this study, the metabolic rates of infants in various thermal environments were determined and correlations computed to determine the relative value of measuring only rectal temperature, skin temperature, or environmental temperature, or only the difference between the skin and environmental temperatures, in reliably predicting what the infant's metabolic rates actually were at the time the temperature measurements were made. The study determined that no correlation existed between rectal temperature and metabolic rate, a slightly better correlation existed between environmental temperature and metabolic rates, a still better correlation with skin temperature existed, and an almost perfect correlation was demonstrated between metabolic rate and the difference between skin and incubator environmental temperatures (Fig. 4). These results can be understood by recalling that when body temperature is stable, heat production or metabolic rate must be equal to the rate of heat loss from the infant. If this balance does not exist, the infant will get either warmer or cooler, depending on the direction of the imbalance. So if heat production equals heat loss and heat loss is proportional only to the difference between the magnitude of the skin and environmental temperatures and not to the magnitudes themselves, it follows that heat production must also be related to the same temperature difference and, similarly, should be relatively independent of any single absolute temperature value.

These discoveries led to an approximate definition of what might constitute an optimal thermal environment in which to raise small infants. This environment is called a neutral thermal environment, referring to that set of thermal conditions existing when an infant is in a minimal metabolic state and has a body temperature that is within a normal range.

From the previous discussion, it might seem reasonable that to provide an infant with a neutral thermal environment it is necessary then only to establish skin-to-environment temperature gradients documented in various published studies to be associated with minimal metabolic rates in infants with normal temperature. Unfortunately, such references can provide only very rough guidelines, since any one infant can achieve different minimal rates of metabolism at different times and, if body temperature is to be kept stable, each change in this minimal achievable heat production rate must be balanced with a change in the amount of heat loss allowed. When the minimal heat production increases, the skin environmental temperature

Figure 4. Metabolic rate expressed as oxygen consumption (V_{O_2}) as correlated with rectal temperatures, skin temperature, incubator environmental temperature, or the difference between the skin and environmental temperature (ΔT_{s-e}). Reproduced by permission from P. H. Perlstein, "Routine and special care—Physical environment." In A. A. Fanaroff and R. J. Martin (Eds.), *Behrman's Neonatal-Perinatal Medicine*, 3rd ed., St. Louis, MO: C. V. Mosby Co., 1983. Adapted from Adamsons et al. (21).

difference needs to be increased, and when the minimal heat production falls, the gradient needs to be decreased. Although concepts such as the neutral thermal environment can be discussed using static equations, it must be remembered that they actually are used only in dynamic settings.

In any case, it is very difficult to provide an infant with truly neutral thermal conditions and becomes practically impossible in some common situations, such as when head hoods or other auxiliary gas delivery devices are used during care. Head hoods are small plastic boxes or tents made to enclose the infant's head when resting on a mattress. The hoods are used to deliver and control the concentration of humidified oxygen to the infant. Since the head of an infant can represent 20% of the infant's body surface, a significant amount of body heat can be lost if the head if the head hood temperature is not carefully controlled. Even if the temperature is controlled by prewarming the oxygen prior to its delivery into the head hood, the infant can lose heat if the gas is delivered at a flow rate that produces an excessive wind chill component to the convective heat flux. It also has been documented that even when total body heat losses are less than usually needed to stimulate a homeothermic response, any local cooling of facial skin tissue can stimulate a baby to become hypermetabolic (36,38).

Since no studies have been published to provide guidelines for establishing neutral thermal conditions in an incubator containing auxiliary sources of heating and cooling, and because such sources are very commonly used during infant care, no incubator manufacturer can guarantee, when an auxiliary devices are used, that such conditions can be produced by any incubator on the market today. As a corollary, unless both body temperatures and infant metabolic rates are continuously monitored, infant caretakers and medical researchers are similarly constrained from claiming precision in their delivery of continuous and certifiable thermal protection that is consistent with the concept of thermoneutrality.

Before we leave this subject, it should also be noted that a significant number of knowledgeable baby care specialists disagree with the idea that a neutral thermal environment represents an optimal goal for incubator control. Their arguments are numerous, but most often include the irrefutable fact that no one has ever documented scientifically that such protection is really beneficial. They also cite the studies by Glass et al. (2,3) in which it was documented that babies tend to lose their very important self-protective ability to react as homeotherms if not exposed to periodic cold stresses. This means that one price paid by an infant raised in a neutral thermal environment is adaptation to that environment and, much as a prolonged stay in the tropics diminishes an adult's capacity to tolerate the northern winters, a baby so adapted may be more susceptible to the damaging effects of unavoidable occasional exposures to the cold.

It must be emphasized that the arguments against the neutral thermal environment are not arguments in favor of letting all babies stay cold; the debate primarily concerns whether a baby is better off in an environment that theoretically maximizes growth by reducing metabolic work to an absolute minimum but might increase the infant's susceptibility to subsequent stresses, or better off in an environment that very mildly stimulates the infant to metabolically contribute to his own ongoing thermal welfare so that important self-protective capabilities are not forgotten. As yet there are insufficient scientific data to resolve this issue. A more recent observation is that the body temperatures of the fetus and older infant are higher than the typical neutral thermal environment proposed for preterm infants, and in both cases, follow a circadian rhythm that is not observed or supported in the typical infant incubator. These considerations imply that while the "neutral thermal environment" is a useful concept for current incubator design, it is not yet known how the "optimal thermal environment" should be defined, especially for the preterm infant.

INCUBATOR STUDIES

In spite of the difficulties encountered when attempting to define, let alone achieve, the optimal environmental conditions that are protective for small babies, it is clear that babies raised in different environments do have different survival rates. The scientific studies documenting these differences in survival in different environments are worth

reviewing, since they have provided insight into features distinguishing some incubators from others and ways in which these features may produce environments that can prove to be both protective to some infants and dangerous for others. These studies have also been the major impetus to changes in designs that have resulted in the kinds of incubator devices in use today.

With few exceptions, until the early 1970s, incubator designers relied only on convective heaters to warm the chamber within which a baby was contained. Such devices were relatively simple to construct and provided a method whereby the chamber mattress could be kept warm thereby limiting conductive heat losses, and a method to keep the surrounding air warm, limiting convective losses. The use of wet sponges early in the history, and later evaporation pans, over which the convective currents of warmed air passed before entering the infant's chamber, provided the humidity needed to limit evaporative losses. Additionally, the warmed air contained in the chamber produced some warming of the chamber walls thereby reducing to some degree radiant heat losses from the infant. The heating units in early models of these incubators were controlled only by simple air temperature-sensitive thermostat mechanisms.

Such an incubator with clear plastic walls for enhancing visualization of the contained infant was used in a famous series of infant survival studies published between 1957 and 1965. In this incubator, a fan was used to force the convective air currents into the infant's chamber after passage over a heating element through a turbulence producing baffle resting in a humidifying pan of water. A highlight of these studies was published in 1958 by Silverman et al. (7) who compared the survival rates of two groups of premature infants cared for in this convectively heated and humidified device. For one group of infants the incubator air was heated to 28°C and for the other group the air was heated to a warmer 32°C. The study resulted in a conclusion that infants cared for in the warmer incubator had a higher survival rate than did infants cared for in the cooler incubator. During the study it was observed that although babies in the warmer incubator had a greater chance of surviving, not all of the infants who survived in the warmer incubator had warm body temperatures; in fact, 10% of the babies in the 32°C incubator had body temperatures ~35.5°C. Dr. Silverman deduced that the reason some of the babies got cold was due to excessive radiant heat losses to the thin plastic chamber walls that were cooled by virtue of their exterior surfaces being exposed to the cooler nursery environment.

Dr. Silverman wished to test whether even better survival rates could be achieved by assuring that an infant was not only in a warm incubator, but that the infant's body temperature also was always kept within a normal range. Along with Dr. Agate and an incubator manufacturer he helped develop a new incubator that was radiantly heated to reduce the radiant losses observed when the incubator was only convectively heated (39). To assure that the contained infant's temperature was maintained within normal range, the new incubator employed an electronic feedback servo-control mechanism that responded to changes in the temperature of a thermistor attached to

Figure 5. Logic leading to development of skin servo-controlled radiantly heated convectively ventilated incubator. (1) An unprotected baby loses heat from skin surfaces by conduction, convection, evaporation, and radiation. (2) A radiant heater eliminates radiant and conductive losses, but not those caused by convection and evaporation. (3) An unhumidified convectively heated incubator eliminates convective and conductive losses, but not those caused by radiation and evaporation. (4) Humidifying a convectively heated incubator eliminates all major losses except for the losses by radiation. (5) Using a radiant heater to warm a convectively ventilated and humidified incubator should eliminate all sources of heat loss from the infant's skin. (6) Normal infant temperature can be ensured by adding a controller to the incubator so that power is delivered to the radiant heater whenever the infant's skin temperature falls below a preset value. Reproduced by permission from P. H. Perlstein, "Routine and special care—Physical environment." In A. A. Fanaroff and R. J. Martin (Eds.), *Behrman's Neonatal-Perinatal Medicine*, 3rd ed., St. Louis, MO: C. V. Mosby Co., 1983.

the infant's skin surface, causing the incubator's radiant heater to turn on or off, depending on whether the transduced skin temperature value was below or above an absolute temperature value considered normal (Fig. 5).

Note that before settling on a servo-controlled, radiantly heated and convectively ventilated system Agate and Silverman did explore alternative methods whereby an incubator could be equipped to guarantee that an infant's temperature was maintained within a normal range. In particular, they considered simply using the well-established convective heating system in the servo-control loop but rejected this approach when they discovered that when servo controlled in response to changes in skin temperature, the convective heater produced massive and unacceptable changes in air temperature within the incubator chamber. The servo-controlled radiant heater, however, produced an environment in which the air temperature was quite stable, especially when compared to the thermal cycling recorded within the convectively heated servo-controlled system.

The radiantly heated, convectively ventilated, and skin servo-controlled enclosed incubator was evaluated in two independent studies, with results published in 1964 (9,10). In these controlled trials, premature infants were divided into two groups: one group of infants was provided care in the new radiantly heated incubator that was servo controlled to maintain the contained infant's skin temperature at 36 °C, while the other group of like babies was cared for using the simpler 32 °C air temperature thermostat-controlled convectively heated incubator that Silverman's group concluded was the best incubator setup in their previous study published in 1958. The two studies in 1964 reached a common conclusion; the skin temperature-controlled radiantly heated system produced higher survival rates when used during the care of the infants studied. Because of fabricating difficulties, though, this radiantly heated incubator model was commercially marketed for only a short period of time; soon after its introduction, it was replaced on the commercial market by a skin servo-controlled convectively heated enclosed

incubator that was easier to fabricate and, like the radiantly heated device, was also capable of keeping an infant's skin temperature at a value considered normal.

The introduction of this convectively heated servo-controlled device on the market was justified by an extrapolated interpretation of the studies reported in 1964. This common interpretation led to a conclusion that the studies simply demonstrated that, in terms of survival, it was only important to keep a baby's skin temperature warm and stable. The interpretation ignored the fact that more than just a difference in skin temperatures distinguished the two study groups. Infants in the two different study environments, the one produced by an air temperature referenced thermostat controlling a convective heater and the other by a skin temperature referenced servo system controlling a radiant heater, were also, as previously well discussed by Agate and Silverman, exposed to environments that differed in the frequency and amplitude of thermal cycling produced by the different systems (39). The radiantly protected infants, who survived better, not

only had warmer and more stable skin temperatures as a group, but were also exposed to a much more stable environment than were the convectively protected infants with the less favorable group outcomes.

The commercially released convectively heated and skin temperature referenced servo-controlled incubator was the most common incubator in clinical use during the late 1960s; not until 1970 was the characteristic rapidly changing air temperatures within the incubator chamber re-described and shown to cause some sick small babies to stop breathing (40). These episodes of respiratory arrest, called apneic spells, were specifically observed during the incubator's heating cycles. The mechanism whereby a sudden rise in temperature causes some babies to become apneic remains unknown, but was an observation well reported even prior to the 1970 publication. Even without knowing the mechanism of this relationship, it remains undisputed, so incubator manufacturers have continued to search for ways to produce stabilization of the incubator environmental temperatures (Fig. 6).

Figure 6. Skin and air temperature characteristics recorded using four different incubator systems. (1) A convectively heated and humidified incubator in which air temperature is thermostatically controlled. This was the device studied by Silverman in 1958 (7). Note cyclic variations in air temperature and wide variation in recorded skin temperatures. (2) A radiantly heated convectively ventilated and humidified incubator that is servo controlled to maintain skin temperature at specified value. This was the device studied by Day (9) and Beutow (10) in 1964. Note that the walls are warm, limiting radiant heat losses and that air temperature is stable and skin temperature variations are minimal. (3) A convectively heated and humidified incubator in which the air temperature heating is servo controlled to maintain skin temperature at specified value. This was the device reported to cause some babies to stop breathing (40) as a response to erratic heating cycles that produces rapid increases in air temperature. (4) A convectively heated and humidified incubator that is computer controlled using Alcyon algorithm (11). Note the stable air temperature and minimal variability in skin temperature.

INCUBATOR DYNAMICS

There are many reasons why attempts to stabilize incubator heating have been only partially successful. It is fairly simple to build a box within which the temperatures can be predictably controlled and stabilized for prolonged periods of time if the box is never opened and the thermal characteristics of both the box and its contents never change, but these simplifying conditions never exist when caring for a sick infant. When infants are cleaned, fed, examined, or otherwise cared for, they must be touched, and the incubator box must be entered. Infant's body positions frequently change, exposing different surface areas with different shapes to the incubator environment causing changes in convective flow patterns and altering the view factors influencing radiant heat flow to the incubator walls. Incubator openings necessitated by the need to touch a contained infant cause both environmental cooling and increased infant heat loss that, in an incubator heated in response to either air temperature or infant temperature changes, causes a logical increase in the incubator's heat output. If any such heating requirement is sustained, the incubator heating element warms to the point where it will retain and release heat even after the incubator is closed and the need for additional heating has passed. Such heat retention and release contributes to what is commonly referred to as the thermal lag characteristic of a heating system and can cause temperatures to overshoot, that is to rise above the temperature level targeted when the heater was activated. This is the same phenomenon observed when an electric stove is turned off, and yet the heating element continues to glow brightly prior to cooling. As with an electric stove heating element, the heater in an incubator is not only slow to cool, but also relatively slow to warm up when first energized after the heater is turned on. Again, just as unintended overheating can occur, the thermal lag due to the mass of the heater can result in an incubator getting colder than intended because of this characteristic delay between action and reaction.

Besides the heater element, there are numerous other places where heat is stored in the incubator system. For example, heat storage occurs in the water used for humidification and in the air masses between the heater and the incubator chamber. Since these must be heated to a temperature higher than the incubator chamber in order to raise the chamber temperature, the heat stored in these parts also will continue to raise the chamber temperatures even after the heater power supply has been turned off. Conversely, when the heater power is turned back on, not only the heater but also the air in the spaces leading to the chamber must heat up before the temperature of the air in the chamber can rise.

It is these delays between the time the heater power is changed and the time the air temperature responds that determines the magnitude and frequency of the air temperature cycles to which an incubated infant is exposed. Thermal lag obviously contributes to the tendency for incubator environments to become unstable and, thereby, potentially threatening to the contained infant. Many hardware and logical software solutions to this problem have been tried in commercially available devices, but all

have been frustrated by the complex nature of newborn care, which results in a degree of unpredictability beyond the compensating capability of any solution thus far tried. The implementation of feedback control on incubator heating is an example of one way to attempt to respond to many of these problems. However, examining how servo mechanisms actually work in a little more detail provides a deeper appreciation of why this logical technology often fails in the dynamic setting of an incubator and may even contribute to instability in the incubator environment.

Feedback Control

Feedback control systems are commonly referred to as closed loop control systems, as contrasted to open loop systems. A cooking stove again can be used to give an example of each type of control system. Stove top heaters are typically controlled by an open loop system. That is, a dial is adjusted controlling the quantity of gas or electricity going to the heater unit. In this manner, a fixed rate of heat production by the heater unit is specified. This is called an open-loop control system because after once setting the rate of heat production, the heater will continue to produce the same heat output regardless of how hot the object on the stove gets.

In contrast, the oven of a modern stove is equipped with a closed-loop temperature control system, in which a dial is adjusted to specify the desired oven temperature. In control system parlance, this specified temperature is referred to as the set point. A temperature sensor inside the oven works in conjunction with the temperature setting dial to control the rate of heat production in the oven heating unit and when the temperature measured by the oven temperature sensor rises to the set point value on the control dial, the oven heat production is reduced or stopped entirely. After the heat production is stopped, the oven temperature slowly falls as the heat escaped from the oven to the surrounding area. At some point, the oven temperature will fall below the temperature set on the control and the heater will again be turned on; this on-off cycling will continue as long as the oven is in operation.

Feedback Control and Incubators

An incubator heated in automatic feedback response to changes in electronically transduced infant temperature is called an infant skin servo-controlled (ISC) incubator. In one type of ISC incubator the heater is instructed to turn completely on when the infant's skin temperature falls below a preset lower limit or turn completely off when skin temperature exceeds a defined upper limit. Because power applied to the heater is either maximal or zero, this form of servo mechanism is called nonlinear or "on-off control". Another form of control is designated as linear proportional servo control. In a proportional control system the amount of power applied to the incubator heater is graduated in a manner to be proportional in some linear fashion to the transduced skin temperature deviation from a predetermined value. The amount of power actually applied to the heater for each incremental change in skin temperature can be different in different realizations of this control method, and this increment determines the amount of

deviation in skin temperature that can occur before full or zero power is applied.

The theoretical advantage of a proportional over an on-off servo-control system is the possibility of limiting the tendency that a large heating element has to overshoot or undershoot a desired heater temperature. In a proportional system, the heater is turned off slowly as the infant's skin temperature warms toward the set point temperature. This contrasts with an on-off system that remains fully energized until the set point is reached. In an incubator system, a properly designed skin temperature referenced proportional control unit will produce very stable environmental temperatures as long as the infant is stable, the temperature sensing the thermistor attached to the skin remains undisturbed, and the incubator chamber is kept closed and protected from outside environmental perturbations. In a clinical setting such stable and undisturbed conditions exists infrequently, so the theoretical advantages of proportional control over on-off control are difficult to demonstrate. In fact, the cycling of temperatures recorded within a proportionally controlled incubator in a dynamic clinical setting can be indistinguishable from that recorded in an on-off controlled incubator, and this functional behavior is predicted in basic feedback control theory (Fig. 7).

The thermal cycles recorded in servo-controlled incubators are produced as a combined consequence of (1) an inherent characteristic of closed-loop feedback systems; (2) periodic extreme perturbations of the skin thermistor that trigger either full or zero energization of the incubator heater; and (3) the incubator's thermal lag characteristic, which causes repetitive over-and undershoot of temperatures targeted by the control logic. Following the initiation of a cycling pattern, the time it takes the system to settle down and reestablish stable control is variable and related to the heat-dissipating speed of the heater material and the thermal buffering capability of the homeothermic infant. In some situations, the cycling, when induced by a single perturbation, has been observed to continue for many

Figure 7. Example of variations in dynamic air temperature changes when an enclosed incubator that was initially servo controlled to maintain a stable air temperature was switched to a skin temperature referenced servo control mode and then was perturbed by changing the site of attachment of the skin temperature-sensing thermistor. The wide thermal cycling illustrated as a consequence of this sequence continued for 3 h before returning to a more stable pattern.

hours and, when an incubator is repeatedly perturbed, for many days. The published evidence that some babies react to these thermal cycles by becoming apneic justifies a reminder that these characteristic thermal cycles represent a profound problem negating some of the advantages intended when feedback control is applied in incubator designs. At least in incubator servo systems that use skin temperature as a reference value to determine heater status, even the theoretical negative effects often outweigh any theoretical or demonstrable effects that are positive. This can be appreciated by recalling that a *sine qua non* of optimal control in a skin temperature referenced servo system is the reliable and accurate measurement of an infant's skin temperature and, using today's technology in a clinical setting, the ability to transduce skin temperatures accurately for prolonged periods of time is marginal at best and, perhaps, even impossible.

Skin Temperature Measurement

Skin temperature measurement accuracy is limited by variability in the characteristics of infant, transducers, and infant care techniques. The surface temperatures of infants are not homogeneous because of difference in (1) skin and subcutaneous tissue thickness over different body parts, (2) differences in structures underlying different skin surfaces, and (3) difference in the vascularity and vasoreactivity-characterizing different body regions. Different skin surfaces have different temperatures, and when temperature transducers are connected to the skin surface, they measure the temperature only at the specific site of their connection. Moreover, thermistors are attached using devices that can compression of superficial skin vessels underlying the thermistor element. Thus, by their very attachment, thermistors modify both the absolute temperature they are expected to measure and the spontaneous dynamic variability in the measured skin temperature that is normally affected by the changing amounts of warm blood flowing through the skin over different time periods. Additional factors also affect thermistor accuracy. Thermistors are faulted as precise skin temperature measuring devices because they are manufactured in various shapes and sizes and are protected using different materials so that each affects transduction in a specific and different way. Thermistors also generally measure temperature three dimensionally (3D). They are affected not only by the temperature of the surface to which they are attached, but also by the environment to which their unattached surfaces are exposed. Depending on the amount and type of insulation used in their manufacture, they are also affected by the temperature of the wires used to connect the thermistor to electronic signal conditioners.

These inherent characteristics of thermistors, added to the fact that they are freely moved during clinical care from one site of attachment to another, provide sufficient cause to explain why the skin temperature-dependent heater-controlling servo mechanism in an incubator can easily be directed into an unstable state that produces thermal cycling in the environment. This environmental instability is even further exacerbated by infant care practices that,

for examples, cause thermistors to be removed from the skin when X rays are taken, or to be covered with sterile towels during surgical procedures. During such care-related events, the thermistor is fooled into measuring environmental and not skin temperature. Obviously, if the thermistor provides the servo electronics with misinformation, the servo control decisions based on this information can be nonsensical.

THE NONTHERMAL ENVIRONMENT

Although infant incubators were initially designed solely to maintain body temperature in high risk infants, they are now seen in a much more complex role, as devices that provide a complete "microenvironment" for high risk infants. To one extent or another, they are used to modify the sensory input an infant receives through visual, auditory, olfactory, and kinesthetic pathways. In addition, incubators are now appreciated as the source of exposure to potentially unwanted environmental toxins, such as electromagnetic radiation (EMR) and chemical compounds used in the manufacture and operation of the incubator. Closed incubators are often used as delivery systems for oxygen and humidification, sometimes in ways unanticipated at the time of their design and manufacture. Incubators have been developed for specialized purposes, such as transport, use in an magnetic resonance imaging (MRI) suite, or cobedding twin infants. Incubators have increasingly been designed as a platform for a modular system of support equipment including ventilators, IV pumps, and monitors. As these devices become increasingly controlled by digital components, they also gain the capability of integrating their data output, so that incubator-derived information, such as air temperature and the infant's skin temperature, can be continuously recorded in an electronic medical record. Incubators have had a role in infection control since their earliest days, but this function is now being increasingly emphasized as infection has emerged as the leading cause of late morbidity in premature infants. These multiple functions of modern incubators increase their complexity exponentially, since many of these factors interact with one another, often in ways unanticipated by either the designers or the users. Because of the recent nature of these nonthermal applications of the infant incubator, there is only a limited scientific foundation to guide designers and caregivers, so not all of these topics will be discussed in greater depth below.

The Infant Incubator as a Sensory Microenvironment

Although the comparison of an incubator to a uterus, the environment it replaces, has been noted since the earliest days of incubator design, it will be evident from the preceding sections of this article that temperature regulation has been the first and primary design consideration: and necessarily so, since it had immediate implications for infant survival. When incubators became used as devices for delivery of supplemental oxygen in the mid-twentieth century, morbidity and mortality were again the primary endpoints: first for improved survival as the benefits of oxygen supplementation were identified, and then for

increased morbidity as an epidemic of oxygen-induced blindness from retinopathy of prematurity followed, again chronicled most eloquently by Dr. Silverman (41). Only recently have the other environmental features of the uterus been compared to the micro and macro environments of the NICU and the implications for design been considered.

Taste, smell, and touch are the earliest fetal senses to develop, beginning in the second trimester of pregnancy, followed closely by auditory development, and finally by visual development as the baby approaches term gestation. While thus far there appears to be no reason to suspect that the sense of taste is stimulated or influenced by the incubator, there is accumulating evidence that the other senses are indeed affected by this microenvironment.

Infants can develop a conditioned response to certain odors that they come to associate with painful procedures, such as alcohol, whereas a pleasant odor has been shown to reduce apnea, and babies will orient preferentially to odors from their mother (42).

In utero, infants are exposed to a fluid environment, frequent movement with circadian rhythmicity, and as they approach term, increasing contact with a firm boundary, features absent in the typical incubator. After-market adaptations that caused the bed or the entire incubator to move in one fashion or another have been introduced sporadically, often with the intent of reducing infant apnea, but none have been documented to be efficacious. Additional modifications of the infant mattress to make it more suitable for the skin and developmental needs of preterm infants have been introduced, again without clear benefit to this point.

Sound is a constant although variable stimulus in the uterus, and different in many ways from that of the modern incubator. *In utero* sounds are delivered via a fluid medium where lower pitched sounds predominate, and the mother's voice, heartbeat and bowel sounds are far more prevalent than any extraneous noise. As such, there is a definite circadian rhythm both to the sounds and to movement associated with them. In the closed incubator, the predominant sound is that of the incubator fan that produces a constant white noise, usually in excess of 50 dB, a level that has been shown to interfere with infant sleep (43) and speech recognition (44). Depending on the NICU in which it is used, this may be louder or softer than the NICU ambient noise level, so the closed incubator may be used as a haven from a noisy NICU, or itself could be noisier than the external environment, in which case the open radiant warmer might provide a more suitable auditory environment. A number of after-market modifications have been suggested to reduce both fan noise and intrusion of noise from outside the incubator, including blankets or quilts to cover the incubator and sound-absorbing panels (45,46), but their use is problematic to the degree that they affect air flow and other operating characteristics of the incubator.

The visual environment of the incubator may be presumed to be neutral, but incubators are often used to control the visual environment of the NICU, particularly in conjunction with the use of incubator covers, to produce a dimly lit environment which may enhance infant sleep (47). Light penetration into the incubator may also affect

circadian rhythmicity in the preterm infant (48), and may be a source of heat gain through the greenhouse effect.

Electromagnetic Radiation in the Infant Incubator

Any electrically powered device emits electromagnetic radiation (EMR), usually at intensities far below those considered to constitute a risk. Since the organs of preterm infants are in a crucial and rapid phase of growth, however, concern about EMR emitted by incubator and radiant warmer heaters and other components has merited special attention. Several studies have documented EMR levels in incubators, with proposed strategies to reduce exposure including shielding panels (49) and increasing the distance between the baby and the EMR source (50).

Incubators for Specialized Purposes

The conventional closed incubator or radiant warmer is used as a static device in the NICU, but the same needs for temperature control and a safe microenvironment exist for infants who require transport from one hospital to another, or to an MRI suite. Transport incubators place a premium on space (so that multiple modular components can be mounted) and weight (especially those used for air transport). Incubators developed for use in an MRI suite must be similarly portable, but use almost exclusively plastic materials and have an integrated coil for scanning (51,52).

SUMMARY

Infant incubators are specially heated devices that provide a bed surface or chamber within which an infant can be cared for and kept warm. Throughout this article both the positive and negative features of today's incubators have been noted and placed into both a context of what is theoretically desirable and of what is practically feasible. It is apparent that, at present, our knowledge of infant physiology and the availability of technical solutions are severely limited, and that all existing incubator devices reflect and are faulted by these limitations. In historical perspective, however, it is clear that incubators over the past 100+ years have steadily been improved by manufacturers to incorporate new items of knowledge and technology as they become available. This historical path has been fruitful and provides, in its continuing course, direction for the future in incubator development. Future iterations of the infant incubator will need to incorporate new information on the optimal microenvironment for the high-risk newborn as well as new capabilities made possible by the ongoing quantum changes in digital technology.

INTEGRATED CIRCUIT TEMPERATURE SENSOR

TATSUO TOGAWA
Waseda University
Saitama, Japan

INTRODUCTION

Temperature can affect the electronic characteristics of semiconductor devices. Although this is a disadvantage

in many applications, especially for analogue devices, it may be turned into an advantage if such a device is used as a temperature sensor. In principle, any parameter in such a device having a temperature coefficient can be used for temperature measurement. For example, a temperature telemetry capsule, in which a blocking oscillator frequency varies with temperature, has been developed for measuring gastrointestinal temperature (1). In this system, the temperature affects the reverse-bias base-collector current, which determines the period of relaxation oscillation. However, it has been shown that the voltage across a p-n junction of a diode or transistor under a constant forward-bias current shows excellent linear temperature dependency over a wide temperature range. Many conventional or specially designed diodes or transistors composed of Ge, Si, or GaAs have been studied for use as thermometers (2-4).

The advantages of diodes and transistors as temperature sensors are their high sensitivity and low nonlinearity. The temperature sensitivity under normal operation is ca -2 mV/K, which is ~50 times higher than that of a copper-constantan thermocouple. The nonlinearity is low enough for many applications, although its value depends on the structure and material of the device. It is known that a Schottky diode, which has a structure composed of a rectifying metal-semiconductor contact, possesses good voltage-temperature linearity (5). Some transistors used as two-terminal devices by connecting the base to the collector also possess good linearity (6,7), and a transistor that has been especially developed for temperature sensing is commercially available (8). This has a linearity that is comparable to that of a platinum-resistance temperature sensor.

It is advantageous to have a diode and a transistor temperature sensor fabricated on a chip with associated interfacing electronics using integrated circuit (IC) technology. Several integrated temperature sensors that provide either analogue or digital outputs have been developed and are commercially available. A diode or transistor temperature sensor fabricated on a central processing unit (CPU) chip is especially useful when used to monitor the temperature of the chip. Such a sensor has been used to detect overheating, and to protect the CPU system by controlling a fan used to cool the chip or to slow down the clock frequency.

THEORY

The characteristics of p-n junctions are well known (9,10). In p-n junction diodes, the current flowing through the forward-biased junction is given by

$$I = I_s(e^{qV/mkT} - 1) \quad (1)$$

where I_s is the saturation current, q is the electron charge, V is the voltage across the junction, k is the Boltzmann constant, m is the ideality factor having a value between 1 and 2, which is related to the dominant current component under the operating conditions used, and T is the absolute temperature. At a temperature close to room temperature, and when the current is relatively high, so that the current

due to the diffusion of the carrier dominates, $m = 1$, and so the second term in Eq. 1 given in parentheses can be neglected. Equation 1 can then be simplified to

$$I = I_s e^{qV/kT} \quad (2)$$

The temperature dependence of the saturation current, I_s , is given by

$$I_s = A e^{-E_g/kT} \quad (3)$$

where E_g is the bandgap energy at $T = 0$ K, and A is a constant dependent on the geometry and material of the device. Strictly speaking, A also depends on the temperature. However, the temperature dependency is very weak compared to the exponential term in Eq. 3. Thus,

$$I = A e^{(qV - E_g)/kT} \quad (4)$$

For a constant current, I , $(qV - E_g)/kT$ is constant. Thus, the voltage across a p-n junction, V , is a linear function of the absolute temperature, T . On extrapolating to $T = 0$, then $qV = E_g$.

The temperature coefficient of V can be derived from Eq. 4 as

$$\left. \frac{dV}{dT} \right|_{I=\text{const}} = \frac{V - E_g/q}{T} \quad (5)$$

Since the value of $qV - E_g$ is always negative, V decreases with increasing T . For silicon, $E_g \sim 1.17$ eV, and for $T \sim 300$ K, $V \sim 600$ mV, and $dV/dT \sim -1.9$ mV/K. In actual diodes, the current-voltage characteristics have been studied in detail over a wide temperature range. The forward voltage exhibits a linear dependence for $T > 40$ K for a constant current (11). The observed value of dV/dT in a typical small signal silicon p-n junction diode ranges between -1.3 and -2.4 mV/K for $I = 100 \mu\text{A}$ (11). In germanium and gallium arsenide p-n junction diodes, and for silicon Schottky diodes, the forward voltage exhibits a similar sensitivity (3-5).

In most p-n junctions, the current through the junction contains components other than those due to carrier diffusion, and therefore, Eq. 4 does not hold. The base-emitter p-n junction in transistors is advantageous in this respect. Here, the diffusion component forms a larger fraction of the total current than that in diodes, even for a diode connection in which the base is connected to the collector. The nonlinear temperature dependence in the forward voltage in diode-connected transistors is lower than that of most diodes (7). Further improvement in linearity is attained under constant collector current operation, since only the diffusion component flows to the collector, while other components flow to the base (12).

From Eq. 2, one can obtain the following expression

$$\ln I = \ln I_s + qV/kT \quad (6)$$

The value of T can be obtained from the gradient of a plot of $\ln I$ versus V , as q and k are known universal constants. This implies that the current-voltage characteristics can be used as an absolute thermometer (6). If $\ln I$ is a linear function of V , only two measurements are required to determine the gradient. If V_1 and V_2 are voltages corre-

sponding to different current levels, I_1 and I_2 , the difference between these two voltages is calculated using

$$V_1 - V_2 = (kT/q)\ln(I_1/I_2) \quad (7)$$

Thus, the difference in voltage corresponding to the different current levels for a constant ratio is proportional to the absolute temperature, without any offset. Using this relationship, a thermometer providing an output proportional to the absolute temperature can be realized, either by applying a square wave current to a p-n junction (12), or by using two matched devices operating at different current levels (13).

FUNDAMENTAL CIRCUITS AND DEVICES

A schematic drawing of the fundamental circuit of the thermometer with a short-circuited transistor or a diode is shown in Fig. 1. A constant current is applied to the transistor or diode in the forward bias direction, and the voltage across the junction is amplified using a differential amplifier. By adjusting the reference voltage applied to another input of the differential amplifier, an output voltage proportional to either the absolute temperature in kelvin or in degrees Celsius or any other desired scale can be obtained. The operating current of small signal diodes and transistors is typically 40–100 A. If the current becomes too high, a self-heating error may be produced due to the power dissipated in the junction. If the current becomes too small, problems due to leakage and the input current of the first stage amplifier may become significant (7).

The nonlinearity in the temperature dependency of the forward voltage is not a serious problem for most applications, and it can be reduced by appropriate circuit design. In a Schottky diode, this nonlinearity is < 0.1 K over the

Figure 1. A fundamental interfacing circuit of a thermometer making use of a transistor or a diode as a temperature sensor to provide a voltage output proportional to temperature, with a zero voltage output at a specific temperature dependent on the reference voltage selected.

Figure 2. A circuit for constant collector current operation in a sensor transistor.

temperature range -65 to 50 °C (5), and a comparable performance is expected for diode-connected silicon transistors (7). Further improvement in the linearity can be attained by linearization of the circuit. Linearization using a logarithmic ratio module reduces the error to < 0.05 °C in the temperature range -65 to 100 °C (7). Linearity is also improved using a constant collector current, as pointed out previously. An example of an actual circuit is shown in Fig. 2. In this circuit, the operational amplifier drives the base-emitter voltage to maintain a constant collector current. By applying a square-wave current and measuring the amplitude of the resulting square-wave base-emitter voltage, a linear output proportional to the absolute temperature is obtained, as expected from Eq. 7(12). Further improvement in accuracy can be attained by employing a curve fitting with three-point calibration, the error due to the nonlinearity can be reduced to 0.01 °C in the temperature range of -50 to 125 °C (14).

Three-terminal monolithic IC temperature sensors that provide a voltage output proportional to temperature using the Celsius scale are commercially available, examples being LM45 (National Semiconductor) and AD22100/22103 (Analog Devices). The LM45 device operates using a single power supply voltage in the range 4–10 V, and provides a voltage output that corresponds to the temperature in degrees Celsius multiplied by a factor of 10 mV, for example, 250 mV = 25 °C. The AD22100 and AD22103 devices provide a ratiometric output, that is, the output voltage is proportional to the temperature multiplied by the power supply voltage. For example, AD22100 has a sensitivity of 22.5 mV/°C giving output voltages of 0.25 V at -50 °C and 4.75 V at 150 °C when the power supply voltage is 5.0 V.

Two matched transistors operated using different collector currents can be used to obtain an output proportional to the absolute temperature (15). The difference in the base-emitter voltages of the two transistors is a linear function of temperature, as shown in Eq. 7. Convenient two-terminal current-output devices using this technique are commercially available. Figure 3 shows an idealized scheme representing such devices. If the transistors Q_1 and Q_2 are assumed to be identical and have a high common-emitter current gain, their collector currents will be equal, and will constrain the collector currents Q_3 and Q_4 . If Q_3 has r -fold base-emitter junctions, and each one is identical

Figure 3. An idealized scheme of a two-terminal IC temperature sensor that provides a current output proportional to the absolute temperature.

to that of Q_4 , the emitter current of a junction in Q_3 is $1/r$ that of Q_4 . From Eq. 7, the voltage across resistance R is obtained from

$$RI = (kT/q)\ln r \tag{8}$$

Thus, the total current, $2I$, is proportional to the absolute temperature. Although the actual components are not ideal, practical devices are available as monolithic ICs, such as AD590 and AD592 (Analog Devices) (16). In these devices, $r = 8$ and R is trimmed to have a sensitivity of about 1 A/K. The output current is unchanged in the supply-voltage range 4.0 to 30 V. A voltage output proportional to the absolute temperature can be obtained by connecting a resistor in series with the ICs. For example, a sensitivity of 1 mV/K is obtained by connecting 1 kΩ resistor in series. By trimming the series resistor, the error in temperature reading can be adjusted to zero at any desired temperature. After trimming, the maximum error depends on the range in temperature under consideration. For example, a maximum error of $0.1, 0.2, \text{ and } 0.3\text{ }^\circ\text{C}$ is obtained for temperature ranges of 10, 25, and 50 °C, respectively (17).

Monolithic temperature sensors that provide a digital output are also commercially available. For example, TMP06 (Analog Devices) sensors provide a pulse-width modulated output. The output voltage assumes either a high or low level, so that the high period (T_1) remains constant at 40 ms for all temperatures, while the low period (T_2) varies with temperature. In the normal operation mode, the temperature on the Celsius scale, T , is given by

$$T = 406 - [731 \times (T_1/T_2)] \tag{9}$$

According to Analog Devices' TMP06 data sheet, for an operating supply voltage between 2.7 and 5.5 V, the absolute temperature accuracy is $\pm 1\text{ }^\circ\text{C}$ in the temperature range 0–70 °C, with a temperature resolution of 0.02 °C.

The National Semiconductor LM75 device is also a monolithic temperature sensor that provides a digital output. It includes a nine-bit analog-to-digital converter, and provides a serial output in binary format so that the least significant bit corresponds to a temperature difference of 0.5 °C.

Newer devices will come along in the future that may be more appropriate than the ones mentioned here. Information about such devices, together with their data sheets, will be available from the internet sites of manufactures.

APPLICATIONS

Although thermistors are still widely used for thermometry in the medical field, IC temperature sensors have potential advantages over thermistors. Integrated circuit sensors can be fabricated using IC technology encompassing interfacing electronics on a single IC chip, and many general purpose IC temperature sensors are now commercially available.

Current-output-type IC temperature sensors, such as AD590, are convenient for use as thermometer probes for body core and skin temperature measurements. Figure 4 shows a scheme for such a simple thermometer. According to the manufacturer's data sheet, although the sensitivity and zero offset are adjustable independently in this circuit, an accuracy of 0.1 °C is attainable with L- or M-grade AD590 devices using a single-trim calibration if the temperature span is 10 °C or less. If a regulating resistor is included in the probe, interchangeability can be realized. Because of the current output capacity, the resistance of

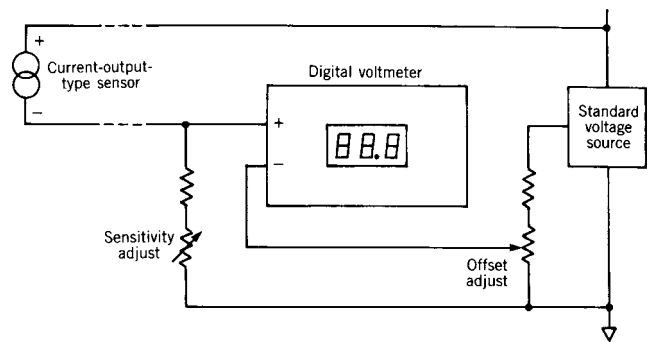

Figure 4. A simple thermometer that makes use of a two-terminal current output-type IC temperature sensor.

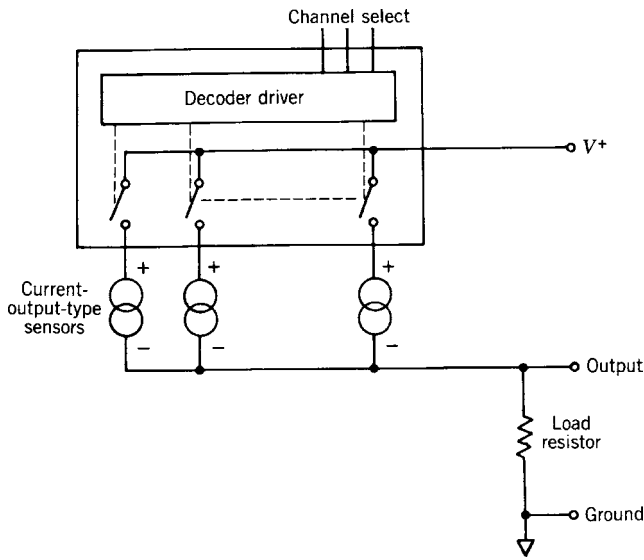

Figure 5. A multiplexing scheme for a current output-type IC temperature sensor.

the cable or connector does not affect the temperature measurement.

This type of device is also convenient for temperature measurements at many other points, especially when the output data are processed using a PC. All the sensors can be connected to a single resistor, as shown in Fig. 5, and by switching the excitation the outputs from each sensor can be multiplexed. To calibrate each sensor individually, all the sensors are maintained at an appropriate temperature, together with a standard thermometer. The outputs from each sensor as well as that from a standard thermometer are input into a PC. Then, the temperature offsets for each sensor can be stored, and all the measurement data can be corrected using these correction factors. Two-point calibration is also realized by using data at two known temperatures. A matrix arrangement of the sensors can be formed using two decoder drivers.

Temperature measurements at many different points can be performed easier using IC temperature sensors that generate serial digital outputs, such as TMP05/TMP06. Connecting these devices as shown in Fig. 6 allows for the realization of a daisy chain operation. When a start pulse is applied to the input of the first sensor, the temperature data from all the sensors is generated serially, so that the temperatures of each sensor are represented in a ratio-metric form, which is the ratio of the duration of the high and low output levels for each period. It is a remarkable advantage of this sensor that a thermometer can be realized without using any analogue parts.

An important application of IC temperature sensors is the monitoring of CPU temperatures to protect a system from overheating. The temperature of a CPU chip can be detected by a p-n junction fabricated on the same silicon chip as the CPU, as shown in Fig. 7. The advantage of fabricating the temperature sensor on the CPU chip is to make the temperature measurement accurate enough and to minimize the time delay due to heat conduction so as to prevent overheating. The CPU can be protected from overheating by controlling a cooling fan or by slowing down the clock speed. Interfacing devices for this purpose are commercially available. For example, the MAX6656 (Dallas Semiconductor) device can detect temperatures at three locations, such as the CPU, the battery, and the circuit board, and the output can be used to control a cooling fan. To control the clock frequency, a specially designed frequency generator can be used. For example, the AV9155 (Integrated Circuit Systems) device allows for a gradual transition between frequencies, so that it obeys the CPU's cycle-to-cycle timing specifications.

FUTURE

It is ~25 years since convenient IC temperature sensors were introduced for scientific and industrial temperature measurements. In medicine, the application of this type of sensor is in its infancy. There are many applications where

Figure 6. (a) The connecting scheme for a daisy chain operation of a serial-digital-output-type temperature sensor, and (b) the output waveform. The temperature using the Celsius scale at each sensor can be determined from the ratio of the duration of the highest and lowest points in each cycle.

Figure 7. A scheme for monitoring the temperature of a CPU to protect it from overheating by fan control or by slowing down the clock.

these sensors can be used effectively, and undoubtedly their use will be wide spread in the near future.

Digital output IC temperature sensors show the most promise. Using such sensors, thermometers can be made without using analog components, and digital signals are convenient when a photocoupler is used for isolation.

Medical thermometry requires a relatively high degree of accuracy within a narrow temperature range. An absolute accuracy of 0.1 °C is required for body temperature measurements. However, this is hard to attain without individual calibration using most temperature sensors. While adjustment of the trimmer resistor has been used in many thermometer units, correcting data using a PC employing initially obtained correction factors will be much simpler, especially when many sensors are used, and digital output IC temperature sensors are advantageous for such a purpose.

Fabricating different types of sensors, such as force and temperature sensors, in one chip, and then applying them in robot hands to mimic all the sensing modalities of human skin, is another promising field. In such applications, the digital output capability will be a great advantage.

INTRAAORTIC BALLOON PUMP

PETER WELLER

INTRODUCTION

The heart is a pump made of cardiac muscle or myocardium. It has four pumping chambers, namely, a right and left atrium and a right and left ventricle. The atria act as primer pumps for the ventricles. The right ventricle pumps deoxygenated blood returning from the body through the pulmonary artery and into the lungs. This is called the pulmonary circulation. The left ventricle pumps oxygenated blood returning from the lungs through the aorta and into the rest of the body. This is called the systemic circulation.

The heart also has four one-way valves that prevent the backward flow of blood. The tricuspid valve lies between the right atrium and right ventricle while the pulmonary valve lies between the right ventricle and the pulmonary artery. Similarly, the mitral valve lies between the left atrium and the left ventricle while the aortic valve lies between the left ventricle and the aorta.

Figure 1. The relationship between the aortic pressure (A – dashed line), the ventricular pressure (B – solid line), the electrocardiogram (C) and the heart sounds (D). Region 1 = isovolumetric contraction and Region 2 = isovolumetric relaxation, Region 3 (green) = tension time index (TTI) and Region 4 (yellow) = diastolic pressure time index (DPTI). S1 represents the closing of mitral and tricuspid valves, S2 represents the closure of aortic and pulmonary valves.

CARDIAC CYCLE

The heart pumps rhythmically. The cardiac cycle is the sequence of events that take place in the heart during one heartbeat (Fig. 1). Thus, the duration of the cardiac cycle varies inversely with the heart rate. At a typical resting heart rate of 60 beats per minute (bpm), the cardiac cycle lasts 1 s or 1000 ms.

Mechanical Events

One cardiac cycle consists of a period of contraction called systole followed by a period of relaxation called diastole. The duration of systole, called the systolic time interval (STI), is relatively constant, but the duration of diastole, called the diastolic time interval (DTI), varies with the heart rate. Thus, when the heart rate increases, the DTI shortens.

When the left ventricle contracts, the pressure in the left ventricle rises above the pressure in the left atrium and the mitral valve closes. Soon afterward, the pressure in the left ventricle rises above the pressure in the aorta and the aortic valve opens. Blood flows from the left ventricle into the aorta. The period between closing of the mitral valve and opening of the aortic valve is called isovolumetric contraction.

When the left ventricle relaxes, the pressure in the left ventricle falls below the pressure in the aorta and the aortic valve closes. This causes a momentary drop in pressure in the aorta called the dichrotic notch. The period between the opening and closing of the aortic valve is called ventricular ejection. Soon afterward, the pressure in the left ventricle falls below the pressure in the left atrium and the mitral valve opens. Blood flows from the left atrium into the left

ventricle. The period between the closure of the aortic valve and opening of the mitral valve is called isovolumetric relaxation.

The left atrium contracts and relaxes just before the left ventricle. This boosts the blood flow from the left atrium into the left ventricle.

These events are mirrored in the right ventricle and right atrium. However, the pressures in the pulmonary circulation are much lower than the pressures in the systemic circulation.

The movements of the chambers, valves and blood can be imaged noninvasively using ultrasound and this is called an echocardiogram.

Electrical Events

The rhythmical pumping of the heart is caused by waves of electrical impulses that spread through the myocardium from the atria to the ventricles. A recording of these waves is called an electrocardiogram (ECG). The P wave represents atrial contraction. The R wave represents ventricular contraction and signals the beginning of systole. The T wave represents ventricular relaxation and signals the beginning of diastole.

Acoustic Events

The opening and closing of the valves in the heart creates sounds that can be heard at the surface of the chest using a stethoscope. A recording of these sounds is called a phonocardiogram. The first heart sound (S1) represents closure of the mitral and tricuspid valves and signals the beginning of systole. The second heart sound (S2) represents closure of the aortic and pulmonary valves and signals the beginning of diastole.

MYOCARDIAL OXYGEN BALANCE

The systemic circulation delivers oxygenated blood to the body. Body tissues use oxygen to generate energy from the oxidation of fuels. All tissues, including the myocardium, need energy to function. The net delivery of oxygen to the myocardium is called the myocardial oxygen balance.

$$M_{OB} = M_{OS} - M_{OD}$$

where M_{OB} = myocardial oxygen balance, M_{OS} = myocardial oxygen supply, M_{OD} = myocardial oxygen demand. In the healthy heart the myocardial oxygen balance is positive, that is supply exceeds demand. In the failing heart the balance can be negative, that is demand exceeds supply.

Myocardial Oxygen Supply

The main blood supply of the myocardium comes from the two coronary arteries and their branches. The small amount of blood that reaches the myocardium transmurally from within the chambers of the heart is insignificant. The coronary arteries arise from the aorta just beyond the aortic valve and ramify within the myocardium. Myocardial oxygen supply depends on the coronary blood flow and the amount of oxygen that can be extracted from the blood.

When the heart contracts the coronary arteries are compressed and the coronary blood flow is decreased. The net driving force for coronary blood flow is called the coronary perfusion pressure.

$$C_{PP} = A_P - V_P$$

where C_{PP} = coronary perfusion pressure, A_P = aortic pressure, V_P = ventricular pressure. The coronary circulation is unique because more blood flows during diastole when the ventricular pressure is low than during systole when the ventricular pressure is high. Thus, the coronary blood flow depends on the coronary perfusion pressure, the diastolic time interval and the patency of the coronary arteries. Myocardial oxygen supply is represented by the area between the aortic pressure wave and the left ventricular pressure wave, called the diastolic pressure time index (DPTI).

Myocardial Oxygen Demand

The myocardium uses energy to perform the work of pumping. The work performed by the heart can be estimated by the mean aortic blood pressure multiplied by the cardiac output. Myocardial oxygen demand depends on the heart rate, the systolic wall tension and the cardiac contractility. Systolic wall tension is developed during isovolumetric contraction and depends upon the preload, the afterload and the wall thickness. The preload is the degree to which the left ventricle is filled before it contracts, that is the left ventricular end diastolic volume. The afterload is the pressure in the aorta or the systemic vascular resistance against which the left ventricle contracts. Myocardial oxygen demand is represented by the area under the left ventricular pressure curve, called the tension time index (TTI).

The myocardial oxygen balance is represented by the ratio DPTI:TTI.

THE PATHOPHYSIOLOGY OF LEFT VENTRICULAR PUMP FAILURE

When the left ventricle begins to fail as a pump, the cardiac output falls. Compensatory physiological mechanisms bring about an increase in left ventricular end diastolic volume, heart rate, and systemic vascular resistance. The result is an increase in preload and afterload with a decrease in coronary blood flow. Thus, the myocardial oxygen demand increases while the myocardial oxygen supply decreases. There may come a point when demand exceeds supply resulting in a negative myocardial oxygen balance. The left ventricle is then deprived of oxygen and cannot generate sufficient energy to do the work required of it. The pump failure is therefore exacerbated and this can precipitate a downward spiral of decline eventually ending in death. The therapeutic goal is to reverse this decline and help the failing left ventricle to recover by restoring a positive myocardial oxygen balance. Diuretics to decrease the preload, inotropic drugs to increase the myocardial contractility and vasodilators to decrease the preload and afterload are the mainstay of treatment. However, in the most severely ill patients, pharmacological

Figure 2. The relationship between the ventricular pressure with counterpulsation (A – solid line), without counterpulsation (B-dashed line), IABP balloon inflation (C) and ventricular systole (D). Region 1 (green) = systolic unloading and Region 2 (yellow) = diastolic augmentation.

measures alone may be insufficient and it is in these extreme circumstances that counterpulsation therapy may be effective.

THE PRINCIPLE OF COUNTERPULSATION

The principle of counterpulsation is the incorporation of an additional pump into the systemic circulation in series with the left ventricle. The pump is operated in synchrony, but out of phase, with the cardiac cycle. Pump systole occurs during ventricular diastole and pump diastole occurs during ventricular systole.

The primary physiological effects of counterpulsation are twofold (Fig. 2): A decrease in the aortic pressure during systole (called systolic unloading). This is evidenced by a decrease in the end diastolic pressure (EDP), the peak systolic pressure (PSP) and the mean systolic pressure (MSP). An increase in the aortic pressure during diastole (called diastolic augmentation). This is evidenced by an increase in the mean diastolic pressure (MDP).

Systolic unloading reduces the work of the left ventricle because it pumps against a lower pressure. This decreases myocardial oxygen demand. Diastolic augmentation increases coronary blood flow because it increases the coronary perfusion pressure. This increases myocardial oxygen supply. Thus, the myocardial oxygen balance is improved.

Among the secondary physiological effects of counterpulsation are increases in the stroke volume (SV, the volume of blood pumped with each heartbeat), the CO (equal to the SV multiplied by the heart rate) and the blood flow to the other vital organs.

HISTORICAL PERSPECTIVE

Counterpulsation was first described in theory in 1958 by Harken (1). It was to be achieved by cannulating the femoral arteries, rapidly withdrawing a set volume of blood during systole and rapidly reinfusing the same volume of blood during diastole. Clauss et al. (2) reported this in clinical practice in 1961 but it was unsuccessful because the rapid movements of blood were difficult to implement and caused severe hemolytic damage to the red blood cells.

In 1958, Kantrowitz and McKennin (3) described counterpulsation achieved by wrapping a part of the diaphragm around the thoracic aorta and stimulating the phrenic nerve, causing contraction of the diaphragm, during diastole. Mouloupoulos et al. (4) and Clauss et al.(5) described counterpulsation achieved by intra-aortic balloon pumping in 1962. Operative insertion of the balloon through a surgically exposed femoral artery was necessary. It was inflated during diastole and deflated during systole. In 1968, Kantrowitz et al. (6) reported a successful clinical study.

In 1963, Dennis et al.(7) described external counterpulsation achieved using a pneumatic compression garment that enclosed the legs and lower torso. It was inflated during diastole and deflated during systole. It was reported to be as successful as the IABP in clinical studies but it is not commonly used. Kantrowitz et al. (8) described counterpulsation achieved by a permanently implantable intra-aortic balloon in 1972. It was unsuccessful in clinical practice because there remained the need for a connection to an external pump and this provided a portal of entry for infection.

In 1979, following the development of thinner catheters, percutaneous insertion of the intra-aortic balloon through a femoral artery puncture was introduced. This could be performed at the bedside and avoided the need for a surgical operation in most patients. Consequently, intra-aortic balloon pumping became the most widely adopted method of counterpulsation.

CLINICAL APPLICATIONS

Indications

The IABP was first used clinically in 1968 by Kantrowitz to support patients with cardiogenic shock after acute myocardial infarction(9). During the 1970s the indications broadened (Table 1) and by 1990 ~70,000 pump procedures were performed worldwide each year (10) although there is wide variation between different countries and centres. The IABP support has been used successfully in patients with left ventricular failure or cardiogenic shock from many causes including myodarditis, cardiomyopathy, severe cardiac contusions and drug toxicity but the commonest are myocardial infarction and following cardiac surgery. The trend has been a move away from hemodynamic support in pump failure towards the treatment, and even prophylaxis of, acute myocardial ischaemia. Patients can be maintained on the IABP for hours, days or even weeks, particularly when used as a bridge to cardiac transplantation or other definitive treatment (11). Of those who survive to hospital discharge, long-term survival is satisfactory (12).

An early series of 747 IABP procedures in 728 patients between 1968 and 1976 was reported by McEnany et al.

(13). Over the course of the study, they observed that cardiogenic shock or chronic ischaemic left ventricular failure as the indication for IABP fell from 79 to 26% of patients whilst overall in-hospital survival rose from 24 to 65% of patients. They also noted an increase from 38 to 58% of patients undergoing cardiac surgery following IABP insertion. They postulated that broadened indications for, and earlier insertion of, the IABP together with more aggressive surgical treatment of any underlying cardiac lesion led to the improvement in survival. In the later Benchmark Registry of nearly 17,000 IABP procedures performed in 203 hospitals worldwide between 1996 and 2000, the main indications were support for coronary angioplasty (21%), cardiogenic shock (19%), weaning from cardiopulmonary bypass (16%), preoperative support in high risk patients (13%), and refractory unstable angina (12%) (14). The overall in-hospital mortality was 21%.

High risk patients undergoing cardiac surgery may have a better outcome if treated preoperatively with IABP therapy. In a series of 163 patients with a left ventricular ejection fraction of <0.25 and undergoing coronary artery bypass grafting (CABG), the 30 day mortality was reduced from 12 to 3% (15). Similar results were obtained in a small randomized study (16). In a series of 133 patients who underwent CABG off cardiopulmonary bypass between 2000 and 2003, the use of adjuvant preoperative IABP therapy in the 32 highest risk patients led to outcomes comparable with the lower risk patients (17). The use of IABP therapy to improve outcome after coronary angioplasty for acute myocardial infarction remains controversial. Early studies suggested an improved outcome (18–20), but two recent large randomized trials have shown no benefit in haemodynamically stable patients (21,22). A report from the SHOCK Trial Registry showed that the in-hospital mortality in patients with cardiogenic shock after acute myocardial infarction could be reduced from 77% to 47% by combined treatment with thrombolysis and IABP, particularly when followed by coronary revascularization (23).

IABP therapy is used infrequently in children, who commonly suffer from predominantly right ventricular failure associated with congenital heart disease. The greater elasticity of the aorta may limit diastolic augmentation and the more rapid heart rate may make ECG triggering difficult. Echocardiographic triggering has been used as an effective alternative (24,25). Survival rates of 57% (26) and 62% (27) have been reported in small series of carefully selected patients.

Contraindications

The only absolute contraindications to IABP therapy are severe aortic regurgitation and aortic aneurysm or dissection. In patients with severe aorto-iliac vascular disease

Table 1. Indications for IABP Therapy

Left ventricular failure or cardiogenic shock	Preoperative support before cardiac or non-cardiac surgery
Refractory unstable angina or ischaemic ventricular arrhythmias	Adjunct to coronary angioplasty or thrombolysis
Weaning from cardiopulmonary bypass	Adjunct to off-bypass cardiac surgery
Bridge to cardiac transplantation	

Table 2. Complications of IABP Therapy

Vascular	Balloon-Related	Other
Hemorrhage	Gas embolism	Infection
Aortoiliac dissection or perforation	Entrapment	Thrombocytopenia
Limb ischaemia		Paraplegia
Visceral ischaemia		

the balloon should not be inserted through the femoral artery.

Complications

The IABP therapy continues to cause a significant number of complications (Table 2), but serious complications are uncommon and directly attributable deaths are rare. Nevertheless, some have argued against its indiscriminate use, feeling that for many patients the risks outweigh the benefits. Kantrowitz reported rates of 41 and 4% for minor and major complications, respectively, in his series of 733 patients. Of these, 29% were vascular (including 7% hemorrhagic) and 22% were infections (28). Vascular complications include haemorrhage from the insertion site and lower limb ischaemia caused by the balloon catheter or sheath occluding the iliac or femoral artery. The vascular status of the lower limbs should be observed closely in patients on IABP therapy. Ischaemia may resolve when the catheter or sheath is removed but surgical intervention including femoral thromboembolectomy, femorofemoral bypass or even amputation is required in up to half of cases (29).

Several risk factors for vascular complications have been identified. They are female gender, diabetes, hypertension, peripheral vascular disease, obesity, old age, sheathed insertion, percutaneous insertion, and insertion via the femoral artery compared to directly into the ascending aorta (13,14,19,28–30). In one study of patients with peripheral vascular disease, the rate of vascular complications was 39% for percutaneous insertion compared to 18% for open insertion (29).

Complications caused by perforation of the balloon are rare, but potentially serious. Embolization of the helium shuttle gas can result in stroke or death. Coagulation of blood within the balloon can result in balloon entrapment. In this situation the instillation of thrombolytic agents may allow the balloon to be retrieved percutaneously but otherwise open surgery is required. It is therefore mandatory to remove the balloon immediately if any blood is detected within the pneumatic system.

Thrombocytopenia (a reduction in the number of platelets) developed in one-half of patients but they rapidly recovered when the balloon was removed (31).

EQUIPMENT FOR CLINICAL APPLICATION

The IABP consists of a balloon catheter and movable drive console. A monitor on the drive console displays the arterial pressure wave and the ECG. Commercial consoles have

Figure 3. A commercial IABP device. (Courtesy of Datascope Corp.)

controls that allow the operator to select the assist ratio and trigger mode and adjust the timing of inflation and deflation and the inflation volume of the balloon. The drive console also contains a helium tank for balloon inflation and a battery as a backup power source in the event that the mains electricity supply is interrupted. In common with medical equipment the IABP console conforms to international safety standards. Figure 3 shows a current commercial model.

The balloon is made of inelastic polyurethane and is cylindrical in shape. Balloons are available in volumes from 25 to 40 cm³ and the correct size is selected according to the height of the patient. The balloon is mounted at the end of a double-lumen catheter. Modern catheters have an outer diameter of 7–8 French gauge. The inner lumen is open at the tip to allow insertion over a guidewire and direct measurement of the aortic blood pressure after the guidewire is removed. The outer lumen forms a closed system connecting the balloon to a pneumatic pump chamber within the drive console. Two views of a current balloon catheter are shown in Fig. 4.

The balloon catheter is most commonly inserted percutaneously through the femoral artery in the groin over a guidewire using a traditional or modified Seldinger technique. An intra-arterial sheath is used to secure and

Figure 4. An IABP catheter. (Courtesy of Datascope Corp.) In both inflated (top image) and uninflated (bottom image) modes.

protect the access site before insertion of the balloon catheter. However, because the sheath has a larger outer diameter than the balloon catheter it can increase the risk of vascular complications and sheathless insertion has now been introduced. Under fluoroscopic guidance the balloon is positioned in the descending thoracic aorta just beyond the origin of the left subclavian artery. Alternatively, the balloon can be inserted through the iliac, axillary or subclavian arteries or directly into the ascending aorta during open surgery.

A shuttle gas is pumped back and forth between the pump chamber and the balloon to cause inflation and deflation. The ideal shuttle gas would have a low density combined with a high solubility in blood. A dense gas is slow to move along the catheter. This introduces a significant delay between the opening of the valves in the pump chamber and the inflation or deflation of the balloon making correct timing more difficult to achieve. An insoluble gas is unsafe if the balloon was to leak or burst allowing it to escape into the blood. There it may form bubbles leading to potentially fatal gas embolism. Originally, carbon dioxide was used as the shuttle gas. It is a dense gas but dissolves easily in blood. More recently, helium has been used as the shuttle gas. It is a less dense gas but dissolves less easily in blood.

Pumping is initiated with an assist ratio of 1:2, which means that one in every two heartbeats is assisted. This allows the arterial pressure wave of each assisted beat to be compared with an unassisted beat to facilitate correct timing.

Pumping is continued with an assist ratio of 1:1, which means that every beat is assisted. As the patient recovers, they can be weaned from the IABP by periodically decreasing the assist ratio until pumping is eventually discontinued.

Weaning can also be achieved by periodically decreasing the inflation volume of the balloon. However, this can lead to problems with blood clotting in the folds of the under-inflated balloon and it is not commonly used.

CONTROL OF IABP

The inflation/deflation cycle of the intra-aortic balloon pump is controlled by a closed loop circuit as illustrated in Fig. 5.

The physiological variables required for determining triggering are measured, filtered and converted into digital signals. These are used in enable the control strategy to determine the appropriate inflation and deflation times of the balloon. This information is then passed to the pneumatic circuit for balloon operation. The results of this strategy are then feed back to the console via a new set of patient variables. The actions of the controller are dis-

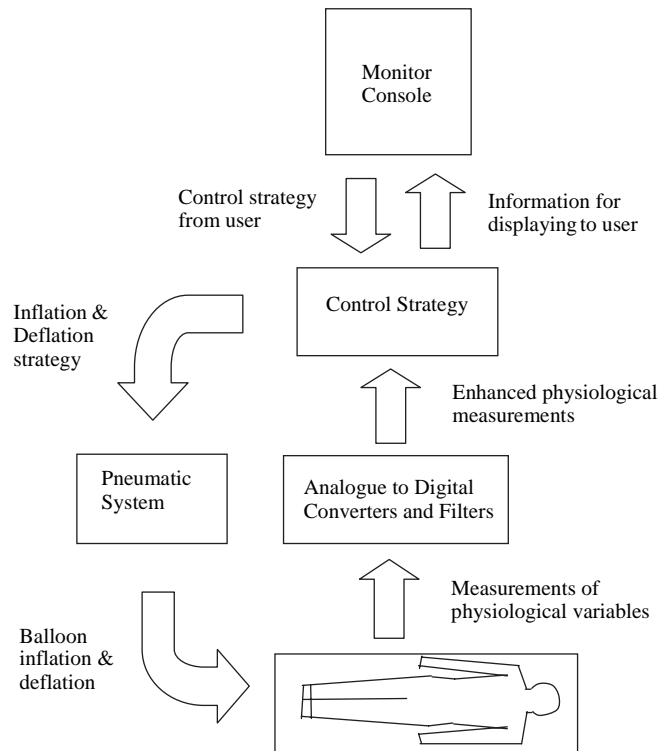

Figure 5. Closed-loop circuit for IABP control. The arrows indicate the flow of information for controlling the IABP.

played on the console monitor. Additionally the control strategy can be set by the clinician.

TRIGGERING

The drive console requires a trigger signal to synchronise with the cardiac cycle. The trigger signal indicates the start of ventricular systole.

Commercial consoles have several modes of triggering: The ECG trigger, where the trigger signal is the R wave of the ECG. This is the most commonly used mode of triggering. Blood pressure trigger, where the trigger signal is the upstroke of the arterial pressure wave. This is used when the ECG signal is too noisy to allow reliable R wave recognition. Pacer trigger, where the trigger signal is the pacing spike of the ECG. This is used when the patient has an implanted cardiac pacemaker. Internal trigger, where the trigger signal is generated internally by the console at a set rate. This is used during cardiac surgery when the heartbeat is temporarily arrested.

TIMING

The safety and efficacy of balloon pumping is dependent upon the correct timing of balloon inflation and deflation during the cardiac cycle. Inflation should occur during the isovolumetric relaxation period of ventricular diastole. Too early inflation is unsafe because it overlaps the ejection period of ventricular systole, impedes ejection and increases the work of the heart. Too late inflation is less effective because it reduces diastolic augmentation.

Safe and effective inflation timing is fairly easy to achieve because the systolic time interval is relatively constant, regardless of heart rate or rhythm. The operator is trained to adjust the time of inflation until it visibly corresponds with the dichrotic notch on the arterial pressure wave display.

Deflation should occur at the end of ventricular diastole or during the isovolumetric contraction period of ventricular systole. Too late deflation is unsafe because it overlaps the ejection period of ventricular systole, impedes ejection and increases the work of the heart. Too early deflation is less effective because it reduces diastolic augmentation.

Safe and effective deflation timing is more difficult to achieve because the length of diastole is variable, depending on the heart rate and rhythm. The operator is trained to adjust the time of deflation until it visibly reduces the EDP and PSP on the arterial pressure wave display. Commercial consoles have two modes of timing:

Conventional Timing

Under conventional timing, the balloon is inflated and deflated at set time intervals after the R wave is detected (called manual timing). This copes badly with alterations in heart rate of >10 bpm. The problem is that when the heart rate increases, the diastolic time interval shortens and the balloon now deflates too late. Conversely, when the heart rate decreases, the diastolic time interval lengthens and the balloon deflates too early.

Conventional timing can be improved by predicting the duration of the current cardiac cycle by averaging the R-R interval of the previous 5–20 heartbeats. The balloon is then deflated at a set time interval before the next R wave is predicted to arrive (called predictive timing). This copes fairly well with alterations in heart rate and is the most commonly used mode of timing.

Both manual and predictive timing cope badly with alterations in heart rhythm, when the length of diastole can vary from beat to beat in an entirely unpredictable way. Unfortunately, cardiac arrhythmias such as atrial fibrillation and frequent ectopic beats are common in these patients making optimal timing difficult to achieve.

Real Timing

Under real timing (also called R wave deflation), the balloon is deflated when the R wave is detected and inflated a set time interval later. This copes very well with alterations in heart rate and rhythm but it tends to cause too late deflation. The problem is that when the R wave is detected there may be insufficient time to fully deflate the balloon before overlapping the ejection period.

The R wave deflation is usually used as a safety mechanism in conjunction with conventional timing. It ensures that the balloon is deflated if an R wave arrives unexpectedly due to a sudden change in heart rate or rhythm.

OPTIMIZATION

As was seen above the standard timing strategies both suffer from problems in certain scenarios and thus control

of IABPs are not efficient in providing the best patient treatment. A natural solution to this is to develop timing strategies that optimize the balloon inflation regime according to the current patient condition. Several teams have reported work in this area.

Jaron et al. in 1979 (32) developed a multielement mathematical model of the canine circulation and the IABP. They expressed inflation and deflation times in terms of the total duration of inflation (DUR) and the time from the R wave to the middle of pump systole (TMPS). Duration of inflation and TMPS were expressed in terms of percentages of the duration of the cardiac cycle.

The model was validated by comparison with anesthetized dogs. They varied DUR and TMPS and measured the effects on EDP, MDP, and CO. Each of the three dependent variables (z axis) were plotted against the two independent variables (x and y axes) to create a three-dimensional (3D) surface. In general, there was considerable similarity between the surfaces obtained from the model and from the dogs. In particular, the similarity was closer for measurements of pressure (EDP, MDP) than for measurements of flow (CO).

Their results indicated that the locations of the desired optima for EDP (75% DUR, 45% TMPS) & CO (55% DUR, 75% TMPS) did not coincide. Furthermore, some combinations of DUR and TMPS within the range used clinically produced detrimental effects. Because not all variables could be optimized at same time, they suggested that the choice of timing settings involved balancing the clinical needs of the patient.

Jaron et al. in 1983 (33) subsequently developed a lumped model of the canine circulation and the IABP. It was validated by comparison with their previous model. They varied the timing of inflation and deflation, the speed of inflation and deflation and the volume of the balloon. The speed was either fast or slow, taking 7% or 33% of the duration of the cardiac cycle, respectively. The fast speed represented the ideal console with near instantaneous balloon inflation and deflation. The slow speed represented commercial consoles with significant inflation and deflation delay due to the movement of the shuttle gas. They measured the effects on EDP, SV, and coronary blood flow.

Inflation at end systole maximized SV and coronary blood flow for fast and slow speeds. Deflation at end diastole minimized EDP for fast speeds. At slow speed, deflation timing involved a trade-off between decreased EDP with early deflation and increased SV and coronary blood flow with late deflation. The overall benefit of the IABP was greater with fast speeds than slow speeds. It was also proportional to balloon volume.

In later experiments (34), they classified dependent variables as either internal, reflecting myocardial oxygen demand, or external, reflecting myocardial oxygen supply. Internal variables measured were TTI and EDP. External variable measured were SV and MDP. They showed that early deflation minimizes internal variables while late deflation maximizes external variables.

Niederer and Schilt in 1988(35) used a mechanical mock circulation and a mathematical model to investigate then influence of timing of inflation and deflation, speed of inflation and deflation and balloon volume on the efficacy

of the IABP. Timing was again expressed in terms of percentage of cardiac cycle duration. The default settings of the model were fast inflation at 30% time, fast deflation at 90% time and a volume of 40 cm³. These were found to produce an increase in SV of 25%, a decrease in left ventricular systolic pressure of 10% and an increase in aortic diastolic pressure of 50%.

The time of inflation was varied between 20% and 50%. This had little effect on SV when the speed was fast, but inflation after 30% caused a slight decrease in SV compared to default when the speed was slow. A time of deflation before 80% caused a slight decrease in SV compared to default. Fast inflation and deflation speeds caused opening and closing shock waves that could be harmful were they to occur in humans. Balloon volume was varied between 10 and 50 mL. There was a nonlinear relationship with SV, but 40 mL was adequate for optimal performance in the mock circulation.

Barnea et al. in 1990 (36) developed a sophisticated computer simulation of the normal, failing and IABP-assisted failing canine circulation. It included simple physiological reflexes involved in the regulation of the cardiovascular system. The failing heart was simulated by reducing the contractility of the normal heart. Myocardial oxygen supply and demand were calculated from the model. They were balanced in the normal circulation and imbalanced in the failing circulation. IABP assistance of the failing circulation was shown to restore the balance.

Sakamoto et al. in 1995 (37) investigated the effect of deflation timing on the efficiency of the IABP in anaesthetized dogs. They compared a deflation time before the R wave (during late diastole) with deflation times after the R wave (during isovolumetric contraction). Deflation during the middle of isovolumetric contraction was the most effective in obtaining optimal systolic unloading.

Morrow and Weller (38) successfully used genetic algorithms and the fitness function proposed by Kane et al. (39) to evolve a fuzzy controller that optimized cardiac assistance in a computer simulation of the IABP-assisted failing heart. The inputs were MDP and PSP and the output was deflation time.

Automatic Control

Kane et al. in 1971 (39) proposed a performance index or fitness function that reflected the overall benefit of IABP assistance at different timing combinations. Inflation and deflation times were expressed in terms of the delay before inflation after the R wave and the duration of inflation. The function included weighted MDP, MSP, and EDP.

$$\text{Fitness} = k_1\text{MDP} + k_2\text{MSP} + k_4\delta(k_3 - \text{EDP})^2$$

$$\text{where, } k_1 = \frac{100}{\text{MDP}_0}, \quad k_2 = \frac{100}{\text{MDP}_0}, \quad k_3 = \text{EDP}_0,$$

$$k_4 = -500 \left(\frac{1}{k_3} \right)^2, \quad \delta = \begin{cases} 1 & \text{if } (k_3 - \text{EDP}) < 0 \\ 0 & \text{otherwise} \end{cases}$$

$$\text{MDP}_0 = \text{unassisted MDP}, \quad \text{EDP}_0 = \text{unassisted EDP}$$

It was tested in a mechanical mock circulation and fitness was found to be a unimodal function of delay and

duration. An automatic controller was developed that used a gradient descent search algorithm to improve the fitness by adjusting the delay and duration at each heartbeat. The performance of the controller was compared with the performance of R wave deflation in simulated cases of heart failure. The controller was considerably better in moderate heart failure and marginally better in severe failure. In severe failure the trade-off between systolic unloading or diastolic augmentation was particularly apparent. In moderate failure, the fitness function emphasized systolic unloading (early deflation) while in severe failure it adapted to emphasize diastolic augmentation (late deflation). Thus, in severe failure the controller tended to simulate R wave deflation.

Martin and Jaron in 1978 (40) developed a manual controller for the IABP that allowed DUR and TMPS to be adjusted. It was tested successfully on anesthetized dogs and was capable of linking to a computer for automatic control.

Jaron et al. in 1985 (34) suggested that SV and TTI index were suitable choices for a fitness function for the fine adjustment of inflation time. Both MDP and EDP were suitable choices for the adjustment of deflation time. However, later work showed that PSP correlated better with myocardial oxygen demand than EDP.

Barnea (41,42), Smith (43) and their co-workers in 1989 proposed a fitness function for optimal control of deflation time. It included weighted MDP and PSP. The permitted interval for deflation time was -200 ms to $+100$ ms relative to the predicted arrival of the next R wave. An automatic controller was developed that used a search and approximation algorithm to converge upon the optimum fitness after a number of heartbeats. It was tested successfully on computer simulations and anaesthetised dogs. It was able to follow a moving optimum, both within the same patient over time and between different patients.

Zelano et al. in 1990 (44) developed an automatic controller for the IABP that used different trigger signals. Balloon inflation occurred either upon detection of S2 or at a set time prior to the predicted time of the next S2. Balloon deflation occurred either during the P-R interval at a set time after the P wave or after the R wave. The advantage of using the P wave, R wave and S2 for triggering is that all can be detected in real time. This allows the controller to follow changes in heart rate and rhythm. It was tested successfully in a semiautomatic open loop operation in anaesthetised dogs with a coronary artery tied to simulate a myocardial infarction. They proposed a fitness function for automatic closed loop control. It used weighted MSP and MDP.

Kantrowitz et al. in 1992 (45) reported a clinical trial of automatic closed loop control of the IABP. They used a rule-based algorithm to adjust the time of inflation and deflation. Its safety was verified in anaesthetized dogs and it was then tested on 10 human patients. Their aims were for inflation to occur at dichrotic notch and for deflation to overlap the first half of ventricular ejection. They were successful in 99 and 100% of recordings respectively. Eight of the patients survived. Neither of the two deaths was attributed to the controller.

Sakamoto et al. in 1995 (46) developed a new algorithm to cope with atrial fibrillation, the most unpredictable cardiac arrhythmia sometimes described as irregularly irregular. The aim was for inflation to occur at the dichrotic notch. They were able to predict the time of arrival of the dichrotic notch from mathematical analysis of the R-R interval from the previous 60 heartbeats. Deflation occurred at the R wave. It was tested on ECG recordings from real patients and performed better than conventional timing.

FUTURE DEVELOPMENTS

The use of IABP therapy for preoperative support and as an adjunct to coronary angioplasty or bypass and off-bypass cardiac surgery is likely to increase although larger studies are required to identify which patients will benefit most. The role of the IABP in left ventricular failure is likely to decrease with the increasing use of left ventricular assist devices.

Manufacturers recent research and development has focused on: Improved automatic control algorithms that better cope with alterations in heart rate and rhythm and adjust inflation and deflation times to optimize cardiac assistance. Better catheter designs that cause fewer vascular complications and permit more rapid movement of the shuttle gas.

INTRODUCTION

Intrauterine surgery of the fetus or fetal adnexae is spreading rapidly throughout the world. In a broad sense, intrauterine surgery includes any procedure in which a medical device is purposely placed within the uterine cavity. For most physicians, however, the concept of intrauterine surgery excludes such commonly performed procedures as amniocentesis and chorionic villous sampling. Rather, the term usually refers to techniques requiring specialized knowledge, experience, and most especially, instrumentation. Procedures most commonly mentioned in discourses on intrauterine surgery include those specifically developed for the treatment of such serious anatomic defects as congenital cystic adenomatoid malformation (CCAM), sacrococcygeal teratoma (SCT), lower urinary tract obstruction (LUTO), myelomeningocele, aortic or pulmonic stenosis, gastroschisis, iatrogenic amniorhexis, twin-to-twin transfusion syndrome (TTTS), and twins discordant for severe anomalies. As no one person in the world is an expert in every one of these procedures, the remainder of

this chapter is divided into individual sections, each authored by someone widely recognized as a leader in the treatment of that particular anomaly.

CONGENITAL CYSTIC ADENOMATOID MALFORMATION AND SACROCOCCYGEAL TERATOMA

Most prenatally diagnosed malformations are managed by appropriate medical and surgical evaluation and treatment following planned delivery near term, with some cases requiring transfer of the mother to a tertiary referral center with obstetrics, maternal fetal medicine, medical genetics, neonatology, and pediatric surgery subspecialties. Certain anatomic abnormalities can have significant fetal developmental consequences, with emergency *in utero* therapy being required due to gestational age and mortality risks for the fetus. Open maternal fetal surgery poses additional risks to the mother. Maternal fetal surgery (1–4) should not be attempted until (1) the natural history of the fetal disease is established by following up on untreated cases, (2) selection criteria for cases requiring intervention are developed, (3) pathophysiology of the fetal disorder and its correction are defined in fetal animal models, and (4) hysterotomy and fetal surgery can be performed without undue risk to the mother and her reproductive potential.

Congenital cystic adenomatoid malformation of the lung (CCAM) (5) is a rare lesion characterized by a multicystic mass of pulmonary tissue with proliferation of bronchial structures. CCAM is slightly more common in males and is unilobar in 80–95% of cases. CCAMs derive their arterial blood supply from the normal pulmonary circulation. CCAMs are divided clinically into cystic and solid lesions, but have been divided traditionally into three types based on their pathological characteristics. Type I CCAM lesions account for 50% of postnatal CCAM cases and consist of single or multiple cysts lined by ciliated pseudostratified epithelium (5). These cysts are usually 3–10 cm in size and 1–4 in number (5). Type II CCAM lesions account for 40% of postnatal cases of CCAM and consist of more numerous cysts of smaller diameter, usually less than 1 cm. They are lined by ciliated, cuboidal, or columnar epithelium (5). Type III CCAM lesions account for only 10% of CCAM cases and are usually large, homogenous, microcystic masses that cause mediastinal shift. These lesions have bronchiolar-like structures lined by ciliated cuboidal epithelium separated by masses of alveolar-sized structures lined by nonciliated cuboidal epithelium (5). Prognosis in Type III CCAM is related to size.

Sacrococcygeal teratoma (SCT) (6) is defined as a neoplasm composed of tissues from either all three germ layers or multiple foreign tissues lacking an organ specificity. SCT is thought to develop from a totipotent somatic cell originating in Hensen's node. SCT has been classified by the relative amounts of presacral and external tumor present, with Type I completely external with no presacral component, Type II external component with internal pelvic component, Type III external component with internal component extending into the abdomen, and Type IV completely internal with no external component (7). A Type I SCT is evident at birth and is usually easily resected and

has a low malignant potential (6). Type II and III SCTs are recognized at birth, but resection may be difficult requiring an anterior and posterior approach (6). A Type IV SCT can have a delayed diagnosis until symptomatic at a later age (6). SCT is one of the most common tumors in newborns and has an incidence of 1 per 35,000 to 40,000 live births (6).

Evaluation of the fetal status for CCAM and SCT requires multiple imaging and functional techniques (8–10), including fetal ultrasound, fetal MRI, and fetal echocardiogram with arterial and venous Doppler assessments (umbilical artery, umbilical vein, ductus venosus). Measurements include combined cardiac output, cardiothoracic ratio, descending aortic blood flow, inferior vena cava diameter, placental thickness, umbilical artery systolic to diastolic Doppler ratio, and amniotic fluid index. Presence of ascites, pleural or pericardial effusion, and skin or scalp edema are important markers for the extent of fetal hydrops and its overall effect on fetal stability. Specific ultrasound imaging of the CCAM and SCT looks for the percentage of cystic and solid components in the tumors as well as an overall mass volume (cc) estimate ($AP \text{ cm} \times \text{transverse cm} \times \text{height cm} \times 0.52$). The SCT consistency and size can be reflected directly in the combined cardiac output and amount of vascular shunting. The CCAM overall size can cause mediastinal shift with cardiac dysfunction and pulmonary deformation. Validated ratio of CCAM/head circumference (CVR) can be used for prognosis and follow-up planning (10). The specific lobar location for the CCAM may have a differential impact on cardiac function. The development of fetal hydrops is due mainly to cardiac dysfunction secondary to compression.

The physiologic changes required in the fetal status to move from expectant management to open maternal fetal surgery is generally dictated by fetal (gestational age and extent of fetal hydrops) and maternal factors (8–10). Criteria for consideration of maternal fetal surgery for CCAM resection (fetal lobectomy) require the absence of maternal risk factors for anesthesia and surgery, a singleton pregnancy with a normal karyotype (amniocentesis, chorionic villus sampling, or percutaneous umbilical blood sampling), no other anatomical abnormalities beyond the associated hydrops, gestational age of 21–31 weeks, and massive multicystic or predominantly solid CCAM ($CVR > 1.6$) (8–10). In selected cases, the failure of *in utero* therapy techniques, such as thoracoamniotic shunting or cyst aspiration for the large Type I lesions, to reverse the fetal hydrops would be required. Criteria for consideration of maternal fetal surgery for debulking of a SCT require the absence of maternal risk factors for anesthesia and surgery, a singleton pregnancy with a normal karyotype, the absence of significant associated anomalies, evidence of impending high output cardiac failure, gestational age of 21–30 weeks, and favorable SCT anatomy classification (Type I or II) (9).

The technique for maternal hysterotomy to allow access to the fetus has been well described and has evolved over 25 years of experimental and clinical work (1,8,9). The uterus is exposed through a maternal low transverse abdominal incision. If a posterior placenta is present, superior and inferior subcutaneous flaps are raised and a vertical midline fascial incision is made to expose the uterus for a convenient anterior hysterotomy with the uterus remaining

in the abdomen. Conversely, the presence of an anterior placenta necessitates the division of the rectus muscles so the uterus can be tilted out of the abdomen for a posterior hysterotomy. A large abdominal ring retractor (Turner–Warwick) is used to maintain exposure and prevent lateral compression of the uterine vessels. Sterile interoperative ultrasound is used to delineate the fetal position and placental location. The edge of the placenta is marked under sonographic guidance using electrocautery or a marking pen. The position and orientation of the hysterotomy is planned to stay parallel to and at least 6 cm from the placental edge but still allow exposure of the appropriate fetal anatomy. The hysterotomy is facilitated by the placement of two large monofilament sutures (PDS II 1 Ethicon; Somerville, NJ) parallel to the intended incision site and through the full thickness of the uterine wall and membranes under sonographic guidance. The electrocautery is used to incise the myometrium between the two stay sutures down to the level of the amniotic membranes. A uterine stapler device (US Surgical Corporation; Norwalk, CT) with absorbable Lactomer staples is then directly introduced through the point of fixation and into the amniotic cavity by using a piercing attachment on the lower limb of the stapler. The stapler is fired, thereby anchoring the amniotic membranes (chorion, amnion) to the uterine wall creating a hemostatic hysterotomy. Careful evaluation for the membrane adhesion status and for any myometrial bleeding sites is undertaken. If required, interrupted PDS sutures are used to control bleeding and membrane separation. The fetus and the internal uterine cavity are continually bathed in warmed lactated Ringers at 38–40°C using a level I warming pump connected to a red rubber catheter that is placed in the uterine cavity through the hysterotomy.

For CCAM resection (1,8,11), once the appropriate fetal area is visualized in the hysterotomy site, the fetal arm is brought out for pulse oximeter monitoring, IV access, and fetal position control. Intraoperative fetal echocardiography is used throughout to monitor cardiac function. The fetal chest is entered by a fifth intercostal space thoracotomy. The lesion usually decompresses out through the thoracotomy wound consistent with the increase in the thoracic pressure from the mass (8). Using techniques initially developed on experimental animals, the appropriate pulmonary lobes containing the lesion are resected (1,11). Fetal resuscitation is performed if needed through intravenous administration of crystalloid, blood, and code-blue medications with fetal echocardiography providing functional information. The fetal thoracotomy is closed and the fetal arm is returned to the uterus.

The technique for debulking of an external fetal SCT has been described in detail previously (1,9,12,13). The fetal foot is used for pulse oximeter monitoring and IV access with intraoperative echocardiography. The fetal SCT is exposed and a Hagar dilator is placed in the rectum. Fetal skin is incised circumferentially around the base of the tumor and a tourniquet is applied to constrict blood flow. The tumor is debulked externally, usually with a 90 mm thick tissue stapler (US Surgical Corporation; Norwalk, CT). The objective of the fetal SCT resection is to occlude the tumor vascular supply and remove the low resistance

tumor vascular bed from the fetal circulation. No attempt is made to dissect the intrapelvic component of the tumor or to remove the coccyx (done with a second procedure after birth). Fetal resuscitation is performed if needed through intravenous administration of crystalloid, blood, and code-blue medications with fetal echocardiography providing functional information. The fetal sacral wound is closed.

Repair of the hysterotomy after fetal surgery (1–4) uses a water-tight two-layered uterine closure, with interrupted full thickness stay sutures placed first and untied using PDS II 1 (Ethicon; Somerville, NJ), and the uterus is then closed with a running continuous stitch PDSII 0 (Ethicon; Somerville, NJ) including the chorion-amnion membrane layer. The interrupted stay sutures are then tied after the amniotic fluid volume has been corrected with warm lactated Ringers through a red rubber catheter and volume confirmed by ultrasound visualization. The omentum is sutured in place over the hysterotomy closure to help seal the hysterotomy site with vascularized tissue and to prevent bowel adherence to the site, especially when a posterior hysterotomy is performed. The maternal laparotomy incision is closed in layers. It is important to use a subcuticular skin closure covered with a transparent dressing so that monitoring devices can be placed on the maternal abdomen postoperatively.

In some specific cases, when the CCAM lesion is not resected *in utero*, it continues to be a large space-occupying lesion with mediastinal shift. Thus, it might be anticipated that respiratory compromise will be present at birth, the delivery may be facilitated with an EXIT procedure (*ex utero* intrapartum therapy) (14). Uterine relaxation is maintained by high concentration inhalational anesthetics, with additional tocolysis if necessary. The EXIT requires only the head and chest to be initially delivered through, preferably, a low transverse hysterotomy wound thereby preserving uterine volume with the lower fetal body and continuous warmed lactated Ringers infusion to prevent cord compression. These maneuvers preserve the uterine-placental circulation and continue placental gas exchange. The EXIT procedure can be done through an anterior or posterior hysterotomy, but its location in the uterus may require that all future pregnancies be delivered by cesarean section with no trial of labor if a low anterior transverse location is not available.

All future pregnancies following maternal hysterotomy for maternal-fetal surgery require cesarean section at term with no trial of labor. Maternal obstetrical risks in a subsequent pregnancy are similar to risks following for a classic cesarean section (15).

LOWER URINARY TRACT OBSTRUCTION

The diagnosis and treatment of fetal lower urinary tract obstruction (LUTO) requires knowledge of the differential diagnosis and the natural history of the condition, a thorough understanding of the criteria for therapy, and management expertise. Fetal LUTO is one of the most commonly diagnosed birth defects. Untreated, and depending on the level of the obstruction, it may lead to hydronephrosis, renal dysplasia, pulmonary hypoplasia, and

perinatal death (16,17). The prognosis depends on the extent of preexisting renal damage and the effectiveness of therapy. Treatment with fetal urinary diversion procedures is aimed at preventing renal damage and pulmonary hypoplasia (18–20).

Obstruction to urine flow has been shown in animal models to result in hydronephrosis and renal dysplasia (21). Release of the obstruction is associated with no or variable renal damage depending on the timing of the release or the creation of the defect (21,22). Pulmonary hypoplasia is another major potential complication of fetuses with obstructive uropathy (23). The association probably results from the attendant oligohydramnios.

Urethral obstruction may result from posterior urethral valves (PUV), anterior urethral valves, megalourethra, urethral duplications, urethral atresia, obstructive ureterocele, or cloacal dysgenesis. Posterior urethral valves (PUV), first described by Young et al. (24), constitute the most common cause of lower urinary tract obstruction in male neonates, with an incidence of 1:8000 to 1:25,000 livebirths (25). The lesions occur only in males because the female counterpart of the verumontanum, from which the valves originate, is the hymen.

In utero therapy is usually limited to fetuses with bladder outlet obstruction. Fetuses with unilateral obstruction are not typically considered candidates for *in utero* therapy, regardless of the magnitude of the obstruction or renal findings. In these patients, the risk/benefit ratio of *in utero* intervention favors expectant management, even if it means loss of the affected renal unit.

Fetal renal function may be assessed by analysis of fetal urinary parameters via vesicocentesis. Patients are considered candidates for *in utero* therapy if fetal urinary parameters are below the threshold for renal cystic dysplasia. If the values are above the threshold, therapy should not be offered.

The application of selection criteria in patients with fetal LUTO for possible *in utero* therapy results in a significant attrition rate. Disqualification from therapy may result both from “too healthy” or “too sick” conditions. Examples of too healthy conditions include normal amniotic fluid volume or suggestion of nonobstructive dilatation of the urinary tract. Examples of too sick conditions include sonographic evidence of renal cystic dysplasia, abnormal fetal urinary parameters, abnormal karyotype, or the presence of associated major congenital anomalies. Of 90 patients referred to the Florida Institute for Fetal Diagnosis and Therapy from October 1996 to October 2003, more than one-half were disqualified from therapy from single or overlapping conditions.

Percutaneous ultrasound-guided vesicoamniotic shunting of fetuses with LUTO began in the early 1980s (16,19,23). The goal of therapy is to avoid development of pulmonary hypoplasia from the attendant oligohydramnios as well as to preserve renal function. Fetal bladder shunting should be offered only to patients without sonographic or biochemical evidence consistent with renal cystic dysplasia, normal karyotype, and lack of associated major congenital anomalies.

The procedure can be performed under local, regional, or general anesthesia. A minimal skin incision is made.

Ultrasound is used to identify the ideal site of entry into the fetal bladder, below the level of the umbilicus. Color Doppler ultrasonography is used to identify the umbilical vessels around the distended bladder and avoid them. Under ultrasound guidance, the trocar is directed through the maternal tissues and up to the fetal skin. Fetal analgesia is achieved with pancuronium 0.2 mg/kg and fentanyl 10 mcg/kg. The trocar stylet is used to enter the fetal bladder with a sharp, swift, and controlled maneuver. If a prior vesicocentesis had been performed, it is advisable to obtain a sample of fetal urine for microbiological purposes to rule out preexisting infection. A sample of fetal urine is sent for further biochemical testing. Placement of the double-pigtail catheter is monitored with ultrasound. After the distal loop is deployed in the bladder, the trocar is retrieved to the level of the bladder wall. A small amount of the straight portion of the catheter may be advanced into the bladder to avoid retracting the distal loop into the bladder wall. The trocar shaft is retrieved slowly while simultaneously maintaining pressure on the catheter to deploy the straight portion within the bladder wall and fetal skin. Once the shaft of the trocar reaches the fetal skin, entrance of the catheter, including the proximal loop, can be safely deployed. If complete anhydramnios is present prior to insertion of the catheter, it is advantageous to attempt an amnioinfusion with an 18 gauge needle prior to shunting to create the space for deployment of the proximal loop. Amnioinfusion is aimed at preventing misplacement of the proximal loop within the myometrium and fetal membranes.

Despite adequate placement, malfunction of vesicoamniotic shunting may occur up to 60% of the time (26). The shunt may pull from the skin into the fetal abdomen, resulting in iatrogenic ascites, or out of the fetal bladder, with no further drainage of urine. The shunt may pull out of the fetus altogether as well. Replacement of the shunt is associated with an additive risk of fetal demise, chorioamnionitis, premature rupture of membranes, and miscarriage or preterm delivery, for a total perinatal loss rate of approximately 5% per instance.

In 1995, we proposed the use of endoscopy to assess the fetal bladder for diagnostic and surgical purposes (27,28). Endoscopic visualization of the fetal bladder with a larger endoscope can be justified during vesicoamniotic shunting. Currently, we use a 3 mm or a 3.9 mm trocar with a 2.7 mm or 3.3 mm diagnostic or operating endoscope. This diameter is slightly larger than the 14 gauge (approximately 2.1 mm) needle used for the insertion of the double-pigtail catheter. Access to the fetal bladder allows remarkable evaluation of the bladder, ureteral orifices, and urethra as well as the opportunity to perform surgical procedures.

In normal fetuses, the urethra is not dilated, appearing as a small hole within the bladder. In patients with a true urethral obstruction, endoscopy will show a variable dilatation of the urethra at the level of the bladder neck. The urethra is located using a 25° or a 70° diagnostic rigid endoscope. Alternatively, a flexible/steerable endoscope may be used. The anatomical landmarks to identify at this level include the verumontanum and the urethral valves. The diagnostic endoscope is then exchanged for a rigid

operating endoscope. A 600 μm YAG-laser fiber is passed through the operating channel of the endoscope, and then ablated using 5–10 w and 0.2 s pulses in successive steps. The fiber is placed as anterior and medial as possible. It is not necessary to evaporate the entire valvular tissue. Instead, only a few defects to either side of the midline are necessary to establish urethral patency (27,29). The dilated urethra may collapse intraoperatively once patency is re-established, which may obscure the field of view and require frequent instillation of saline to the side port of the trocar to distend it. Color Doppler may also be used to document fetal urination through the penis.

A urethrectal fistula may occur from thermal damage beyond the posterior wall of the urethra into the perirectal space. To avoid this complication, only 5–10 w of energy in short bursts should be used while ablating the valves.

The management of fetuses with lower obstructive uropathy continues to be one of the most challenging subjects in fetal therapy. The difficulties include establishing the correct differential diagnosis, accurately predicting subsequent renal function, and providing the best treatment.

MYELOMENINGOCELE

Myelomeningocele results from the failure of caudal neural tube closure during the fourth week of gestation. The lesion is characterized by protrusion of the meninges through a midline bony defect of the spine, forming a sac containing cerebrospinal fluid and dysplastic neural tissue. Affected infants exhibit varying degrees of somatosensory loss, neurogenic sphincter dysfunction, paresis, and skeletal deformities (30). Virtually all such infants also have the Chiari II malformation, and up to 95% develop hydrocephalus (31). Although myelomeningocele is not a lethal disorder, the neurologic sequelae are progressive, and worsen until the lesion is closed. Observational and cohort studies have demonstrated improvement of the Chiari II malformation (32,33), decreased hydrocephalus (34), and improved lower extremity function after intrauterine repair of myelomeningocele (35).

On the day of surgery, the pregnant patient is taken to a standard obstetrical operating room. An epidural catheter is placed and, after induction of general endotracheal anesthesia, she is prepared as if for a cesarean section. Many of the general anesthetic agents cross the placenta and provide analgesia for the fetus, and the epidural catheter enables the administration of continuous postoperative analgesics if needed. The gravid uterus is exposed with a Pfannenstiel incision and exteriorized. The uterine contents are then mapped with a sterile ultrasound transducer, and the location of the fetus and the placenta are determined. Initial uterine entry is obtained with a specialized trocar developed at Vanderbilt University Medical Center (Cook Incorporated; Bloomington, IN). The Tulipan–Bruner trocar consists of a tapered central introducer covered by a peel-away Teflon sheath. Use of this trocar has demonstrated to reduce operative time and blood loss while providing atraumatic entry into the uter-

ine cavity (36). Two through-and-through chromic sutures are passed through the uterine wall and membranes on either side of the selected entry point. The introducer is then passed into the uterine cavity under direct ultrasonographic guidance using a modified Seldinger technique. The central introducer is then removed, leaving only the trocar sheath. Excess amniotic fluid may be aspirated and stored in sterile, warm syringes. The footplate of a U.S. surgical CS-57 autostapling device (United States Surgical Corporation; Norwalk, CT) is then inserted through the peel-away sheath, and the sheath is removed, leaving the stapler in proper position. When activated, the stapler creates a 6–8 cm uterine incision. At the same time, all the layers of the uterine wall are held together, much like the binding of a book.

The fetus is directly visualized and manually positioned within the uterus so that the myelomeningocele sac is located in the center of the hysterotomy. Proper position is maintained by grasping the fetal head and trunk through the flaccid uterine wall. During the procedure, the fetal heart rate is monitored by continuous ultrasonographic visualization.

The myelomeningocele is closed in routine neurosurgical fashion. Approximately 20% of patients will not have a well-formed myelomeningocele sac, but a crater-like lesion termed myeloschisis. As fetuses with myeloschisis have less viable skin for closure, it may be necessary to use bilateral vertical relaxing incisions in the flanks to create bipedicular flaps that can be advanced and closed over the dural sac. The resulting full-thickness cutaneous defects are covered with cadaveric skin (37).

After repair of the spina bifida lesion, the uterus is closed in layers using #1 PDS sutures. The first layer incorporates the absorbable polyglycolic acid staples left by the autostapling device. As the last stitches of this layer are placed, the reserved amniotic fluid or physiologic crystalloid solution, mixed with 500 mg of nafcillin or an equivalent dosage of an antibiotic effective against *Staphylococcus* species, is replaced in the uterus. The sterile, warm fluid is added until the uterine turgor, as determined by manual palpation, is restored to the preoperative level, which is followed by an imbricating layer. A sheet of Interceed absorbable adhesion barrier (Johnson & Johnson Medical, Inc.; Arlington, TX) or omentum is attached over the incision to prevent adhesion formation. The uterus is returned to the abdomen. The fascial layer is closed in routine fashion, and the dermis closed with a running subcuticular suture or staples. The fetus is monitored postoperatively using continuous electronic fetal monitoring (EFM) and intermittent transabdominal ultrasonography.

Postoperative uterine contractions are monitored using continuous EFM. Uterine contractions are initially controlled with intravenous magnesium sulfate and oral or rectal indomethacin, and subsequently with subcutaneous terbutaline or oral nifedipine, supplemented by indomethacin as needed. Patients are monitored with weekly transabdominal ultrasonographic examinations. Delivery of each child is accomplished via standard cesarean section. Although the same abdominal incision is used for the cesarean section as for the fetal surgery, the fetus is preferably delivered via a lower uterine segment incision.

The uterus and abdominal incisions are closed in routine fashion.

VALVULOPLASTY

Severe aortic stenosis in midgestation may lead to left ventricular myocardial damage and can ultimately result in hypoplastic left heart syndrome. Paradoxically, in these fetuses, which are likely to progress to HLHS, the left ventricle initially appears normal in size, or even enlarged, in the setting of left ventricular systolic dysfunction. As gestation progresses, diminished flow through the diseased left ventricle leads to decreased flow, and the ventricle experiences growth arrest, resulting in left heart hypoplasia at birth. Early relief of fetal aortic stenosis may preserve left heart function and growth potential by maintaining flow through the developing chamber. To this end, a number of operators have developed techniques to perform fetal aortic valvuloplasty in second trimester fetuses.

The mother is placed under general anesthesia in a supine position with left lateral uterine displacement. Transabdominal ultrasound imaging and external manipulation are employed to achieve ideal fetal position. In this position, a line of approach from the anterior abdominal surface traverses the apex of the fetal left ventricle (LV), paralleling the LV outflow tract, and crossing the valve into the ascending aorta. The fetus is given intramuscular anesthetic and muscle relaxant prior to catheterization. If unable to position the fetus using external maneuvers, the operators perform a limited laparotomy to enable direct uterine manipulation and transuterine imaging.

A low profile, over-the-wire coronary angioplasty catheter is chosen with a balloon diameter based on the measurement of the aortic annulus, using a balloon:annulus ratio of 1:2. The balloon catheter is mounted on a floppy-tipped guidewire, with 3 cm of distal wire exposed. The wire/catheter assembly is then advanced through the 19G 12 cm stainless-steel introducer cannula until the balloon emerges. Affixing a visible and palpable marker on the proximal catheter shaft allows the operator to reproduce this balloon/cannula relationship during the procedure without relying wholly on the ultrasound imaging.

The introducer is advanced through the fetal chest wall and to the LV epicardium under ultrasound guidance. The LV is entered with the introducer, and the obturator removed with the tip of the cannula just below the aortic valve (Fig. 1). Blood return through the cannula confirms an intracavitary position.

The wire/catheter assembly is passed through the cannula, and the tip of the wire is identified as it emerges. While maintaining imaging of the aortic valve and ascending aorta, the precurved wire tip is manipulated to probe for the valve. Valve passage, confirmed echocardiographically by imaging the wire in the ascending aorta, is followed by catheter insertion to the premarked depth. The balloon is then inflated, by hand or by pressure gauge, to a pressure at which it achieves the intended balloon:annulus ratio. Upon completion of the dilation, the entire apparatus is removed from the fetus.

Figure 1. Transabdominal ultrasound imaging during introducer cannula insertion into dilated fetal left ventricle. The tip of the introducer is positioned in the left ventricular outflow tract directed at the stenotic aortic valve.

When first reported in the 1990s, fetal aortic valve dilation was performed with minimal technical success (38). Using the technique described above, technical success rates are now over 80% in fetuses between 21 and 26 weeks (39). As the technical aspects of the procedure continue to be refined, and safety is established, issues of patient selection will become the major focus of ongoing research. Anatomic and physiologic variables predicting left ventricular normalization following successful fetal aortic valvuloplasty remain poorly understood.

AMNIOEXCHANGE

Gastroschisis is a paraumbilical defect of the anterior abdominal wall associated with intrauterine evisceration of the fetal abdominal organs. The incidence of gastroschisis is approximately 1:4000 births, with a 1:1 male:female ratio. Most cases are sporadic and aneuploidy is uncommon.

Gastroschisis is characterized by a full-thickness defect of the abdominal wall, usually located to the right of the umbilical cord, which has a normal insertion. The defect in the abdominal wall is generally quite small (3–5 cm). The herniated organs include mainly bowel loops, although, in rare cases, the spleen and liver may be involved. Intestinal atresias and other gastrointestinal disruptions are found in as many as 15% of cases, and malrotation is also universal.

Although the prognosis is excellent with an ultimate survival of greater than 90%, many factors may jeopardize the outcome of these infants. A chronic aseptic amniotic fluid peritonitis (perivisceritis) often occurs. The herniated organs become covered by an inflammatory peel in the third trimester, resulting from chemical irritation by exposure to digestive enzymes in the amniotic fluid. Thickening, edema, and matting together of the intestines occurs in these cases, and may result in a secondary ischemic injury

to the bowel as the abdominal defect becomes too small. Meconium is frequently found in the amniotic fluid of affected fetuses. Its presence probably reflects intestinal irritation. Intrauterine growth restriction (IUGR) is frequent, occurring in up to 60% of fetuses. Oligohydramnios can occur, and may lead to fetal stress by cord compression. Premature birth is a frequent and still poorly understood complication. At birth, infants have low serum albumin and total protein levels, which probably results from chronic peritonitis.

The obstetrical management of the fetus with gastroschisis is controversial. Some studies have shown no clear benefit of cesarean delivery over vaginal delivery, where as others demonstrate an improved perinatal outcome in infants delivered by elective cesarean section prior to labor. Postoperative infection and delayed total enteral nutrition are the major acute complications of the newborn. Although all neonates with gastroschisis require surgery shortly after birth, repair may be by primary fascial closure, or by delayed fascial closure using temporary coverage with a silastic/Dacron intra-abdominal pouch. The repair as a primary or secondary procedure depends on the degree of chemical peritonitis with matting of the bowel that is present. Delayed intestinal function with poor enteral nutrition is expected in most patients. Central venous access and early total parenteral nutrition are therefore usually required.

In a study by Luton et al. (40), gastroschisis was created at mid gestation in 21 lamb fetuses. Saline was amnioinfused in some fetuses every 10 days until term. Thickness of the bowel muscularis, thickness of the serous fibrosis, and plasma cell infiltration were all significantly improved in amnioexchanged animals when compared with fetal lambs that were not amnioexchanged (40). Histologic analysis of appendices removed from human newborns demonstrated increased fibrosis in those with gastroschisis; after amnioinfusion, the serosa was still edematous, but no inflammation was seen (41). In a pilot study in human pregnancies (42), the same authors investigated the effect of amnioinfusion on the outcome of prenatally diagnosed gastroschisis. Following up on their work showing that an inflammatory response exists in the amniotic fluid of fetuses with gastroschisis, they hypothesized that amniotic fluid exchange would improve the outcomes of prenatally diagnosed cases. The outcome of 10 amnioinfused fetuses with gastroschisis was compared with 10 nonamnioinfused matched controls. Results showed that fetuses undergoing amnioinfusion had a shorter duration of curarization after surgical repair (2.2 ± 1.9 versus 6.8 ± 6.9 days, $+ = 0.019$), a shorter delay before full oral feeding (49.7 ± 21.5 versus 72.3 ± 56.6 days, NS) and a shorter overall length of hospitalization (59.5 ± 19.7 versus 88.5 ± 73.6 days, NS). The authors confirmed their previous data showing that amniotic fluid displays a chronic inflammatory profile, and they speculated that a reduction of the inflammatory response could improve the outcome of human fetuses with gastroschisis (42).

Amnioexchange for treatment of gastroschisis begins after 30 weeks' gestation, and is repeated approximately every two weeks until delivery. A complete obstetrical ultrasound examination is performed prior to the amnioex-

Figure 2. Views of the uterus.

change. The patient is admitted to the labor and delivery suite, and a nonstress test is performed before and after the amnioexchange. An intravenous line or a heplock is placed, and a single vial of blood is obtained and held for routine admission laboratory studies, in the case that urgent delivery is required. Prophylactic tocolysis may be given in the form of intravenous or subcutaneous terbutaline. Light IV sedation may also be given if desired.

After performing a sterile abdominal prep and drape, amnioexchange is performed using a "closed system." The closed tubing system materials are illustrated in Fig. 2. All of the materials are sterile except the graduated cylinder. Two sterile three-way stopcocks (b and c) are connected end-to-end. Sterile IV solution (a) is connected to stopcock (c) by way of sterile IV tubing (a). Three lengths of sterile connecting IV tubing (b) are connected to the remaining exposed ports of the stopcock assembly. Tubing from the side port of stopcock (b) is allowed to drain to the graduated cylinder (d). A 60 mL syringe (e) is connected to the tubing attached to the inline port of stopcock (b). The tubing attached to the inline port of stopcock (c) will connect to the therapeutic amniocentesis needle. Stopcock (c) is closed off to the IV solution (a). Stopcock (b) is closed off to the graduate (d). Amniocentesis is performed under continuous ultrasound guidance. Once access is obtained, the stylet is removed from within the needle lumen and the connection tubing is attached. With the stopcocks positioned as noted above, amniotic fluid is withdrawn into the syringe (e) until the syringe is filled. Stopcock (b) is then closed off to the patient and the fluid is expelled into the graduate (d). Stopcock (b) is then turned off to the graduate (d), and this step is repeated until the desired amount of amniotic fluid has been withdrawn (300–900 ml). With stopcock (b) closed to the graduate (d), stopcock (c) is closed off to the patient. The syringe is then filled with sterile warmed saline. Stopcock (c) is then closed to the IV solution (a) and the fluid is infused into the patient. This step is repeated until the desired amount of fluid is infused. These steps are repeated serially until the infusion procedure is complete. If the amniotic fluid volume falls within normal range, the amniotic fluid volume at the end of the amnioexchange should be the same as at the beginning of the procedure. In the presence of oligohydramnios, additional sterile warmed fluid can be added to the uterine cavity in order to achieve a normal fluid volume by the end of the procedure.

If the fluid volume is normal, the placenta is located posteriorly or fundally, and the fetus is quiescent, all of the toxic amniotic fluid planned for removal might be aspirated in one step. With an anteriorly implanted placenta, however, or in the presence of oligohydramnios or an active fetus, it may be necessary to remove a small amount of amniotic fluid, and then replace it with warmed normal saline, repeating the procedure serially until the amnioexchange is completed.

After completion of the amnioexchange, electronic monitoring of the fetal heart rate and uterine activity continues until the patient fulfills the usual criteria for discharge.

AMNIOPATCH

Iatrogenic preterm premature rupture of membranes (PPROM) occurs in approximately 1.2% of patients after genetic amniocentesis (43), 3–5% of patients after diagnostic fetoscopy (44), and approximately 5–8% of patients after operative fetoscopy. Although the membranes might seal spontaneously in this setting (45,46), most patients continue to leak fluid and are at a risk for pregnancy loss.

The overall perinatal mortality of previable PPRM managed expectantly is 60% (47,48). Nearly one-third of these deaths occurs *in utero*. Pulmonary hypoplasia occurs in 50% of cases diagnosed before 19 weeks (49). Serious sequelae in surviving infants include blindness, chronic lung disease, and cerebral palsy.

Patients with iatrogenic PPRM between 16 and 24 weeks gestation who do not have clinical evidence of intra-amniotic infection are candidates for amniopatch therapy. PPRM is confirmed with a sterile speculum examination showing vaginal pooling of fluid, ferning, and a positive Nitrazine test. The maximum vertical pocket of amniotic fluid is measured sonographically. Patients are placed on intravenous antibiotics and bed rest for one week to allow for spontaneous sealing of the membranes. If spontaneous sealing does not occur, 1 unit of autologous platelets and cryoprecipitate are prepared if the patient is eligible for autologous donation. Otherwise, donor platelets and cryoprecipitate are prepared.

After informed consent, an amniocentesis is performed using a 22 gauge needle. The needle is directed into an available pocket of fluid regardless of the site of the previous invasive procedure. A K-51 tubing extension attached to a three-way stopcock is connected to the hub of the needle. Platelets are administered first, followed by cryoprecipitate. In our original protocol, 1 whole unit of platelets was injected. We have subsequently reduced the dose of platelets to one-half a unit because of an unexplained fetal death demise, an adverse effect probably caused by sudden activation of a large number of platelets.

In our series of 28 cases, the average gestational age at the time of the procedure was 19 weeks and 3 days. The average gestational age of delivery in patients who did not have an intrauterine fetal demise was 33 weeks and 4 days. Overall, membrane sealing occurred in 19 of 28 patients (67.9%). Of the 28 patients treated, 11 had a large membrane detachment but no overt leakage of fluid. The detachment of the membrane occurred from fluid escaping

the amniotic cavities through the membrane defect, causing dissection of the chorionic cavity. In these patients, only the chorion separates this fluid from leaking grossly to the vagina. In this group, the amniopatch was successful in resealing the amniotic membrane in 7 of the 11 patients (63.6%).

The precise mechanism by which the amniopatch works is unknown. Presumably, platelet activation at the site of rupture and fibrin formation initiates a healing process that enables the membranes to seal.

TTTS

Feto-fetal transfusion syndrome can be described in all monochorionic multiple pregnancies but has been extensively reported in twins. Twin-to-twin transfusion syndrome (TTTS) develops in approximately 15% of all monochorionic pregnancies (50), and carries a high perinatal mortality rate (50). The fetuses are morphologically normal, and inter-twin vascular communications on the chorionic plate are thought to be responsible for the development of the disease through unidirectional blood transfusion from the donor to the recipient twin. Besides the primary hemodynamic imbalance between the twins, the disease may lead to disruptive lesions in both twins. Before the development of antenatal ultrasound, TTTS was diagnosed at birth as a discordance of at least 20% in weight and 5 g/dL in the hemoglobin concentrations of two twins of the same sex (52). These criteria were abandoned because these features could not be consistently recognized *in utero*. With the development of ultrasound, the polyhydramnios-oligohydramnios sequence has been found to be the condition carrying one of the highest perinatal mortality rates in obstetrics, up to 90% without treatment.

Laser coagulation of placental anastomoses by fetoscopy is the most effective first-line treatment of FTTTS, which leads to at least one survivor at birth and intact survival at 6 months of age in 76% and 76% respectively, as compared with 56% and 51% in cases treated by serial amnioreduction in the Eurofetus randomized trial (53).

The selection criteria to qualify for percutaneous endoscopy-directed laser coagulation of placental anastomoses include:

1. Gestational age of less than 26 weeks.
2. Ultrasound diagnosis of a single monochorionic placenta by ultrasound in the first trimester of pregnancy.
3. Polyhydramnios in the recipient's amniotic cavity with a deepest vertical pool ≥ 8 cm or ≥ 10 cm before or after 20 weeks of gestation, respectively.
4. Oligohydramnios in the donor's amniotic sac with a deepest vertical pool ≤ 2 cm.

Preoperative evaluation consists of ultrasound examination, including morphological examination, fetal Doppler, cardi thoracic index, identification of placental location, and cord insertions. Amniocentesis or amniore-

duction prior to laser may cause intra-amniotic bleeding and therefore make the procedure more difficult, or even impossible, due to impaired visualization. The site of entry is chosen as demonstrated in Fig. 1, for the scope to be entered at a right angle to the long axis of the small twin in order to maximize the chance to ensure adequate visualization of the placental surface and intertwin membranes. Ideally, the scope should also be entered alongside a virtual line joining the two cord insertions. When these criteria are met, the vascular equator of the placenta as well as the vascular anastomoses on the chorionic plate are more likely to be visualized in the operative field.

Prophylactic cefazolin 2 g, indomethacin suppository 100 mg, and oral flunitrazepam are given before surgery and local anesthesia with nonadrenalinized xylocaine is injected down to the myometrium. A 10 Fr cannula for a central venous catheter loaded with a trocar is introduced percutaneously under continuous ultrasound guidance. A 2 mm 0° fetoscope (Storz 26008 AA) is passed down a straight or curved sheath to operate on posterior or anterior placentas, respectively. The sheath also has a working channel carrying a 1 mm diode laser fiber.

A systematic examination of the chorionic plate alongside the insertion of the inter-twin membrane is performed. Identification of crossing vessels and of their arterial or venous nature is possible because arteries cross over veins and show a darker red color than veins owing to a lower oxygen saturation in the circulating blood (54). Selective coagulation of anastomotic vessels is performed with the aim of separating the monochorionic placenta into two distinct fetal-placental circulations, sparing the normal cotyledons of each placental territory. Nonselective coagulation of crossing vessels is only performed when the distal end or the origin of the vessel cannot be identified. The power of the diode laser is set at 30–50 w. At the end of the procedure, excessive amniotic fluid is drained through the sheath of the fetoscope until normal amniotic fluid volume is obtained with a deepest vertical pool of 5–6 cm.

BIPOLAR UMBILICAL CORD OCCLUSION

Selective reduction in complicated monochorionic (MC) multifetal pregnancies is performed to prevent the delivery of an anomalous or severely compromised fetus and improve the perinatal outcome for the surviving co-twin by delaying delivery or risk associated with spontaneous loss of the affected. The use of cardiotoxic agents, such as potassium chloride, is contraindicated in MC pregnancies because of the potential vascular transmission of the agent and compromise of the co-twin due to the presence of placental vascular anastomoses. Thermal vascular occlusive techniques, such as bipolar umbilical cord occlusion (BPC), have been shown to achieve the stated goals with minimal maternal morbidity. Indications for BPC that are unique to MC gestations include twin reverse arterial perfusion, discordant fetal anomalies, and isolated severe growth lag. BPC has also been used as a primary intervention in advanced twin-twin transfusion syndrome or as a secondary procedure when alternative therapies such as

amnioreduction or laser have failed to correct the disease process.

The procedure was originally described by Deprest et al. (55). In brief, using the standard sterile technique, the patient's abdomen is properly prepared and draped. An abdominal ultrasound is performed to confirm fetal position, viability, and umbilical cord locations. General and conduction anesthesia may be used; however, intravenous sedation with local infiltration of 1% lidocaine or 0.25% bupivacaine for subcutaneous, deep muscle, and fascia anesthesia is usually sufficient and is associated with less maternal morbidity. A small skin incision is made to allow insertion of an endoscopic trocar. Under continuous ultrasound guidance, the instrument is inserted through a placental free window toward the targeted umbilical cord, ideally avoiding the gestational sac of the normal co-twin. Once the trocar is secured in the amniotic sac, the obturator is removed. The bipolar forceps are inserted and advanced to the umbilical cord.

The cord is grasped and positioned away from the amnion before thermal energy is applied. The duration and wattage (W) necessary for occlusion will vary, from 20–60 s and 20–50 W, respectively, based on the gestational age and umbilical cord thickness. When a full-thickness grasp exists, application of the thermal energy will result in turbulence and “streaming” of amniotic fluid adjacent to the forceps. It is not uncommon to have an audible “pop” secondary to the heating of Wharton's jelly and subsequent rupture of amnion at the site of occlusion, which should not be perceived as a sign of completed coagulation. As a result of the natural spiral of the umbilical cord, complete occlusion of all vessels requires 2–3 applications of the forceps at adjacent sites. Pulse and color flow Doppler blood flow studies are performed to confirm cord occlusion at each site.

The size of the BPC forceps that have been used for these procedures has varied from 2.2–5.0 mm. The majority of procedures have been performed with commercially available single-use 3.0 mm bipolar diathermy forceps (55–58).

Intravenous prophylactic antibiotics and indomethacin for tocolysis are generally given prior to the procedure. Postoperative monitoring for uterine contractions and, depending on the gestational age, continuous or intermittent fetal heart rate should be done for at least 2 hours. The majority of programs will observe patients for an extended period of 12–24 h with limited activity. Subsequent doses of antibiotics and tocolytic treatment are given during this time. Prior to discharge, a limited ultrasound is performed to determine the amniotic fluid volume and assess for signs of hydrops and anemia, including Doppler velocimetry of the middle cerebral artery and, where appropriate, similar studies of the umbilical artery and ductus venosus. If no evidence of preterm labor, leaking of amniotic fluid, or bleeding exists, the patient is discharged with instructions to continue with modified bed rest at home for 7–10 days, take her temperature bid, and report an elevation, leaking of vaginal fluid, bleeding, or contractions. An ultrasound is performed in 10–14 days and then at a minimum every 4 weeks thereafter. Additional ultrasounds and fetal monitoring should be performed as clinically indicated by the primary disease and gestational age.

IONIZING RADIATION, BIOLOGICAL EFFECTS OF

ZELENA GOLDBERG
Department of Radiation
Oncology
Davis, California

INTRODUCTION

Radiation biology refers to all biologic responses induced in cells and tissues by ionizing radiation, a term that encompasses the study of all action of ionizing radiation on living things. Ionizing radiation (IR) is radiation that has sufficient energy to cause the ejection of an orbital electron from its path around the nucleus, which indicates that the photon or charged particle can release large amounts of energy in a very small space. IR is separated into electromagnetic radiation and particulate radiation. Electromagnetic radiation consists of X rays or γ rays, which differ only in their mode of production, not in their physical effects in interacting with biologic tissue. X rays are produced by machines that accelerate electrons and then focus them to hit a target usually made of tungsten or gold. The kinetic energy is transferred from the electrons to the target and then is released as photons. These are the most common medical exposures through diagnostic or therapeutic radiation. In contrast, γ -radiation is produced within the nucleus from radioactive isotopes. The γ rays result from the unstable nuclear configuration decaying to a more stable state and releasing the "extra" energy in this transition in the form of the γ ray. Natural background radiation is of this type. Particulate radiation is those radiation sources that are not photons and consist of electrons, protons, α -particles, neutrons, and heavy charged particles such as the nuclei of carbon, neon, argon, or iron. These particles are positively charged because the orbiting electrons have been stripped from them.

As noted, IR is defined by its causing the ejection of an orbital electron when the radiation interacts with tissue. These ionizing events can be further subdivided by being directly ionizing or indirectly ionizing. Directly ionizing events are those in which a charged particle with sufficient kinetic energy interacts with the tissue, directly resulting in the ejection of the orbital electron. These events happen frequently within an exposed tissue, so the charged particle rapidly transfers its energy to the tissue, a concept codified as linear energy transfer (LET). Charged particles have a high LET. In contrast, indirectly ionizing radiation such as γ - or X-radiation is first absorbed in the material and secondary, energetic charged particles (electrons) are released. Because this latter process only occurs when the photon is close enough to an atom to interact, it is referred to as sparsely ionizing radiation and has a low linear energy transfer (LET).

A longstanding paradigm in radiation biology has been that many effects induced by IR, including its carcinogenic effects and ability to kill cancer cells, are the result of DNA damage arising from the actions of IR in cell nuclei, especially interactions of IR and its products with nuclear DNA (1–3). When a charged particle or secondary electron produced by the interaction of a photon with an orbital electron damages DNA itself, it is known as the direct action of IR. Yet, DNA represents a small fraction of the actual size of the cell. Therefore, it was recognized that most of the interaction of IR within a cell would be with more abundant biomolecules, specifically water. If the action is mediated through the intracellular production of radiolytic reactive products, e.g., OH, H, O₂, and H₂O₂, that are generated in aqueous fluid surrounding DNA, then the DNA damage is called indirect action. These processes unquestionably can result in a variety of types of DNA damage, including DNA single- and double-strand breaks, modifications of deoxyribose rings and bases, intra- and inter-strand DNA–DNA cross-links, and DNA–protein cross-links (1,4,5). About a third of all DNA damage is caused by the direct effects of sparsely ionizing γ and X rays, with the remaining balance being attributable to the indirect actions of IR. With high-LET radiation such as the more densely ionizing α -particles that are emitted by radon and radon progeny, the direct actions of IR on DNA become more predominant and the nature of the DNA modifications become much more complex. Regardless of the type of IR, all of the above forms of DNA damage can lead to untoward effects in cells if unrepaired or misrepaired. With specific regard to carcinogenesis, genomic mutations caused by IR are widely thought to arise from DNA damage that is subsequently converted into a mutation as a result of misprocessing by DNA repair mechanisms or that is converted into a heritable mutation when DNA undergoes replication.

This classic view of radiation biology is giving way to a more complex and complete understanding that the cell membrane and other intracellular compartments, as well as the tissue vasculature, are important targets of IR. Furthermore, as detailed below, although intracellular effects are better defined, we now recognize that the extracellular environment and cell–cell contact play important roles in modulating the effects of IR at the cellular and tissue levels.

MOLECULAR RADIATION BIOLOGY/BYSTANDER EFFECTS

IR is a cellular toxin that is sensed at the cellular level through the ATM-p53-p21 pathway (6,7). Although the upstream sensor of ATM remains to be definitively elucidated, the initial radiation sensing protein likely has a redox sensor and undergoes a conformational change, or possibly is phosphorylated, resulting in the phosphorylation of ATM (8). This, in turn, activates the p53 pathway leading to cell cycle arrest, nuclear translocation of transcription factors such as NF- κ B, and either cellular repair or apoptosis. How an individual cell commits to a given fate (repair or apoptosis) remains unclear, but undoubtedly it represents the final integrated response to many simultaneous intracellular events. Several excellent reviews on

this topic have been written (9,10). It should be noted that IR also affects the 26s proteasome, which is another level of non-nuclear intracellular response affecting cell survival, presumably through alterations in the removal of activated (phosphorylated) proteins, or proteins active in apoptotic processes such as Bcl2 (11,12).

Radiation effects in cells not directly hit by a radiation ionizing event are called bystander effects. Although initial interest in this effect can be found in the medical literature as far back as into the 1950s, the current interest in the area was stimulated by a study published in 1992 in which Nagasawa and Little (13) observed increases in the frequency of sister chromatid exchanges in ~30% of immortalized Chinese hamster ovary cells that received low-dose exposure to α -particles, even though less than 1% of the cells' nuclei were estimated to actually receive direct nuclear hits by an α -particle. That a relatively low percentage of the cells experienced one or more direct "hits" by the α -particles, be they in the cytoplasm or in the nuclei, suggested the possibility that some mechanism was conveying a radiation-associated response to unirradiated cells. Other groups went on to confirm and extend on this finding. It is now well recognized that cells do not require a direct nuclear traversal to result in radiation changes. There are extracellular responses, predominantly TGF- β mediated through media (cell culture experiments) or extracellular fluids (tissues), but other factors cannot be excluded (14). Furthermore, it is recognized that cell–cell contact and gap junctional communications are critical in transmitting the signal from the directly irradiated cell to the neighboring, bystander cells (15).

TIME, DOSE, AND FRACTIONATION

The biologic effects of IR in tissue relate to the size of the dose delivered, time between radiation exposures and the total dose of IR given. Although environmental exposures are chronic and (usually) low level, medical exposures are acute and can be repetitive when given for the treatment of cancer. Radiation therapy for the treatment of malignancy remains the most effective anti-cancer agent discovered, and treatment schedules are predicated on the "4 R's of radiobiology": repair, repopulation, redistribution, and reoxygenation.

Repair of radiation-induced damage underlies the intrinsic radiation sensitivity of the cell to radiation cell killing. Cells can be broadly grouped into those that can repair significant amounts of damage and those with more limited repair capacity. The former descriptive category corresponds to tissue types where there is limited normal cell turnover, such as lung, kidney, or brain, and these are tissues that display damage after a more prolonged time and are therefore known as late responding tissues. The cells with more limited intrinsic repair capacity are known as acute responding tissues and are typified by skin or gut. These cell types have a limited life span and are constantly being replaced within normal physiologic functioning.

Repopulation refers to the generation of new cells to replace those killed by the IR exposure. Although therapeutically beneficial for containing normal tissue toxicity,

repopulation is also active in malignant tissue and thereby allows greater numbers of tumor clonogens to develop after treatment. For some types of tumors, an acceleration of repopulation begins after 4 weeks of radiation therapy, which can compromise clinical outcome if prolonged therapeutic IR fractionation schemes are used.

Redistribution refers to the changes in cell assortment across the cell cycle. It has long been established that cells vary in their sensitivity to the cytotoxic effects of IR depending on where in the cell cycle they are at the time of irradiation (16,17). Cells are most sensitive to IR effects in the G2/M phase and are most resistant during the S-phase. G1 is intermediate between these two. Thus, clinical radiation therapy schedules use multiple fractions to overcome the relative resistance of the cells in S-phase of the cell cycle on a given treatment day. This difference in radioresistance across stages in the cell cycle also underlies one mechanism of the synergy between radiation therapy and many chemotherapeutic agents in the treatment of malignant disease. Although S-phase cells resist killing from the IR, they are more sensitive to some chemotherapeutics that are active during S-phase when the DNA is most exposed and is replicating. Furthermore, this alteration of cell cycle sensitivity to IR cytotoxicity also has been an area of research for IR-biologic response modifiers. If one can increase the percentage of cells in G2/M at the time of IR, then the relative cell kill per fraction of IR will increase.

Reoxygenation refers to the presence or absence of molecular oxygen within the cell at the time of IR delivery. As detailed at the beginning, most of the cellular damage from IR is mediated through the production of free radicals within the cell. If molecular oxygen is present, these free radicals can be transformed into more complex peroxide radicals, which are more difficult for the cell to repair. This is classically known as “fixing the radiation damage” in the British use of the term “fix” (make more solid), not the American (repair). The increase in cell killing from IR in the presence of oxygen versus under hypoxic conditions is known as the oxygen enhancement ratio, and it is approximately a factor of 2–3, dependent on where in the cell cycle the irradiated cell sits. Although normal tissues have a well-maintained vascular supply so that oxygenation is essentially constant, tumors have a tortuous and unstable vasculature, so that the vessels can open and close erratically. This type of hypoxia is referred to as “acute hypoxia.” Chronic hypoxia occurs when the tumor outgrows its blood supply and the tumor cells are simply beyond the diffusion capability of molecular oxygen. Attempts to exploit this differential, either by sensitizing the hypoxic cells or by specifically targeting them, have been explored and remain active areas of research. Furthermore, identification of the presence of hypoxia remains a significant clinical strategy (18).

The four R's of radiobiology reflect intracellular controls of overall radiation response. The tissue level effects from IR in the treatment of cancer are dependent on several parameters: volume, dose per fraction, total dose, and time between fractions. The volume of tissue irradiated is critical for determining the long-term repair by repopulation by normal cells to fill in for those irreparably damaged by the IR. Each cell type has its own intrinsic radiation

sensitivity, and the tissue organization (serial or parallel cellular arrangement) as well as the tissue vasculature play critical roles in tissue repair and thus radiosensitivity. Tissues are subdivided into two categories of radiosensitivity based on when they display their damage. Tissues that display their radiation induced damage during a standard course of medical radiation therapy are known as “acute responding tissues.” These tissues naturally have a large amount of cellular turnover, such as skin or gut, and at a cellular level, this corresponds to lesser ability to repair sublethal DNA damage (i.e., a larger proportion of DNA damage is lethal and nonrepairable). In contrast, tissues where there is little or no normal cellular turnover, such as brain, kidney, lung, or spinal cord, there is a substantial ability to repair sublethal damage, and tissue toxicity from radiation therapy is displayed late, long after therapy has finished. These tissues are therefore labeled “late responding tissues.” Therapeutic strategies are designed to separate these two types of responses as malignant tumors are models of acute responding tissues, whereas the dose limiting side effects from radiation therapy are secondary to late responding tissue effects (19,20).

THE LINEAR NO-THRESHOLD MODEL OF RADIATION EFFECTS

Based on the data collected from the victims of the bomb detonations at Hiroshima and Nagasaki, a linear no-threshold model of radiation effects was developed and adopted for public policy applications. In essence, the model states that (1) all radiation exposures are biologically active, (2) the response in the cells/tissue is linear with dose, and (3) there is no threshold below which there is no or negligible effects. The model was developed from the moderately low-dose exposure ranges of 0.5–2 Gy and the medically significant sequelae of increased mortality (carcinogenic and noncarcinogenic, predominantly cardiovascular) (21–23). Hiroshima and Nagasaki data represent the effects of a single acute dose exposure delivered to the whole body with the nutritional deprivation from WW2; as such, they are subject to criticism and questions of their applicability to modern healthy populations where low-dose radiation exposure is often of a more chronic nature. Nevertheless, they remain the best available population-based data, and they have been painstakingly collected and analyzed. As detailed below, however, the shape of the response curve at the lowest doses remains controversial.

LOW-DOSE EXPOSURES

Low-dose ionizing radiation (LDIR) in the 1–10 cGy range has largely unknown biological activity in the human. Current modeling for health and safety regulations, as well as prediction of carcinogenesis, presupposes a linear, no-threshold model of radiation effects based on the nuclear bomb explosion data, which estimates the effect and risk at low dose by extrapolation from measured effects at high doses. Yet the scientific literature presents a more complex picture, and few data clearly support a linear

dose-response model and none in humans. Numerous studies suggest some effects of LDIR may be benign or even beneficial under some circumstances (24,25). Reported benefits include stimulated growth rates in animals, increased rates of wound healing, reductions in cell apoptosis, enhancements in the repair of damaged DNA, and increases in radioresistance via the induction of an adaptive response, among others (26–28). Other lines of evidence, however, suggest LDIR can be hazardous, and if a threshold for detrimental responses does exist, it is operational only at very low dose levels, e.g., ≤ 1 cGy. Schiestl et al. (29) found that 1–100 cGy doses of X rays could cause genetic deletions in mice in a linear dose-response manner. This remains an active area of research (30).

Little is known regarding individual variability in sensitivity to radiation exposure. Studies are actively ongoing to develop methods to best assess interindividual variability. This understanding will have both a health risk assessment and medical applications (31).

GENOMIC INSTABILITY

Radiation-induced genomic instability encompasses a range of measurable endpoints such as chromosome destabilization, sister chromatid exchanges, gene mutation and amplification, late cell death, and aneuploidy, all of which may be causative factors in the development of clinical disease, including carcinoma.

Kadhim et al. identified the persistence of radiation-induced chromosomal instability following α -particle irradiation in clonal populations of murine bone marrow cells (32). The same group followed up this seminal work with an examination of four human bone marrow samples, subjected to an *ex vivo* α -particle IR (33). Further research then demonstrated that the genomic instability phenotype could be transmitted *in vivo* when murine hemopoietic cells that had been irradiated *in vitro* were transplanted into mice that had previously had their native bone marrow purged (34). However, when Whitehouse and Tawn examined radiation workers in Sellafield, England, who had bone marrow plutonium deposition evidence for genomic instability was not found (35). Whether γ -IR could induce genomic instability was then examined. The original reports from Kadhim et al. were negative (32,33), but further research examining *hprt* locus mutations convincingly demonstrated that genomic instability was inducible by γ -irradiation (36). Thus, although genomic instability can clearly be demonstrated in the laboratory, whether it occurs in humans after IR exposure remains uncertain (37).

Our understanding of the biologic effects of IR is evolving and ever growing. Research has been active in this field for over 100 years, and it remains a vibrant research area with the new molecular tools now available. The target of interest and concern is as small as the individual DNA base or as large as the whole organism. Mechanistic studies of the subcellular targets of IR and the cellular response signaling cascades must be matched with more complex system evaluations so that the summative effect of these pathways becomes known. Cell signaling exists within and between cells, and this cross-talk affects the

ultimate response to IR exposure. Improving our understanding of radiation response at the cellular and tissue levels will undoubtedly yield advances for medical/therapeutic radiation as well as general cellular biology.

INTRODUCTION

The pH of a solution is defined as

$$\text{pH} = -\log[\text{H}^+] \quad (1)$$

where $[\text{H}^+]$ is the concentration of hydrogen ions in the solution. The standard laboratory method of measuring the pH of a solution uses a glass electrode with a thin-walled, bulb-shaped membrane at the bottom. The electrode is filled with a standard solution (usually 0.1 M HCl), into which a silver wire coated with silver chloride is dipped (Fig. 1). Hydrolysis of both the inside and outside of the glass membrane forms thin gel layers, separated by dry glass inside the membrane. Hydrogen ions from the test solution are able to diffuse into the outside gel layer. The glass is doped with mobile ions (e.g., Li^+), which are able to cross the membrane and “relay” the concentration of H^+ ions in the test solution to the inside of the bulb. To make pH measurements, the potential of the internal silver wire is measured with respect to a reference electrode. Since the glass membrane is selective toward $[\text{H}^+]$ ions, the overall cell potential (at room temperature) is given by the Nernst equation:

$$\psi = \text{const} + \frac{kT}{q} \ln[\text{H}^+] \quad (2a)$$

$$= \text{const} + 25.7 \times 10^{-3} \ln 10 \log[\text{H}^+] \quad (2b)$$

$$= \text{const} - 0.0592 \text{pH} \quad (2c)$$

where k is the Boltzmann constant, T the absolute temperature, and q the electronic charge.

A conventional reference electrode consists of a glass tube containing a filling solution of known composition (e.g., saturated KCl). In an Ag/AgCl electrode, electrical contact is made to the filling solution by a silver wire that has been coated with silver chloride. If saturated KCl is used, the wire develops a potential of 199 mV versus the standard hydrogen electrode (SHE). This potential remains constant as long as the chloride concentration remains constant. The internal filling solution is separated from the test solution by a permeable membrane or “liquid junction”, usually made from porous glass or ceramic. Diffusion of ions through the junction provides the conductive path between the reference electrode and the test solution. The KCl is usually used as the filling solution, as the mobility of the K^+ and Cl^- ions are nearly equal, minimising any build-up of junction potential.

The glass-electrode, with its complicated materials and internal reference solution, does not lend itself to miniaturization. However, with the arrival of the metal oxide semiconductor field-effect transistor (MOSFET) in 1960, another method of measuring the interface potential became available. The MOSFET is a three-terminal device in which the voltage on a gate electrode controls the current flowing between source and drain electrodes. The MOSFET has a metal or polysilicon gate electrode, separated from the bulk silicon by a thin, insulating gate oxide layer to provide an extremely high input impedance (Fig. 2a). In an n-channel MOSFET, a positive voltage applied to the gate electrode attracts electrons from the bulk of the p-type silicon to the surface beneath the oxide and creates an inversion region that is rich in mobile electrons. This inversion region forms a channel that allows current to flow between source and drain. The minimum gate voltage

Figure 1. Diagram of the glass electrode together with a silver–silver chloride reference electrode.

that is required to produce “strong” inversion is termed the threshold voltage and is given by

$$V_T = \frac{\Phi_M - \Phi_S}{q} - \frac{Q_I}{C_I} - \frac{Q_S}{C_I} + 2\psi_F \quad (3)$$

The threshold voltage incorporates the work function difference between the metal gate and the silicon ($\Phi_M - \Phi_S$), any fixed charge in the oxide or in the oxide–silicon interface Q_I and the charge in the depletion region of the silicon Q_S . The term $2\psi_F$ is twice the Fermi level of the p-type silicon and arises from the definition of strong inversion, that is the inverted material must have a free-electron density that is equivalent to the acceptor density in the p-type material (1). The parameter C_I is the capacitance of the oxide (insulator) layer, and all charges and capacitances are expressed per unit area.

In 1970, Bergveld (2) recognized that the MOSFET structure could be adapted to create an ion-sensitive FET (ISFET) by omitting the metal gate. He found that by applying a voltage between the source and drain of this device and placing it in solution, the current flowing would vary with the pH of the solution. This first ISFET used the native gate oxide (SiO_2) as the ion-sensing layer and was sensitive to the concentration of both Na^+ and H^+ ions in the solution (3). The silicon dioxide, used to insulate the metal gate from the silicon substrate, has a similar struc-

ture to the permselective membrane used in the glass electrode, and will therefore respond to the concentration of hydrogen ions in a solution. A reference electrode, the electrical contact of which can be regarded as the gate terminal, is used to bias the ISFET (Fig. 2b).

A model for an ISFET, made by excluding the metal gate from a MOSFET, will include all the contributions to its threshold voltage considered in equation 3. There are an additional two terms, one due to the potential of the reference electrode ψ_{REF} , and the other due to the potential at the solution–oxide interface $\Delta\psi + \chi_{\text{SOL}}$. Here, χ_{SOL} is the constant surface dipole potential of the solvent (usually water), and $\Delta\psi$ is the concentration-dependent interface potential. The threshold voltage of the ISFET is then

$$V_T = \psi_{\text{REF}} - \Delta\psi + \chi_{\text{SOL}} - \frac{\Phi_S}{e} - \frac{Q_I}{C_I} - \frac{Q_S}{C_I} + 2\psi_F \quad (4)$$

since the gate metal of the MOSFET is replaced by the metal in the reference electrode and its work function has been included in ψ_{REF} .

The only term in equation 4 that varies with ionic concentration is $\Delta\psi$, so measuring the concentration is simply a matter of measuring V_T . The ISFET is then an ideal transducer with which to measure ionic concentrations since it has an extremely high input impedance, and hence does not require any bias current to flow in the solution. It also uses the same fabrication process as a MOSFET, suggesting that not only can it be made very small, but that it can be integrated on the same substrate as the sensor electronics.

Figure 2. Diagrams showing the similarity in cross-section between a MOSFET and an ISFET.

THE SITE-BINDING MODEL

Initially, it was assumed that the silicon dioxide insulator used in the ISFET would obey the Nernst equation, in the same way as the membrane used in the glass electrode did. This meant that, for a pH-ISFET, $\Delta\psi$, and hence V_T , would be a linear function of pH with a response of $59 \text{ mV}\cdot\text{pH}^{-1}$. The model for the ISFET simply substituted the Nernst equation in place of $\Delta\psi$ in equation 4 (4). While this

suggested how to operate the ISFET in a circuit, it did not provide any insight into the chemical processes that occur at the solution–oxide interface. Nor did it provide an explanation for the sub-Nernstian and pH dependent sensitivities that were measured for SiO_2 ISFETs (5).

The so-called site-binding model assumes that the insulator surface has ionizable sites that react directly with the electrolyte to bind or release hydrogen ions. The surface becomes more or less charged depending on the concentration of ions in the solution. The charged surface induces a layer of complementary charge in the solution that forms a double-layer capacitance across which the interface potential is developed. The solution side of the insulator–electrolyte interface is thought to be made up of several “layers” as shown in Fig. 3. The solvent molecules and any ions that are specifically adsorbed onto the surface make up an inner layer. The locus of the electrical centers of the adsorbed ions is called the inner Helmholtz plane (IHP) or Stern layer. The total surface charge density in this plane due to the ions is σ_0 . Solvated ions in the solution cannot approach as close to the surface, and their locus of closest approach forms the outer Helmholtz plane (OHP). The interaction of the solvated ions with the surface is purely electrostatic and they are referred to as nonspecifically adsorbed ions. Because of thermal mixing in the solution, these ions are distributed throughout the diffuse layer that extends from the OHP into the bulk of the electrolyte. The excess charge density in the diffuse layer is σ_D so that the total charge in the solution is $\sigma_D + \sigma_0$.

The charge density in the semiconductor region is σ_S , so applying the requirement of charge neutrality:

$$\sigma_D + \sigma_0 + \sigma_S = 0 \quad (5)$$

If the potential in the semiconductor bulk is defined to be zero and the potential of the electrolyte bulk is fixed at ψ_{REF} , then

$$\psi_{\text{REF}} + (\psi_D - \psi_{\text{REF}}) + (\psi_0 - \psi_D) + (\psi_S - \psi_0) - \psi_S = 0 \quad (6)$$

In addition,

$$\psi_0 - \psi_S = -\frac{\sigma_S}{C_I} \quad (7)$$

$$\psi_0 - \psi_D = -\frac{\sigma_D}{C_H} \quad (8)$$

$$\psi_D - \psi_{\text{REF}} = -\frac{2kT}{e} \sinh^{-1} \frac{\sigma_D}{\sqrt{8\epsilon kTc}} \quad (9)$$

where k is the Boltzmann constant, ϵ is the permittivity, and c is the total ionic concentration of the solution. The last equality (eq. 9) is the Gouy–Chapman model for the diffuse layer (6), and C_H is the capacitance formed between the inner and outer Helmholtz planes. Combining equations 6–9 produces:

$$\psi_{\text{REF}} + \underbrace{\frac{-2kT}{e} \sinh^{-1} \left(\frac{\sigma_D}{\sqrt{8\epsilon kTc}} \right)}_{\psi_{\text{EI}} \equiv -\Delta\psi} - \frac{\sigma_D}{C_H} + \underbrace{\frac{\sigma_S}{C_I}}_{\psi_{\text{IS}}} - \psi_S = 0 \quad (10)$$

This equation provides a link between the interface potential $\Delta\psi$ and the charge density of the EIS system.

The “site-binding” model was developed by Yates et al. (7) to describe the interactions at a general oxide–electrolyte

Figure 3. Model of the electrolyte–insulator–semiconductor (EIS) system.

interface. It was later applied to the electrolyte– SiO_2 –Si system by Siu and Cobbold (8) and Bousse et al. (9), whose approach is outlined here. When an SiO_2 surface is in contact with an aqueous solution, it hydrolyzes to form surface silanol (SiOH) groups. These groups are amphoteric, meaning that they can react with either an acid or a base. The acidic and basic character of a neutral SiOH site is described by the following reactions (Fig. 4) and dissociation constants. (The dissociation constant is the equilibrium constant for a reversible dissociation reaction. It expresses the amount by which the equilibrium favors the

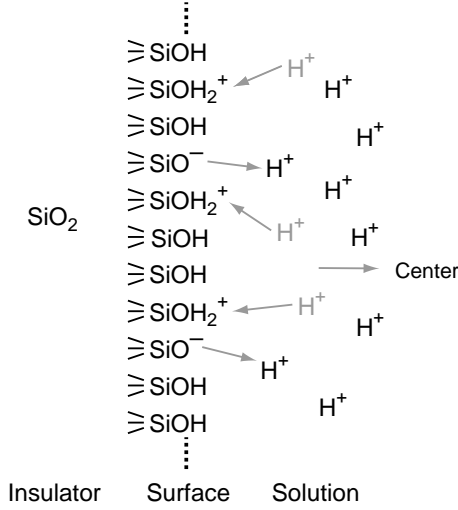

Figure 4. Diagram illustrating the surface sites and hydrogen-ion reactions for SiO_2 .

products over the reactants.)

where the square brackets indicate concentrations and the subscript 0 is used to indicate a surface quantity. Reactions between surface sites and other ions in the supporting electrolyte (e.g., Na^+ , Cl^-) are ignored since they have been shown to have a negligible effect on the interface potential (10).

The density of sites on the surface is

$$N = [\text{SiOH}_2^+] + [\text{SiO}^-] + [\text{SiOH}] \quad (13)$$

and the surface charge per unit area is

$$\sigma_0 = e([\text{SiOH}_2^+] - [\text{SiO}^-]) \quad (14)$$

Due to thermal mixing, the surface concentration of H^+ ions can be related to the bulk H^+ concentration by Boltzmann statistics:

$$[\text{H}^+]_0 = [\text{H}^+] \exp\left(\frac{-e\Delta\psi}{kT}\right) \quad (15)$$

as $\Delta\psi$ is the potential difference from the electrolyte bulk to the insulator surface. Multiplying equation 11 by equation 12 and substituting for $[\text{H}^+]_0$ using equation 15 gives

$$[\text{H}^+] = \sqrt{K_1 K_2} \exp\left(\frac{e\Delta\psi}{kT}\right) \sqrt{\frac{[\text{SiOH}_2^+]}{[\text{SiO}^-]}} \quad (16)$$

For the case that $\Delta\psi = 0$ and $\sigma_0 = 0$ (i.e., $[\text{SiOH}_2^+] = [\text{SiO}^-]$), we can see from equation 16 that $[\text{H}^+] = \sqrt{K_1 K_2}$. This is the hydrogen ion concentration in the solution required to produce an electrically neutral surface, and is called the point of zero charge (pzc). The pH at this point is denoted $\text{pH}(\text{pzc})$ and this can be substituted in 16 to

Table 1. Values for the Parameters of pH Sensitive Insulators Found in the Literature

	K_1	K_2	N_A (sites $\cdot \text{m}^{-2}$)	Reference
SiO_2	$10^{1.8}$	$10^{-6.2}$	5×10^{18}	11
Al_2O_3	10^{-6}	10^{-10}	8×10^{18}	12
Ta_2O_5	10^{-2}	10^{-4}	10×10^{18}	12

yield

$$2.303(\text{pH}(\text{pzc}) - \text{pH}) = \frac{e\Delta\psi}{kT} + \ln \mathcal{F} \quad (17)$$

This equation provides the link between charge, potential, and pH. The function

$$\mathcal{F} = \sqrt{\frac{[\text{SiOH}_2^+]}{[\text{SiO}^-]}} \quad (18)$$

plays a key role in the response of the surface. It can be written in terms of the “normalized” net charge on the surface $\hat{\sigma}_0 = \sigma_0/eN$, and the parameter $\delta = 2\sqrt{K_2/K_1}$:

$$\mathcal{F} = \frac{\hat{\sigma}_0/\delta + \sqrt{(\hat{\sigma}_0/\delta)^2(1 - \delta^2) + 1}}{1 - \hat{\sigma}_0} \quad (19)$$

Equations 17 and 19 give the solution pH as a function of both $\Delta\psi$ and σ_0 , so now it remains to find the relationship between $\Delta\psi$ and σ_0 . This is done by using the definition of $\Delta\psi$ in equation 10, the charge neutrality condition in equation 5:

$$\sigma_D + \sigma_0 = \Delta\sigma = -\sigma_S \quad (20)$$

It is usually assumed that $\Delta\sigma = 0$ (9), so that $\sigma_0 = -\sigma_D$. Finally, the interface potential $\Delta\psi$ can be found as a function of the solution pH, by using a parametric method in $\hat{\sigma}_0$. Values of the dissociation constants and surface site density of SiO_2 obtained from the literature are shown in Table 1, and used to generate the SiO_2 pH response curve in Fig. 5. Not only does the SiO_2 surface have a low sensitivity of -46.3 mV/pH (at pH 7), it also has a nonlinear response, especially in the acid pH range.

Figure 5. Graph of the theoretical pH response for SiO_2 , Al_2O_3 , and Ta_2O_5 surfaces.

The insulators Al_2O_3 and Ta_2O_5 also have amphoteric surface groups, so can be modelled using the same parametric method. As shown in Fig. 5, these surfaces produce a linear response with sensitivities much closer to the Nernstian ideal of $-59.2 \text{ mV}\cdot\text{pH}^{-1}$. As a result, Al_2O_3 and Ta_2O_5 have been widely used as the pH sensitive layer for fabricating ISFETs. The measured sensitivities for these insulators ($53\text{--}57 \text{ mV}\cdot\text{pH}^{-1}$ for Al_2O_3 , $56\text{--}57 \text{ mV}\cdot\text{pH}^{-1}$ for Ta_2O_5 ; see Table 2) are close to the theoretical values shown in Fig. 5.

DEVELOPMENT OF THE ISFET

Much of the subsequent work on ISFETs has concentrated on measuring pH, as this plays a vital role in many biochemical systems. Because silicon dioxide has a low pH sensitivity, the magnitude of which varies with pH (5), Matsuo and Wise (13) experimented with the use of silicon nitride (Si_3N_4) instead. Their ISFET was made by depositing a layer of nitride on top of the thermally grown gate oxide. The ISFET was located at the tip of a needle-shaped probe, which was covered in a thick layer of SiO_2 to insulate it from the solution (Fig. 6). The ISFET was found to have an almost ideal pH response and very low sensitivity to sodium and potassium ion concentrations. Selectivity between ion species is important to differentiate changes in pH from changes in the total ionic concentration of the solution.

In a sense, silicon nitride was an obvious material to investigate as it was, and still is, widely used as a passivation layer to protect devices, such as integrated circuits from the ingress of moisture. Other well-known materials included the oxides of aluminium and tantalum (Al_2O_3 and Ta_2O_5). The pH sensitivity, ion selectivity, response times, and drift rates for these materials have been extensively studied (5). Silicon oxynitride (SiO_xN_y) and other more exotic insulators, such as zirconium and tin oxides (ZrO_2 , SnO_2), and even diamond-like carbon (DLC) have all been used to make pH ISFETs. Oxides and nitrides of metals have also been investigated to try and improve parameters, such as response time and maximum operat-

Figure 6. Diagram of the cross-section through an ISFET formed by depositing silicon nitride directly on top of the gate oxide (13).

ing temperature. These include platinum oxide (PtO_2), titanium nitride (TiN), iridium oxide (Ir_2O_3), and indium tin oxide (ITO). The published pH sensitivity and drift rates (where available) for these materials are summarized in Table 2.

Apart from the choice of pH sensitive material, development of the ISFET has mostly focused on achieving compatibility with the CMOS process. CMOS devices use complementary pairs of n-type and p-type MOSFETs to implement circuits. The CMOS process is the dominant technology for integrated circuits (ICs), so achieving compatibility would allow complex devices containing ISFETs to be fabricated by a standard, industrial process. Figure 7 is a simplified cross-section of a CMOS inverter, showing the polysilicon gate electrodes, the source and drain regions and the metal interconnections.

ISFETs have been made using both NMOS and PMOS transistors. However, in a p-substrate process, the bulk terminal of a PMOS ISFET can be biased above the substrate ground potential, permitting more flexibility in circuit design. The reverse is true for an n-substrate CMOS process. It has also been shown that the noise performance of an ISFET is dominated by $1/f$ or “flicker” noise (23), which is lower in PMOS transistors (24).

Initial attempts to integrate ISFETs involved significant modifications to the standard CMOS process. Wong and White (15) followed the standard sequence of CMOS process steps, until the metallization stage. They then removed the oxide, the polysilicon gate electrode, and the gate oxide above the ISFETs by wet etching. A thinner

Table 2. Values of pH Sensitivity and Drift Rates for ISFETs Made Using a Range of Materials, Obtained from the Literature

Material	pH Range	Sensitivity, ($\text{mV}\cdot\text{pH}^{-1}$)	Drift, ($\text{mV}\cdot\text{h}^{-1}$)	Reference
SiO_2	4–10	25–35 (pH < 7) 37–48 (pH > 7)	Unstable	5
SiO_xN_y	2–8.3	57.4 ± 0.4	0.8 (pH 7)	14
	4–9	18–20	Not mentioned	15
PtO_2	1–10	40.5 ± 4.0	0.5 (pH 6.86)	16
Si_3N_4	1–13	45–56	1.0 (pH 7)	5

Figure 7. Diagram of the cross-section through a CMOS inverter.

oxide layer was regrown and the sensing layer of Si_3N_4 or Ta_2O_5 was deposited on top of this. The contact windows were then opened and the aluminum deposited to form the interconnects as for a normal CMOS process.

Bousse et al. (25) took a similar approach, but completed the CMOS process before etching away the deposited SiO_2 above the polysilicon gate of the ISFET. They then deposited Si_3N_4 over the whole wafer so that the polysilicon was retained as a floating electrode in the ISFET. This floating electrode did not reduce the ISFET sensitivity to pH, and had the additional benefit of making the ISFET less sensitive to changes in light levels. It does this by shielding the channel from photons that can generate electron-hole pairs, which contribute to the ISFET current. However, since the nitride they used was deposited by low pressure chemical vapor deposition (LPCVD) at 785°C , the aluminium interconnect had to be replaced with tungsten silicide, which was able to withstand this high temperature step. This meant that a specially modified CMOS process had to be used to fabricate the ISFETs.

Bausells et al. (26) extended the floating electrode idea to a two-metal CMOS process by connecting the polysilicon gate and both metal layers together. In addition, they used the silicon oxynitride passivation layer as the pH sensitive material for the ISFET (Fig. 8). This meant that the ISFET could be fabricated by a commercial foundry using a standard CMOS process, without the need for any process modifications. The fabricated ISFETs had a sensitivity of $47\text{ mV}\cdot\text{pH}^{-1}$ and a lifetime of > 2 months. As well as the advantages of using of a well-characterized industrial process, there are additional “system-on-chip” design ben-

Figure 8. Diagram of the cross-section through an ISFET fabricated by an unmodified commercial CMOS process (26). The floating electrode allows the passivation layer to be used as a pH sensitive insulator.

efits. These include access to libraries of components such as amplifiers and digital gates that greatly ease the design of the whole system.

Unfortunately, the unmodified CMOS ISFETs were found to have large threshold voltages; they were also based on silicon oxynitride, a material that has been found to have a widely varying sensitivity, depending on the deposition conditions (Table 2). The large threshold voltage has been shown to be caused by trapped charge left on the floating electrode during fabrication (27). To avoid these problems, Jakobson et al. (28) removed the passivation layer by using the aluminum of the floating electrode as an etch-stop. They then experimented with low temperature evaporation of pH sensitive layers onto the exposed aluminium. The best performance was obtained by using a layer of platinum (to prevent the aluminum from corroding), followed by a layer of tantalum oxide.

The floating-electrode ISFETs can be considered as special cases of the extended-gate ISFET that was first proposed in 1983. The idea was to separate the electronics from the chemically active region, and by doing so make the device easier to passivate and package than a standard ISFET with an exposed gate insulator. A coaxial polysilicon structure was used to provide a screened connection between the chemically sensitive area and the gate of a MOSFET (29). A more recent CMOS extended-gate ISFET design used a long (unscreened) aluminium track with one end connected to the polysilicon gate and the other exposed by the final pad-etch step (21). This idea has been taken to its limit by using a discrete, off-the-shelf MOSFET and connecting the gate terminal to the pH-sensitive material with a length of wire (20). This method is clearly not applicable to a sensor system-on-chip design, but it does provide a simple method of characterizing the behavior of the material.

The floating-electrode ISFET has also been used to protect against electrostatic discharge (ESD). In the first ESD-protected devices, the polysilicon gate was left intact and connected to a terminal via a MOSFET switch. This provided a reverse-biased diode between the floating electrode and the substrate that would breakdown (reversibly) before the gate insulator was damaged (30). However, current leakage through the “off” MOSFET was such that any response to changing pH decayed to zero in a matter of seconds. To achieve a steady-state response, a large platinum electrode was connected to the ISFET gate to supply current from the solution to replace that being lost through the MOSFET. To avoid the problem of leakage current altogether, ESD-protected ISFETs have been fabricated with a separate platinum ring electrode around the sensitive gate area (31). The platinum electrode is a preferential discharge path to the substrate, protecting the ISFET in the same manner that a lightning conductor protects a building.

ISFETs have also been adapted to create chemically modified FETs (CHEMFETs), which are sensitive to the concentration of ions other than hydrogen. This is achieved by attaching a polymer membrane containing a suitable ionophore to the pH sensing surface of the ISFET. The stability of the ISFET-membrane interface is improved by the addition of an intermediate hydrogel layer. In this way, CHEMFETs sensitive to K^+ (32), Na^+ (33), and other cations have been developed.

Figure 9. Diagram of the cross-section through an ISFET-based device in a recessed PCB, encapsulated using a layer of polyimide and two layers of photoresist (34).

PACKAGING

One of the main obstacles that has prevented the commercialization of ISFET based devices is the repeatability and reliability of the encapsulation procedure. It is normal for the encapsulant to be applied by hand, covering the chip and bond wires, but leaving a small opening above the sensing area. Epoxy is the most extensively used material although it is important to select a composition that is stable, a good electrical insulator, and does not flow during encapsulation. Many commercially available epoxies have been assessed for their suitability by making measurements of their electrical impedance over time (34–37).

By using ultraviolet (UV) curable polymers, it is possible to increase the automation of the packaging process using a standard mask aligner. A lift-off technique was developed using a sacrificial layer of photosensitive polyimide to protect the ISFET gates. Alumina-filled epoxy was applied by screen printing and partially cured, before the polyimide was etched away leaving a well in the epoxy (38). After 10 days in solution, leakage currents of 200 nA were observed. Better results were achieved by direct photopolymerization of an epoxy-based encapsulant. The ISFETs packaged using this method showed leakage currents of 35 nA after 3 months in solution (38). To avoid polarizing the reference electrode, a leakage current of < 1 nA is desirable (5). This photolithographic patterning of the encapsulant was done at the wafer-level, to all the devices simultaneously. Subsequently, the wafer was diced up and the individual chips were wire-bonded and coated with more encapsulant by hand. At the chip-level, wire-bonded ISFET chips have been covered (again by hand) with a 0.5–1 mm thick photosensitive, epoxy-based film, then exposed and developed (39).

Some degree of automation was introduced by Sibbald et al. (34) who used a dip-coating method to apply the polymers. They first recessed the chip into a PCB and wire-bonded the connections, before coating it with a layer of polyimide. Two layers of photoresist followed, before the underlying polyimide was etched away (Fig. 9). The packaged devices showed < 10 pA leakage current after 10 days in solution. However, the encapsulation did exhibit electrical breakdown for applied bias voltages in excess of 1.5–2 V, which was attributed to the high electric field in the thin layer of resist covering the bond wires. In a separate study, photosensitive polyimide has also been used to create the wells that separate the ion-selective membranes on a multiple ISFET chip (40).

The structure of the ISFET has also been modified to improve the lifetime and ease of manufacture of the packaged device. One solution was to make the ISFET chip long and thin (1.2×12 mm) with the sensing area at one end and the bond pads at the other so that the bond-wires did not enter the solution (14). The chip itself was encapsulated with a thick layer of silica. More radical solutions involved bulk micromachining to form back-side contacts to the ISFET so that the bond wires were on the opposite side of the chip to the solution. The front side of the chip is protected by anodic bonding of glass (Fig. 10). A review of back-side contact ISFETs is provided by Cané et al. (41), but the technique is not particularly suited to a CMOS chips, which have many bond-pads arranged around the perimeter.

ISFET CIRCUITS

When an ISFET is placed in solution, a concentration-dependent potential ($\Delta\phi$) is formed at the interface

Figure 10. Diagram of the cross-section through a back-side contacted ISFET chip with liquid and electrical contacts on opposite sides (41).

Figure 11. Diagram of the circuit symbol and a graph of the I - V transfer characteristics (4) for an n-type ISFET.

between the gate insulator and the solution. This potential modulates the threshold voltage (V_T) of the ISFET (eq. 4), an internal quantity that cannot be directly measured. Some circuitry is therefore required to convert changes in the threshold voltage into changes of a measurable signal. The solution to this problem lies in the use of feedback control to maintain a constant drain current in the ISFET. For a FET, operating in the linear region³, the drain current is given by:

$$I_D = k' \frac{W}{L} \left[(V_{GS} - V_T)V_{DS} - \frac{V_{DS}^2}{2} \right] \quad (21)$$

where k' is a process-dependent constant, and W , L are the width, length of the device. (In the linear region, $0 < V_{DS} \leq (V_{GS} - V_T)$ and I_D varies with V_{DS} .) The parameters V_{GS} and V_{DS} are, respectively, the gate-source and drain-source voltages applied to the FET. For an ISFET, a reference electrode in the solution acts as the gate terminal as shown symbolically in Fig. 11a. The I_D vs. V_{GS} curves for an ISFET as measured by Moss et al. (4) are shown in Fig. 11b. It is clear from this graph that biasing an ISFET at a constant drain current is only possible if both V_{DS} and V_{GS} ($= V_G - V_S$) are maintained constant. If a reference

electrode is used to control V_G , then from equation 21, as V_T changes with I_D held constant, V_S must change by an equal and opposite amount to compensate. Measuring $\Delta\psi$ (and hence pH) then becomes a straightforward matter of measuring the terminal voltage V_S .

In his original paper on the operation of the ISFET, Bergveld (3) stated that one of the important advantages of ISFETs, compared with conventional pH electrodes, is that there is no need for a reference electrode. Instead, he used a feedback circuit to control the bulk terminal of the ISFET and maintain a constant drain current. However, this makes the assumption that the solution is perfectly isolated from the ISFET source and drain terminals, as well as the circuit. Any current (even leakage current through the packaging), that flows into the solution will affect its potential. To a bulk-feedback circuit, this will be indistinguishable from a change in solution concentration. It is therefore safer to assume that the solution is grounded, or at least at some well-defined potential with respect to the circuit, and use a reference electrode to ensure that this is the case. For this reason, all of the subsequently published circuits relating to ISFETs include a reference electrode.

The probe fabricated by Matsuo and Wise (13) contained an ISFET and a MOSFET of identical dimensions. The ISFET was configured as a source follower with the MOSFET acting as a constant current source. A saturated calomel electrode (SCE, shown in Fig. 1) was used as a reference, and the output voltage measured at the source terminal of the ISFET. Bergveld (42) used a grounded reference electrode to avoid the problem of a short circuit if the solution is already at ground potential (e.g., in an earthed metal container). He used an instrumentation amplifier arrangement to maintain a constant current in a constant drain-source voltage (Fig. 12). Amplifiers A_1 and A_2 set V_{DS} as determined by the fixed current flowing in R_1 . Current feedback from amplifier A_4 adjusts the drain voltage via R_2 to keep the current constant as the threshold voltage changes. One disadvantage of this circuit is that the output (measured across R_9) is not referenced to a fixed voltage such as ground.

There have been many other circuit topologies proposed to keep the drain current and/or the drain-source voltage constant. A straightforward circuit that achieves both of

Figure 12. Circuit diagram of an ISFET source and drain follower circuit used to maintain a constant drain current at a constant drain-source voltage (42).

Figure 13. Circuit diagram of constant drain current, constant drain-source voltage ISFET bias circuit (43).

these objectives was presented by Ravezzi and Conci (43). It used a pair of unity-gain, noninverting operational amplifiers (op-amps) to ensure that the voltage dropped across a resistor is also dropped across the ISFET (Fig. 13). Constant current was maintained in the resistor by a current source, and in the ISFET by a current sink. This arrangement allows the source and drain potentials to adjust as the threshold voltage changes, allowing the reference electrode to remain at a fixed potential.

The first integrated ISFET circuit was the so-called operational transducer published by Sibbald (44) in 1985. It used an ISFET and a MOSFET with identical geometries as the active devices in the “long-tailed pair” input stage of an amplifier. Feedback was used to control the gate voltage of the MOSFET to ensure that the same current flowed in both devices. The MOSFET gate voltage tracked that of the ISFET and so measured the changes in threshold voltage. The key advantage of this circuit was that changes in temperature affected both devices equally and were canceled out.

Wong and White (15) recognized that there was little to be gained from an integrated, miniaturized sensor if it relied on a large, external reference electrode. Instead, they used an on-chip gold contact as a quasi-reference electrode (qRE) and a differential circuit to make measurements between two ISFETs with different pH sensitivities. The potential difference between the solution and the qRE will depend on the solution composition. However, like temperature, this is a common-mode signal, which will affect both ISFETs equally. Hence, it can be rejected by means of a differential circuit. Tantalum oxide and silicon oxynitride were used as sensing layers for the two ISFETs, which formed the input stages of op-amps integrated onto a CMOS chip (Fig. 14a). The outputs from the two op-amps were fed into an off-chip differential amplifier. The overall circuit gave a response of $40\text{--}43\text{ mV}\cdot\text{pH}^{-1}$. The benefit of the differential approach can be seen in Fig. 14b, which shows the single-ended (V_{O1} and V_{O2}) and differential (V_{OUT}) responses as electrical noise was deliberately applied to the solution. Two copies of the bias circuit in Fig. 13 have also been used to create a differential system with Si_3N_4 and SiO_2 ISFETs (45).

The concept of integration has been extended by Hammond et al. (46) who created a complete digital pH meter on a single CMOS chip. This design makes use of the libraries of components provided by the CMOS foundry to integrate not only the ISFET, but also analog bias circuits, digital signal processing, and storage onto the same chip (Fig. 15a). The chip was mounted in a recessed PCB and covered with a thick layer of photoresist so that only the ISFET area was exposed. The digital response of the device to the changing pH of the solution in which it is immersed is shown in Fig. 15b.

MINIATURE REFERENCE ELECTRODES

The first attempt to incorporate a reference electrode on an ISFET chip used a thin-film Ag/AgCl electrode (47). Electrodes like this, with no internal reference solution, are sensitive to changes in concentration of their primary ion (in this case Cl^-), and are referred to as quasi-reference electrodes. To solve this problem, Smith and Scott (48) also

integrated the reference solution and porous membrane into the chip. Wells were etched into the back-side of a silicon wafer, to leave a membrane 10–70 μm thick. The membranes were anodized to porous silicon in a bath of concentrated hydrofluoric acid. The wells were filled with saturated KCl and sealed with glass coverslips that had been coated with thin films of Ag/AgCl. The reference electrode exhibited a low drift rate of 80 $\mu\text{V}\cdot\text{h}^{-1}$ (worst-case) and a lifetime of > 2 weeks. However, a method of mass producing an integrated, liquid-filled electrode has yet to be developed.

Recent developments of miniature reference electrodes have focused on the use of polymer-supported electrolyte gels, to replace the liquid filling solution. Suzuki et al. (49) developed an electrode that uses finely ground KCl powder supported in a matrix of poly(vinylpyrrolidone) (PVP). An exploded diagram of the electrode is shown in Fig. 16. First, a layer of silver was evaporated onto a glass substrate, inside a U-shaped gold backbone. A layer of polyimide was applied to protect the silver and to define the electrode structure. The AgCl was grown through a slit in the polyimide, and a liquid junction was formed by casting a hydrophilic polymer into the square recess. The electrolyte layer, containing the KCl powder, was then screen-printed over the AgCl and the liquid junction. Finally, a passivating layer of silicone rubber was applied. The electrode can be stored dry, and activated when required by the injection of a saturated solution of KCl and AgCl through the silicone. This miniature reference electrode showed a stability of ± 1.0 mV over a period of 100 h. No difference was observed between experimental data obtained with the miniature reference electrode and with a large, commercial reference electrode.

REFERENCE FETs

The sensitivity of the differential circuits already discussed can be increased if one of the devices has no response to

Figure 16. Exploded diagram showing the construction of a miniature Ag/AgCl reference electrode based on a polymer-supported electrolyte gel (49).

Figure 17. Diagram of the cross-section through a REFET created using encapsulated pH buffer solution (50).

changes in pH. Such a device is called a reference FET (REFET). The first REFET was presented by Comte and Janata (50) in 1978. It consisted of an ISFET surrounded by a well of epoxy that was filled with a buffered agarose gel. A glass capillary was inserted into the gel and sealed in place with more epoxy (Fig. 17). This acted as a liquid junction between the internal reference gel and the external solution. The response of the REFET was only $3 \text{ mV} \cdot \text{pH}^{-1}$ and it provided temperature compensation of $\pm 0.01 \text{ pH} \cdot \text{C}^{-1}$ when used in a differential arrangement. However, the techniques required to prepare this REFET are not well suited to mass production.

The pH sensitivity of an ISFET is due to the presence of chemical sites on the surface of the insulator (Fig. 4) that can exchange hydrogen ions with the solution. Attempts to reduce the density of these sites, and hence the sensitivity, by chemical modification of the surface proved unsuccessful (51). Instead a thin membrane of parylene was used to cover an ISFET and convert it into a REFET (52). Parylene has an extremely low density of surface sites and the REFET was found to have a very low pH sensitivity of only $0.5 \text{ mV} \cdot \text{pH}^{-1}$. However, parylene forms an insulating (or ion-blocked) layer that affects the electrical properties of the underlying ISFET. Even a very thin membrane reduces the gate capacitance, and hence transconductance, dramatically. This is a problem for differential circuits, which rely on ISFET and REFET having well-matched electrical properties. If a membrane could be found whose ion-conducting properties were sufficient to pass the electrical voltage of the solution to the sensing layer of the underlying ISFET, the transconductance would not be changed. Clearly, such "ion-unblocking" membranes must be insensitive to variations in pH.

Bergveld et al. (53) investigated several candidate polymers for REFET membranes and found that polyacrylate gave the best performance. An intermediate layer of buffered poly(hydroxyethyl methacrylate) (p-HEMA) hydrogel was necessary to fix the interface potential and to improve the adhesion of the membrane (54). The REFET showed $< 2 \text{ mV} \cdot \text{pH}^{-1}$ sensitivity, good mechanical properties, and its transconductance matched that of the ISFET. Despite these useful properties, the acrylate membrane was selectively permeable for cations (e.g., potassium ions). This problem was solved by optimizing the amount of didodecylmethylammonium bromide (DDMAB) added to the membrane (Fig. 18a). This large immobile cation repels mobile cations (e.g., potassium), from the membrane. Figure 18b shows the performance of the ISFET-REFET

Figure 18. Graphs of the response of an acrylate REFET, and an ISFET, to changes in potassium and hydrogen ion concentrations (53).

differential system, as compared to the individual devices, measured using a platinum qRE.

An alternative approach was developed by van den Vlekkert et al. (55) who used a thick layer of p-HEMA hydrogel to produce an ISFET with a retarded pH response. By controlling the diffusion coefficient of hydrogen ions, a pseudo-REFET with a nonresponse time of ~ 10 min was created. Such a REFET is only really useful in a flow-through system where the analyte is pumped through in short bursts followed by rinsing and calibration solutions (34). The p-HEMA hydrogel was also used by Chudy et al. (56) as the base layer for chemically sensitive FETs (CHEMFETs) and REFETs. The CHEMFET uses an additional ion-selective membrane containing an ionophore, selected to target the ion of interest. Exclusion of the ionophore from the membrane enabled the creation of a REFET that showed almost no response to pH, potassium, or calcium ions.

APPLICATIONS

According to Bergveld (57), ~ 20 companies have commercialised ISFETs based on 150 patents. Product offerings and specifications vary, but in general terms ISFETs have found applications where small size, fast response, robustness, wide operating temperature range, and operation in nonaqueous environments are desirable. The ISFET can also be stored dry, making it more convenient to use than traditional glass electrodes, since the lifetime of a stored ISFET is almost indefinite. ISFETs are used for high resolution applications and products are available with specified resolutions $< 0.01 \text{ pH}$ units. However, many of the devices on the market have a resolution of $\sim 0.1 \text{ pH}$ units.

The ISFET has made a significant impact on a number of industries where it is a requirement to monitor and control the addition of reagents. It made an early appearance in the food industry where its robust construction allowed measurement to be made in foodstuffs. In addition,

its ability to operate in nonaqueous environments is an advantage when working with meat and dairy products. The ISFET has also found applications in the pharmaceutical industry, where a fast re-sponse and high operating temperatures are required. It has also been used in electroplating where it is able to withstand the corrosive plating solutions. In addition to manufacturing industries, the ISFET is also used in waste water management and in the treatment of effluent.

Early researchers considered medical applications ranging from monitoring the pH in the mouth (particularly in the context of tooth decay), to direct measurement of ionic balance in the blood. ISFETs been built into dental prosthetics to enable the direct measurement of pH in the presence of plaque (58). Recent data on tooth decay was obtained using a pH imaging microscope (59) although, unlike the ISFET device, this does not allow for *in situ* observations to be made. ISFETs are also used indirectly for dental applications, for example, in the evaluation of potential prosthetic materials (60). The ISFET has been modified in a manner similar to that for the REFET for use in blood analysis beyond measuring ionic concentrations. In this embodiment, the ISFET can be made into a sensitive enzyme sensor. In their paper, Sant et al. (61) demonstrated a sensor for creatinine based on an ISFET with a sensitivity of $30 \text{ mV} \cdot \text{pCreatinine}^{-1}$. The application is in renal failure and haemodialysis in particular.

Recently, there has been a growth of interest in the use of ISFETs in a device known as a diagnostic pill. The concept of a diagnostic pill was developed in the 1950s and 1960s (62). Such devices are small enough to be swallowed by a patient, and once inside the gastrointestinal tract, can measure and wirelessly transmit data to an external receiver over a period of many hours or even days. The earliest devices were used to measure pressure changes in the gut, but glass-electrode-based pills were also made to measure gut pH. The diagnostic pill has made something of a comeback in recent years, particularly with the invention of the video pill (63), a device that is capable of wirelessly transmitting images of the gut with considerably less patient discomfort than would be caused by an endoscopic procedure. Various new examples of pH measuring pills have also been developed. The Bravo capsule, which does not actually use an ISFET, is designed for use in the esophagus (64). During operation it is pinned to the lining of the esophagus so that it can monitor conditions such as gastro-esophageal reflux disease (GERD) over a period of 2–3 days. The IDEAS capsule (65) that does use an ISFET, has been built for use in the lower gastrointestinal tract. The device is designed pass naturally through the gut with as little intervention as possible and is required to be able to operate in difficult conditions where biofouling of the sensor is a potential problem.

CONCLUSIONS

The ISFET first appeared in 1970 as an offshoot of the rapidly growing capability of the microelectronics industry. In its simplest form, the ISFET is a modification of the traditional MOSFET in which the gate electrode is

removed and the gate oxide exposed to solution. The ISFET uses changes in the surface chemistry of the gate oxide to modify the threshold voltage of the transistor and produce an electronic signal. The sensitivity and performance of the ISFET is highly dependent on the material used to form the gate oxide layer. The behavior of such materials is best modeled using a site-binding approach to calculate the variation in surface charge with solution pH. A wide variety of materials have been experimented with, those found to give the best performance are the oxides of aluminium and tantalum. However, in a standard CMOS manufacturing process, the passivation layer is made of silicon nitride, which is also a good pH sensitive material. It is therefore possible to make good ISFETs using a standard foundry process with little or no additional effort. As a result it has become possible to implement integrated ISFET circuits. A number of circuit topologies for detecting the change in ISFET threshold voltage have been designed, those using voltage followers to maintain the ISFET bias conditions produce the best results. Further development of ISFET integrated circuits has enabled complete instruments to be fabricated on a single IC. To avoid the use of a bulky reference electrode, differential circuits using matched pairs of ISFET and REFET have been designed. However, difficulties in creating a good REFET have increased interest in developing miniature reference electrodes that are compatible with IC processing. The ISFETs have already found widespread application in manufacturing industries, environmental monitoring and medicine. It is expected that with improved miniaturization, integration, and packaging technologies, new applications will emerge.

INTRODUCTION

The human skeleton is a system of bones joined together to form segments or links. These links are movable and provide for the attachment of muscles, ligaments, tendons, and so on. to produce movement. The junction of two or more bones is called an articulation. There are a great variety of joints even within the human body and a multitude of types among living organisms that use exo- and endoskeletons to propel. Articulation can be classified according to function, position, structure and degrees of freedom for movement they allow, and so on. Joint biomechanics is a division of biomechanics that studies the effect of forces on the joints of living organisms.

Articular Anatomy, Joint Types, and Their Function

Anatomic and structural classification of joints typically results in three major categories, according to the predominant tissue or design supporting the articular elements together, that is, joints are called fibrous, cartilaginous, or synovial.

Synovial joints are cavitated. In general, two rigid skeletal segments are brought together by a capsule of connective tissue and several other specialized tissues, that form a cavity. The joints of the lower and upper limbs are mainly synovial since these are the most mobile joints. Mobility varies considerably and a number of subcategories are defined based on the specific shape or architecture and topology of the surfaces involved (e.g., planar, saddle, ball and socket) and on the types of movement permitted (e.g., flexion and extension, medial and lateral rotation) (Table 1). The basic structural characteristics that define a synovial joint can be summarized in four features: a fibrous capsule that forms the joint cavity, a specialized articular cartilage covering the articular surfaces, a synovial membrane lining the inner surface of the capsule that also secretes a special lubricating fluid, the synovial fluid. Additional supportive structures in synovial joints include disks, menisci, labra, fat pads, tendons, and ligaments.

Cartilaginous joints are also solid and are more commonly known as synchondroses and symphyses, a classification based on the structural type of cartilage that intervenes between the articulating parts (Table 2). This cartilage is hyaline and fibrocartilage for synchondroses and *symphyses*, respectively. *Synchondroses* allow very

little movement as in the case of the rib cage that contributes to the ability of this area to expand with respiration. Most *symphyses* are permanent; those of sacrum and coccyx can, however, degenerate with subsequent fusion between adjacent vertebral bodies as part of the normal development of these bones.

Fibrous joints are solid. The binding mechanism that dominates the connectivity of the articulating elements is principally fibrous connecting tissue, although other tissue types also may be present. Length, specific arrangement, and fiber density vary considerably according to the location of the joint and its functional requirements. Fibrous joints are classified in three groups: sutures, gomphoses, and syndesmoses (Table 3);

In addition to the obligatory components that all the synovial joints possess, several joints contain intraarticular structures. Discs and menisci are examples of such structures. They differ from one another mainly in that a disc is a circular structure that may completely subdivide a joint cavity so that it is, in reality, two joints in series, whereas a meniscus is usually a crescent-shaped structure that only partially subdivides the joint. Complete discs are found in the sternoclavicular and in the radiocarpal joint. A variety of functions have been proposed for intraarticular discs and menisci. They are normally met at locations where bone congruity is poor, and one of their main functions is to improve congruity and, therefore stability between articular surfaces. Shock absorption facilitation and combination of movements are among their likely roles. They may limit a movement or distribute the weight over a larger surface or facilitate synovial fluid circulation throughout the joint.

The labrum is another intraarticular structure. In humans, this structure is only found in the glenohumeral and hip joints. They are circumferential structures attached to the rim of the glenoid and acetabular sockets. Labra are distinct from articular cartilage because they consist of fibrocartilage and are triangular in their middle section. Their bases are attached to the articular margins and their free apical surfaces lined by synovial membrane. Like discs, their main function is to improve fit and protect the articular margins during extremes of movement.

Fat pads are localized accumulations of fat that are found around several synovial joints, although only those in the hip (acetabular pad) and the knee joint (infrapatellar pad) are named. Suggested functions for fat pads include protection of other intraarticular structures (e.g., the round ligament of the head of the femur) and serving as cushions or space-fillers thus facilitating more efficient movement throughout the entire available range.

Bursae are enclosed, self-contained, flattened sacs typically with a synovial lining. They facilitate movement of musculoskeletal tissues over one another and thus are located between pairs of structures (e.g., between ligament and tendon, two ligaments, two tendons or skin, and bone). Deep bursae, such as the iliopsoas bursa or the deep

Table 1. Diarthroses: Synovial Joints

Ball and socket

Other names: Spheroidal; endarthroses
 Description: Ball-shaped head fits into concave socket
 Movement: Widest range of all joints; triaxial
 Example: Shoulder and hip joints

Hinge

Other name: Ginglymus
 Description: Spool-shaped head fits into concave surface
 Movement: In one plane about single axis (uniaxial); like hinged-door movement (namely, flexion and extension)
 Examples: Elbow, knee, ankle, and interphalangeal joints

Pivot

Other name: Trochoid
 Description: Arch-shaped surface rotates about rounded or peglike pivot
 Movements: Rotation: uniaxial
 Example: Between axis and atlas; between radius and ulna

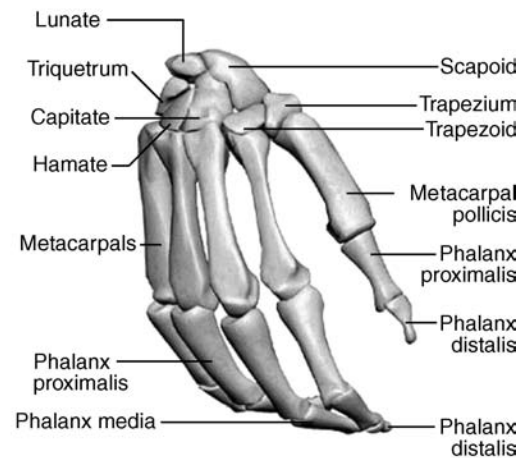

Table 1. (Continued)**Ellipsoidal**

Other names: Condylod, ovoid

Description: Arch-shaped condyle fits into elliptical cavity

Movements: In two planes at right angles to each other – specifically, flexion, extension, abduction, and adduction; biaxial

Example: Between radius and carpals

**Saddle**

Other name: Reciprocal

Description: Saddle-shaped bone fits into socket that is concave-convex in opposite direction; modification of condyloid joint

Movements: Same kinds of movement as condyloid joint but freer; like rider in saddle; biaxial

Example: Thumb, between first metacarpal and trapezium

Gliding

Other name: Arthroidal

Description: Articulating surfaces; usually flat

Movement: Gliding, a nonaxial movement

Example: Between carpal bones; between sacrum and ilium (sacroiliac joints)

retrocalcaneal bursa, develop along with joints and by a similar series of events during the embryonic period.

Tendons are located at the ends of many muscles and are the means by which these muscles are attached to bone or other skeletal elements. The primary structural component of tendons is type I collagen. Tendons almost exclusively operate under tensile forces.

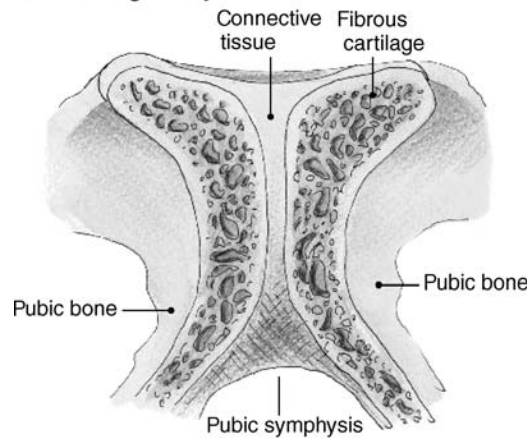

Ligaments are dense bands of connective tissue that connect skeletal elements to each other, either creating (as in the case of syndesmoses) or supporting joints. According to their location they are classified as intra-capsular, capsular, or extracapsular. Structurally, they resemble the tendons in that they consist predominantly of type I collagen.

Table 2. Amphiarthroses: Cartilaginous Joints

Cartilaginous
 Other name: Synchondroses
 Description: The joint formed by each of the costal cartilage
 Movement: Bending and twisting, or slight compression
 Example: Between the ribs and the sternum; between carpal and tarsal bones

Fibrocartilaginous joint

Fibrocartilaginous
 Other name: Symphyses
 Description: Within the joint, separating the bones, is a fibrocartilaginous pad – these pads, or discs, serve as shock absorbers
 Movement: Compression, flexion, extension, and rotation
 Example: Intervertebral and pubic joints

Articular Cartilage

Articular cartilage, the resilient load-bearing tissue that forms the articulating surfaces of synovial joints functions through load distribution mechanism by increasing the area of contact (thereby reducing the stress) and provides these surfaces with the low friction, lubrication, and wear characteristics required for repetitive gliding motion.

Biomechanically, cartilage is another intraarticular absorption mechanism that dampens mechanical shocks and spreads the applied load onto subchondral bone (Fig. 2). Articular cartilage should be viewed as a multiphasic material. It consists primarily of a large extracellular matrix (ECM) with a sparse population of highly specialized cells (chondrocytes) distributed throughout the tissue. The

primary components of the ECM are water, proteoglycans, and collagens, with other proteins and glycoproteins present in lower amounts (1). The solid phase is comprised by this porous-permeable collagen-PG matrix filed with freely movable interstitial fluid (fluid phase) (2). A third phase is the ion phase, necessary to describe the electromechanical behaviors of the system. The structure and composition of the articular cartilage vary throughout its depth (Fig. 2), from the articular surface to the subchondral bone. These differences include cell shape and volume, collagen fibril diameter and orientation, proteoglycan concentration, and water content. These all combine to provide the tissue with its unique and complex structure and mechanical properties. A fine mechanism of interstitial fluid pressurization

Table 3. Synarthroses: Fibrous Joints

Sutures

Other name: —
 Description: The edges of the bones have interdigitations or grooves that fit very closely and firmly together; the connecting fibers are very short
 Movement: None
 Examples: Between the flat bones of the skull

Syndesmoses

Other name: Ligamentous
 Description: Two bones, that may be widely separated tied together by ligaments; the ligaments may be in the form of cords, bands, or flat sheets
 Movement: None (some give)
 Example: Between the distal ends of the tibia and fibula

Gomphosis

Other name: —
 Description: A joint in which the surfaces of bony components are adapted to each other like a peg in a hole
 Movement: None
 Example: The conical process of a tooth is inserted in the bony socket of the mandible or maxilla

Figure 1. Basic structure and components of a synovial joint (also called diarthroses).

Figure 2. Zones of articular cartilage.

results from the flow of interstitial fluid through the porous-permeable solid matrix that in turn defines the rate dependent load-bearing response of the material. It is noteworthy that articular cartilage provides its essential biomechanical functions for eight decades or more in most of the human synovial joints and no synthetic material performs this well as a joint surface.

The frictional characteristics between two surfaces sliding over each other are significantly influenced by the topography of the given surfaces. Anatomical shape changes affect the way in which loads are transmitted across joints, altering the lubrication mode in that joint and, thus, the physiologic state of cartilage. Articular surfaces are relatively rough, compared to machined bearing surfaces, at the microscopic level. The natural surfaces are surprisingly much rougher than joint replacement prostheses. The mean of the surface roughness for articular cartilage ranges from 1 to 6 μm , while the metal femoral head of a typical artificial hip has a value of $\sim 0.025 \mu\text{m}$, indicating that the femoral head is apparently much smoother. Topographic features on the joint surfaces are characterized normally by primary anatomic contours, secondary roughness ($<0.5 \text{ mm}$ in diameter and $<50 \mu\text{m}$ deep), tertiary hollows on the order of 20–45 μm deep; and, finally, quaternary ridges 1–4 μm in diameter and 0.1–0.3 μm deep. Scanning electron micrographs (SEMs) of arthritic cartilage usually depict a large degree of surface irregularity and anomalous microtopography. These surface irregularities have profound effects on the lubrication mechanism. They accelerate the effects of friction and the rate of degradation of the articular cartilage. The types of joint surface interactions vary greatly between different joints in the body, different animals, between different size animals of the same species, different genders, and different ages. For example, the human hip joint is a deep congruent ball and socket joint (where the cartilage thickens peripherally at the acetabulum); this differs greatly from the bicondylar nature of the distal femur in the knee joint, and the saddle shape of the carpometacarpal joint in the thumb. The degree of shape matching between the various bones and articulating cartilage surfaces composing a joint is a major factor affecting the distribution of stresses in the cartilage and subchondral bone.

Effects of Motion and External Loading on Joints

The articular joint is viewed as an organ with complicated mechanisms of memory and adaptation that accommodates changes in its function. Joint loading results in motion and the couple load–motion is required to maintain normal adult articular cartilage composition, structure, and mechanical properties. The type, intensity, and frequency of loading necessary to maintain normal articular cartilage vary over a broad range. The intensity or frequency of loading should not exceed or fall below these necessary levels, since this will disturb the balance between the processes of synthesis and degradation. Changes in the composition and microstructure of cartilage will result. Reduced joint loading, as has been observed in cases of immobilization by casting or external fixation, leads to atrophy or degeneration of the cartilage. The

changes affect both the contact and noncontact areas. Changes in the noncontact areas resulting from rigid immobilization include fibrillation, decreased proteoglycan content and synthesis, and altered proteoglycan conformation, such as a decrease in the size of aggregates and amount of aggregate. Normal nutritive transport to cartilage from the synovial fluid by means of diffusion and convection has been diminished, resulting in these changes. Increased joint loading, either through excessive use, increased magnitudes of loading, or impact, also may affect articular cartilage. Catabolic effects can be induced by a single-impact or repetitive trauma, and may serve as the initiating factor for progressive degenerative changes. Osteoarthritis, a joint disease of epidemic proportions in the western world, is characterized by erosive cartilage lesions, cartilage loss and destruction, subchondral bone sclerosis and cysts, and large osteophyte formation at the margins of the joint (3).

Moderate running exercise may increase the articular cartilage proteoglycan content and compressive stiffness, decrease the rate of fluid flux during loading, and increase the articular cartilage thickness in skeletally immature animals. However, no significant changes in articular cartilage mechanical properties were observed in dogs in response to lifelong increased activity that did not include high impact or torsional loading of their joints. Disruption of the intraarticular structures (e.g., menisci or ligaments) will alter the forces acting on the articular surface in both magnitude and areas of loading. The resulting joint instability is associated with profound and progressive changes in the biochemical composition and mechanical properties of articular cartilage. In experimental animal models, responses to transection of the anterior cruciate ligament or meniscectomy have included fibrillation of the cartilage surface, increased hydration, changes in the proteoglycan content, reduced number and size of proteoglycan aggregates, joint capsule thickening, and osteophyte formation. It seems likely that some of these changes result from the activities of the chondrocytes, because their rates of synthesis of matrix components, breakdown of matrix components, and secretion of proteolytic enzymes are all increased. *In vitro* studies have shown that loading of the cartilage matrix can cause all of these mechanical, electric, and physicochemical events, but thus far it has not been clearly demonstrated which signals are most important in stimulating the anabolic and catabolic activity of the chondrocytes. A holistic physicochemical and biomechanical model of cartilage function in health and disease remains a challenge in the scientific community.

KINEMATICS OF JOINTS

General Comments

Mechanical analysis can refer to kinetics (forces) and/or kinematics (movement), with kinetics being the cause and kinematics the result. Mechanical analysis can develop models proceeding from forces to movements or vice versa. The analysis that starts from the cause (force) is called direct or forward dynamics, and produces a defined set of forces that caused the unique movement. This approach has one solution, and hence is deterministic. Starting from

the movement the analysis is called inverse dynamics. In this case, an infinite number of combinations of individual forces acting on the system can be the causes of the same unique movement, which makes the inverse dynamics approach not deterministic. The simplest and most essential system of mechanical formulations for explaining and describing motion is the Newton's second law. More advanced techniques include the Lagrange, d'Alembert, and Hamilton's methods. In general all of these methods start by describing equations of motion for a rigid body for translation, rotation, or combinations of them for both two (2D) and three-dimensional (3D) space. If the model assumes that the articulated segments that create the articulation are modeled as rigid bodies the remaining task is to calculate the relative motion between the two segments by applying graphics or joint kinematic analysis.

Kinematics is the study of the movements of rigid structures, independent of the forces that might be involved. Two types of movement, translation (linear displacement) and rotation (angular displacement), occur within three orthogonal planes; that is, movement has six degrees of freedom. Humans belong to the vertebrate portion of the phylum chordata, and as such possess a bony endoskeleton that includes a segmented spine and paired extremities. Each extremity is composed of articulated skeletal segments linked together by connective tissue elements and surrounded by skeletal muscle. Motion between skeletal segments occurs at joints. Most joint motion is minimally translational and primarily rotational. The deviation from absolute rotatory motion may be noted by the changes in the path of a joint's "instantaneous center of rotation". These paths have been measured for most of the joints in the body and vary only slightly from true arcs of rotation. For human motion to be effective, not only must a comparatively rigid segment rotate its position relative to an adjacent segment, but many adjacent limb movements must interact as well. Whether the hand is trying to write or the foot must be lifted high enough to clear an obstacle on the ground, the activity is achieved via coordinated movements of multiple limb segments. To provide for the greatest possible function of an extremity, the proximal joint must have the widest range of motion to position the limb in space. This joint must allow for rotatory motions of large degrees in all three planes about all three axes. A means is also provided to translate the limb, so that an extremity can function at all locations within its global range. Rotational motion of the elbow and knee joints allows such overall changes as adjacent limb segments move. Finally, to fine-tune the use of this mechanism with respect to the extremities, for their functional purposes, the hand and foot are required to have a vast amount of movement about all three axes, although the rigid segments are relatively small. Such movement requires the presence of relatively universal joints at the terminal aspect of each extremity.

Characterization of the General Mechanical Joint System: Terminology and Definitions

The displacement of a point is simply the difference between its position after a motion and its position before that motion. It can be represented by a 3D vector drawn

from the initial position of the point to its final position. The components of the displacement vector will be the changes in the coordinates of the point's position from measurement in the reference coordinate system. It is apparent that not only the positions, but also displacements measured are relative to some reference. Rigid body (RB) displacements are more complicated than point displacements since for a rigid body a displacement is a change in its position relative to some reference, but more than three parameters are needed to describe it. Two simple types of RB displacement can be described: translation and rotation. An important property of pure translation of a RB is that the displacement vectors of all points in the body are identical and are nonzero. In pure rotation of a RB, although points in the body experience nonzero displacements, one point in that body experiences zero displacement. In addition to that rule, Euler's theorem shows that in pure rotation all points along a particular line through that undisplaced point also experience zero displacement. This line is also known as the axis of rotational displacement. Chasles theorem further states that any displacement of a RB can be accomplished by a translation along a line parallel to the axis of rotation that is defined by Euler's theorem plus a rotation about that same parallel axis. Simply that suggests that any displacement in 3D is equivalent to the motion of a nut, representing the body, on an appropriate stationary screw that was centered on the line described above. Indeed, it can be shown that any displacement in 3D is equivalent to a translation plus a rotation.

Degrees of Freedom

The biological organisms capable of propelling themselves through different media consist of more than one rigid body. A system consisting of a 3D reference frame and an isolated rigid body in space has six degrees of freedom (DOF). To describe the position of each body relative to the ground reference frame it would be necessary to use six parameters, so for two unconnected rigid bodies 12 parameters would be necessary. The system consisting of these two unconnected bodies and the fixed -ground reference would have 12 DOF. The human-animal body consists of a combination of suitably connected bodies. The connections, joints between the bodies, serve to constrain the motions of the bodies so that they are not free to move with what would otherwise be six DOF for each body. Therefore, we can define the number of DOF that the joint removes as the number of degrees of constraint that it provides. It can be shown that every time a joint is added to a system, the number of degrees of freedom in that system is reduced by the number of degrees of constraint provided by that joint. This suggests the following generic formula for the calculation of the degrees of freedom of a system:

$$F = 6(L - 1) - 5J_1 - 4J_2 - 3J_3 - 2J_4 - J_5$$

where F is the number of degrees of freedom in the system of connected joints; L is the number of joints in the system, including the ground joint (which has no degrees of freedom), and J_n is the number of joints having n degrees of freedom each.

Table 4 contains a description of the major joints in the human body along with the segments-bones that they

Table 4. Characteristics of Major Human Joints

Joint	Bones	Type	DOF	Type of motion	Range of Motion (deg)
Shoulder	Humerus-Scapula	Diarthrosis (spheroidal)	3	Flexion	150
				Extension	50–60
				Abduction	90–120
				Abduction	Complete
Elbow	Humerus-ulna	Diarthrosis (ginglymus)	2	Flexion	145–160
				Extension	0–5
				Rotation (radius)	
Radioulnar	Superior radius-ulna	Diarthrosis (trochoid)	1	Pronation	70–75
Wrist	Radius-carpal	Diarthrosis (condyloid)	2	Supination	85–90
				Flexion	90–95
				Extension	60–70
				Radial deviation	20–25
Metacarpal-phalangeal	Metacarpal-phalanges	Diarthrosis (condyloid)	2	Ulnar deviation	55–65
				Circumduction	Complete
				Flexion	80–90
				Extension	20–30
Finger	Interphalanges	Diarthrosis (ginglymus)	1	Radial deviation	20–25
				Ulnar deviation	15–20
				Flexion	80–90
Thumb	First metacarpal-carpal	Diarthrosis (reciprocal)	2	Extension	0–10
				Flexion	80–90
				Abduction	20–25
				Abduction	40–45
Hip	Femur-acetabulum	Diarthrosis (spheroidal)	3	Abduction	0–10
				Circumduction	Complete
				Flexion	90–120
				Extension	10–20
				Abduction	30–45
				Abduction	30
Knee	Tibia-femur	Diarthrosis (ginglymus)	2	Medial rotation	30–40
				Lateral rotation	60
				Circumduction	Complete
				Flexion	120–140
Ankle	Tibia-fibula-talus	Diarthrosis (ginglymus)	1	Extension	0
				Medial rotation	30
				Lateral rotation	40
Intertarsal	Tarsals	Diarthrosis (arthroidal)	2	Flexion	20–30
Metatarsal-phalangeal	Metatarsals-phalanges	Diarthrosis (condyloid)	2	Extension	40–45
				Abduction	15–20
				Abduction	Limited
				Flexion	25–30
Interphalangeal	Phalanges	Diarthrosis (arthroidal)	1	Flexion	80–90
				Extension	0
Tibio-fibular	Distal tibia-fibula	Synarthrosis (syndesmosis)	0	Slight movement	Give
Skull	Cranial	Synarthrosis (suture)	0	No movement	
Sterno-costal	Ribs-sternum	Amphiarthrosis (synchondrosis)	0	Slight movement	
Sacroiliac	Sacrum-ilium	Amphiarthrosis (synchondrosis)	0	No movement	Elastic
Intervertebral	Cervical vertebrae	Diarthrosis (arthroidal)	3	Flexion	40
				Extension	75
				Lateral flexion	35–45
				Axial rotation	45–50
				Flexion	105
	Thoracic vertebrae	Diarthrosis (arthroidal)	3	Extension	60
				Lateral flexion	20
				Axial rotation	35
				Flexion	60
				Extension	35
	Lumbar vertebrae	Diarthrosis (arthroidal)	3	Lateral flexion	20
				Axial rotation	5
Flexion				60	
Extension				35	
Lateral flexion				20	
	Atlas axis	Diarthrosis (trochoid)	1	Pivoting motion	

articulate, their respective type DOF and type/range of motion they provide.

Planar Motion

Some human joints move predominantly in one plane (e.g., the knee joint) in which case the motion can be approximated and analyzed by graphical methods. Here the rotation is characterized by the motion of all points on concentric circles with an identical angle of rotation around the undisplaced center of rotation (CR). The CR may be located inside and outside of the boundaries of the rotating body. The most common graphical method for the calculation is the so-called bisection technique. If the initial and final states of the body are known, the position of the center of rotation and the angle of rotation may be reconstructed (Fig. 3).

Instantaneous Center of Rotation

When a 2D body is rotating without translation, for example, a rotating stationary bicycle gear, any marked point P on the body may be observed to move in a circle about a fixed point called the axis of rotation or center of rotation. When a rigid body is both rotating and translating, for example, the motion of the femur during gait, its motion at any instant of time, can be described as rotation around a moving center of rotation. The location of this point at any instant, termed the instantaneous center of rotation (ICR), is determined by finding the point which, at that instant, is not translating. Then by definition, at that instant, all points on the rigid body are rotating about the ICR. For practical purposes, the ICR is determined by noting the

Figure 3. Points S and S' as well as Q and Q', lie on the arcs of circles around the center of rotation ICR (used synonymously with CR after the section Instantaneous Center of Rotation). If lines SS' and QQ' are bisected perpendicularly, the center of rotation CR is located at the intersection of these perpendicular bisectors. This construction assumes that the perpendicular bisectors are differently orientated but a special case arises if the bisectors are identically orientated. Then the points S, Q and the center of rotation ICR lie on a straight line.

paths traveled by two points, S and Q, on the object in a very short period of time to S' and Q'. The paths SS' and QQ' will be perpendicular to lines connecting them to the ICR because they approximate, over short periods, tangents to the circles describing the rotation of the body around the ICR at that instant. Perpendicular bisectors to these two paths will intersect at the instantaneous axis of rotation.

If the ICR is considered to be a point on a moving body, its path on the fixed body is called a fixed centrode. If the ICR is considered to be a point on a fixed body, its path on the moving body is called the moving centrode.

Although in principle two objects may move relative to one another in any combination of rotation and translation, diarthroidal joint surfaces are constrained in their relative motion. The articular surface geometry, the ligamentous restraints, and the action of muscles spanning the joint are the main constraining systems. In general, joint surface separation (or gapping-proximal-distal) and impaction are small compared to overall joint motion. Mechanically, when surfaces are adjacent to each other they may move relative to each other in either sliding or rolling contact. In rolling contact, the contacting points on the two surfaces have zero relative velocity, that is, no slip. Rolling and sliding contacts occur together when the relative velocity at the contact point is not zero. The instant center will then lie between the geometric center and the contact point. All diarthroidal joint motion consists of both rolling and sliding motion. In the hip and shoulder, sliding motion predominates over rolling motion. In the knee, both rolling and sliding articulation occur simultaneously. These simple concepts affect the design of total joint prostheses. For example, some total knee replacements have been designed for implantation while preserving the posterior cruciate ligament, which appears to help maintain the normal kinematics of rolling and sliding in the knee. Other knee prostheses substitute for ligament control of kinematics by alterations in articular surface contour through constraining congruity.

Analytical Methods

Simple kinematic analysis of pure planar translations and rotation or combinations of the two as well as complicated 3D analysis of a rigid body requires the positional information of a minimum of three noncolinear points to describe this motion uniquely. If the position of three points at two instants is known, the displacement from one position to another may be interpreted as translation, rotation or both. Therefore, the first task is to continually monitor the positions of three points on each rigid body. This analysis is conveniently divided into data collection and data analysis.

Data Collection. A constant challenge for the experimental motion analyst is the collection of accurate spatial displacement kinematics of a joint. Several methods have been employed. A review is presented here.

Video and digital optical motion capture (tracking) systems offer state-of-the-art, high resolution, accurate motion capture options to acquire, analyze, and display 3D motion data. The systems are integrated with analog

data acquisition systems to enable simultaneous acquisition (1–300 Hz) of force plate and electromyographic data. Clinically validated software analysis packages are used to analyze and display kinematic, kinetic, and electromyographic data in forms that are easy to interpret.

The major components of a video and digital motion capture system are the cameras, the controlling hardware modules, the software to analyze and present the data, and the host computer to run the software. These systems are designed to be flexible, expandable (from 3 to up to 200 cameras in motion analysis tracking for Hollywood animation movies) and easy to integrate into any working environment. This system collects and processes coordinate data in the least amount of time and requires minimal operator intervention. This system uses motion capture cameras to rapidly acquire 3D coordinate positions from reflective markers placed on subjects. Illuminating strobes with differing wavelengths are used to track the spatial displacement (between 1 and 10 mm resolution) of spherical reflective markers attached to the subject's skin at appropriately chosen locations, preferably on bony landmarks on the human body to minimize skin movement. They can be infrared (IR), visible red, or near-IR strobes to fit the lighting conditions of the capture environment. Also, the lenses can be of fixed or variable focal length for total adaptability. Images are processed within the optical capture cameras where markers are identified and coordinates are calculated before being transferred to the computers. After the completion of the movement, the system provides 3D coordinate and kinematic data. The disadvantages of the system include the skin movement error whose effect is more prominent (3 cm error) at high movement speeds. These high speed motion tasks (impact biomechanics, e.g.) are handled by high speed cine cameras with data acquisition rates several orders of magnitude greater than clinical motion analysis systems. The processing method that is almost real time uses combinations of skin markers (minimum three at each segment) to produce coordinate systems for each segment and eventually describe intersegmental relative motion or relate all the different segment motions to the laboratory fixed-coordinate system. Recently, methods employing clusters of markers have shown to somewhat reduce the skin marker artifact but are yet to be adopted in the clinical practice.

A more accurate method (<1 mm translation and up to 1000 Hz) is the cineradiographical method, which employs an X-ray machine and uses special cameras for capture of sequences of the digital radiographs. In addition to accuracy, these systems directly access the *in vivo* skeletal kinematics so that the resulting analysis can be directly related to bony landmarks. Radiation issues, magnification, and distortion factors are some drawbacks that can be overcome by appropriate image analysis techniques. This method is, however, prone to occlusion errors when two segments overlap and simultaneously cross the field of view of the X-ray source. Stereosystems with more than one X-ray sources can limit this artifact. A biplane radiographic system consists of two X-ray generators and two image intensifiers optically coupled to synchronized high speed video cameras that can be configured in a custom gantry to enable a variety of motion studies. The system

can be set up with various set-up modes (e.g., a 60° inter-beam angle), an X-ray source to object distance of 1.3 m, and an object to intensifier distance of 0.5 m. Images are acquired with the generators in continuous radiographic mode (typically 100 mA, 90 kVp). The video cameras are electronically shuttered to reduce motion blur. Short (0.5 s) sequences are recorded to minimize radiation exposure. X-ray exposure and image acquisition are controlled by an electronic timer–sequencer to capture only the desired phase of movement.

CODA is an acronym of Cartesian Opto-electronic Dynamic Anthropometer, a name first coined in 1974 to give a working title to an early research instrument developed at Loughborough University, United Kingdom. The 3D capability is an intrinsic characteristic of the design of the sensor units, equivalent to but much more accurate than the stereoscopic depth perception in normal human vision. The system is precalibrated for 3D measurement, which means that the lightweight sensor can be set up at a new location in a matter of minutes, without the need to recalibrate using a space-frame. Each sensor unit must be independently capable of measuring the 3D coordinates of skin markers in real-time. As a consequence, there is great flexibility in the way the system can be operated. For example, a single sensor unit can be used to acquire 3D data in a wide variety of projects, such as unilateral gait. Up to six sensor units can be used together and placed around a capture volume to give “extra sets of eyes” and maximum redundancy of viewpoint. This enables the system to track 360° movements that often occur in animation and sports applications. The calculation of the 3D coordinates of markers is done in real-time with an extremely low delay of 5 ms. Special versions of the system are available with latency shorter than 1 ms. This opens up many applications that require real-time feedback, such as research in neurophysiology and high quality virtual reality systems, as well as tightly coupled real-time animation. It is also possible to trigger external equipment using the real-time data. The automatic intrinsic identification of markers combined with processing of all 3D coordinates in real-time means that graphs and stick figures of the motion and many types of calculated data can be displayed on a computer screen during and immediately after the movement occurs. The data are also immediately stored to file on the hard drive.

A new concept in measuring movement disorders utilizes a unique miniature solid-state gyroscope, not to be confused with gravity sensitive accelerometers. The instrument is fixed with straps directly on the skin surface of the structure whose motion is of interest. It has been successfully used to quantify: tremor (resting, posture, kinetic), rapid pronation–supination of the hand, arm swing, lateral truncal sway, leg stride, spasticity (pendulum drop test), dyskinesia, and alternating dystonia. The system (Motus) senses rotational motion only and is ideal for quantifying human movement since most skeletal joints produce rotational motion. This disadvantage is outweighed by its miniature size that allows it to be of great value for certain types of studies. A different system (Gypsy Gyro) uses 18 small solid-state inertial sensors (gyros) to accurately measure the exact rotations of the actor's bones in real-time for motion capture. The system can easily be worn beneath

normal clothing. With wireless range these systems—suits can be used to record up to 64 actors simultaneously.

Another concept for 3D motion analysis is the measurement system CMS10 (Zebris) designed as a compact device for everyday use. The measurement procedure is based on the travel time measurement of ultrasonic pulses that are emitted by miniature transmitters (markers placed on the skin) to the three microphones built into the compact device. A socket for the power pack (supplied with the device) as well as the interface to a computer are located on the back of the device. The evaluation and display of the measurement data are carried out in real-time. It is possible to use either a table clamp or a mobile floor stand with two joints to support the measurement system.

Data Analysis

Coordinate Systems and Transformation. In the analysis of experimental joint mechanics data, the transformation of point coordinates from one coordinate system to another is a frequent task (4). A typical application of such a transformation would be gait analysis data recorded in a laboratory fixed coordinate system (by means of film or video sequences) that must be converted to a reference system fixed to the skeleton of the test subject. The laboratory fixed coordinate system may be designated by *xyz* and the body reference system by *abc* (Fig. 4). The location of a point *S*(*a*/*b*/*c*) in the body reference system is defined by the radius vector $s = a \cdot e_a + b \cdot e_b + c \cdot e_c$. Consider the reference system to be embedded into the laboratory system. Then the radius vector $r_m = x_m \cdot e_x + y_m \cdot e_y + z_m \cdot e_z$ describes the origin of the reference system in the laboratory system. The location of *S*(*x*/*y*/*z*) is now expressed by the coordinates *a*, *b*, *c*. The vector equation $r = r_m + s$ gives the radius vector for point *S* in the laboratory system (Fig. 4). Employing the full notation we have: $r = (x \cdot e_x + y \cdot e_y + z \cdot e_z) = (x_m \cdot e_x + y_m \cdot e_y + z_m \cdot e_z) + (a \cdot e_a + b \cdot e_b + c \cdot e_c)$. A set of transformation equations results after some intermediate matrix algebra to describe the coordinates. The scalar products of the unit vectors in the *xyz* and *abc*

Figure 4. Changing the coordinate systems, transformation of point coordinates from one coordinate system to another.

Figure 5. A rigid body (shoebox) moves parallel to itself. The radius vectors from *O* to *P* and from *O* to *P'* are designated by *r* and *r'* so that $r' = r + t$, where *t* is the difference vector.

systems produce a set of nine coefficients C_{ij} . The cosine of the angle between the coordinate axes of the two systems corresponds to the value of the scalar products. Three “direction cosines” define the orientation of each unit vector in one system with respect to the three unit vectors of the other system. Due to the inherent properties of orthogonality and unit length of the unit vectors, there are six constraints on the nine direction cosines, which leaves only three independent parameters describing the transformation. Employing the matrix notation of the transformation equation we have

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} x_m \\ y_m \\ z_m \end{bmatrix} + \begin{bmatrix} c_{11} & c_{12} & c_{13} \\ c_{21} & c_{22} & c_{23} \\ c_{31} & c_{32} & c_{33} \end{bmatrix} * \begin{bmatrix} a \\ b \\ c \end{bmatrix}$$

In coordinate transformations, the objects remain unchanged and only their location and orientation are described in a rotated and possibly translated coordinate system. If a measurement provides the relative spatial location and orientation of two-coordinate systems the relative translation of the two systems and the nine coefficients C_{ij} can be calculated. The coefficients are adequate to describe the relative rotation between the two coordinate systems.

Translation in Three-Dimensional Space. In translation in 3D space, the rigid object moves parallel to itself (Fig. 5). Pure translation in 3D space leaves the orientation of the body unchanged as in the case of pure 2D translation.

Rotations about the Coordinate Axes. A rotation in 3D space is defined by specifying an axis and an angle of rotation (Fig. 6). The axis can be described by its 3D orientation and location (5). A rotation, as does the translation explained earlier, leaves all the points on the axis unchanged; all other points move along circular arcs in planes oriented perpendicular to the axis (6,7).

This rotation moves an arbitrary point *P* to location *P'* with constant distance *z* from the *xy* plane ($z = z'$). This produces the following matrix notation for the respective equations for the rotation that changes *x* and *y* coordinates

Figure 6. Rotation about the z axis of the coordinate system.

but leaves the z coordinate unchanged.

$$r' = \begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} = \begin{bmatrix} \cos\gamma & -\sin\gamma & 0 \\ \sin\gamma & \cos\gamma & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x \\ y \\ z \end{bmatrix} = D_z(\gamma)r$$

The matrix describing a rotation about the z axis is designated $D_z(\lambda)$. The matrices describing a rotation about the y axis through angle β and about x axis through angle α are similar.

$$r' = \begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} = \begin{bmatrix} \cos\beta & 0 & \sin\beta \\ 0 & 1 & 0 \\ -\sin\beta & 0 & \cos\beta \end{bmatrix} \cdot \begin{bmatrix} x \\ y \\ z \end{bmatrix} = D_y(\beta)r$$

$$r' = \begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\alpha & -\sin\alpha \\ 0 & \sin\alpha & \cos\alpha \end{bmatrix} \begin{bmatrix} x \\ y \\ z \end{bmatrix} = D_y(\alpha)r$$

Combined Rotations as a Result of a Sequence of Rotations.

Assume that the first rotation of a rigid body occurs about the z axis of a coordinate system. The rotation matrix related to the unit vectors e_x, e_y, e_z is

$$D_z(\gamma = 90^\circ) = \begin{bmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

The second rotation occurs supposedly about the x' axis, that is, about a body-fixed axis on the body (previously rotated about its z axis). The rotation matrix related to the unit vectors e'_x, e'_y, e'_z is

$$D_{x'}(\alpha = 90^\circ) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{bmatrix}$$

Matrix intermediate calculation here gives

$$r'' = D_{z'} * D_{x'} * r$$

In this calculation the sequence of the matrices is very important especially as this sequence differs from what one might expect. First, the matrix of the second partial rotation acts on the vector r and then, in a second step on the matrix of the first partial rotation. If the sequence of the two partial rotations is interchanged, the combined rotation is described by

$$r'' = D_x * D_{z'} * r$$

For rotations about body-fixed axes it is true that in general, the matrix of the last rotation in the sequence of rotations is the first one to be multiplied by the vector to be rotated. The matrix B describing the image resulting from n partial rotations about body-fixed axes is composed according to the formula:

$$B_{\text{body - fixed}} = D_1 * D_2 * D_3 * \dots * D_{n-1} * D_n$$

where the indexes indicate the sequence of the rotations. Alternatively, if the n rotation were to be produced about axes fixed in space (i.e., fixed in the ground, laboratory frame) and not about body-fixed axes, the sequence of the matrices in the matrix product would be different:

$$B_{\text{space - fixed}} = D_n * D_{n-1} * \dots * D_2 * D_1$$

Euler and Bryant-Cardan Angles. Any desired orientation of a body can be obtained by performing rotations about three axes in sequence. There are, however, many ways of performing three such rotations. One can do this task at random, but for reasons of clarity two conventions are frequently used: the Euler's and Bryant-Cardan's rotations. In the Euler notation, the general rotation is decomposed of three rotations about body-fixed axes in the following manner:

Rotation 1: about the z axis through the angle φ rotation matrix $D_z(\varphi)$ (Fig. 7).

Rotation 2: about the x' axis through the angle θ rotation matrix $D_{x'}(\theta)$.

Rotation 3: about the z'' axis through the angle ψ rotation matrix $D_{z''}(\psi)$.

The matrix describing Euler's combined rotation is given by the matrix product

$$B = D_z(\varphi) * D_{x'}(\theta) * D_{z''}(\psi) \text{ (Euler)}$$

According to the Bryant and Cardan the general rotation is decomposed of three rotations about body-fixed axes in the following manner:

Rotation 1: about the x axis through the angle φ_1 rotation matrix $D_x(\varphi_1)$ (Fig. 7).

Rotation 2: about the y' axis through the angle φ_2 rotation matrix $D_{y'}(\varphi_2)$.

Rotation 3: about the z'' axis through the angle φ_3 rotation matrix $D_{z''}(\varphi_3)$,

Figure 7. General rotation composed of three partial rotations. The first rotation according to the Bryant–Cardan convention (above). The first of the general rotations using Euler as the selection of the axes and angles of rotation (below).

in which case the matrix of combined rotation is given by

$$B = D_x(\varphi_1) * D_{y'}(\varphi_2) * D_{z''}(\varphi_3) \text{ (Bryant – Cardan)}$$

For reasons of simplicity, we have presented single or combined rotations about coordinate axes, but more complicated rotational laws can be applied as we deal with rotations about arbitrary axes. Rotation and translation can also be integrated into one single motion with Chasles theorem. Chasles theorem states that “the general motion in 3D space is helical motion”, or “the basic type of motion adapted to describe any change of location and orientation in 3D space is helical motion”. The relevant axis of rotation is designated the “helical axis”. Chasles theorem is also known as the “helical axis” theorem.

KINETICS OF JOINTS

The study of the forces that bring about the movements discussed above is called kinetics. Because kinetics pro-

vides insights into the cause of the observed motion, it is essential to the proper interpretation of human movement processes. Forces and loads are not visually observable; they must be either measured with instrumentation or calculated from kinematics data. Kinetic quantities studied include such parameters as the forces produced by muscles; reaction loads between body parts as well as their interactions with external surfaces; the load transmitted through the joints; the power transferred between body segments; and the mechanical energy of body segments. Inherent to such studies are the functional demands imposed on the body. The structure and stability of each extremity and its joints reflect different systems and functional demands. The functional demands on the upper extremity are quite different from those on either the upper and lower axial skeleton or those on the lower extremity. Depending on which joint and/or structure is addressed, different types and degrees of rotational motion are allowed and are functional. How much structural strength is needed versus how much movement is allowed in each area dictates the nature of the material, size, shape, and infrastructure of the joint system established to perform a given movement.

Equations of Motion

The kinetics deal with the effects of forces on the motion of a body. When the motion is known, the problem is then to find the force system acting on the body. There are joint forces and joint moments. With all the kinematic quantities known, it is possible to find the joint forces and moments from the resulting force system that acts on each element. This is done by solving a system of simultaneous equations at successive time intervals. Since muscles are an unknown force system, the resolved muscle force and the real joint force are treated as totally unknown joint forces in the analysis. The three equations of motion for linear motions are

$$\sum F = ma_x \quad \sum F = ma_y \quad \sum F = ma_z$$

The three equations of motion for rotation are

$$\begin{aligned} \sum M_x &= I_{xx}\alpha_x - (I_{yy} - I_{zz})\omega_y\omega_z - I_{xy}(\alpha_y - \omega_x\omega_z) \\ &\quad - I_{yz}(\omega_y^2 - \omega_z^2) - I_{xx}(\alpha_z + \omega_x\omega_y) \\ \sum M_y &= I_{yy}\alpha_y - (I_{zz} - I_{xx})\omega_z\omega_x - I_{yz}(\alpha_z - \omega_y\omega_x) \\ &\quad - I_{xx}(\omega_z^2 - \omega_x^2) - I_{xy}(\alpha_x + \omega_y\omega_z) \\ \sum M_z &= I_{zz}\alpha_z - (I_{xx} - I_{yy})\omega_x\omega_y - I_{zx}(\alpha_x - \omega_z\omega_y) \\ &\quad - I_{xy}(\omega_x^2 - \omega_y^2) - I_{yz}(\alpha_y + \omega_z\omega_x) \end{aligned}$$

where M is the moment, I is the mass moment of inertia, α the angular acceleration, and ω is the angular velocity. The moment equations can be simplified if the axes of the reference frames coincide with the principal axes, with the origin at the center of gravity. These equations, called Euler equations, are

$$\begin{aligned} \sum M_x &= I_x\alpha_x - (I_y - I_z)\omega_y\omega_z \\ \sum M_y &= I_y\alpha_y - (I_z - I_x)\omega_z\omega_x \\ \sum M_z &= I_z\alpha_z - (I_x - I_y)\omega_x\omega_y \end{aligned}$$

Continuity conditions are derived based on the fact that equal and opposite forces and moments occur at the joint between the two segments.

The anthropometric data for the mass, the center of gravity, the moment of inertia, and so on for the different parts of the human body are available in the literature (8,9).

Motion and Forces on Diarthroidal Joints

In vivo experimental measurements on the relative motions between articulating surfaces of a joint, which correspond to daily activities, are limited. Most quantitative information is obtained from gait studies that do not provide the accuracy and precision for the detailed information required for lubrication studies. However, even simple calculations show that translational speeds between two articulating surfaces can range from $\sim 0.06 \text{ m}\cdot\text{s}^{-1}$ between the femoral head surface and the acetabulum surface during normal walking, to $\sim 0.6 \text{ m}\cdot\text{s}^{-1}$ between the humeral head surface and the glenoid surface of the shoulder when a baseball pitcher throws a fastball. Cartilage to cartilage contact or fluid-film layers, or a mixture of both are normally the contact mechanisms at the joint. During a normal walking cycle, the human hip, knee, and ankle joints can be subjected to loads on the order of six times body weight, with these peak loads occurring just after heel-strike and just before toe-off. The average load on the joint is approximately three to five times body weight, which lasts as long as 60% of the walking cycle. During the swing phase of walking, only light loads are carried. During this phase, the articular surfaces move rapidly over each other. In addition, extremely high forces occur across the joints in the leg during jumping. Descending stairs can load the knee with up to 10 times body weight, suggesting that the load on the joint surface is dependent on the task performed, that is, the loading sites change drastically as the articulating surfaces move relative to each other.

MATHEMATICAL AND MECHANICAL MODELS OF JOINTS

Locomotion results from complex, high dimensional, nonlinear, dynamically coupled interactions between an organism and its environment. Simple models called templates have been and can be made to resolve the redundancy of multiple legs, joints, and muscles by seeking synergies and symmetries. The simplest model (least number of variables and parameters) that exhibits a targeted behavior is called a template (10). Templates can be used to test control strategies against empirical data. Templates must be based in more detailed morphological and physiological models to ask specific questions about multiple legs, the joint torques that actuate them, the recruitment of muscles that produce those torques and the neural networks that activate the ensemble. These more elaborate models are called anchors. They introduce representations of specific biological details of the organism. The control of slow, variable-frequency locomotion appears to be dominated by the nervous system, whereas during rapid, rhythmic locomotion, the control may reside more within the mechanical system. Anchored templates of many-legged, sprawled-postured animals may suggest that passive,

dynamic self-stabilization from a feedforward, tuned mechanical system can reject rapid perturbations and simplify control. Future progress would benefit from the creation of a field embracing comparative neuromechanics. Both templates and anchors are part of a system of mathematical and structural definitions and standard methods of description and dissemination of knowledge. In the next few sessions an attempt is made to describe some of those methods.

The human musculoskeletal system is often modeled by joining rigid links with continuous mass distribution. The joint may be of the revolute or spherical type, with restrictions consistent with body construction. Usually, the human segments form an open linkage.

Knowing all the kinematics at the center of mass of the segments, the joint force and the moment analysis proceeds by drawing free-body diagrams of the segments involved. The free body diagrams for the hip joint, the knee joint, and the ankle joint in a sagittal plane are illustrated in Fig. 8 as an example:

Assessment of Mechanical Factors Associated With Joint Degeneration: Limitations and Future Work

Joint degeneration results from complex, multidimensional, nonlinear, dynamically coupled interactions between the organism and its environment. The assessment of mechanical factors associated with joint degeneration has traditionally combined longitudinal clinical studies with carefully designed experimental techniques and theoretical computational analyses. The quality of

Figure 8. Relationship between the free body diagram and the link-segment model. Each segment is “broken” at the joints, and the reaction forces and moments of force acting at each joint are shown.

such assessments depends both on the accuracy–precision of the measurement methodology and the theoretical framework for its interpretation (i.e. joint mathematical models). To capitalize on the increasing level of measurement accuracy, theoretical analysis requires more detailed morphological and physiological models (11). For example, because of variations between individuals, the detailed, morphological analysis required for accurate modeling of cartilage stresses must be patient specific. In addition, the dynamics of the human task to be modeled (for e.g., human jumping) as expressed in the strain rate of tissue deformation must be accounted for in the analysis. Once the error estimate (simulation versus experiment) is established, model predictions can address specific clinical-biological questions. Traditionally, *in situ* methodology (cadaveric experiments and *in vitro* tests) is applied when an *in vivo* measurement is impossible. This limitation presents a number of implications and assumptions that weaken the theoretical analysis. Recent developments have further improved accuracy in the experimental measurement of *in vivo* knee kinematics. These developments allow significant improvements upon previous limitations by applying patient-specific task-dependent models in the study of joint pathogenesis.

The vast majority of dynamic knee studies have been performed with conventional motion analysis techniques, using markers attached to the skin. Conventional motion analysis is not sufficiently accurate to enable analysis of cartilage stress. Previous studies have shown that skin markers move substantially relative to underlying bone, with RMS errors of 2–7 mm and peak errors as large as 14 mm in estimates of tibial position during gait (12). A study of four subjects during running and hopping (using 250 frame-s⁻¹ stereo radiography) has demonstrated skin marker motion relative to the femur averaging 1–5 mm throughout the motion, with peak-to-peak errors of the oscillation at impact averaging 7–14 mm (13). Errors were both subject and activity specific (14). Techniques have been developed for improving estimates of bone dynamics from skin markers using large numbers of markers and optimization–modeling of soft tissue deformation (15,16) but the performance of these methods for *in vivo* studies has only been validated for the tibia (during a slow, impact-free 10 cm step-up movement of a single patient with an external fixator). Average errors were low, but peak errors routinely exceeded 1 mm. Errors would likely increase significantly during faster movements and movements involving impact, and also where the soft tissue layer between skin and bone is thicker (e.g., for the femur). However, if the kinematic measurements are to be used in conjunction with musculoskeletal models to estimate dynamic loads and stresses on joint tissues, then even errors as small as 1 mm may be unacceptable. For example, when estimating strains in the ACL, a ± 1 mm error in tibio–femoral displacement could introduce uncertainty in the ligament length of approximately $\pm 3\%$ (assuming a nominal ligament length of 30 mm). This error is similar in magnitude to estimated peak ligament elongation occurring during common activities, such as stair climbing (17). For investigating cartilage deformation, this error magnitude would be even less acceptable. A 1 mm displacement

would be equivalent to a cartilage strain of $\sim 25\%$, relative to the average thickness of healthy tibio–femoral cartilage (18). A displacement error of this magnitude would translate into huge differences in estimates of contact forces. Thus, efforts to model, predict and correct for soft tissue deformation are unlikely to achieve sufficient accuracy for assessing soft tissue behavior. Alternatively, kinematics from a high speed stereoradiographic system capable of tracking implanted tantalum markers *in vivo* with 3D accuracy and precision better than 0.072 mm in translation and 0.35° in rotation (19) are more appropriate in use with advanced computational models. This accuracy is an order of magnitude or greater of improvement over conventional motion analysis techniques, and is uniquely capable of providing the accuracy necessary to model joint stresses.

From Experimental to Advanced Theoretical Analysis in Joint Mechanics

In addition to measuring joint kinematics and contact areas, investigators have attempted to measure articular contact stresses and pressures. However, stresses throughout the cartilage layer cannot be measured experimentally. Direct measurements of stress can be made at the articular surface using pressure sensing devices (20–22) (e.g., pressure sensitive Fuji film, piezoresistive contact pressure transducers, dye staining, silicone rubber casting). For cadaver studies, Fuji film sheets (Fuji Prescale Film; Itoh, New York, NY) are inserted in a joint and if pressed produce a stain whose intensity depends on the static applied pressure. Alternatively, digital electronic pressure sensors (e.g., K-scan, Tekscan, Boston, MA) can be placed onto the articular surface. These sensors are thin and flexible, and can be made to conform to the anatomy of the medial and lateral knee compartments. They consist of printed circuits divided into grids of load-sensing regions. Each load-sensing region within the grid has a piezoresistive pigment that can be used to determine the total compressive load within that region. After appropriate calibration procedures, dynamic pressure distributions can be calculated. In addition to providing a continuous, dynamic readout, K-scan has been reported to more accurately estimate contact areas than Fuji film (23,24).

There are significant concerns with the use of these sensors for estimating actual contact pressures. These techniques measure only surface-layer stresses, they alter the nature of cartilage surface interactions and are too invasive for *in vivo* human use. Thus, the clinical validity of articular pressure measurement with such sensors is questionable. They can, however, be important tools for the evaluation of the predictive power of joint models (2). By including the sensor in a finite element model, the effects of the sensor film on the actual contact mechanics can be accounted for (25). Thus, contact pressure predictions from such models can be directly compared to the pressure sensor measurements for finite element (FE) model validation.

Many *in situ* experimental studies have been conducted to obtain 3D knee joint kinematics and force-displacement data (21,26–30). Cadaver studies, however, cannot reproduce the complex loading seen by the joint during strenuous movements, since the muscle forces driving the

movement cannot be simulated. Because of these fundamental limitations of experimental measures, mathematical models are favored for obtaining comprehensive descriptions of the spatial and temporal variations of cartilage stresses. A numerical model could be used to perform parametric studies of geometry, loading or material properties in controlled ways that would not be possible with tissue samples.

Theoretical Analysis of Joint Mechanics

During the last two decades, a number of theoretical joint mechanics studies with different degrees of accuracy and predictive power have been presented in the literature (31–39). Computational modeling work has included anatomical or geometrical observation (40,41) and analytical mathematical modeling (42–46). More recently, advanced FE modeling approaches allowed for improvements in the predictive power of localized tissue deformation (47–54). Joint biomechanics problems are characterized by moving contacts between two topologically complex soft tissue layers separated by a thin layer of non-Newtonian synovial fluid. A prime example is the multibody sliding contact problem between the tibia, femur, and menisci. The complexity of such problems requires implementation of sophisticated numerical methods for solutions (55–58). The finite element method is ideally suited for obtaining solutions to joint contact problems. Thus far, much of the finite element analysis has been applied to the study of hard tissue structures, often as it relates to prosthetic devices (59,60). When addressed, soft tissue layers are treated as single-phase elastic materials. As a consequence of the relative dearth of precise patient specific geometric data, material properties and insufficiency in accuracy of *in vivo* kinematics for input, no patient specific computational models have been reported for longitudinal clinical joint studies.

Surface Modeling

Surface modeling methods calculate the shape variations of joints and visualize the proximity of subchondral bone surfaces during static loading or dynamic movement. These methods can combine *in situ* data, motion analysis optical system data or high speed biplane radiographic image data and 3D bone surface information derived from computed tomography to determine subchondral bone motion. This method can be used to identify the regions of contact during static loading or dynamic motion, to calculate the surface area of subchondral bone within close contact, and to determine the changing position of the close contact area during dynamic activities (Fig. 9).

In vivo dynamic joint surface interaction information would be useful in the study of osteoarthritis changes in joint space and contact patterns over time, in biomechanical modeling to assist in finite element modeling, and in identifying normal and pathological joint mechanics pre- and postsurgery. Previous attempts to quantify the interaction between bones have utilized various methods including castings (62,63), pressure sensitive film (64), mathematical surface modeling (65,66), implant registra-

Figure 9. Example applications showing dynamic *in vivo* tibio-femoral bone surface motion using joint proximity (Euclidian distance) mapping during human one-legged hopping.

tion (67) and cine phase contrast magnetic resonance imaging (MRI) (68). The casting method can only be applied to cadaver models under static loading conditions. Pressure sensitive film also requires a cadaver model and necessitates inserting material into the joint space. Mathematical surface modeling allows analysis of dynamic motions *in vivo*, however, the joint must be disarticulated after testing. Implant registration requires either surgical implants or nonsubject specific image matching algorithms. Cine phase contrast MRI requires repeatedly performing the same motion pattern during testing and is limited to a small range of motion. The process described below is an improvement on these previous techniques because it utilizes live subjects performing dynamic tasks with unrestricted motion. Direct measurement of articular cartilage behavior *in vivo* during dynamic loading is problematic. In order to estimate the behavior of articular cartilage, the surface proximity interaction method that precisely tracks the motion of subchondral bone surfaces *in vivo*. Articular cartilage behavior is then estimated from these subchondral bone measurements.

Anderst et al. (61) described a method to estimate *in vivo* dynamic articular surface interaction by combining joint kinematics from high-speed biplane radiography with 3D bone shape information derived from computed tomography (CT). Markers implanted in the bones were visible in both the CT scans and the radiographic images, and were used to register the subchondral bone surfaces with the 3D bone motion. Joint surface interactions were then estimated by analyzing the relative proximity of the subchondral bone surfaces during the rendered movement. Computed Tomography data can be also used for joint geometry–shape characterization. The method is referred as reconstruction of volumetric models into rendered joint surface geometry models.

Computed Tomography data are typically collected for this method with slice spacing between the different images of $\sim 0.625 - 1.25$ mm and the in-plane resolution

Figure 10. Articular surface matching (femoral condyle on top and tibial plateau below) using geometrical objects (69).

is ~ 0.293 – 0.6 mm depending on the size of the bone. The CT scans are reconstructed into 3D solid figures using software that employs reconstruction techniques, that is, the regularized marching tetrahedra algorithm by Treece et al. (70). If necessary, threshold values are adjusted to ensure the entire bone surface appeared in the reconstruction and the opposing bone surfaces never overlapped in computer animations of the motion.

Anterior–posterior and lateral radiographs are commonly used to preoperatively determine prosthetic size and proper donor selection for osteochondral allografts. By using 3D computer aided design tools and the reconstructed 3D joint geometry from CT described above, size determination is less prone to out-of-plane imaging errors associated with sagittal and coronal roentgenograms. Assessment of surface size, curvature analysis and knee incongruity is possible with *in vivo* CT [Fig. 10 (69,71,72)]. After the 3D joint surface reconstruction models the distal articular femur ($n = 16$) can be represented by six circles, the diameters of these circles, their angular arcs, and the distances between their centers varied with the size of the femur (Fig. 11; Table 5). There is a statistically significant association between several geometry parameters when the lateral or the medial distal femur is studied independently. These associations do not exist when we correlate medial versus lateral compartments across the population.

Figure 11. All the sagittal view measured parameters in the study of femoral head congruity (69).

The Joint Distribution Problem

Much attention has been devoted to the solution to what has become known as the general joint distribution problem that is, the problem of estimating the *in vivo* forces transmitted by the individual anatomical structures in the joint neighborhood during some activity of interest (73). The prediction of forces in joint structures has many applications. In the field of medicine, these predictions are useful for obtaining a better understanding of muscle and ligament function, mechanical environment within which prosthetic components must operate, and mechanical effects of musculoskeletal diseases. In the realm of sport biomechanics, these predictions are useful for better understanding of the kinetic demands, performance constraints, and mechanisms for improving athletic performance. Industrial applications include the optimization of occupational performance and safety considerations. Although the general techniques for predicting forces in joint structures may be used throughout this broad range of applications, the particular method of choice and the details of the analysis depend on the application.

The general force distribution problem normally arises in the following way. The musculoskeletal system or a relevant portion thereof is modeled as a mechanical system consisting of a number of essentially rigid elements (body segments) subjected to forces due to the presence of a gravitational field, and segmental contact with external objects, neighboring segments, and soft tissue structures that produce and constrain system motion. The associated inverse dynamics problem is then formulated and solved to determine the variable intersegmental (joint) force and moment resultants during the activity of interest. The joint resultants are abstract kinetic quantities that represent the net effect of all the forces transmitted by the anatomic structures crossing the joint. At a typical joint, these forces normally include the forces transmitted by the muscles, ligaments, and articular (bony) contact surfaces.

The unknown forces transmitted by the joint structure are next related to the known intersegmental resultants by writing the joint equilibrium equations. These equations express the fact that the vector sum of all the forces in the individual anatomic structures, and the vector sum of all the moments about the joint center produced by those forces, are equal to the intersegmental resultant force and moment, respectively. Assuming that all joint geometry (point of application and orientation of forces) is known and that these two independent vector equations (or six independent scalar equations) involve as unknowns the M muscle and L ligament forces, together with the $3C$ scalar components of the C bony contact forces, these joint equilibrium equations are indeterminate whenever the sum ($M + L + 3C$) of the unknown forces exceeds six. Thus, if the system model includes only one bony contact force ($C = 1$) and more than three muscle and/or ligament forces ($M + L > 3$), the corresponding joint distribution problem will be indeterminate and therefore have an infinite number of solutions.

Finally, the joint resultants are decomposed or distributed to the individual joint structures at each instant of

Table 5. Femoral ($n = 16$) Medial and Lateral Compartment Measurements^a

	Medial	SD	Lateral	SD	Ratio M/L
DC mm	68.28	5.003	67.839	5.865	1.006
DA mm	42.45	10.086	44.41	4.608	0.955
DP mm	40.364	1.231	41.212	3.069	0.979
XY mm	24.519	2.686	23.529	3.069	1.042
F°	100.374	10.572	102.631	5.834	0.978
E°	151.168	10.9	139.629	12.509	1.0824

interest during the activity, using some appropriate solution methodology.

The general joint distribution problem may thus be stated in the following way. At any instant of time when the joint resultants are known, the forces transmitted by the individual joint structures are determined such that the equilibrium equations, and all relevant constraints on the forces in the individual joint structures, are simultaneously satisfied. The classical studies of joint distribution problems use essentially two different methods to solve the indeterminate joint distribution problem: the reduction method, and the optimization method.

The mathematical modeling of human anatomy and its functions has been influenced by two main simulation approaches or philosophies. In the first the joint structures are of no importance in the mathematical modeling while in the second simulation of the geometry and structural relationships of the joint components in addition to their behavioral properties are the main tasks. Hefzy et al. categorized these different approaches as phenomenological and anatomical, respectively (74).

Phenomenological Joint Models. The phenomenological models include two groups: the rheological models and the advanced figure animation models. The rheological models analyze the dynamic behavior of a system by treating it as viscoelastic, being composed of springs and dampers. However, the noncorrespondence of these components to the structure of the components in the knee leads to no structural information in the model output.

The advanced figure animation models provide information on body dynamics by taking into account body segment dimensions, masses, moments of inertia, and so on, but do not model the detailed geometry of joints.

Anatomical Models. Two different approaches to modeling categorization exist in the experimental literature. According to the first, the categorization of the models depends on the type of motion reproduced by the mathematics. The second approach categorizes models according to their structural basis. There is a vast number of studies attempting to model specific component structure and behavior that will be evaluated in order to identify the optimum method for the modeling of each specific component.

The Reduction Method. The reduction method reduces the number of unknown forces to correspond with the number of equations governing the distribution problem (or increases the number of equations to agree with the

number of unknowns, e.g., the deformation-force relations for the unknown forces). For the general 3D distribution problem, this implies that the number of unknown scalar forces ($M + L + 3C$) must be reduced to six to allow for a unique solution. Previous investigators have reduced the number of unknowns by (1) grouping muscles and ligaments with apparently similar functional roles, (2) grouping multiply connected bony contact force regions, (3) assuming a direction for the unknown bony contact force, (4) using EMG data to determine when a muscle is active, (5) ignoring ligament forces except near the limits of the range of motion, and (6) ignoring antagonistic muscular activity. Several models [(73,75); Fig. 12a, b] predicted muscle forces and the bony contact force at the hip during locomotion. In these studies, the indeterminate distribution problem at the hip or the knee was made determinate through several simplifying assumptions. The hip muscles were combined into six functional groups (long flexors, short flexors, long extensors, short extensors, abductors, and adductors), and ligament function at the hip was assumed to be negligible. The forces transmitted by these six muscle groups, combined with the three components of bony contact force, comprised nine unknown scalar quantities. Only two of the three components of the resultant hip moment were considered; analysis of the component tending to internally or externally rotate the femur relative to the pelvis was rejected as inaccurate. Previous reports of EMG activity were to demonstrate that there is little antagonistic muscle action, and only muscle agonists were considered. Despite these simplifications, the possibility of activity in both the long and short flexors and extensors still made the problem indeterminate. A solution was obtained, however, by assuming activity in only one flexor (either long or short, but not both) and one extensor.

The Optimization Method. The previous discussion indicates that the distribution problem at a joint is typically an indeterminate problem, since the number of muscles, ligaments and bony contact regions available to transmit forces across a joint in many cases exceeds the minimum number required to generate a determinate solution to the joint equilibrium equations. Determinate solutions are obtainable only with significant simplification of joint function or anatomy. In contrast, the optimization method of solving the general joint distribution problem does not require such simplification. Rather, it retains many of the anatomical complexities incorporated in defining the problem, and seeks an optimum solution (i.e., a solution that maximizes some process or action). Optimization techniques may be divided into linear and

Figure 12. Forward and inverse analysis driven mathematical models, (a) the Strathclyde model animated using SIMM Musculographics-Motion Analysis Software. (From Ref. (77)) (b) Force distribution method-inverse dynamics, the vector of bony contact force is shown on the tibial plateau. (From Refs. (71) and (77)). (c) the Delft forward and Inverse shoulder model (78).

nonlinear methods Simultaneous use of linear cost and constraint functions in the model formulation constitutes the so-called linear optimization method. In contrast, if the cost function and/or one or more of the constraint functions is nonlinear, solution of the problem requires the use of nonlinear optimization methods. Both of these optimization methods have been made practical with high speed computers, since the techniques require many iterations of equation-solving to find an optimum solution. Neuromuscular function is complex and poorly understood at the conceptual, if not detailed level. However, it is generally assumed that physiological functions are optimized in some way. In 1836, the Weber brothers commented that we walk and run in “the way that affords us the least energy expenditure for the longest time and with the best results”. Experimental evidence suggests that oxygen consumption (and presumably energy expenditure) is minimal at freely selected walking speeds, supporting the assumptions of optimal physiological neuromuscular function.

The optimization criteria that the neuromuscular control system “chooses”, either consciously or unconsciously, to select muscle action may vary considerably with the nature of the physical activity to be performed and the physical capabilities of the individual. For example, muscle control in sprint running may serve to maximize velocity, while in walking the control process may serve to maximize endurance. In a painful pathological situation, such as degenerative joint disease, muscular control may serve to minimize pain. If this pain occurs due to the joint surface pressure, the appropriate optimization criterion may be to minimize to bony contact force. Muscular control may also serve to minimize the forces transmitted by passive joint structures such as ligaments. These examples indicate that there are possible optimization criteria to choose from, and the choice of a criterion to solve a particular distribution problem may not be obvious.

Given that gait presents a relatively unambiguous performance criterion, one can claim that it fits into the framework of optimum control theory. Additionally, gait presents a characteristic bilateral symmetry that leads to relatively simple representation of the dynamic system.

Activity in the stance phase of gait is described by equality constraints on the “states”, knowing that each gait stage involves dynamic constraints that reflect the particular nature of the phasic activity. However, our motivation in the use of optimum control for the study of movement relies upon the belief that it is currently the most sophisticated methodology available for solving extremely complex problems. Optimal control theory requires not only that the system dynamics are precisely determined and formulated but also that an appropriate performance criterion is chosen. Therefore, deficiencies in the modeling that are present in either the system dynamics or the performance criterion are indicated by differences between model and experiment.

Forward Analysis. The technique of forward simulation allows the study of the causal relationship between forces acting on a mechanical structure and the resulting movement (79). A first approach requires the description of joint moments, initial positions and velocities for each body segment as input variables. The forward dynamics problem then is expressed as a set of differential equations of motion with associated restraints and solved to yield angular accelerations. Angular velocities and displacements are then determined by integration (80). Modifications to input variables, either joint moment profiles or initial segmental configuration, can then be introduced and the resulting changes in the movement pattern evaluated.

Due to recent improvements in musculoskeletal modeling, forward simulation driven by muscle activity rather than joint moments is now possible. The definition of muscle activation sequences and the initial configuration of the mechanical system (angles and angular velocities) are entered into the forward simulation. A physiological model describing muscle excitation characteristics as well as muscle mechanics is used for calculating the individual muscle force production and the resulting motion is calculated.

Because of the inherent complexity of the musculoskeletal model and the multiple interaction of parameters, forward simulation alone is unlikely to contribute to the

identification of aberrant muscle action which affects timing or force production, causing an aberrant gait pattern. Matching the system response to the joint movement profiles observed in an individual patient would require extensive trial and error with no guarantee of ever finding the parameter setting responsible for the aberrant joint movement.

Optimization has been used previously as a curve-fitting tool in addition to forward simulation techniques to reproduce the movement pattern observed in an individual subject. In the studies of Chao and Rim (81), and also Townsend (82), optimization techniques were used to determine the applied joint moments by iteratively varying them until the theoretical limb displacement fits those measured in the laboratory. Chou et al. (83) predicted the minimum energy consumption trajectory of the swing limb using a similar approach. Using approximate muscle-force and/or joint moment trajectories, Pandy and Berme (84,85) evaluated body segment motion and ground reaction forces during single stance, based on a 3D model incorporating 7 DOF. In Jonkers et al. (76), initial inputs to the forward simulation process were the normalized quantified muscle activation patterns of 22 muscles, and the initial segmental configuration (both angles and angular velocity) derived from Winter (86). Two distinct musculoskeletal models (one including 6 DOF, the other 7 DOF) were defined and a muscle driven forward simulation was implemented. A series of optimization sequences then were executed to modify the muscle activation patterns and initial segmental configuration, until the system output of the forward simulation approximated the angle data reported by Winter (86). The accuracy and effectiveness of the analysis sequence proposed and the model response obtained using two distinct musculoskeletal models were verified and analyzed with respect to the kinesiology of normal walking.

Based on the integrated use of optimization and forward simulation techniques, a causal relation between muscle action, initial segmental configuration and resulting joint kinematics during single limb stance phase of gait was successfully established for a musculoskeletal model incorporating 22 muscles and 7 DOF (Fig. 12). Despite the inherent simplifications of the planar models used in this study, several kinesiological principles of normal walking were confirmed by the analysis and a reference base for exploring the causal relation between muscle function and resulting movement pattern was established.

Finite Element Analysis of Human Joints. Adaptation of finite element analysis (FEA) to the analysis of stress in human joints, requires fundamental studies in the following areas: (1) three dimensional FEA of moving contact problems utilizing finite deformation laws (linear elastic versus biphasic) for cartilage and non-Newtonian laws for synovial fluid; (2) automated adaptive methods for the generation and control of 3D computational models using error estimates and controls that account for nonlinearities, singularities, and boundary layer effects; (3) improvements in geometry of FE models by using patient specific MRI and CT imaging data. Recently

available semiautomatic 3D mesh generation tools (reconstructed mesh from the volumetric imaging data), and numerical methods for processing the material and geometric data required for the contact analysis considerably reduce the time requirements of such efforts; (4) implementation of recently available high accuracy 3D joint *in vivo* kinematics to calibrate the FE models, and to assist in simulating strenuous activities; (5) Parallel solution algorithms for the nonlinear time-dependent problems utilizing high performance computer architectures.

Several models of articular cartilage have been proposed to describe its mechanical behavior; however, none of these models have been able to address the full spectrum of this tissue's complex mechanical responses. Typically, these models implement a subset of known tissue behavior, for which material properties must be determined from experiments. Experimental results indicate that cartilage exhibits flow-dependent viscoelasticity, anisotropy, and tension compression nonlinearity due to its ultrastructure and composition (87). These characteristics are further compounded by the inhomogeneity of the tissue through its thickness. It is widely accepted that the time-dependent response of cartilage can be accurately represented by the biphasic theory derived by Mow et al. (21). Under isotonic conditions, this biphasic theory of incompressible solid and fluid phases is appropriate for most applications involving cartilage modeling for infinitesimal or finite deformations (26,88). Numerical methods are required to solve these nonlinear problems, even for relatively simple geometries. Linear 3D elements (89) and nonlinear 3D formulations have been presented for the biphasic theory (90–92). However, full nonlinear 3D analysis for joints of realistic geometry and strains remains a computationally challenging problem.

Hirsch (1944) proposed to use the Hertz contact theory for contacting elastic spheres to model cartilage indentation (28). Askew and Mow (1978) analyzed the problem of a stationary parabolically-distributed normal surface traction acting on a layered transversely isotropic elastic medium to assess the function of the stiff surface layer of cartilage (29). More recently, complex, biphasic models have been developed that target slow, quasistatic loading response (89,90,93–95). Under high loading rates, however, the cartilage demonstrates a mechanical behavior that does not deviate substantially from a linear elastic model (38,96), so complex and numerically unwieldy biphasic models may not be necessary for rapid loading events. Eberhardt et al. (1990) (36) and (1991) (97) developed a solution for the contact problem of normal and tangential loading of elastic spheres, with either one or two isotropic elastic layers to model cartilage. A modified Hertzian (MH) theory that takes into account the thickness effect of the elastic layer has been used for articular joint contact analysis by several investigators (23,32,37,97). The results from the studies listed above have demonstrated that considerable differences may be found in cartilage stress predictions depending on the particular cartilage constitutive model being employed, that is linear elasticity theory versus linear biphasic theory. In view of the above, it has been proposed that it is adequate to use a transversely

Figure 13. (a) Knee FE model components shown in different color-implicit formulation (102) (b) the knee FE model during simulation of single leg-hopping-explicit formulation (103).

isotropic, linearly elastic, homogeneous constitutive relationship to model the normal contact pressure distribution of the tibial plateau (33,98).

In the case of FE modeling applied to impacts and very rapid movements, model formulation problems must be accounted for by the solution. Implicit techniques are not widely used as they can be limited by problems of convergence. This method does not use kinematics to verify whether contact occurs at the calculated points at the associated load levels. For those applications, explicit techniques have proven useful in their ability to simulate deformations and contact conditions simultaneously as well as large segmental displacements (70,99–101) (Figs. 13b and 14). Explicit finite element analysis was also proven to be a valuable tool when simulating total knee replacement motions due to loads applied by a knee simulator (44,45). Stability of solution and low computational cost are the two main advantages of the explicit methods over classic implicit techniques when forces are used to drive the models (44,98,103–109). The main limitation of the explicit technique is that the method is only conditionally stable. Combination of both techniques is suggested so that the explicit formulation will be used to

“educate” the implicit algorithms. Implicit formulations are used when the localized effect of articular stress needs to be addressed at the cartilage level with increased subject specific refined geometry since these techniques are more appropriate for the task (Fig. 13a).

Toward Patient-Specific and Task-Dependent Morphological FE Models. In order to apply FE computational methods to problems of joint mechanics, precisely measured anatomical data must be used to construct a 3D solid model from which the appropriate finite mesh can be constructed and analysis performed (110,111). Computed tomography (112) and MRI (113,114), or reshaped digital calipers and machine-controlled contact digitization (23) are commonly used methods to obtain soft-hard tissue geometry. Clinical modalities of these imaging techniques have resolutions that are typically limited to 500 μm . Considering that the articular cartilage of the knee joint is only $\sim 4\text{ mm}$ thick (14), a resolution of 500 μm is generally inadequate and special protocols are required for the imaging procedure (19). Note that all properly calibrated 3D FE knee joint models to date, have been developed from images of cadaveric knees (43,115). Models with patient specific geometry are possible using

Figure 14. Tibial plateau pressure at 10 and 30 degrees flexion during single-legged hopping (103).

combined appropriate MR and CT imaging modalities that will result in increased model detail (100).

With recent technological advances in 3D imaging, computer hardware, and FE formulations, it has become possible to estimate human tissue properties (100,103). Estimation of the stiffness of hard tissue (i.e., cancellous bone) using large-scale finite element (LSFE) models or microFEs at both the apparent and trabecular levels is therefore possible (47,52,70,116–122). This direct analysis approach has advantages over traditional statistical methods in that (1) all morphometric measurements available from the 3D image data are contained in the FE model, and (2) the FE model of the structure is a mechanistic rather than statistical approach to the prediction of biological tissue properties. Application to these techniques in the clinical environment with *in vivo* data is gaining considerable ground. These recent improvements in imaging, allow the generation of 3D models in a semi-automatic fashion (23,69,123,124). Models now provide the opportunity to study the mechanical effects of individual geometrical variation (125). Such **subject specific finite element models** are mainly useful under two conditions: (1) In the statistical analysis, if the differences between subjects are large relative to the differences in model predictions related to the choice of input parameters that can only be estimated. (2) In a contact FE problem with high accuracy 3D kinematics refined meshes are needed in the vicinity of the contact zone (114).

The inherent ability of FEM to overcome geometrical and topological modeling problems is no longer burdened by some of the limitations apparent in early studies. Such limitations have been overcome by recent computational and experimental advances. These limitations included insufficient accuracy of *in vivo* kinematics–kinetics input data, inadequate hard–soft tissue imaging, excessive computational cost and the inherently complex process of material characterization in relation to some of the components of the stress tensor in biological material.

JOINT STABILITY

Newton's third law states that forces always exist in pairs that are equal and opposite in direction, such that if one body pushes against another, the second body will push back against the first with a force of equal magnitude if the state of motion is constant. This would mean that in order for muscles to be able to pass movement on to a limb segment, there has to be an interaction between the segment and another bone, and a joint structure that will allow the desired rotational direction and force. Such a mechanism prevents translational movements, which can "dislocate" one rigid bony limb segment from another.

Bones, ligaments, and muscles all contribute to joint stability. The extent each structure participates in maintaining joint stability differs between joints. Because bones are rigid relative to the other tissues in the joint, they can provide great stability to the joint. In general, the greater the circumference of the bony segment enclosed by its counterpart, the greater the amount of translational stability that exists in the joint. For example, the femoral head is almost completely enclosed by the acetabulum in the hip

joint, whereas the humeral head is only slightly enclosed by the glenoid in the shoulder. It is obviously easier to dislocate the shoulder than the hip.

Ligaments, much like cables, can restrict rotational or translational motions depending on their location and the direction of the force. For example, the cruciate ligaments limit the anteroposterior translation of the tibia on the femur at the knee joint, while talocalcaneofibular ligaments prevent rotational motions as well as translational motions between talus, fibula and calcaneus. However, ligaments, unlike bones, cannot provide rigid constraints as they are relatively soft and flexible.

Muscles–tendons are also soft and flexible and, like ligaments, provide nonrigid constraints to the joint. A significant difference between the two, however, is that muscles are active in controlling the joint motion whereas ligaments are only passive stabilizers. Muscle action is usually complementary to that of ligaments and, in fact, can protect ligaments from damage or can protect the joint from further damage in case that the ligament is ruptured. Tensile forces exerted on muscles are counterbalanced by compressive forces across the joint surfaces providing stability to the joint against forces acting to open up the joint space. Thus, muscles can support or limit motions and serve the dual function of providing desired movements while contributing to joint stability.

The Hip Joint

The hip joint is the link of the upper body and the pelvis–trunk with the lower limbs, the main locomotion facility of the body. It is a ball-and-socket joint (Table 4) in which the head of the femur resides in the acetabulum of the pelvis, making one of the largest and most stable joints in the body. The surface area and the radius of curvature of the articular surface of the acetabulum closely match that of the articular surface of the femoral head. The hip joint is structurally a highly constrained joint. Because of the inherent stability conferred by its bony architecture, this joint is well suited for performing the weightbearing supportive tasks that are imposed on it.

The femoral ball is embraced by the acetabular socket, allowing rotation to occur with virtually no translation. The cartilage that covers the acetabulum thickens peripherally (126). A plane through the circumference of the acetabulum immediately at its opening would project with the sagittal plane intersections at an angle of 40° (opening posterior) and 60° (opening laterally). This architectural constraint imparted by the bony shapes almost eliminates the need for ligamentous and soft-tissue constraints to maintain the stability of the hip articulation. Although this increased constraint provides stability to the hip, there is a structural drawback. Such constraint limits the global range of motion of this joint at the fulcrum of the lower extremity. Fortunately, human biomechanics and everyday tasks performed by the hip do not violate these limitations and the hip's range of motion is very rarely subjected to extremes. During most ambulatory activities, such as normal bipedal locomotion, the lower extremity is positioned anteriorly in the sagittal plane with only small rotations necessary in the other two

planes. Hip flexion of at least 120° , abduction of at least 20° , and external rotation of at least 20° are necessary for carrying out normal daily activities. Activities such as descending stairs sitting, rising from a chair, and dressing require greater degrees of flexion and rotation at the hip joint. For example descending stairs requires 36° of motion whereas squatting requires 122° of motion in the sagittal plane (127).

The hip joint reaction force (at a neutral position) can reach three times body weight (BW) in single legged stance, but could get up to six times BW during the stance phase of gait and increases significantly with gait velocity. The main mechanism influencing this magnitude is the ratio of the abductor muscle force and the effect of the gravitational force moment arms. The rule normally suggests greater reaction forces expected at low ratios (128). Bracing and use of a cane can decrease the hip joint force.

The Knee Joint

The knee consists of a two joint structure: the femorotibial joint and the patellofemoral joint. The femorotibial joint is the largest joint in the body and is considered to be a modified hinged joint containing the articulating ends of the femur and tibia. The patellofemoral joint consists of the patella, the largest sesamoid bone, and the trochlea of the femur. Taken together, the knee joints function to control the distance between the pelvis and the foot as a control link. Because of the role of the knee in weight-bearing, its surrounding of very strong musculature and its location between the two longest bones in the body, tremendous forces are generated across it. Surface motion occurs simultaneously in both sagittal and the transverse plane with the first being the dominant plane of motion (129). During activities such as running, landing, and pivoting, the knee functions to maintain a given leg length and acts as a shock absorber. During stair climbing, crouching, and jumping, large propulsive forces at the knee (several times BW) are generated to control the degree and speed of shortening and lengthening of the leg. In these situations, knee stability is a dynamic process maintained through fixed bony and ligamentous constraints and modified by the action of the muscles crossing the joint. The higher the rate of the loading the more demanding the role of the knee in sustaining

stability. The bony morphology of the femur, tibia, menisci, cruciate–collateral ligaments, and patella contribute to joint stability, but to a lesser extent than that of other more constrained joints such as the hip. Static constraints play a very significant role in knee stability as compared with the shoulder for example where stability is maintained through the dynamic action of the surrounding muscles. The cruciate and collateral ligaments are the major structures limiting motion at the knee. The posteromedial and posterolateral capsular complexes augment the four primary ligaments, with the menisci playing a lesser role. The muscles crossing the knee contribute to dynamic stability and are particularly important in the presence of pathologic laxity. A method that describes the constraining mechanism of the anterior and posterior ligament has used the notion of the 2D “four bar linkage”. The instant center of rotation, designated primarily by the femoral condyle surface shape, follows a semicircular pathway, and the direction of displacement of the femorotibial contact points is tangential to the surface of the tibia, indicating gliding throughout the range of motion. However, the axis of rotation at the knee does not remain fixed during flexion. Indeed, as the knee flexes the screw axis will sweep out a ruled surface in space, known as the axode. This fluctuation in the screw axis signifies that the knee is not truly a hinge joint, for which the axode would degenerate to a fixed line in space. Usually, the knee is approximated as a hinge joint, a simplification that may be acceptable for flexion angles between 45° and 90° where the moving screw axis remains very close to the line passing through the centers of curvature of the two posterior femoral condyles. The motion at the articular surfaces is not one of pure rolling, but a combination of rolling and sliding as indicated by the screw axis that never lies near the articular surfaces of the tibiofemoral joint.

The Foot Structure; the Ankle Joint

The ankle joint can be described as a saddle-shaped lower end structure of a long bone (tibia and fibula) Fig. 15. Its inferior transverse ligament encloses the superior aspect of the body of the talus (the trochlea). It is the joint that first receives the transient impact that travels through the tibia in gait or other movement. It alternates in both form and function to receive load as a shock absorbing

Figure 15. The Wayne State University Ankle joint and foot Finite element model (130).

mechanism and to propel significant leverage based force during fast locomotion. The subtalar and ankle joint act like a mitered hinge. The tibial surface forming the superior dome of the ankle is concave sagittally, is slightly convex from side to side, and is oriented $\sim 93^\circ$ from the long axis of the tibia (it is higher on the lateral than the medial side). The upper articulating surfaces of the talus appear to match closely that of the cavity formed by the tibiofibular mortise. The superior part of the body of the talus is wedge-shaped. It is about one-fourth wider in front than behind, with an average difference of 2.4 mm; anteriorly a minimal difference of 1.3 mm and a maximal difference of 6 mm. From front to back, the articular surface spans an arc of $\sim 105^\circ$. This surface contour, having a smaller diameter medially than laterally, has been compared to a section or rostrum of a cone. The primary motion of the ankle joint is dorsiflexion–plantarflexion. Its axis of rotation is obliquely oriented with respect to all three anatomic planes with ankle dorsiflexion and tibial internal rotation being associated with subtalar eversion (pronation) whereas the ankle plantarflexion and tibial external rotation are associated with subtalar inversion (supination). The axis extends from anterior, superior, and medial to inferior, posterior, and lateral as it is passing through the inferior tips of the malleoli. It is at angles of 93° with respect to the long axes of the tibia and $\sim 12^\circ$ to the joint surface. However, rather than a true single ICR, the ankle has been noted to have multiple instant centers, all of which perturbate and fall very close to a single point within the body of the talus. Through a complete arc of ankle rotation, the center may be displaced anywhere from 4 to 7 mm. The oblique orientation of the axis of rotation to the sagittal, coronal, and transverse planes, translation of the talus in the mortise can occur in all three directions. The talus has been observed *in vitro* to rotate easily in the ankle mortise implying relative movement between the malleoli. Because the trochlea is wider anteriorly than posteriorly, it has been suggested that lateral play of the talus within its mortise occurs only when the ankle is in plantarflexion. Subtalar motion has been described as screw-like influencing the flexibility of the transverse tarsal joint. Others suggest that instability exists in dorsiflexion, while others yet believe that with intact ligaments translation, occurs only in the sagittal direction. These differences can be explained by behavior of >100 ligaments and by the roles played by the subtalar joint, the kinematic chain of the hindfoot, and the muscles that traverse this area in transmitting forces across this area during plantarflexion and dorsiflexion. The talus is unique because this bone has seven articulations that connect it to four other bones, it lies between the foot and the leg, and contains no muscular attachments. The stability of the talus and its articulations, therefore, relies heavily on the ligamentous attachments and musculotendinous complexes that traverse the talus and attach distally. Therefore the main characteristic of ankle joint is its strong passive stability attributed to a variety of factors. First is the bony stability provided by contact of the trochlea with the tibial plafond. Second are the medial and lateral cartilaginous slightly concave surfaces that articulate with the two malleoli.

Third are the ligamentous connections between the tibia, fibula, talus, and calcaneus. Ankle stability increases during weight bearing and depends more on articular surface congruency.

The tarsometatarsal joints are relatively mobile and intrinsically stable joints that produce the arch-like configuration allowing wide range of motion at the first metatarsophalangeal joint with gliding during most of its range and jamming artful extension. The medial longitudinal arch functions as a beam and a truss.

The mode of foot–ankle mobility and muscular control is the most significant determinant of both limb stability and body progression (131).

Standing barefooted we load our heels with two-thirds of the load while the other third is loading the forefoot. During walking and at the early phase of stance, the center of pressure moves from the posterolateral heel rapidly across the midfoot, a phenomenon coupled with the firing of the anterior tibial musculature to slow foot plantarflexion and prevent foot slap. Then, at mid- and late stance the posterior calf musculature fires, propelling the body over the foot towards toe-off phase where the hallux bears the most pressure.

At higher speeds/rates of mobility it is the intrinsic mechanical properties that provide control rather than the neuromuscular control system. The force at the ankle joint can reach magnitudes up to six times body weight during walking and thirteen times BW during running. The heel fat pad is a very effective shock absorbing mechanism and it has been shown that high heels, or narrow shoes, narrow toebox, can lead to altered foot mechanics that ultimately result in foot deformities and pain.

The Spine

The spine is composed of a series of vertebrae (7 cervical, 12 thoracic, 5 lumbar, the sacrum and coccyx) and intervening soft tissues, such as intervertebral disks, ligaments, and muscle attachments. It provides important functions including support of the body structure and protection of vital tissues such as the spinal cord, nerves and arteries. Yet it is flexible and allows mobility to the torso. Several studies have described the passive and active range of motion of spinal segments differently (Table 4). The motion of the spine is usually analyzed through consideration of motion segments that are comprised of two adjacent vertebrae with the intervertebral disk and other intervening soft tissues. These structures, also called functional spinal units (FSU), move with 6 DOF, however, the motion is quite complex due to six articulate faces between the two bony segments and attachment of multiple ligaments and muscles. Normally simultaneous translations and rotations of FSU are coupled in the analyses (134). Creep, relaxation and hysteresis are the three prevailing viscoelastic characteristics of the intervertebral disks (1). At high rates of loading the disks serve as a shock absorber with compression strength being higher from upper cervical to lower lumbar levels. Although this is true for most joints, vibrational properties of spinal segments have attracted particular attention as they are thought to be related to injury and pain. The spinal cord exhibits some longitudinal

Figure 16. The Wayne State University full body impact model and the spine model (130,135).

elasticity but very poor axial translation. These translational forces are the ones primarily associated with neurological injury. Apparently muscular support is of vital importance is stability. If for example bilateral facet resection exceeds 50% the significant increase in annulus stresses may occur. Seatbelts can adequately protect front seat occupants against frontal impact in an airbag equipped vehicle (135).

Several models of the spine have been developed (130,135). A nonlinear finite element model of lumbar spine segment L3–L5 is shown in Fig. 16. The effects of upper-body mass, nucleus injury, damping, and different vibration frequency loads were analyzed for the whole body vibration (WBV) using this model. Anterior regions of L3–L5 segment show small vibration amplitudes, but posterior regions show large amplitudes. The posterior regions of intervertebral discs of lumbar spine are easy to injury during long-term WBV compared with anterior regions. The vibration of the human spine is more dangerous to facets, especially during WBV approximating a sympathetic vibration, which may lead to abnormal remodeling and disorders of lumbar spine.

The Shoulder

The shoulder complex allows the arm to move with respect to the thorax. The biomechanics of the shoulder involves the study of four different articulations, namely, the acromioclavicular, sternoclavicular, glenohumeral joints, and the scapulothoracic joints. The shoulder complex has the greatest range of motion among joints in the body (Table 4). Traditional descriptions of humeral motion are based on the angle between the humerus and the thorax in the sagittal plane (flexion and extension) and the coronal plane (abduction), with one very common characteristic: the glenohumeral articulation is inherently unstable due to the shallow nature of the glenoid fossa, containing only one-third of the diameter of the humeral head. The ligaments, capsular and muscular structures are the main

stability mechanisms. Axial rotation of the humerus is conventionally described by the degrees of internal or external rotation when the humeral axis is parallel to the thorax, or perpendicular to the thorax (abducted 90°). The primary anterior stabilizers of the shoulder when the arm is abducted at 90° are the inferior glenohumeral ligaments. Horizontal abduction and adduction, also known as horizontal extension and flexion, respectively, are commonly used to describe arm position when the axis of the humerus is perpendicular to the thorax. The muscles surrounding the structure produce a barrier effect by applying compressive forces and by eccentric contraction resulting in active stability. The level of elevation of the normal arm is $167\text{--}168^\circ$ and $171\text{--}175^\circ$ for men and women, respectively. Average extension or posterior elevation is approximately 60° . When the arm is adducted by the side of the body, it is possible to achieve approximately 180° of rotation. With abduction of the arm to 90° , however, the total arc of rotation is reduced to 120° . The range of motion of the shoulder decreases with normal aging. The maximum loads that are characteristic for the glenohumeral joint can reach magnitudes of one and a half body weight (132).

The Elbow

The elbow joint consists of the proximal end of ulna and the capitulum of the humerus. Three articulations are present: Humeroulnar, humeroradial, and proximal radioulnar (133). It is a hinge-type joint whose functions include positioning and stabilizing the hand, providing lever-type support during lifting and weight-bearing during activities, such as a pommel horse exercise. The humerus-ulna joint itself has only one degree of freedom, however, the rotational motion of the radius over ulna provides another degree of freedom to the elbow. Thus the elbow can be considered to have two degrees of freedom. Basically its changing center of rotation during flexion-extension makes it more than a hinge joint: flexion-extension ($0\text{--}160^\circ$)

and axial rotation, or pronation–supination (70–80° and 80–85°, respectively). The functional range of motion for most activities of daily living is 100° for flexion–extension (30–130°) and pronation–supination ($\pm 50^\circ$) at the elbow joint. The instantaneous axes of rotation for flexion–extension are localized at the center of the lateral projected curvature of the trochlea and capitulum. The size of this region measures only 2–3 mm.

The axis of forearm rotation passes through the capitulum and head of the radius, extending to the distal ulna. The carrying angle, the angle between the long axis of the humerus and the long axis of the ulna, averages 7° in men and 13° in women.

Motion in the plane of varus–valgus rotation at the elbow indicates joint instability and such motions are restricted. The rotational forces are mainly resisted by the anterior and posterior oblique fibers of the medial collateral ligament; the former is stretched during flexion and extension, whereas the latter is stretched only during flexion. In addition to the medial collateral ligament, the shape of the articular surface and the anterior capsule contribute to the resistance to valgus stress while the articular congruity and the radial head provide stability in flexion. The same structures resist valgus stress in extension as well. It is the lateral collateral ligament, anconeus, and joint capsule that provide stability under varus stress. Force generated at the elbow can reach up to three times body weight in everyday activities (136).

The Wrist

The wrist or carpus is a very complicated joint consisting of multiple articulations. It provides a stable support for the hand, allowing for the transmission of grip forces as well as positioning of the hand and digits for fine movements. Wrist position affects the ability of the fingers to operate (flex–extend) and to effectively grasp. The main function of the wrist is to fine-tune grasp by controlling the length–tension relationship in the extrinsic muscles to the hand (137). The hand is the principal instrument of touch and its combination of sensibility and motor function has classified it as the ultimate supportive organ of information, accomplishment, and evolution. The self-selected wrist position for maximal power grip has been shown to be 35° of extension with 7° of ulnar deviation. In addition, full wrist flexion deteriorates the efficiency of the finger flexors and the grip strength to 25% of that available when the wrist is in extension. Martial arts experts have exploited this knowledge for a long time to disarm assailants. When the wrist is positioned in flexion, the combination of a passive extensor tenodesis effect, increasing resistance to flexion, and decreasing excursion of the flexors results in a weakened grip. The assailant, therefore, is unable to maintain a grip on the weapon. The strength of the finger flexors is more than twice that of extensors. The unique feature of the metacarpophalangeal (MCP) joints is their structural asymmetry, which assisted by the ligament positions and the bony configuration of the metacarpal heads results in effective stabilization and finely tuned motion.

OVERVIEW

Human diarthroidal joints can support high levels of mechanical load for several decades, yet degenerative joint diseases occur in epidemic proportions every year. Understanding the role of mechanics in diseases, such as osteoarthritis, requires analysis of the behavior of both healthy and pathological joints under a full range of physiological loading conditions. Relationships between joint function, meniscus injury, and osteoarthritis after trauma (e.g., ACL injury–reconstruction) requires detailed knowledge of internal tissue stresses. Such knowledge is necessary to advance our understanding of cartilage–ligament–meniscus failure mechanisms at the macroscopic level, as well as mechanotransduction at the cellular level.

Experimental measurements alone are not sufficient to delineate the detailed biomechanics of the human joint. Recent publications have confirmed that mathematical modeling can be an effective tool for the simulation and analysis of complex biological structures (e.g., the human knee). However, existing modeling strategies, based on generic geometry and/or driven with simplistic kinematics and loading assumptions, have been of limited value in addressing clinical hypotheses. Research efforts in the biomechanics community have focused on cadaveric studies for the characterization of tolerances on material, geometry, and attachment parameters that will restore contact pressure distribution to within a specified deviation from accepted normal values. Models driven directly by *in vivo* kinematic data have not been possible due to the relatively poor accuracy available from traditional motion analysis methods, limiting the predictive power of FE modeling techniques in the study of knee pathogenesis. New advances in modeling problem formulations that take advantage of patient-specific geometry and unique motion analysis systems (cineradiography) for high accuracy 3D knee kinematics can overcome limitations of previous approaches. This should generate high quality estimates of internal tissue stresses, providing new insight into the role of tissue loading in the development and progression of musculoskeletal diseases such as osteoarthritis.

INTRODUCTION

The larynx is a uniquely complicated organ strategically located at the division of the upper aerodigestive tract into the gastrointestinal tract and the airways. Alteration of its function can have a significant impact on vocal, digestive, and respiratory physiology (1–6). The hyoid bone, the thyroid cartilage, and the cricoid cartilage form the outside framework of the larynx. The mobile interior framework consists of the leaf-shaped epiglottis and the arytenoid cartilages. Each vocal cord stretches from an anterior projection of the arytenoid to the anterior midline of the inside thyroid cartilage. The arytenoid cartilages move in both a rocking and sliding motion on the cricoid cartilage to abduct and adduct the true vocal cords. The intrinsic muscles of the larynx control the movement of the vocal cords.

A section of the larynx is shown in Fig. 1, which is a posterior view of the cartilages and membranes (skeleton of larynx).

Figure 1. Section of the larynx: posterior view of cartilages and membranes.

The larynx has three important functions: protection of the lower airways during swallowing; respiration; and phonation.

Phonation is a complicated process in which sound is produced for speech. During phonation, the vocal folds are brought together near the center of the larynx by muscles attached to the arytenoids. As air is forced through the vocal folds, they vibrate and produce sound. The tone and level of the sound can be changed by contracting or relaxing the muscles of the arytenoids. As the sound produced by the larynx travels through the throat and mouth, it is further modified to produce speech.

Cancer of the larynx represented ~0.7% of the total cancer risk in 2001, and is the most common of all head and neck cancers. However, head and neck cancers account for only ~9% of all cancers diagnosed annually.

Laryngeal cancer occurs about five times more frequently in males than females. It is rare prior to age 40, after which the incidence in males increases rapidly with age. Cigarette smoking is the most important cause of laryngeal cancer, with smokers having a roughly 10-fold higher risk than nonsmokers. Heavy alcohol consumption also is a well-established risk factor.

Though laryngeal cancer is infrequent compared to cancer of the breast, lung, and prostate, the literature regarding this disease is substantial. This apparently disproportionate body of writing reflects the perceived importance of this neoplasm, which is in turn related to its potential impact on people's communicative ability: the threat to a patient's vocal organ is associated with profound psychological and socioeconomic overtones.

Originally, larynx cancer treatment focused primarily on cure by relentless and aggressive surgery. That era has been followed by the emergence of conservative partial laryngectomy, the development of more sophisticated radiation methods, and organ-sparing strategies in which chemotherapeutic, radiotherapeutic, and surgical techniques are used in a variety of combinations.

Total laryngectomy is one of the standard operations for laryngeal carcinomas. The prognosis associated with laryngeal carcinoma has improved: As the curability of laryngeal carcinoma is now >60%, many patients thus survive for a long time after surgery.

Laryngectomy changes the anatomy: The lower respiratory tract is separated from the vocal tract and from the upper digestive tract, and the laryngectomee breathes through a tracheostoma. The direct connection between the vocal tract and the upper digestive tract remains unchanged.

Figure 2 shows the anatomic structure before laryngectomy (a) and after laryngectomy (b). Before laryngectomy (Fig. 2a), air can travel from the lungs to the mouth (as represented by the arrows), and the voice can be produced and modulated. After the laryngectomy (Fig. 2b), air issuing from the tracheostoma cannot reach the mouth, and sounds cannot be produced.

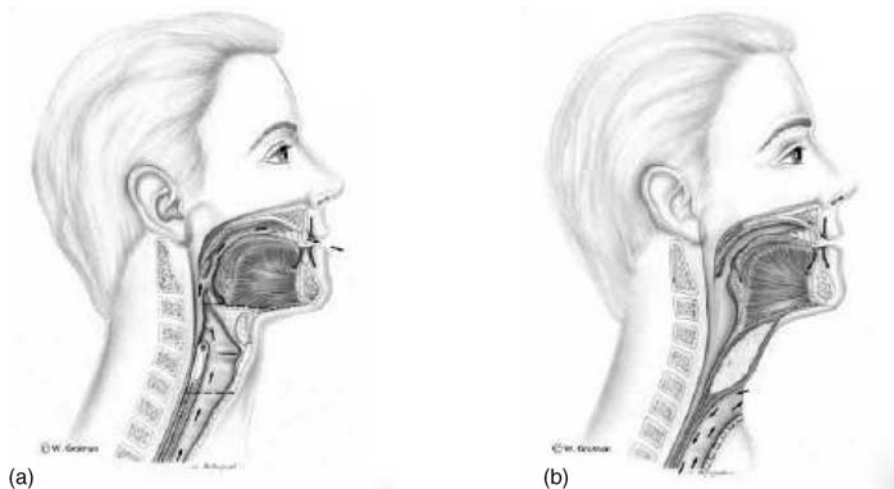

Figure 2. Anatomy before (a) and after (b) laryngectomy. (From Ref. 6.)

THE VOICE AFTER A LARYNGECTOMY

After laryngectomy, the patient is deprived of both the vibrating sound source (the vocal folds) and the energy source for voice production, as the air stream from the lungs is no longer connected to the vocal tract (1–9).

For some laryngectomy patients, the loss of speech is more important than survival itself. Consequently, a number of different methods for recovering phonation have been developed, including: esophageal speech; artificial larynx; and surgical laryngoplasty.

Numerous internal or external mechanical vibration sources have been developed that cause the air in the vocal tract to vibrate. These vibration sources can be powered by air pressure (expired air from the tracheostoma in some cases) or by an electric source with battery, and are thus classified as pneumo-larynges or electrical larynges.

ESOPHAGEAL SPEECH

Rehabilitation of the laryngectomized patient is usually a delayed process following recovery from surgery. After surgery, some patients try aphonic lip speech enhanced by buccal air trapping, while others choose written language as the method of communication.

Though most laryngectomized patients begin to learn esophageal speech, this method of speech rehabilitation requires a sequence of training sessions to develop the ability to insufflate the esophagus by inhaling or injecting air through coordinated muscle activity of the tongue, cheeks, palate, and pharynx.

Patients are encouraged to attempt esophageal sound soon after they are able to swallow food comfortably and learn to produce esophageal sound by trapping air in the mouth and forcing it into the esophagus. This produces a “burp-like” tone that can be developed into the esophageal voice.

There are various techniques for transporting air into the esophagus.

With the injection technique, the tongue forces air back into the pharynx and esophagus. This takes place in two stages, with the tongue forcing the air from the mouth back

into the pharynx in the first stage, and the back of the tongue propelling the air into the esophagus in the second stage. For air to be transported into the esophagus, it is extremely important that these two stages be correctly synchronized.

With the inhalation method of esophageal speech, the patient creates a pressure in the esophagus that is lower than atmospheric pressure. As a result of this pressure difference, air will flow through the mouth past the upper segment of the esophagus into the lower esophagus. The patient will need to inhale air to be able to create a low endotheracic and esophageal pressure.

The last technique of capturing air is by swallowing air into the stomach.

Voluntary air release or “regurgitation” of small volumes vibrates the cervical esophageal inlet, hypopharyngeal mucosa, and other portions of the upper aerodigestive tract to produce a “burp-like” sound. Articulation by the lips, teeth, palate, and tongue produces intelligible speech.

Esophageal speech training is time consuming, frustrating, and sometimes ineffective.

Its main disadvantage is the low success rate in acquiring useful voice production, which varies from 26 to 55%. In addition, esophageal speech results in low-pitched (60–80 Hz) and low intensity speech, whose intelligibility is often poor. Age is the most important factor in determining success or failure: older patients are less successful in learning esophageal speech.

The airway used to create the esophageal voice is shown in Fig. 3. Direction of flow is indicated by the arrows, making it possible to distinguish between the pulmonary air used for breathing and the mouth air used for speech.

THE ELECTRONIC ARTIFICIAL LARYNX

Wright introduced the first electrolarynx in 1942. The most widely used electronic artificial larynx is the handheld transcervical device, or electrolarynx. This electrical device contains a vibrating diaphragm, which is held against the throat and activated by a button to inject vibratory energy through the skin and into the hypopharynx. By mouthing

Figure 3. Oesophageal speech. (From Ref. 6.)

words, the laryngectomy converts the vibrations into a new, low frequency voice for speech.

An example of electrolarynx application is shown in Fig. 4, where it is possible to distinguish the airway from the sound way and the positioning of the device in contact with the neck. Examples of commercial electrolarynges are shown in Fig. 5.

The same operating principle has been used in recent years to develop a transoral device (Fig. 6), which is placed in the mouth, where it is housed in an upper denture or an orthodontic retainer. The system consists of a control circuit, a loud speaker, and rechargeable batteries positioned inside the denture, as well as a charging port so that the batteries can be recharged outside the mouth.

FROM THE PNEUMOLARYNX TO THE VOICE PROSTHESIS

The artificial larynx has undergone many transformations over the years, and continues to do so today. The first types

Figure 4. Electrolarynx speech. (From Ref. 6.)

Figure 5. Examples of commercial electrolarynx. (From Ref. 5.)

of pneumolarynges, which included neck or mouth types and internal or external types were developed in 1860, when the first attempts at voice rehabilitation through surgery or prosthetization were made. A device was used to direct air from the lungs via a small tube to the mouth (1,3,5,7,9).

Experimental research started in 1860 with Ozermack and Burns, though it was not until 1874 that Billroth used an internal prosthesis designed by Gussenbauer (Fig. 7). This device was fitted in the trachea via the stoma with a cannula featuring a branch that entered the oral cavity.

Other similar prostheses were developed and used (Gosten, Gluck, etc.). Results, however, were not particularly satisfactory, as these devices were plagued by problems, such as tissue necrosis and leakage of food and liquids into the windpipe and lungs, thus causing infections (i.e., pneumonia).

Figure 8 shows the external prosthesis developed by Caselli in 1876. Figure 9 shows the application of the external prosthesis developed by Briani in 1950.

Figure 8. The Caselli prosthesis. (From Ref. 3.)

Figure 9. The Briani prosthesis. (From Ref. 3.)

Figure 10. Example of removable prosthesis (Bivona).

Since 1960, surgical technique has been improved and a number of different types of prosthesis have been invented that take the importance of reproducing a voice that is similar to the original voice into account.

Tracheoesophageal puncture (TEP) or fistula with a voice prosthesis is the most popular of the new techniques, and has become the standard method of voice restoration after laryngectomy. However, it is usable only for selected patients.

Singer and Blom introduced the first TEP in 1980 (7,8). The aim was to create a permanent fistula (puncture or shunt) into the posterior tracheoesophageal wall between the trachea and the esophagus tract, so the pulmonary air can shunt from the airway into and up the esophagus. In this way, the vibration of the anatomic structures produces a noise.

A removable or fixed one-way type prosthesis can be positioned in the fistula.

The removable, or nonindwelling, prosthesis (Bivona, Blom-Singer duckbill) can be removed daily for cleaning by the patient, and is taped to the peritracheostomal skin. Figure 10 shows a photo of two Bivona valves; lengths differ in order to adapt the prosthesis to the patient.

The fixed, or indwelling, prosthesis cannot be removed daily, but is surgically placed in the fistula under local anesthesia. The operating principle of this type of prosthesis (known as a phonatory valve or voice button) can be explained with reference to Fig. 11.

Pulmonary air can be pushed through the valve into the esophagus for speech during expiration in two ways: by the laryngectomee, who covers the tracheal stoma with a finger (bottom left, Fig. 11) or automatically by a tracheostoma breathing valve (bottom right, Fig. 11).

Figure 11. Speech with phonatory prosthesis. (From Ref. 6.)

The tracheostoma breathing valve contains an elastic diaphragm installed in a peristomal housing, which permits normal respiration during silent periods. Expiratory air for speech shuts off the pressure-sensitive diaphragm, and is thus diverted through the valve into the esophagus. This device eliminates the need for manual stoma occlusion during speech.

In both cases, air from the lung reaches the esophagus and causes the mucosal tissue to vibrate. The resulting sound can be modulated by the mouth, teeth, oral cavity, and so on, to produce the new voice.

Most speakers that have prosthesis do not have difficulties with articulation, rate of speech, or phonatory duration.

If esophageal speech depends on gulping or trapping air using the phonatory valve, the resulting speech depends on expiratory capacity. Voice quality is very good, and may resemble the "original" voice.

Poor digital occlusion of the tracheostoma as well as poor tracheostoma valve adherence allows pulmonary air to escape from the stoma prior to its diversion through the prosthesis into the esophagus for voice production. In fact, the bleeding off of pulmonary air limits phonatory duration and, therefore, the number of words that can be spoken.

The one-way valve design of the prosthesis prevents aspiration (of food and liquid) from the esophagus to the trachea. An example of a phonatory valve is shown in Fig. 12 (11,12). The prosthesis illustrated in this sketch consists of an air-flow tracheal entry, whereby an endo-

Figure 12. Sketch of phonatory valve or prostheses.

Figure 14. Resistance of commercial valves.

Figure 13. Examples of fixed commercial prosthesis. (Staffieri, Groningen standard, Groningen low pressure, Panje, Provox).

tracheal retention collar is connected to the mucosa (or tracheal flange), a hollow cylindrical tube (whose length depends on the patient's physical characteristics) connecting the trachea to the esophagus, an endoesophageal flange, and a dome (or hat) that closes the proximal endoesophageal end of the tube. Via the razor-thin slit (or esophagus exit), the hat enables airflow to pass from the trachea to the esophagus when there is a positive differential pressure, and prevents the reverse flow of liquid (or food) when the differential pressure becomes negative. The arrows represent the airflow paths.

Hat shape and the extension of the razor-thin slit can differ according to valve type. The razor-thin slit may be located at the base of the hat (Staffieri, Groningen low pressure), at the center of the hat (Panje, Groningen standard), or inside the hollow tube (Provox, Blom-Singer).

Though valve geometry and shape may vary, the operating principle remains the same.

Several commercial prostheses are shown in Fig. 13: from left to right, they include the Staffieri, Groningen standard, Groningen low pressure, Panje, and Provox types.

Fixed and removable prostheses are available in different lengths, which usually range from 6 to 12 mm to enable the surgeon to select the dimensions that are best suited to the patient's physical characteristics, for example, posterior tracheoesophageal wall thickness.

To compare valve performance in the laboratory, most authors use valve airflow resistance (7,11), which is defined as the ratio of pressure to flow-rate. Figure 14 shows an example of resistance versus flow-rate characteristics obtained with experimental tests on commercial valves (11).

Low resistance allows air to pass freely through the prosthesis with little effort on the part of the patient, and

is thus the most favorable condition. Different materials have been used for phonatory prostheses. For indwelling prostheses, silicone rubber is the material of choice, though other materials such as polyurethane have also been used. The most significant problem affecting voice prostheses is the formation of a thick biofilm on the esophageal surface, as the esophageal environment around the prosthesis provides ideal growing conditions for bacteria, fungi, and yeast.

In this area, secretions from the trachea, the mucous membranes in the oropharynx and esophagus, and saliva from the oral cavity create an optimal "pabulum" for microorganisms, which can thus adhere to the prosthesis surface. Though biofilm does not lead immediately to valve malfunction, colonies growing around the prosthesis can increase airflow resistance, blocking the valve or preventing it from closing correctly. This causes saliva to leak from the oral cavity through the esophagus lumen. The biofilm also grows into the valve material (silicone rubber).

Massive microorganism growth is more frequent in indwelling prostheses than in non-indwelling types, as the latter are regularly removed and cleaned.

The first step of this colonization is the formation of a very thin layer of organic origin, called a conditioning film. Microorganisms adhere to the thin layer of saliva conditioning film on the inner esophageal surface of the device and form the first stratum of biofilm, which is nearly impossible to eradicate. There are few methods for reducing the growth of bacteria and fungi: One possibility is to apply (through oral instillations) antimycotic drugs that reduce biofilm formation and increase prosthesis life (1,2,7,8,13,14). The valve has a limited life, varying from ~4 to 8 months. After this period, the valve must be removed and changed in an outpatient procedure because of a dysfunctional mechanism caused by the biofilm, which causes food and liquids to leak from the esophageal area to the trachea.

Figure 15 shows a new Provox valve (left) and a Provox valve after eight months of use by a patient (right). Silicon rubber deterioration caused by microbial action and adherent deposits of microorganisms is clearly apparent.

Current work with voice prostheses focuses on improving their aerodynamic characteristics (low airflow resistance) and developing more resistant materials that can extend the life of the device. For the patient, in any case, the most important thing after a total laryngectomy is to be hopeful: a prosthesis can provide a new voice, improving the quality of life.

INTRODUCTION

Ridley's implantation (1949) of the first intraocular lens (IOL) marked the beginning of a major change in the practice of ophthalmology. The IOLs are microlenses placed inside the human eye to correct cataracts, nearsightedness, farsightedness, astigmatism, or presbyopia. There are two types of IOLs: anterior chamber lenses,

which are placed in the anterior chamber of the eye between the iris and the cornea, and posterior chamber IOLs, which are placed in the posterior chamber behind the iris and rest against the capsular bag. Procedures for implanting the IOLs and technologies for manufacturing them in various sizes, thicknesses, and forms as well as with various materials progressed tremendously in the last decade. Multifocal IOLs are one of the important signs of this progress. While monofocal IOLs, the most commonly used, are designed to provide clear vision at one focal distance, the design of multiple optic (multifocal) IOLs aims to allow good vision at a range of distances.

INTRAOCULAR LENSES: WHAT AND WHY?

An intraocular lens, commonly called IOL, is a tiny artificial lens implanted in the eye. It usually replaces the faulty (cataractous) crystalline lens. The most common defect of the natural lens is the cataract, when this optical element becomes clouded over. Prior to the development of IOLs, cataract patients were forced to wear thick coke bottle glasses or contact lenses after the surgery. They were essentially blind without their glasses. In addition to IOLs replacing the crystalline lenses, a new family of IOLs, generally referred to as phakic lenses, is nowadays subject of active research and development. (Phakos is the Greek word for lens. Phakic is the medical term for individuals who have a natural crystalline lens. In Phakic IOL surgery, an intraocular lens is inserted into the eye without removal of the natural crystalline lens.) These IOLs are placed in the eye without removing the natural lens, as is completed in cataract surgery. They are used to correct high levels of nearsightedness (myopia) or farsightedness (hyperopia).

An IOL usually consists of a plastic lens with plastic side struts called haptics to hold the lens in place within the capsular bag. The insertion of the IOL can be done under local anesthesia with the patient awake throughout the operation, which usually takes <30 min in the hands of an experienced ophthalmologic surgeon (Fig. 1).

HISTORICAL OVERVIEW

The idea of the IOL dates back to the beginning of modern cataract surgery when Barraquer developed keratomileusis (1). However, the first implantation of an artificial lens in the eye was probably attempted in 1795 (2). References to the idea of the IOL before World War II in ophthalmic literature are rare. There has been mention of limited animal experiments using both quartz and plastic material performed in the 1940s, but nothing had come of these efforts (3).

The most important step toward the implantation of IOLs came as a result of World War II pilots, and the injuries sustained when bullets would strike the plastic canopy of their aircraft (Fig. 2), causing small shards of plastic to go into their eye. In the late 1940s, Howard Ridley was an RAF ophthalmologist looking after these unfortunate pilots and observed, to his amazement, little or no reaction in cases in which the material had come from

Figure 1. Implantation of an IOL: Since the natural lens is left undisturbed, the operation is much simpler than a cataract operation. The entire procedure consists of making a small incision at the edge of the cornea and placing the appropriate tiny plastic lens in the space between the iris and the cornea, (the anterior chamber). Stitches are used to close the incision.

Spitfire planes. He then concluded the poly(methyl methacrylate) (PMMA) material of the canopies (windshield) was compatible with eye tissue (4). This observation sparked the idea for inserting an artificial lens in the eye. Ridley, who was convinced this lens should be placed in the posterior chamber, designed a disk-shaped lens, much like the natural lens, with a small peripheral flange allowing him to hold the lens with forceps (4). The artificial lens, made entirely of PMMA, weighed slightly >100 mg in air and was ~8.35 mm in diameter. In several cases, he attempted to implant the lens following intracapsular surgery using the vitreous base for support (5). On November 29, 1949, the first successful IOL implantation was performed at St. Thomas Hospital in London (6,7). While far from perfect, the procedure worked well enough to encourage

Figure 2. Invention of the IOL: During World War II, Fighter pilots were sometimes involved in accidents where the plastic windshield (canopy) of their aircraft was shattered. Doctors found that fragments of the canopy that entered the eye were tolerated by the eye tissues. They might remain inside the eye for years, and the eye would not react.

further refinement. Then, over a decade, Ridley implanted several hundred IOLs (8).

Though Ridley was ahead of his time, his method was subject to serious criticism. Complications were common and failure rates $> 50\%$ were often contemporaneously quoted. Fixation was dependent on the formation of adhesions between the iris and the capsule. Several ophthalmologists strongly opposed to his procedure. Implantation in the anterior chamber was technically easier and was compatible with intracapsular surgery. Also, fixation could be achieved at the time of implantation by adding haptic struts to the lens that could be wedged into the angle. The first anterior chamber lens was implanted by Baron in 1952 (8).

To make intraocular lens implantation safe, developments in lens design and surgical techniques were required. Lens implantation did not become widely adopted as an integral part of cataract surgery until the 1980s. Key advances were the introduction of viscoelastic fluids to protect the cornea during implantation and flexible haptics to enhance long term stability of the IOL (9).

With traditional single vision monofocal IOLs, people generally experience good vision after surgery at a single focal point, either near or at a distance. The multifocal IOL (10) was designed in the mid-1990s to provide a full range of vision with independence from glasses in most situations.

Besides, the invention of phakic lenses is no less important than Ridley's invention. These IOLs were introduced by Strampelli (11) and later popularized by Barraquer in the late 1950s (12). Phakic IOLs are becoming more popular because of their good refractive and visual results and because they are easy to implant in most cases (13). In the beginning, the design was a biconcave angle-supported lens. These lenses were abandoned following serious angle- and endothelium-related complications. By the late 1980s, Baikoff (14,15) introduced a myopia lens with Kelman-type haptics (16). This design had many problems, leading to its design modification a number of times. Fyodorov, the inventor of radial keratotomy (17), introduced the concept of a soft phakic lens in the space between the iris and the anterior surface of the crystalline lens (18).

Based on earlier works of Worst, winner of the Binkhorst Award for innovation in ophthalmology in 1976, Fechner introduced phakic myopia lens of iris claw design in 1986 (19). This IOL is then referred to as Worst-Fechner lens (20). Many companies around the world manufactured it in various models. Today, people usually identify it by the name of Artisan IOL.

MATERIAL OF THE IOL

Many factors, such as the optical quality of the system of the eye (aberrations, . . .), presence of inflammation, cost, and wound size, depend on the material and the form of the IOL.

From the point of view of flexibility, there are two families of IOLs: foldable and inflexible lenses. Foldable IOLs are generally made of acrylic or silicone. They can be rolled up and inserted through a tube with a very small incision not requiring any stitches. Inflexible IOLs, typically made of PMMA, require a larger incision because they are unfoldable. Most lenses are biconvex, thus optically equivalent upside down. However, most lenses have haptics which are generally angled to push the posterior optics.

Four basic materials are used for IOLs: PMMA, silicone, acrylic and collamer. Other materials are also used. For example, some manufacturers replace silicon by a hydrophilic biocompatible polymer, called collamer. Many IOLs have been made from PMMA plastic, the same plastic the original hard contact lenses were made of. Silicon IOLs are foldable. Folding an IOL allows it to be inserted through a smaller incision. A smaller incision heals faster and induces less postop astigmatism. Some foldable lenses are now being made of acrylic plastic. While acrylic and silicone lenses are very popular, PMMA is the time-tested material but, as stated above, requires a large incision. Silicone oil is also a problem for silicone IOLs in that the view of the fundus can be severely degraded. This is less so for PMMA and hydrophobic acrylic IOLs and least for hydrophilic acrylic. Although this is a relative contraindication for silicone IOLs in the face of significant vitreoretinopathy, a solvent exists that eliminates the problem (21). Collamer is a new hydrophilic material just recently released that has shown some interesting properties. It has been shown to exhibit less internal reflectance than other lens materials including silicone, acrylic, and PMMA (22). It reduces the risk of long-term inflammation (23). Table 1 summarizes the characteristics of the four materials.

VARIOUS PARAMETERS FOR IOLs

Are age, race, and sex important parameters for IOL implantation? Age at which surgery is performed turned out to be of great importance (24–28). The ideal age should be at around 18 years when the refraction stabilizes. However, in specific circumstances, in the interest of the minor patient, the parents and the surgeon can opt to perform phakic lens implantation at an earlier age. Studies

Table 1. Four Commonly Used IOLs Materials and their Advantages and Drawbacks

Material	Flexibility	Advantages	Drawbacks
PMMA	Rigid	Low cost, less inflammation, long-term experience, good biocompatibility	larger incision, not foldable
Silicone	Foldable	Smaller incision, injectable	high cost, more inflammation, cannot use with silicon oil
Collamer	Foldable	Smaller incision, less inflammation, very good biocompatibility	high cost, short term experience
Acrylic	Foldable	Smaller incision, less inflammation, high refraction index (thin IOL), good biocompatibility	high cost

of the suitable age of IOL implantation in children have been carried out (24). A 3-year-old child has been qualified with IOL implantation, the child younger than 9 years old should be implanted with a normal adult IOL and then corrected with glasses, and a child after 10 years old should be directly implanted with a proper dioptric IOL (24). Some researchers evaluated the influence of cataract surgery on the eyes of children between 1 and 5 years old. They concluded that cataract surgery, either extraction with or without IOL implantation, did not retard axial elongation in children above 1 year old (25). Comparisons between children with congenital or developmental lens opacities who underwent extracapsular cataract extraction and children with normal eyes have been carried out (26). The pattern of axial elongation and corneal flattening was similar in the congenital and developmental groups to that observed in normal eyes. No significant retardation or acceleration of axial growth was found in the eyes implanted with IOLs compared with normal eyes. A myopic shift was seen particularly in eyes operated on at 4–8 weeks of age and it is recommended that these eyes are made 6 D hyperopic initially with the residual refractive error being corrected with spectacles (26).

To our knowledge, IOL implantation does not depend on race and sex.

OPTICAL QUALITY

Two optical qualities are distinguished: the intrinsic optical quality of the IOL and the optical quality of the system of the eye including the IOL. Many factors, such as the material and the geometrical profile of the IOL, influence the intrinsic quality of this optical element. Axial shift (decentration), transversal rotation (not around the optical axis), and deformation (mechanical stresses, . . .) of the IOL are examples of factors affecting the optical quality of the whole system of the eye even in case the IOL alone is a perfect optical element. Thus, the optical quality of the IOL is certainly important. However, for vision, the determinant factor is the optical quality of the whole system of the eye in which the IOL is implanted. Several studies have been undertaken to assess the optical quality of the IOL and the optical quality of the whole system of the eye. Before progressing in this section, let us briefly introduce the notion of optical quality.

Aberrations

Stated in wave optics, the system of the eye should transform the input wavefront into a perfect convergent spherical wavefront that has the image point as center (29–31). Note that an optical wavefront represents a continuous surface composed of points of equal phase. Thus all image-forming rays, which travel normal to the exit spherical wavefront, meet in the focal point in phase, resulting in maximum radiant energy being delivered to that point. In reality, this situation never occurs. The rays modified by the optical system do not converge entirely to a common point image. For one object point correspond several image points that form a blurred image. This deviation from the ideal case is called optical aberration, or merely aberration,

and is a measure of the optical quality of the system. Aberration can be quantified either with respect to the expected image point or to the wavefront corresponding to this ideal point. If the real output wavefront is compared to the ideal one, it is called the difference between them wavefront aberration (29). All human eyes suffer from optical aberrations that limit the quality of the retinal image (32–36). Several metrics have been proposed to measure the optical quality of the system of the eye (37–41). Let us return back to IOLs now. Optical quality of multifocal IOLs will be treated in the section devoted to this kind of lens.

Optical Quality of the IOL

The optical quality of IOL was the subject of intensive studies. Several common but some contrasted results have been obtained. An exhaustive study goes beyond the scope of this document. We limit our attention to some recent results. Tognetto et al. (42) evaluated the optical quality of different IOLs by using an optical test bench. The purpose of the study was to evaluate the optical quality of IOLs and not to evaluate the optical performance of these lenses once implanted. Three randomly acquired samples of 24 different models of foldable IOLs were compared. The conclusion is that different IOLs can transmit different spectra of spatial frequencies. The best frequency response was provided by acrylic IOLs, particularly those with an asymmetrically biconvex profile. This could be due to a reduction of optical degradation provided by this type of profile. A lens with a higher frequency response should create a better quality of vision once implanted, and the frequency response should therefore be considered when choosing the intraocular lens model (42).

Negishi et al. (43) evaluated the effect of chromatic aberrations in pseudophakic eyes with various types of IOLs. Their results show that longitudinal chromatic aberrations of some IOLs may degrade the quality of the retinal image. They concluded that attention must be paid to the detailed optical performance of IOL materials to achieve good visual function.

In a comparative study (44), Martin found that the collamer IOL reduced the number of induced higher order aberrations when compared with acrylic and silicone lenses. Indeed, he found that the collamer IOL has 55–117% fewer induced higher order aberrations than acrylic or silicone materials. As a consequence, it produces less postop glare. He concluded the collamer lens provides clearer vision than the other lenses.

Optical Quality of ARTISAN Lenses

Brunette et al. (45) evaluated the optical quality of the eye before and after the insertion of an ARTISAN phakic intraocular lens for the treatment of high myopia (range –20.50 to –9.75D). Consecutive patients implanted with the ARTISAN lens by a single surgeon were prospectively enrolled. One eye per subject was tested. The wavefront aberration was calculated from images recorded with a Hartmann-Shack sensor (46,47). The PSF and the MTF were also computed from the wavefront aberration. It was concluded that preliminary data using the Hartmann–Shack wavefront sensor have not revealed a tendency

toward deterioration of the optical performance following the insertion of an ARTISAN lens for the treatment of high myopia. The Hartmann–Shack sensor is a useful tool for the objective assessment of the image optical quality of eyes with a phakic intraocular lens.

MULTIFOCAL IOLs

Unlike the natural lens, the curvature of current intraocular lenses cannot be changed by the eye. Standard intraocular lenses provide good distance vision, and the patient needs reading glasses for near vision. Newer bifocal intraocular lenses give distance vision in one area and near vision in another area of the vision field. How does it work?

The basic idea consists in providing a lens with two posterior focal points instead of one. The IOL is no longer monofocal. It becomes bifocal. Two solutions are possible: refractive or diffractive bifocal lens. A third solution consists in combining both approaches together.

Diffractive Lenses

The idea comes from the principle of the Fresnel zone plate. It consists in designing a binary diffractive phase element so when the incident wave comes across this diffractive element, all the resulting waves, coming from all points of the zone plate, arrive in phase at a certain (focal) point. They then superimpose constructively, yielding a focusing behavior. As shown in Fig. 3, waves traveling along various segments arrive in phase at the focal point since the optical paths differ by a multiple of the wavelength. To fulfill this condition, the thickness d is chosen so that it introduces a phase shift of π : $d = (2k + 1) \lambda / [2(n - 1)]$ (optical path: $(2k + 1) \lambda / 2$). In Fig. 3, $k = 0$, yielding $d = \lambda / [2(n - 1)]$, where n is the refraction index of the diffractive lens. The radii of the rings (Fig. 3) verify the following rule:

Figure 3. Binary diffractive phase element: Fresnel zone plate. Waves traveling along various segments arrive in phase at the focal point since the optical paths differ by a multiple of the wavelength. To fulfill this condition, the thickness d is chosen so that it introduces a phase shift of π : $d = (2k + 1) \lambda / [2(n - 1)]$ (optical path: $(2k + 1) \lambda / 2$). In the figure, $k = 0$.

$r_m = \sqrt{m} \cdot r_1 = \sqrt{m\lambda f}$, where r_1 is the radius of the smallest circle and f is the focal length. Without grooves on the diffractive, the waves traveling along the segments, represented by dashed lines in Fig. 3, would arrive in phase opposition with respect to other waves. In reality, the binary form (two phase levels) of the diffractive lens does not fully ensure the condition of coming in phase at the focal point. For rigor, several phase levels are required (Fig. 4). In general, the diffraction efficiency η , which is defined as the ratio of the focused energy to the incident energy, increases with the number of phase levels L according to the following formula (48): $\eta = \sin^2(\pi/L) / (\pi/L)^2$. Using two phase levels (binary), only 41% of the energy is focused. The rest is scattered in space. A four level diffractive lens focuses 81% of the input energy (it scatters only 19% of the incident energy).

To obtain a bifocal diffractive lens, we need to focus rays on two focal points at distances f_1 and f_2 . It can be done by providing two series of zones (rings). The first series, the inner one, involves radii verifying $r_m^{(1)} = \sqrt{m\lambda f_1}$ (with $m = 1, 2, \dots, M$), whereas the radii in the second series, the outer one, satisfy the condition $r_p^{(2)} = \sqrt{p\lambda f_2}$ (with $p = M+1, \dots, P$). To obtain a multifocal diffractive lens, we need more series of radii.

Refractive Lenses

An alternative to obtain a multifocal length consists in modifying the surface profil of a conventional biconvex lens so that it provides two or more different focal points for light convergence. The technique consists in designing a spherical refractive surface that has additional refracting surfaces to give a near add (Fig. 5), or a near and intermediate add. The principle of multifocal refractive lenses is illustrated in Fig. 6a. Refractive IOLs with several focal points are commercialized in various models. For example, one of the models includes five refractive zones targeting distance, intermediate and near vision (Fig. 6b). The IOL uses continuous aspheric optics to ensure that 100% of the light entering the eye reaches the retina. The lens uses five concentric zones with the first, third, and fifth zones being far dominant and second and fourth zones being near dominant (49). The light distribution is arranged so that 50% of light is distant focussed, 13% is focussed for intermediate vision and 37% for near vision. The near add

Figure 4. Bifocal hybrid refractive/diffractive IOL: Anterior surface broken up into a refractive zone and a second zone composed of concentric diffractive rings.

Figure 5. Bifocal refractive IOL: Spherical refractive surface that has additional refracting surfaces to give a near add.

comprises of 3.5 dioptre intraocular power equivalent to a 2.75–2.85 add in the spectacle plane (49).

Optical Quality of Refractive and Diffractive Lenses

This discussion will be limited to some recent results. Pieh et al. (50) compared the optical properties of bifocal diffractive and multifocal refractive intraocular lenses. The IOLs were manufactured by different companies. A model eye with a pupil 4.5 mm in diameter was used to determine the point spread function (PSF) (30,51) of the distance focus and near focus of the IOLs to compare them with PSFs of foci of corresponding monofocal lenses. For interpreting the PSFs the through focus response, the modulation transfer function (MTF) (51), and the Strehl ratio (51) were evaluated. They concluded the modulation transfer functions

Figure 6. Multifocal refractive IOLs: (a) several refractive surfaces with different curvatures. Each one provides a focal point (b) a commercial zonal progressive IOL with five concentric zones on the anterior surface. Each zone repeats the entire refractive sequence corresponding to distance, intermediate and near vision, resulting in wide-range vision.

reveal comparable properties for distance vision and a superiority of the bifocal diffractive lens over the refractive multifocal lens for near vision. This mean due to the fact that the incoming light is distributed over different zones in the refractive lenses.

Hybrid Lenses

Diffractive and refractive optics (Fig. 4) can be combined. In this type of lens, the basic spherical refractive surface is broken up into a refractive zone and a second zone composed of concentric diffractive rings. This combination of zones creates two different focal points for light convergence, one for near objects and one for distant objects. Hybrid IOLs are basically bifocal lenses (Fig. 4). The usual strategy has been to have a distance component with a near component targeting the usual near distance. However, multifocal hybrid lenses are possible.

IOLs AND ACCOMODATION

New research into accommodating intraocular lenses indicates that many patients who get these implants will enjoy good distance and near vision (52). The first hint that intraocular lens implants could accommodate came back in 1986, when Thornton used A-scan biometry to report on anterior movement of a three-piece loop IOL (53). He found that this forward movement allowed some patients to have good uncorrected distance and near vision simultaneously.

The mechanisms of presbyopia remain incompletely understood. A review of the variety of such mechanisms has been presented by Atchison (54). Accommodation in the youthful, phakic human eye is accomplished by contraction of the ciliary body and subsequent release in the resting tension of the zonular fibers by which the crystalline lens is suspended, resulting in increased lens curvature (55–57). The weight of current evidence seems to suggest that although some loss of ciliary body action might contribute to reduced accommodation (58), significant ciliary body function persists into advanced maturity, and that loss of lens and capsule elasticity in concert with changes in the geometry of zonular attachments are probably most culpable in producing the distress of presbyopia (59). If so, replacement of the crystalline lens with a lens that responds to ciliary body contraction should restore accommodative function (60). Attempts to replace the crystalline lens by refilling the capsular bag with appropriately deformable gels have been made (59,61,62). McLeod et al. aimed at designing an accommodating intraocular lens with extended accommodative range that can be adapted to current standard phacoemulsification and endocapsular implantation technique (60). They concluded that a dual optic foldable IOL design can increase the optical effect of a given displacement and suggests improvements for accommodating intraocular lenses.

LIGAMENT AND TENDON, PROPERTIES OF

G AZANGWE
RM ASPDEN

INTRODUCTION

Tendons and ligaments are fibrous connective tissues that play a mechanical role in the stability and locomotion of the body by transmitting tension. Unlike muscle, which actively contracts, ligaments and tendons are passive. Tendons transmit mechanical forces from muscle to bone, whereas ligaments join bone to bone. Both tendons and ligaments contain relatively few cells (1), and their extracellular matrices are made up of several components. These components are combined in various proportions, and with different organizations to give mechanical properties appropriate to the function of the particular tendon or ligament. There have been a number of reviews in recent years covering specific ligaments, for example, in the rabbit (2), or tendons, such as the human achilles (3), or aspects of their behavior such as healing and repair (4). In this article, the emphasis is on properties the ligaments have in common, which will provide an insight into how and why they behave as they do. This will be based around their functioning as fiber-reinforced materials whose properties are regulated by the cells they contain that produce and maintain the extracellular matrix.

First, this article considers the components of the tissue, not from a biochemical point of view, but as components

that may be combined to produce mechanically stable materials. The constituents are considered in terms of the matrix in which are embedded fibers of collagen and varying amounts of elastin. Following this is a discussion of the ways these components interact in ligaments and tendons to yield composite materials with the required mechanical properties. A consideration of some of the ways in which ligaments and tendons may be damaged, and the mechanisms by which they might recover or be repaired, leads to a final, brief review of their surgical replacement. A small section on work being conducted in order to produce a tissue engineered ligament and tendon is also included.

COMPONENTS

Tendons and ligaments are composed primarily of collagen fibers surrounded by a matrix. Here the matrix refers to all the materials that surround the collagen fibers providing both structural support and a medium for diffusion of nutrients and gases. Note this is in contrast to its use in biological terms in which it generally includes the fibrous components. The matrix contains proteoglycans and adhesive glycoproteins and is highly hydrated (typically 65–80% water) (5,6).

Collagen

Collagen fibrils are able to reinforce the weak matrix because of their much greater stiffness and strength in tension (7). The collagen molecule is a long, stiff rod made up of three polypeptide chains wound as a triple helix structure (8). Each fibril is like a rope in which linear molecules are packed together with their axes parallel, within a few degrees, to the fibril axis. Molecules are held together by covalent cross-links so that the fibril is very strong in tension. The regular arrangement of molecules along the axial direction in a fibril gives rise to the characteristic periodicity of 67 nm, which may be seen in electron micrographs (Fig. 1). Although to date, 21 genetically different types of collagen have been identified, types

I and III fibrous collagens dominate in tendons and ligaments.

There is a hierarchical structure within tendons (9) that has been reviewed often [e.g., (10)], and that appears to have been based on an earlier description of keratin. In this model, collagen molecules are arranged successively into microfibrils, subfibrils, fibrils, and fascicles that are finally packed into the tendon sheath. Evidence for micro- and subfibrils is still equivocal, but a principal mechanical structure is the fibril. These generally have a unimodal distribution of diameters in the newborn, typically a few tens of nanometers, but assume a bimodal distribution in mature tendons and ligaments with mode diameters typically $\sim 100\text{--}300$ nm (11,12). The ends of fibrils are rarely seen in electron micrographs, and even when they are seen, it is not clear whether they are artifacts of sectioning. Fibrils appear to grow by end-to-end addition of short fibrils and there is evidence from 12-week old mouse skin that fibril tips may eventually fuse with the central region of other fibrils to create a meshwork (13). It is not known whether this happens in tendon or ligament or whether the fibrils are as long as the tendon or ligament. Fibrils are arranged into fascicles, which are $\sim 80\text{--}300$ μm in diameter and these have a "crimped" morphology that is seen most clearly using polarized light (6,9). This crimp is generally described as a planar zigzag with a sharp change in direction of the collagen fibrils with a periodicity of $\sim 200\text{--}300$ μm (Fig. 2). On application of a tensile load, initial elongation of the fiber requires a relatively low stress because it simply leads to removal of the crimp (14,15). Once the crimp is removed, the fibers become very stiff. This crimp structure, which is also found in ligaments, explains the characteristic shape of the stress-strain curve for ligaments and tendons (14).

There are many studies of the mechanical properties of tendon and ligament. Most tendons have similar properties, because of their role transmitting forces from muscle to bone and the need to do this most efficiently (16–19). In contrast, every ligament has unique properties that fit it to its function at that particular site in the body. These may range, for example, from the highly extensible ligamentum flavum, helping control spinal posture, to the relatively stiff cruciate ligaments in the knee. Most information on the mechanical properties of collagen has been inferred from experiments on tendon; and though they contain a large proportion of collagen, $\sim 70\text{--}80\%$ of the dry weight, the fibrils are surrounded by matrix, and therefore

Figure 2. Schematic diagram of the crimp structure in collagen fibers seen from the side. (a) relaxed state [this is grossly exaggerated; the true crimp angle (θ) is $\sim 15^\circ$]. As the fiber is stretched, the crimp straightens out (b) until at strains of a ~ 0.03 , the fiber becomes straight (c), at which point it becomes much stiffer.

the tissue is really a composite material (6). This makes it difficult to separate the behavior of the individual components.

Proteoglycans

The proteoglycans found predominantly in tendon and ligament belong to the small leucine-rich proteoglycan (SLRP) family; decorin, biglycan, lumican, and fibromodulin though there are small amounts of the large proteoglycans aggrecan (20,21) and versican (21,22). The SLRPs all comprise a repeating structure that is rich in leucine residues, between 13 and 16% of all residues (23). They are present in different tissues in differing amounts and appear at different stages of development (24). Their function is poorly understood though gene knockout studies in mice have shown marked osteopenic effects on bone, skin laxity, and irregular collagen fibers in tendon (25). Most of these SLRPs have one or two glycosaminoglycan (GAG) chains of varying lengths attached, generally either dermatan sulfate or chondroitin sulfate, which can interact electrostatically with collagen (26,27). The proteoglycan decorin has been found to be localized in the tissue to a specific region of a collagen fibril (28). It is also reported to play a regulatory role in collagen fibrillogenesis, by affecting fibril radius (13), and increases the strength of uncross-linked fibers (29,30). In regions where tendons pass over bone and are subjected to compressive loading in addition to tension, a fibrocartilaginous tissue containing large amounts of aggrecan and biglycan develops (31,32). The adhesive glycoproteins include fibronectin and thrombospondin (33–35), both of which contain possible attachment sites for cells. In humans, these were reported to be more common in the tendon sheath than in the fibrous bulk (36) and fibronectin was found to be up-regulated at sites of injury (34).

The matrix is weak in shear; that is, if it is loaded in compression, it tries to slide out sideways unless it is contained. This behavior may be readily seen in jelly (Jello in the United States) and is not surprising given its high water content, since fluids simply flow when sheared. It is not easy to measure the shear strength of matrix. Proteoglycans at similar concentrations have a very low shear strength (37); however, matrix may be stiffer than this because of the interactions between its macromolecular components. An analysis of the behavior of tendon suggests that its matrix would have a shear modulus of ~ 100 kPa (38). Because of this low stiffness in shear, the matrix alone is not well suited to bearing loads. Also, its proportion in ligament and tendon is quite low, $\sim 10\text{--}20\%$ of the dry weight. The ways in which matrix may transmit stress to the fibers and prevent crack propagation will be discussed later.

Elastic Fibers

Electron microscopy reveals the presence of elastic fibers in ligaments and tendons (39,40). Elastic fibers have two components; elastic fiber microfibrils and elastin. The microfibrils have a diameter of 10–12 nm and consist of glycoproteins. Elastin is composed of mainly hydrophobic nonpolar amino acids with a high content of valine (41).

Elastic fibers are highly extensible, they do not creep and their extension is reversible at high strains. Their mechanical properties are thus very different from collagen. Most of our knowledge of elastic fibers comes from experiments on ligamentum nuchae, a ligament from the cervical spine, which contains ~70% elastin by dry weight (42). Elastin closely resembles a rubber in many respects and its mechanical properties are certainly very similar (43). Purified samples of ligamentum nuchae will extend to roughly twice their resting length before breaking.

The extensibility of a tendon or ligament depend in part on the elastin content of the tissue. Ligamentum flavum, from the spine, which may typically be strained to ~50% contains roughly 70% elastin, by dry weight (44), whereas tendon, which works at strains <4% contains only 2% elastic fibers by dry weight (1). It is fairly easy to see why highly extensible tissues have a high proportion of elastin, but not quite as easy to explain the presence of elastic fibers in a relatively inextensible tissue such as tendon. A clue is provided by some synthetic fibrous composite materials that contain two different kinds of fiber (45). Here a small proportion of strong, low stiffness fibers added to the composite produces a material that is less susceptible to failure under sudden application of load than one that contains only stiff fibers; that is, it makes the material less brittle. It may be that the small proportion of elastic fibers in tendon provide some protection against the sudden application of load that may occur, for example, if an animal is startled.

Fiber–Matrix Interactions

The combination of strong fibers in a weak matrix leads to materials that are less susceptible to mechanical damage while maintaining a high proportion of the strength of the fibers. In particular, they are less susceptible to sudden failure than a homogeneous material would be; a property called “toughness” (46). This composite nature has been recognized for many years (6) and provides a theoretical framework for understanding the properties of the tissues. It also enables some useful comparisons to be made between relatively simple synthetic composites and biological tissues in which the complexities of composition and structure make modeling very difficult. The aim is to obtain an understanding of how the similarities in the tissues, fibers in a matrix, enable them to function in general terms before considering the differences (in composition, and organization), which give them their specific properties. The function of collagen fibrils and fibers in such a composite is to withstand axial tension, since, like any rope, they have little resistance compression and flexion (7). As the tissue is stretched the matrix will try to flow and this will exert a shear force along the surface of the collagen fibers tending to stretch and orient them (7,47). This length increase, which is normally expressed as a fraction of the original length and is then termed “strain”, leads to a restoring force in the fiber that balances the applied force. The behavior is rather like a loaded spring that stretches to enable it to bear load, but returns to its relaxed length on removing the load. Similarly, collagen fibers are able to reinforce a tissue if they are oriented so that an applied

load tends to stretch them. The nature of the shear force exerted by the gel is unknown, but two simple models, those of elastic and plastic (or frictional) stress transfer, have been used to investigate stresses in the fibers and the force that has to be generated at the fiber surface to enable them to function in this way (47–49). Fibers that are shorter than the tissue are still able to provide reinforcement (50). Some fibrils observed in tissues (51) and those grown *in vitro* (52,53) appear to be tapered, rather than having a uniform radius. Analytical and finite element models of idealized single-fiber composites have shown that tapered fibers have two distinct advantages over uniform fibers: the axial stresses within the fiber are more uniformly distributed and they contain a much smaller amount of material, though their effectiveness at reinforcing is just as great. A more uniform stress within the fiber means more of the fiber is carrying a significant stress, thus making better use of the fiber, and avoids the generation of stress concentrations that are potentially damaging and could lead to fiber fracture. In addition, the volume of material in a cone, for example, is only one-third of that in a straight cylinder and, therefore, a tapered fiber incurs a far smaller metabolic cost by the cells to produce it. In straight-cylindrical fibers it has been calculated that interactions at the fiber surface do not have to be great in order to load fully the fiber. In tendon, assuming conservatively only one interaction per 67 nm D-period, it was estimated that fiber–matrix interaction forces of the order of only 10 pN was sufficient to load fully the fiber (47). These forces are similar in magnitude to van der Waals forces or hydrogen bonds. This suggests that permanent bonds or covalent interactions between fiber and matrix are not essential for the mechanical functioning of the tissue though, of course, it does not preclude them. Regulating the interaction between fibers and matrix is clearly important in this model of how the tissues function and decorin, as described above, is a prime candidate for a role in this. Changes in the concentration and orientation of collagen and its interactions with the matrix have been used to explain the dramatic changes in a similar fibrous tissue, the uterine cervix, that occur during parturition (54). The presence of the matrix around the collagen fibrils is also important when it comes to preventing crack propagation. This will be considered in more detail in the context of the tissues themselves.

LIGAMENT

Ligaments are short bands of tough, but flexible, fibrous connective tissue that bind bones together and guide joint motion, or support organs in place. The word ligament is derived from the Latin word “ligare,” which means to bind. Generally, ligaments can be classified into two major subgroups. There are those connecting the elements of the skeletal system (usually crossing joints) and those connecting other soft tissues, such as the suspensory ligaments in the abdomen. This section only considers skeletal ligaments. The main function of the skeletal ligaments, such as the anterior cruciate ligament (ACL) of the knee joint, is to stabilize and control normal kinematics, to prevent

Figure 3. (a) Video image showing a ligament failing under tensile strain. (b) A schematic diagram showing a longitudinal section through a fiber composite illustrating how a weak matrix prevents crack propagation from one fiber to another and dissipates its energy by creating cracks in directions other than across the composite.

abnormal displacements and rotation that may damage the articular surfaces (2,55). At the insertion to bone, the ligaments change from flexible ligamentous tissue to rigid bone, mediated by a transitional zone of fibrocartilage and mineralized cartilage. This helps to prevent stress concentration at the attachment site by allowing gradual change in stiffness (56,57).

Similar to tendon, ligaments are primarily composed of collagen embedded in a weak matrix (7). The collagen molecules in ligaments pack together to form fibrils and the fibrils aggregate into larger fibrous bundles (2). As described previously, the function of collagen fibrils is to provide tensile reinforcing for the matrix. The proportion of fibers within the ligamentous structure and the orientation of the collagen fibers are the main factors that govern the mechanical behavior of the tissue (7). In contrast to tendon, there is commonly less collagen, which is less highly oriented than in tendon, conferring a generally greater extensibility to these tissues.

The collagen fibrils also prevent damaged tissues from failing suddenly. For example, most ligaments do not tear straight across when they are damaged (Fig. 3). Instead, small tears in the matrix are diverted when they encounter the strong collagen fibrils (see below on failure). There is then a possibility that a damaged ligament can heal while, in the meantime, retaining the ability to withstand some load. Some ligaments, however, (e.g., the ACL), have a limited ability to heal when ruptured and this means that it often needs to be replaced or reconstructed when ruptured. A brief summary of different options available for treating ruptured ligaments will be presented in a later section.

Unlike tendons that all have very similar composition, structure, and function, the same cannot be said of ligaments, and it is far harder to make general comments about their properties. Much less is known, too, about the relationship between their structures and functions as the arrangements of their collagen fibrils are more complex than those in tendons (58,59). This greater complexity is understandable when it is realized that the function of a ligament is very dependent on its position in the body; for example, the medial collateral ligament in the knee of a sheep operates at strains of ~ 0.02 (60),

whereas the ligamentum flavum of the human spine operates at strains of up to 0.6. Figure 4 shows that ligamentum flavum is much less stiff than tendon.

It is not surprising that some ligaments contain a high proportion of elastin ($\sim 60\text{--}70\%$ of the dry weight), which enables them to withstand the high strains to which they are subjected without fracture (61). Ligaments are viscoelastic, that is their properties are time dependent and they appear stiffer if stretched more rapidly. These ligaments exhibit hysteresis, that is, they lose energy on being taken through a cycle of stretching and relaxing. Tkaczuk (61) published a detailed account of the mechanical properties of longitudinal ligaments from the human spine. These deform elastically up to strains of ~ 0.25 , when the stress is ~ 5 MPa, and rupture at a stress of ~ 20 MPa. Shah et al. (62) also showed that, like tendons, the collagen fibers are crimped and this crimp disappears at strains of $\sim 1.2\text{--}2.8\%$ depending on the ligament. When ligaments are cut from the joint, they can often be seen to contract rapidly, suggesting that they are held in a state of tension even when the joint is in a relaxed state.

Figure 4. Comparison of force-strain curves obtained for extension of tendon and ligamentum flavum.

Figure 5. Full width at half-maximum (fwhm), Δ , of the distribution of orientations of collagen fibers in ligamentum flavum, (o) and posterior longitudinal ligament, (+) as a function of strain.

Spinal ligaments provide a good example of the mechanical function of ligaments in a joint (58). The longitudinal ligaments and the ligamentum flavum act together with the intervertebral disc to achieve a mechanically stable joint and serve to limit its mobility. The ligamentum flavum is almost twice as far from the axis of rotation in forward bending as the posterior longitudinal ligament, and hence it can be seen that it needs to be roughly twice as extensible (58,63). This is partly explained by a higher elastin and lower collagen content in ligamentum flavum (61), but also by a less highly aligned organization of collagen fibers (63). As the ligament is stretched, the fibers become more highly aligned and this will increase the stiffness of the tissue, that is its resistance to extension. X-ray diffraction experiments have measured the spread of orientations of fibrils in these ligaments and modelling has shown how this decreases with increasing extension (47). Figure 5 shows that the width of the distribution, $\Delta\theta$, as measured at half the peak height, is greater for ligamentum flavum than posterior longitudinal ligaments. This mechanism provides an explanation for the form of the force-strain curve, shown in Fig. 4. One final point about ligaments is that they have a nerve supply that makes them potential sources of pain. It has also been suggested that they may function as proprioceptors as part of a reflex arc, that is, the ligaments would act as sensors to detect the position of a joint and the information would then be used to control the muscles around the joint thereby controlling its movement and stability (64).

In summary, ligaments are composite materials containing crimped collagen fibers that are prestressed in the relaxed joint. They have a nonlinear stress-strain curve

and are viscoelastic. The collagen fibers are relatively disoriented in the unstretched tissue and become more highly aligned as the tissue is stretched. They often contain a proportion of elastin. Their composition and structure depend on their position in the body and their dynamic behavior, that is, the change in structure with strain, becomes more important.

TENDON

The function of tendon is to transmit the force generated by a contracting muscle to the correct point of application on a bone so as to manipulate a joint. Tendons are often preferable to direct attachment of muscle to bone because of various functional requirements. Muscles have a low tensile strength, defined as load at fracture per unit cross-sectional area. This means that they must have a large cross-sectional area in order to transmit sufficient force without tearing. Around many joints (e.g., the fingers), there is insufficient space to attach many muscles. The muscle, therefore, is located further away and attachment made by a tendon, which may be tens of centimeters long in the hand and forearm. Tendons, therefore, need to be strong, so that they can be relatively slender, and stiff, so that the force developed by the muscle is transmitted to the bone without energy being wasted on stretching the tendon. A graph of force as a function of strain for a tendon is shown in Fig. 6. This type of curve is obtained by subjecting the tendon to various forces and recording the amount by which the tendon is stretched, and many of the early studies have never been bettered (6,9,18,40,65). The steepness of the stress-strain curve is a measure of the stiffness of the material. Figure 6 shows that for small strains the tendon requires very little force to stretch it but thereafter it stiffens considerably. The stress at this point is ~ 10 MPa, which is several orders of magnitude greater than the stresses needed to shear the matrix (6). If the stiffness did not increase, a muscle would continue to stretch the tendon and the force would not be transmitted to the bone.

Tendons are believed to function in the body at strains up to ~ 0.04 (66,67). Beyond this strain, a tendon does not return to its original length when the applied stress is removed. A tendon will break at strains of ~ 0.1 (67). The

Figure 6. Force-strain curve for tendon.

Figure 7. Schematic of stress–strain showing energy stored in a stretched tendon.

initial stages of tendon extension involve straightening the crimp of the collagen fibers described previously.

The energy stored in the stretched tendon is given by the area under the stress–strain curve, as shown in Fig. 7, and it is this energy that must be used to create a tear in the tissue. This energy is lower in a material with a J-shaped stress–strain relationship than if, for example, it were linear. Minimizing the energy available to cause a fracture in this way gives the tissue a property known as resilience, that is, a tendon does not suddenly fail if it is overloaded—unlike a steel wire. While the crimped collagen fibers are being straightened, the weak matrix must be sheared. Because of the fluid-like nature of the matrix, it tends to flow. The rate of flow depends on the force applied to it and the amount of flow is greater the longer the force is applied. The result is that tendons are “viscoelastic” (18,38,68). The effect of the rate at which force is applied to the tendon is shown in Fig. 8.

This time dependence of mechanical behavior leads to a phenomenon known as “creep”. For example, when a load of 10 N was applied to a human flexor digitorum tendon, the initial strain was 0.015, but 100 s later under the same load, the strain had increased to 0.016 (69). Thus, if a

Figure 8. Schematic stress–strain curves for tendon to show the effects of different loading rates. These curves correspond to slow loading (continuous curve) and rapid loading (dashed curve).

Figure 9. Stress–strain curves for tendon that is stretched (continuous curve) and then relaxed (dashed curve), showing hysteresis; that is, not as much energy is recovered on relaxing as was initially used to stretch the tissue.

tendon is stretched rapidly, the matrix has less chance to flow and creep in the material is less resulting in the tendon being stiffer as shown in Fig. 8. Viscous flow of the matrix also provides a mechanism for dissipating energy; more work is done in stretching a tendon than is recovered when the tendon is allowed to relax. This phenomenon is known as hysteresis and is illustrated in Fig. 9. The behavior of a tendon is therefore intermediate between that of a steel wire that stores all the energy used to stretch it, and a viscous liquid that simply flows to a new position and does not store any of the energy put in to cause it to flow.

MEASURING THE PROPERTIES OF LIGAMENTS AND TENDONS

To quantify the physical properties of ligaments and tendons, mechanical testing of bone–ligament/tendon–bone complexes is often performed (70–73). That this method is often used is partly due to the difficulty in testing isolated ligaments and tendons. Ideally, testing isolated ligaments and tendons would provide measures of the material properties of the tissue alone, but such tests are complicated by difficulties in effectively securing the cut ends (2). Putting the free ends in clamps often results in stress concentrations at the grips, which may contribute to premature failure. Although the use of bone–ligament/tendon–bone complexes still provides more secure clamping, it also increases the difficulty of separating the properties of the ligament from those of the insertion sites. When such complexes are subjected to tensile loading, the resulting load–displacement curve represents the mechanical properties of the bone–ligament/tendon–bone complex as whole rather than specifically about the material that makes up the ligament or tendon.

In order to obtain the material properties of the ligaments, one needs to measure their length (to calculate strain from deformation divided by original length) and cross-sectional area (to calculate stress from applied force divided by original area). From stress–strain curves material properties such as Young’s modulus (slope of stress–strain curve), maximum stress, maximum strain, and energy density (area under stress–strain curve) can be

determined. Special devices such as buckle transducers (74) and Hall-effect displacement transducers (75) have been used to measure ligament strains during testing. The drawback of such devices is that they rely on direct contact with the tissue sample and that may influence the results. Optical analysers have also been employed as a noncontact method to measure ligament strains (2). However, inaccuracies may occur because the irregular dye blobs used as markers change shape on stretching making it difficult to define unique points. Another technique that has been employed to measure strain is the use of video dimension analyser (VDA) (76,77). This method requires no direct contact with the specimen, but relies on a recorded video image.

The irregular and complex shape and geometry of ligaments and tendons also make it difficult to measure their cross-sectional area. Although flexible callipers, which are able to follow contours better, have been used to measure ligament cross-sectional areas (2), they still require contact, and this results in errors in measurements. Other investigators have calculated the cross-sectional area of a known length of ligament from measurements of its density by floatation in a mixture of xylene and carbon tetrachloride (78). A number of noncontact methods, such as the use of a rotating microscope (79), use of the VDA (80) and the laser micrometer (81) have also been employed to measure the cross-sectional area.

When mechanical properties of ligaments and tendons are being determined, it is important to consider the rate at which they are loaded since they are viscoelastic, that is, their mechanical properties depend on the rate at which they are deformed (82–86). This sensitivity to strain rate means that ligaments and tendons exhibit properties of stress relaxation (decreased stress with time under constant deformation) and creep (increased deformation with time under constant load) (87,88).

Because of the complex geometry of tendons and ligaments, the orientation of the specimens during mechanical testing affects their physical properties and the manner in which they fail, and should therefore be taken into account when performing mechanical tests. Torsion has been implicated as a factor in the rupture of the ACL during sporting injuries (89–91). Cyclic loading has also been found to lower the yield point or soften the ligament by increasing its compliance (decrease the slope of the linear region of the stress–strain curve) (55). Azangwe et al. (92) showed that, when combined, tension–torsion loading affects both structural and mechanical properties of anterior cruciate ligaments.

LIGAMENT AND TENDON FAILURE MECHANISMS

Since ligaments and tendons consist of collagen fibers reinforcing a weak matrix, it is reasonable to compare their behavior under tensile loading with that of synthetic fiber-reinforced composites, since their failure mechanisms are well established. This section describes some of the modes of failure of fiber-reinforced composites and how they are related to those of the ligaments and tendons. Detailed accounts of failure modes of synthetic

fiber-reinforced composites can be found in textbooks, for example, Agarwal and Broutman (45), and Kelly and Macmillan (50). When a material is subjected to any kind of loading, it can absorb energy by two basic mechanisms:

1. Material deformation.
2. Creation of new surfaces.

Material deformation occurs whenever a material is subjected to load. However, if the energy supplied is sufficiently large, cracks may be initiated. Whether they propagate depends on the relative amounts of energy required to create new surfaces compared with that stored in the deformed matrix. For brittle materials such as glass, the energy required to create a new fracture surface is small and though only a small amount of deformation takes place, this is elastic and the associated energy is sufficient to propagate the crack. This means that brittle materials have a low energy-absorption capability. On the other hand, for ductile materials, large plastic deformations occur, which dissipate energy, resulting in large energies being absorbed rather than being available to drive a fracture. This finding shows that the total energy-absorbing capability or “toughness” of a material can be enhanced by increasing either the length of the path of the crack during separation or the material-deformation capability. In metals, the latter mechanism frequently occurs and metallurgical processes are developed to maintain ductility. In composites, replacing low energy-absorbing constituents with greater energy-absorbing constituents can enhance the toughness.

As is the case with many materials, failure in a fiber-reinforced composite emanates from small inherent defects in the material. Several failure events may occur during the fracture of a fiber reinforced composite material, such as,

1. Microcracking of the matrix.
2. Separation of fibers from the matrix (debonding and pull-out).
3. Breaking of fibers,

Forcing a crack to take a longer path is the main mechanism encountered in fiber composites to increase toughness. In fibrous materials, when a matrix crack encounters a strong fiber placed perpendicular to the direction of crack propagation, if the crack cannot cross the fiber because it is too strong, the crack is forced to branch to run parallel with the fiber (Fig. 10). If the crack goes right around the fiber, this may result in fiber debonding, and pull-out, that is, becoming detached from the matrix and pulled out leaving fiber ends showing as the material is stretched. In many cases the surface area produced by secondary cracks is much larger than the area of the primary cracks. This may increase the fracture energy many times and is an effective way of increasing the toughness of composites or the total energy absorbed during fracture. Fibers may eventually fracture when their strength is exceeded. For most synthetic fiber-reinforced composites, fibers are separated by matrix and therefore are unable to pass energy directly

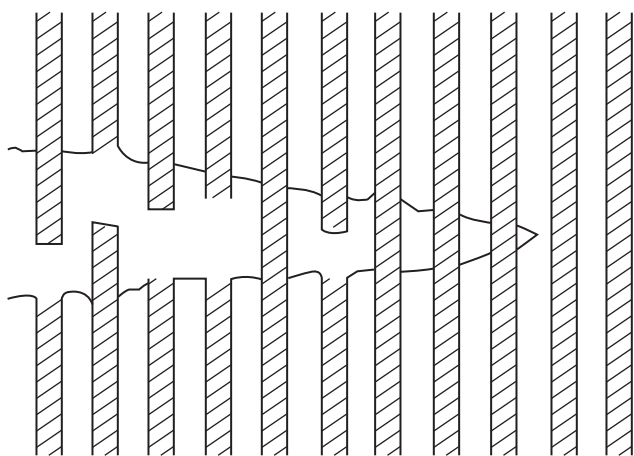

Figure 10. Model of crack tip in a fiber-reinforced composite showing how a crack may propagate. Fibers become debonded from the matrix and are pulled out as the crack widens.

from one to another, hence it is unlikely that they all fail together. Collagen fibers in ligaments are similarly separated by the matrix, and hence the transmission of stress from fiber to fiber in the ligament is indirect (7). The situation is more complicated in biological tissues because of the complexity of the components and their arrangement within the tissue and because of the possibility of repair. It seems reasonable to assume that a crack will start first in the weak matrix rather than in the strong collagen fibers. It is unlikely that the crack will spread into a fibril, as previously discussed, but it will be deflected by the fibrils into new directions.

It appears that tendons and ligaments can continue to withstand stress long after they are damaged, but before complete fracture occurs (70,71,93). However, since damage implies an irreversible change, at least until the biological repair process begins, the tissue will not return to its original dimension when the stress is removed. When testing bone–tendon/ligament–bone complexes, an additional failure mode may occur at the ligament insertion to bone. For example, the ligamentum flavum tears at the enthesis, the junction with the bone, leaving virtually no possibility of natural healing (72). Fortunately, this injury does not appear to occur *in vivo* and can occur in isolation or in combination with other failure modes. As mentioned previously, most ligaments appear to be prestressed within the body so that if they are severed or avulsed they retract and the damaged ends are no longer in contact. This makes it very difficult for cells within the tissue then to bridge the gap by synthesizing new matrix.

The tearing of tendons is a fairly common injury, though rupture of the tendon tends to occur at the junction with bone. Healing of torn tendons in humans is slow, and is not always improved by surgical intervention (3). Healing starts with the invasion of cells into the damaged area that first lay down fine, poorly oriented collagen fibrils (94). These fibrils later increase in diameter and become increasingly oriented as the cell population drops and the structure becomes more akin to that of the original tendon (95).

Damage to and repair of ligaments follows a very similar pattern to that described for tendons. A point to note in all

this is that there are differences in healing characteristics between different ligaments. The ACL of the knee joint, for example, appears to have a poor healing capacity when injured prompting the need for reconstruction. At the junctions of ligaments to bone, the fibers of the ligament become more compact, then cartilaginous and finally calcified before finally merging into the bone and there are changes in cell phenotype and expressed proteins (96,97). This complex structure reflects the difficulty of attaching a tough, flexible material to a hard, brittle one.

LIGAMENT AND TENDON REPAIR

Because of the slow rate of healing of certain ligaments and tendons, their reconstruction with synthetic materials has been attempted, with varying degrees of success, for many years (98). The area of prosthetic materials and methods is so vast that only a very brief survey will be attempted here. The main approaches that have been tried are replacement using tissues taken from another part of the body, or from an animal, and complete substitution by a synthetic material. None of these approaches has so far proved entirely satisfactory. Success rates of 80–90% are reported for both techniques (99–101), but some long-term studies have shown that this success rate may fall to 40–50% after ~5 years (102) and there are reports of high, ~50%, incidence of degenerative change (101,103). Friedman et al. (104), reviewed the autogenous reconstruction of the ACL using patellar tendon, iliotibial band, gracilis tendon, semitendinosus, or meniscus that gives some idea of the range of tissues that have been tried. Unfortunately, most repairs stretch with time resulting in loss of stability (105); this is probably due to the differences in structure and mechanical properties between the original tissue and the replacement, described earlier. If the replacement tissue is stretched too much while being fixed in position, it may be irreversibly strained.

Early attempts at the synthetic replacement of ligaments and tendons, using silk, for example, were not successful. These prostheses were intended to be permanent, but had not the strength and fatigue resistance to withstand the millions of cycle of loading imposed on them during the lifetime of the recipient. More recently polyester (106), carbon fiber (107,108), or various combinations of synthetic materials and autogenous tissue have all been tried but still seem not to overcome this particular problem (103,109,110).

Another approach that is currently being explored for augmenting or reproducing ligaments and tendons is that of tissue engineering (111,113), though this has not yet reached the stage of clinical utility. These techniques may include the development of biodegradable scaffolds, on which it is hoped to encourage cells from the patient to grow a replacement tissue (113), and growth factors (114) and their introduction into the tissue using gene transfer (112,115).

SUMMARY

Tendons and ligament are connective tissues subject primarily to tensile forces. They comprise crimped collagen

fibrils and some elastin embedded in a weak matrix. Collagen fibers in tendon, composed of bundles of fibrils, are highly aligned along the direction of applied force. The initial structural response to the application of force is straightening of the crimp, which occurs at a strain of ~2%, after which the tendon stiffens considerably. Higher strains are not immediately reversibly and may lead to structural damage to the tissue. The function of the crimp appears to be to minimize the energy stored in the stretched tissue thus reducing the energy available to cause fracture. Many ligaments can be stretched more than tendons, because of their more complex collagen fibril organization and, sometimes, the high proportion of elastin present. Tendons and ligaments are viscoelastic; they do not store all the energy used to stretch them, their response to load depends on the rate at which it is applied, and they continue to deform even if the applied load remains constant. Because a lot of energy is required to produce a large fracture surface, they do not break easily, that is, they are tough materials. Because some ligaments do not heal well when injured, there is a need to replace them. However, success in this area is still limited. Future replacements may include tissue engineered ligaments.

ACKNOWLEDGMENTS

We thank Professor D.W.L. Hukins for valuable discussions over many years and the many other colleagues who have contributed to some of the work we have described here. We also thank the Medical Research Council, the Engineering and Physical Sciences Research Council, and the Arthritis Research Campaign for financial support.

LINEAR VARIABLE DIFFERENTIAL TRANSFORMERS

SUNIL KESAVAN
Akebono Corporation

NARENDER REDDY
The University of Akron
Akron, Ohio

INTRODUCTION

Several methods of transduction are available to convert physiological events into electrical signals. Basic physiological variables are first converted by sensing elements into variables that can easily be measured by available transducers. One such transducer, the linear variable differential transformer, commonly abbreviated as LVDT (some manufacturers designate it as LDVT — linear differential voltage transformer), is used to convert mechanical displacement into proportional electronic signals. LVDTs are capable of measuring physiological variables, such as displacement, pressure, force, and acceleration, which are either available in the form of a linear displacement or can be converted into such movement.

THEORY

An LVDT is an inductive electromechanical transducer that uses a primary (energizing) coil and two series-opposed secondary coils. This mode of connecting the secondaries serves to mutually cancel out the secondary voltages. In this popular configuration, due to Shaevitz (1), the primary winding is symmetrically placed with respect to the secondary windings on a cylindrical former. The former surrounds a free-moving rod-shaped magnetic core, which provides a path for the magnetic flux linking the coils (Fig. 1). The magnetic core is connected to a sensing device like a movable diaphragm. Movement of the sensor induces core movement, which in turn produces voltage variations that are measured directly.

When the sliding magnetic core is in the central (null) position, the electromotive forces (emfs) generated in the secondaries are equal, and the net output voltage, e_0 is, therefore, zero. Movement of the core from this central position causes the mutual inductance (coupling) for one coil to increase and the other coil to decrease. The amplitude of the output voltage, e_0 , being the difference between the emfs in the two secondaries, varies approximately linearly with the position of the core on either side of the null position (Fig. 2). The differential secondary con-

Figure 1. Schematic of the cutaway view of an LVDT showing the core, primary coil, and two secondary coils: (e_i) excitation voltage; (e_0) output voltage.

nection in the LVDT causes the phase of the output voltage to change by 180° as the core passes through the null position. The output voltage, e_0 , is generally out of phase with the excitation voltage, e_i . The phase shift is dependent on the frequency of e_i , and each LVDT has a particular frequency at which phase shift is zero.

FABRICATION

The LVDT features essentially frictionless measurement and long mechanical life, because there is no mechanical

Figure 2. Output voltage of an LVDT as a linear function of core position.

contact between the enclosed coil assembly and the separate freely moving core within the coil assembly (Fig. 1).

A typical alternating current (ac) LVDT core consists of a uniformly dense cylindrical slug of a high permeability nickel-iron alloy. The core is internally threaded to accept nonmagnetic core rods from an external sensing or actuating element. The core moves within a cylindrical coil assembly. Hollow cores are employed when a low mass core is desired. Recently, researchers have developed light-weight glass-covered amorphous wire cores that can be used to fabricate high sensitivity LVDTs with good mechanical and corrosion resistance (2). The primary and secondary windings are spaced symmetrically by winding them on a slotted cylindrical former. To avoid material corrosion or insulation leakage, the windings are impregnated with an insulating varnish under a vacuum. The coils are encapsulated in epoxy for further mechanical and moisture protection. Magnetic or ferromagnetic materials in the proximity of an LVDT can disrupt its magnetic field. The magnetic field of an LVDT may also induce eddy currents into nonmagnetic materials in its vicinity. These currents in turn would create a magnetic flux that would interfere with the LVDT output. These problems are avoided in practice by enclosing the LVDT in a case fabricated from an alloy, a high permeability iron, or a stainless steel. The LVDT assembly is then mounted in a C- or split block. LVDTs that can measure rotational movement are also available.

In addition to the ac LVDTs described in the previous sections, direct current (dc) LVDTs are also available (3,4). These LVDTs, in addition to having all the advantages of ac LVDTs, possess the simplicity of dc operation. They consist of two integral parts: an ac-operated LVDT and a carrier generator-signal conditioning module. The small carrier system eliminates the need for the ac excitation, demodulation, and amplification equipment required for conventional ac LVDTs. This cuts down the cost and reduces the volume of LVDT instrumentation; dc units can be battery operated or be supplied by a simple dc power supply (3,4). Also, any dc meter can be employed to read the LVDT output. These advantages, coupled with the small size of the dc LVDTs, make them attractive for use in hospitals and other medical environments.

The LVDTs have several advantages and a few disadvantages (3-6) as briefly reviewed next.

1. Essentially frictionless operation and long mechanical life: As described in the previous section, the LVDT has no moving mechanical contact between the moving core and the windings. This ensures that LVDTs have a fast dynamic response as no additional load apart from the core mass is imposed on the measured event. In addition, this helps LVDTs to have a long, essentially infinite, mechanical life.
2. Good in hostile environments: LVDTs can be manufactured to withstand the vagaries of chemical corrosion and extremes of temperature and pressure. This is facilitated by the separation between the core and windings of the LVDT. Only a static seal is required to isolate the coil assembly from hostile environments.

3. Extremely high resolution: LVDTs can respond to extremely small displacements. Microdisplacement LVDT transducers capable of measuring displacements down to 100 pm have been fabricated (7).
4. Null repeatability: The null position of an LVDT is very repeatable, even with large temperature variations.
5. Input-Output isolation: Since the primary and secondary windings are isolated from each other, the signal ground can be isolated from the excitation ground.
6. Cross-axis rejection: The LVDT is only responsive to axial core motion. Cross-axis motion induced by conditions such as jarring or continuous vibration will not affect the LVDT output.
7. Overtravel damage resistance: As the LVDT core can pass completely through the coil assembly, the transducer is inherently immune to damage from unanticipated overtravel that can be encountered in applications where materials or structures can yield or fail.
8. Absolute output: Unlike a lot of other transducers that are incremental output devices, LVDTs are absolute output devices, that is, the displacement information from an LVDT is not lost if the system loses power. When the measuring system is restarted, the LVDTs output value will be the same as it was before the power failure occurred.

All these advantages, in addition to their reasonable cost, have made the LVDT an attractive displacement measurement technique. However, LVDTs for use in medical applications have the following disadvantages: (1) They require a constant amplitude excitation of high frequency. (2) They cannot be used in the vicinity of equipment that creates strong magnetic fields.

LVDT INSTRUMENTATION

Instrumentation normally used with an ac LVDT should perform the following functions (3,4).

Excitation

An LVDT needs an ac input of constant amplitude at a frequency that is not readily available. Hence, an oscillator of the appropriate frequency has to be connected to an amplifier with amplitude regulation on its output.

Amplification

As in the case of most transducers, the low level outputs of LVDTs require amplification. One procedure for amplification employs two steps: (1) use of an ac carrier-amplifier before demodulation; and (2) a dc amplifier after the demodulator (3,4).

Demodulation

As discussed earlier, the output of an LVDT remains proportional to the displacement while it undergoes a

Figure 3. Block diagram for an LVDT employing a series 1000 oscillator–demodulator supplied by Trans-Tek, Inc. (Courtesy of Trans-Tek Inc.)

phase shift of 180° when the core goes through the null. When this LVDT output is connected to a voltmeter, the meter will register the same reading for equal amounts of core displacement on either side of the null position. This lack of directional sensitivity has to be overcome if one has to tell to which side of the null the core is displaced. Two techniques can be used to confer directional sensitivity on an LVDT output. In one technique, the core is offset, and the operation is centered on a position other than the null point. In this case, the output signal either increases or decreases. The other procedure uses a phase-sensitive demodulator (also called a detector). Several such devices are available and are discussed in detail elsewhere (8). The simplest forms employ diode rectification while the complex forms involve synchronous demodulation. Figure 3 shows the block diagram for an LVDT employing a series 1000 oscillator–demodulator supplied by Trans-Tek, Inc. (9).

The demodulator confers directional sensitivity on its input (output of the LVDT), which is either in phase with, or 180° out of phase with, the carrier signal (10). The demodulator output e_0 is usually sent to a low pass filter that will pass only the frequencies present in x and reject all higher frequencies created by the modulation procedure. Obviously, demodulation is not required if the LVDT transducer is to be used only on one side of the null position.

Recent developments allow all LVDT support circuitry to be accomplished using an inexpensive flexible field programmable analog array (FPAA). The FPAA consists of “configurable analog blocks” consisting of switched-capacitor op-amp cells surrounded by a programmable interconnect and I/O structure (11).

dc Power

Stable dc voltage sources are required for operation of the electronics associated with LVDTs. The dc LVDTs available at the present time employ a microcircuit module including all the electronics needed to provide ac excitation to the primary of the LVDT and to demodulate and amplify the analog LVDT signal. The module is mounted in tandem with the LVDT and only increases the effective LVDT length slightly.

Figure 4 shows the block diagram for a dc LVDT (9). The oscillator produces a constant amplitude sine wave excitation for the primary of the LVDT. A phase sensitive demodulator and an RC filter network process the secondary coil output. Some dc LVDT modules are furnished with

a reverse polarity protector for the dc power input. dc LVDTs are becoming increasingly popular due to their advantages in the areas of calibration and signal conditioning.

SELECTION CRITERIA

Several criteria have to be considered in selecting a particular LVDT for a certain application (12). The manufacturer supplies several of these parameters as specification criteria.

Total Stroke

Stroke-length specification in the selection of an LVDT for a particular application is governed by the displacement to be measured. LVDTs can be custom-made for either short- (up to 0.01 m) or long-stroke (up to 1.5 m) operation; however, cost of fabrication increases greatly with increase in length, and lengths over 0.03 m may not be cost effective.

Linearity and the Nominal Linear Range

The output of an LVDT is a nearly linear function of core position for a rather wide range on either side of the balance (null) position (Fig. 2). A nominal linear range is defined for an LVDT as the core displacement on either side of the balance position for which the LVDT output as a function of displacement remains a straight line. Outside this range, the output starts to deviate gradually from the ideal straight line in the form of a smooth curve. Linearity of an LVDT is defined as “the maximum deviation from a best-fit straight line (applied to a plot of LVDT output voltage vs. core displacement) within the nominal linear

Figure 4. Block diagram of a dc LVDT. (Courtesy of Trans-Tek Inc.)

range" (12). Linearity is usually expressed as a percentage of the full scale. A typical LVDT has a linearity of about $\pm 0.25\%$.

Sensitivity

The sensitivity of an LVDT is usually expressed as the output in millivolts (or V) per 0.001 m core displacement per volt input. Normally, both the input voltage and the frequency are specified as well, because voltage sensitivity may vary with frequency over a limited frequency range. A typical miniature LVDT transducer has a sensitivity of $\sim 8\text{--}200$ mV out/0.001 m/V input.

Resolution

Resolution of an LVDT is the smallest core movement that can produce an observable change in the voltage output (12). With careful circuit design, displacements smaller than 100 nm can be detected.

Armature Mass

The mass of the armature (core) of the LVDT should be small so as not to unduly load the measured event. A reduction in the length of the LVDT results in a reduction in either the linearity or the maximum linear range, whereas sensitivity increases.

Excitation Frequency and Voltage

The sensitivity of the LVDT depends on both the excitation voltage and frequency. Normally, a sinusoidal voltage of 3–15 V rms amplitude and a frequency of 60 Hz–20 kHz is used for the excitation of LVDTs. The sensitivity of an LVDT increases with the excitation frequency, particularly at the lower part of the operating frequency range (12). Normally, an excitation frequency range of 1–5 kHz produces optimal LVDT operation.

Operating Environment

LVDTs have the advantage of being available in hostile-environment-proof format. Transducers designed to withstand both high and cryogenic temperatures and high pressures are available. Immersion-type LVDTs resistant to corrosive liquids are also available. Normally, specification criteria for an LVDT include information on the temperature range of operation and the temperature coefficient.

Residual Voltage Output

The residual voltage output is the LVDT output when the core is in the null position. This should ideally be zero; however, the null voltages and the harmonics of the excitation source do not cancel, resulting in a nonzero residual output (12). In practice, the residual voltage is about 1% of that obtained with maximum displacement.

Repeatability

Repeatability, the ability of the LVDTs to give the same output if the core is displaced and returned to the

original position is an important consideration. LVDTs with repeatability better than 100 nm are available for some critical applications.

MEDICAL APPLICATIONS

LVDTs are used in medical applications and research to measure physiological variables that are either available in the form of a linear displacement or can be converted into such movement. LVDTs for medical applications can be readily fabricated in very small sizes with low mass cores. This will ensure that only a negligible force is imposed on the measured physiological event. Also, due to the low alternating currents in the windings, negligible magnetic load is imposed. When not in use, the core remains in the null position, and no force is imposed on the measured event. Even when the core is displaced from null, the load imposed on the event is small. These advantages, coupled with the general advantages of LVDTs discussed in the previous paragraphs, make these transducers very attractive for physiological measurements.

One early application of LVDTs was in the fabrication of invasive blood pressure measurement transducers (13). These transducers consisted of three essential parts: (1) a dome with pressure fittings, (2) a stainless steel diaphragm and core assembly, and (3) the LVDT coils. Pressure transmitted via the catheter exerts a force on the diaphragm. This causes a movement of the diaphragm, which in turn manifests itself in a movement of the core attached to it. Movement of the core of the LVDT creates a proportional output that can then be recorded after suitable electronic circuit processing. Catheter tip and implantable transducers employed the same principle (13). However, these rugged LVDT blood pressure transducers have been supplanted by cost-effective microelectromechanical system (MEMS) type transducers (14).

Another application for LVDT transducers is in indentation tests on tissue to determine mechanical properties. The authors have developed an LVDT indenter for the characterization of the mechanical properties of skin and the underlying soft tissue (Fig. 5). The indenter uses a loaded hemispherical tip coupled with a load cell-LVDT system for simultaneously measuring both the force and displacement during indentation tests. This information in turn was used to evaluate soft tissue properties. Walsh and Schettini (15) used a similar indenter to measure the *in vivo* viscoelastic response properties of brain tissue. Oculotonometers operating on the same principle and designed to indent the corneal shell use LVDTs to measure deflections in the micrometer range (16). In another similar application, Gunner et al. (17) used an LVDT transducer-mounted extensometer to measure the *in vivo* recoil characteristics of human skin. The device consisted of two flat rectangular tabs, one fixed and the other capable of rectilinear sliding motion, attached to the test skin surface with double-sided adhesive tape. This combination was attached to an LVDT displacement transducer. Behavior of the skin resulting from the movement of the tabs was converted by the LVDT into electronic signals that were then analyzed to characterize the skin.

Figure 5. An LVDT skin and tissue indenter. (Courtesy of N. P. Reddy, J. Kagan and G. V. B. Cochran.)

Christiansen et al. (18) used a similar device for the viscoelastic characterization of skin. These examples are just a few of the myriad potential applications for LVDT transducers in soft tissue characterization.

Several radiological and neurological devices have incorporated LVDTs. For example, Laser Diagnostic Technologies of San Diego, CA, incorporated a position-sensing DC-DC LVDT into a scanning laser tomography instrument designed for retinal topography (9). The stable and repeatable DCDT output is part of a continuous feedback loop in the scanner's on-board logic control system. Radionics, Inc., employed an LVDT in a sophisticated modular probe drive used to support the precise implantation of deep brain stimulating electrodes (9). The device uses a push-pull cable drive mechanism to move the carrier that guides the probe to the desired location in the brain. The LVDT is mounted at the top of the mechanism and is used to accurately monitor probe position (Fig. 6). The LVDT used in this application was sealed to resist moisture and was modified to withstand the rigors of steam sterilization.

LVDTs have been used in endocrinology and pharmacology to evaluate *in vitro* and *in vivo* contractile properties of vascular smooth muscle. Erdos et al. (19) designed an

Figure 6. Mechanism of modular brain probe drive showing the LVDT used to help in precise electrode placement. [Courtesy of Radionics (a division of Tyco Healthcare).]

in vitro isotonic myograph employing an LVDT. The device resembled a beam-type balance. One arm of the device was connected to the contracting muscle specimen, and the other arm was counterbalanced by a suspended weight. Motion of the weight was translated via the movement of an LVDT core into electronic signals.

Gow (20) employed a novel LVDT electronic caliper for the continuous monitoring of arterial diameter changes during pulsation. This low mass device was found to possess a rapid response time with a natural resonant frequency greater than 180 Hz. Shykoff et al. (21) used LVDT measurements of changes in diameter of dorsal hand veins to establish diameter, pressure, and compliance relationships. LVDT-based devices have been used to evaluate the *in vivo* vascular effects of drugs with the dorsal hand vein technique (22). For example, Landau et al. (23) used an LVDT-based device to evaluate the magnesium-induced vasodilation in the dorsal hand vein. A similar technique was used by Streeten and Anderson (24) to measure venous contractile responses to locally infused norepinephrine.

LVDTs have been used in numerous orthopedic and dental devices. Chen et al. (25) used an LVDT bonded to the mandibular first molars to quantify mandibular deformation during mouth opening. Other possible medical applications are the mapping of facial contours before and after maxillofacial surgery and the profiling of spinal deformation in abnormalities like scoliosis. Buhler et al. (26) and Flamme et al. (27) used LVDTs to quantify micromotion in orthopedic implants. Recently, Dong et al. (28) incorporated an LVDT into a device for quantitative assessment of tension in wires of fine-wire external orthopedic fixators.

An LVDT was used to calibrate finger movements and to correlate these movements with surface electromyograms from the flexor digitorum superficialis muscles in the forearm (29,30). This work was designed to develop techniques for control of anthropomorphic teleoperator fingers

using surface electromyographic signals obtained from the forearm.

Wang et al. (31) used six spring-loaded LVDTs in an experimental technique to measure three-dimensional (3D), six-degrees-of-freedom motion of human joints. Rotary LVDTs are useful for measuring joint angles. For measuring 3D rotations, rotary LVDTs are incorporated into six-degree-of-freedom motion linkages.

As illustrated in the applications discussed above, LVDTs are highly suited for biomedical device and research applications requiring accurate displacement measurements with high resolution, input-output isolation, and cross-axis rejection. Although LVDTs are being replaced by miniaturized, cost-effective transducers utilizing advanced fabrication technologies in many applications, their advantages still render them excellent candidates for biomedical applications.

INTRODUCTION

The clinical introduction of shock wave lithotripsy (SWL) by Chaussy in 1980 has revolutionized the way in which patients with renal and ureteral calculi are treated. Shock wave lithotripsy is a noninvasive method of fragmenting stones located inside the urinary tract. Since its initial introduction, SWL technology has advanced rapidly in terms of the means for shock wave generation, shock wave focusing, patient coupling, and stone localization. Despite rapid technological advances, most current commercial lithotripters are fundamentally the same; they produce a similar pressure waveform at the focus, which can be characterized by a leading shock front with a compressive wave followed by a trailing tensile wave (Fig. 1). The acoustic fields produced by different lithotripters differ from each other in terms of the peak amplitudes of the pressure waveform, pulse duration, beam size, total acoustic energy, and therefore, their overall performance.

Clinical experience has guided the technical development of second and third generation lithotripters with the aim of providing user convenience and multifunctionality of the device, rather than on further understanding of how SWL fragments calculi or injures surrounding renal tissue. Furthermore, the evolution of lithotripter design thus far has overwhelmingly relied upon the importance of the compressive wave component of the shock wave (positive portion of the sound wave), with almost total neglect of the contribution of the tensile component of the waveform. Consequently,

Figure 1. Pressure-time relationship of typical shock waves. Typical pattern of a lithotripter-generated shock wave. The shock wave is characterized by a leading positive or compressive component (P^+) followed by a negative or tensile component (P^-).

current lithotripters have suffered from inferior fragmentation rates compared to the original HM3 lithotripter.

In contrast, significant progress in SWL basic science research has been made in the past 5 years to improve our understanding of the primary mechanisms for stone comminution (fragmentation) and tissue injury. It is now recognized that the disintegration of renal calculi in a lithotripter field is the consequence of dynamic and synergistic interaction of two fundamental mechanisms: stress wave-induced dynamic fracture in the form of nucleation, growth, and coalescence of preexisting microcracks inside the stone (1) and cavitation erosion caused by the violent collapse of bubbles near the stone surface (2,3). Similarly, two different mechanisms have been proposed for SWL-induced tissue injury: shear stress due to shock front distortion (4) and cavitation induced inside blood vessels, especially the expansion of intraluminal bubbles (5).

To understand how SWL fragments stones and causes tissue injury, the basic components of current lithotripters, the mechanisms behind stone fragmentation and kidney injury, and clinical results of the original electrohydraulic lithotripter in fragmenting kidney stones in patients will be described. In addition, the future directions of SWL will be reviewed based on current research that is investigating ways to make lithotripters more efficient and safer.

HISTORY AND EVOLUTION OF SWL

Physicists at Dornier Systems, Ltd. and Friedrich Shafen, Germany began experimenting with shock waves and their travel through water and tissue in 1963. Throughout the 1970s, numerous experimental lithotripters were developed that used new methods of shock wave generation and focusing as well as different techniques of stone localization. In addition, experimental studies were being performed *in vitro* and *in vivo* (in animal models) examining the effects of shock waves on various organs and tissues.

In 1980, Chaussy and associates successfully treated the first human and reported their first series of 72 patients in 1982 (6). Subsequently, > 1800 articles have been published in the peer-reviewed literature, detailing the use of SWL for the management of renal and ureteral calculi. Moreover, numerous second and third generation devices have been introduced and are currently being used throughout the world. To understand how SWL results in stone fragmentation, the fundamentals of this technology are reviewed.

SWL PRINCIPLES

Despite the tremendous number of lithotripters currently available for fragmentation of renal and ureteral stones, all of these devices rely on the same laws of acoustic physics. Shock waves (i.e., high pressure sound waves) consisting of a sharp peak in positive pressure followed by a trailing negative wave are generated extracorporeally and passed through the body to fragment stones. Sound waves readily propagate from a water bath or water medium into the human body, due to similar acoustic impedances.

As a consequence, all lithotripters share four main features: an energy source to generate the shock wave, a

Figure 2. Schematic of different shock wave lithotripters. (2a) Electrohydraulic lithotripsy. Spark electrode generates shock wave which is focused at F2 by an ellipsoid reflector. In the original electrohydraulic lithotripter, a water bath served as a coupling medium to allow passage of the shock wave from the source (F1) to the patient and stone (F2). Fluoroscopy or ultrasound can be used to focus to identify and focus the shock waves on the stone. (2b) Piezoelectric lithotripsy. Many ceramic elements are arranged in a spherical pattern. When energy passes through them, they vibrate and send shock waves through a coupling medium to the stone. (2c and d) Electromagnetic lithotripsy. An electromagnetic coil (2c) or cylinder (2d) are stimulated to vibrate by passage of electric current. Their shock waves are focused on the stone (F2) by an acoustic lens (2c) or a parabolic reflector.

device to focus the shock wave at a focal point, a coupling medium, and a stone localization system. (Fig. 2a) The original electrohydraulic lithotripter utilized a spark plug energy generator with an elliptical reflector for focusing the shock waves. A water bath transmitted the shock waves to the patient with stone localization provided by biplanar fluoroscopy. Modification of the four basic components of this first generation lithotripter has provided the development of second and third generation devices that are currently available.

Shock Wave Generation and Focusing

While all lithotripters share the four aforementioned features, it is the mode of shock wave generation that determines the actual physical characteristics of that particular device. The types of energy sources differ in how efficient they are in fragmenting stones and how many treatments are required to adequately treat the stone. Figure 2 diagrammatically

summarizes the three different shock wave generation sources used in commercially available lithotripters.

Electrohydraulic Generator. In the original Dornier HM3 lithotripter, the electrohydraulic generator (Fig. 2a) was located at the base of a water bath and produced shock waves by electric spark discharges of 15,000–25,000 V of 1 μ s duration. This high voltage spark discharge produced the rapid evaporation of water that created a shock wave by expanding the surrounding fluid. The generator was located in an ellipsoidal reflector that concentrated the reflected shock waves at a second focal point, F2, with F1 being the point of origin of the primary shock waves. While the HM3 continues to be the gold standard lithotripter for stone fragmentation, the short half-life of its electrode results in variable pressure between shocks the longer it is used. In addition, minimal displacement of the electrode, as it deteriorates at F1, results in displacement of the F2 resulting in inaccurate focusing of the shock wave on the

stone. The need for frequent replacement of the electrode increases the cost of electrohydraulic lithotripsy.

Piezoelectric Generator. Piezoelectric shock waves are generated (Fig. 2b) by the sudden expansion of ceramic elements excited by a high frequency, high voltage pulse. Thousands of these elements are placed along the inner surface of a hemisphere at the base of a pool of water. While each of these elements moves only slightly in response to a pulse of electrical energy, the summation of the simultaneous expansion of multiple elements results in a high energy shock wave directed to the focal area, at the center of the sphere. The shock wave is propagated through either a small water basin or a water-filled bag to the focal point, F2. The spherical focusing mechanism of the piezoelectric lithotripters provides a wide area of shock wave entry at the skin surface, which causes minimal patient discomfort, but a very small focal area with the smallest amount of energy at F2 compared to other energy sources (7). The small focal area necessitates greater precision to focus and fragment the stone inside the kidney.

Electromagnetic Generator. In electromagnetic devices (Fig. 2c and d), shock waves are generated when an electrical impulse moves a thin, spherical metallic membrane, which is housed within a cylindrical shock tube. The resulting shock wave, produced in the water-filled shock tube, passes through an acoustic lens and is thereby directed to the focal point, F1 (Fig. 2c). The shock wave is coupled to the body surface with a moveable water cushion and coupling gel (8). Alternatively, when energy is passed through a cylindrical coil, the resulting magnetic field pushes away the surrounding cylindrical membrane producing a shock wave that can be focused by a parabolic reflector (Fig. 2d). While these devices produce reliable shock waves with consistent pressures and focus on F2, they also produce small focal regions that may result in reduced stone fragmentation and higher tissue parenchymal injury.

Shock Wave Focusing. Shock waves must be focused in order to concentrate their energy on a calculus. The type of shock wave generation dictates the method of focusing used. Machines that utilize point sources, such as spark-gap electrodes (electrohydraulic lithotripters), generate shock waves that travels in an expanding circular pattern. All of these machines use ellipsoid reflectors for focusing shock waves at the second focal point, F2.

Since a single piezoelement produces a very small amount of energy, larger transducers with multiple ceramic elements are required for piezoelectric lithotripters. The array of elements is positioned in a spherical dish that allows focusing in a very small focal region, F1. Finally, the vibrating metal membranes of the electromechanical lithotripters produce an acoustical plane wave that uses an acoustic lens for focusing the shock wave at F1.

Coupling Medium

The original Dornier HM3 machine utilized a 1000 L water bath to transmit shock waves into the patient. This method of patient coupling required unique positioning of the patient, since the anesthetized subject had to be lowered

into the tub and the calculus accurately positioned at the second focal point. Second generation lithotripters were designed to alleviate the physiologic, functional, and economic problems of a large water bath. Current models utilize an enclosed water cushion, or a totally contained shock tube, to allow simplified positioning and "dry" lithotripsy (9).

Stone Localization

Stone localization during lithotripsy is accomplished with either fluoroscopy or ultrasonography. Fluoroscopy provides the urologist with a familiar modality and has the added benefits of effective ureteral stone localization. However, fluoroscopy requires more space, carries the inherent risk of ionizing radiation to both the patient and medical staff and is not useful in localizing radiolucent calculi (certain noncalcium-containing stones are not seen on fluoroscopy or conventional radiographs).

Ultrasonography utilizes sound waves to locate stones. These sound waves are generated at a source. When they encounter different tissue densities, part of the sound wave is reflected back and these reflected waves are used to generate a two dimensional image that can be used to focus the shock wave on a calculus. Sonography-based lithotripters offer the advantages of stone localization with continuous monitoring and effective identification of radiolucent stones, without radiation exposure (7). Additionally, ultrasound has been documented to be effective in localizing stone fragments as small as 2–3 mm, and is as good or better than routine radiographs to assess patients for residual stone fragments following lithotripsy (8). The major disadvantages of ultrasound stone localization include the basic mastery of ultrasonic techniques by the urologist and the inherent difficulty in localizing ureteral stones. While there are several systems that utilize both ultrasound and fluoroscopy to aid in stone localization, many commercially available lithotripters now use a modular design in which the fluoroscopy unit is not attached to the lithotripter reducing storage space as well as allowing use of the fluoroscopy unit for other procedures.

MECHANISMS OF STONE FRAGMENTATION

Due to recent advances made in the basic science of shock wave lithotripsy, there is a better understanding of how shock waves result in stone fragmentation. Both the positive and negative portions of the shock wave (Fig. 1) are critical in stone fragmentation and also play a role in renal tissue injury. The four mechanisms described for stone comminution include compressive fracture, spallation, cavitation, and dynamic fatigue. As the calculus develops *in vivo*, it is formed by both crystallization of minerals as well as organic matrix material. This combination forms an inhomogeneous and imperfect material that has natural defects. When the shock wave encounters this inhomogeneous structure, the force generated in the plane of the shock wave places stress on these imperfections resulting in compression-induced tensile cracking. This mechanism is known as compressive fracture. Spallation, another mechanism of shock wave induced stone fragmentation, occurs when the shock wave encounters fluid behind the

stone and part of the wave is reflected back onto the stone placing tensile stress on the same imperfections.

Shock waves cause bubbles to form on the surface of the stone. These bubbles grow during the negative or tensile component of the shock wave. When the positive component of the next wave passes, these bubbles violently collapse releasing their energy against the stone surface as secondary shock waves and/or microjets. This phenomenon, known as cavitation, represents the third mechanism of stone fragmentation. Dynamic fatigue describes the sum of accumulated damage to the stone that coalesce to result in stone fragmentation and eventually destruction of the stone (10,11).

CLINICAL RESULTS OF SHOCK WAVE LITHOTRIPSY

Because many experts continue to consider the Dornier HM3 (the original electrohydraulic lithotripter, Dornier MedTech America, Inc., Kennesaw, GA) the gold standard in lithotripsy, the available clinical literature comparing the Dornier HM3 (first generation) lithotripter to other commercially available lithotripters is summarized in Table 1. This type of summary does not truly allow a comparison between different lithotripters currently in use. Yet, this comparison demonstrates that modifications to second and third generation lithotripters have traded better patient comfort for a lessening of stone free rates. This current clinical data has been one of the driving forces behind the modifications that are currently being investigated to improve SWL.

Summarized results of five large early series on the clinical efficacy of SWL using the unmodified Dornier HM3 lithotripter demonstrate stone free rates for renal pelvis (RP), upper calyx (UC), middle calyx (MC), and lower calyx (LC) stones were 76% (48–85), 69% (46–82), 68% (52–76), and 59% (42–73), respectively. Stone free rates in these series were better for smaller stones (0–10 mm) and RP stones with relatively poorer stone free rates for LC stones. In comparison, results of five large published series on the Siemens Lithostar, a lower power machine demonstrated stone free rates for RP, UC, MC, and LC stones of 69% (55–80), 67% (46–90), 63% (43–82), and 60% (46–73). A comparison of integrated stone free rates stratified by size in a regression model of the HM3 and Lithostar found significantly greater stone free rates across all stone sizes for the HM3 lithotripter (11). While most studies have evaluated the efficacy of SWL for adults, stone free rates with the HM3 are similar for children (21). The limited number of comparative studies of newer machines and the explosion in the number of commercially available lithotripters makes it difficult to assess their clinical efficacy.

While the HM3 has been shown to produce excellent stone free rates for renal calculi, there continues to be debate on the clinical efficacy of SWL for ureteral stones. The main problem is that stones in the ureter are more difficult to locate and therefore more difficult to target with the shock wave. However, several studies have demonstrated stone free rates close to 100% for the treatment of proximal ureteral stones with SWL (22). However, stone free rates appear to decline to 70% for mid-ureteral stones for many lithotripters (23). Treatment of distal ureteral stones with SWL typically involves a prone or a modified

sitting position to allow shock wave targeting of the stone below the pelvic brim. Stone free rates of distal ureteral stones with the HM-3 lithotripter have been as high as 85–96% (24). Endoscopic methods (ureteroscopy) can also be employed for ureteral stones, especially those located in the distal ureter with equivalent or better stone free rates.

While many of the lithotripters sighted in Table 1 are no longer in clinical use or have been updated, these studies clearly demonstrated several key points. The HM3 continues to provide equivalent and likely superior stone free rates when compared to other lithotripters in studies. While most commercially available lithotripters provide acceptable stone free rates for stones located within the kidney, these stones often require more treatment sessions and adjunctive procedures to achieve the stone free rates of the HM3 device. Additionally, success rates with all lithotripters declines the further the stone progresses down the ureter and poses positioning challenges with alternative methods indicated to remove ureteral stones.

TISSUE INJURY WITH CLINICAL LITHOTRIPSY

Clinical experience treating patients with SWL has demonstrated that while SWL is generally safe, shock waves can cause acute and chronic renal injury. This concept has been confirmed by multiple animal studies and a few human clinical studies (11). Originally, shear stress to the tissue was believed to be the main cause of this renal injury. However, recent studies have suggested that SWL induced renal injury is a vascular event induced by vasoconstriction or cavitation-induced injury to the microvasculature (25). Additionally, this initial tissue damage may promote further renal injury via the effects of free radical production (26). Acute damage to the kidney appears to be mainly a vascular insult.

While clinicians have long recognized the acute effects of SWL, most have believed that there was no long-term sequela to shock wave treatment. The > 25 years of clinical experience with SWL serves as a testament to its safety and effectiveness. However, several chronic problems may develop as a consequence of SWL. Table 2 summarizes the acute and chronic effects of SWL. Perhaps the most serious long-term problem of SWL is the increased risk of hypertension. A review of 14 studies on the impact of SWL on blood pressure demonstrated that when stratified according to the number of shock waves administered, higher doses of shock waves seem to correlate with a greater likelihood of increased rates of new-onset hypertension or changes in diastolic blood pressure (11). The impact of hypertension on cardiovascular disease including the risk of myocardial infarction, stroke, and renovascular disease make this a serious long-term effect that needs further investigation.

Three mechanisms of SWL induced tissue injury have been reported: cavitation, vasoconstriction, and free radical induced tissue injury. Investigators have demonstrated *in vitro* that cavitation bubble expansion can rupture artificial blood vessels (5). Other investigators have shown in animal models that cavitation takes place in kidneys exposed to shock waves (27). While cavitation bubbles that form on the stone surface contribute to stone fragmentation,

Table 1. Literature Comparison of Lithotripters to Gold Standard Dornier HM3

Study Type	Reference	HM3 Compared to:	Stone Location	Number of Patients	Stone Free Rates (SFR), %	Auxiliary Procedures	Retreatment Rate, %	Comment
Prospective	12	Wolf Piezolith	Kidney	HM3: 334 Wolf: 378	HM3: 75Wolf: 72		HM3: 15.5 Wolf: 45	Wolf required more retreatment, more shocks, treatment rates decreased dramatically for ureteral stones with Wolf
	13	EDAP LT01	Kidney	HM3: 500 EDAP: 500	HM3:77.2-90.4 EDAP: 42.5-87.5		> with EDAP	More sessions, increased shocks required with EDAP
	14	MFL 5000	Kidney	198 total	HM3: 80MFL: 56			Increased subcapsular hematoma and longer treatment times with MFL
	15	Wolf Piezolith 2300	Ureter	70 total	HM3: 74Wolf: 76.6			Comparable 3 month SFR but used plain radiographs for comparison
	16	Siemens Lithostar	Kidney	HM3: 91Siemens:85	HM3: 91Siemens: 65		HM3: 4 Siemens: 13	SFR comparable at 3 months, Increased tissue injury with HM3 by urinary enzymes
	Retrospective	17	EDAP LT01 Sonolith 2000	Kidney and ureter	HM3: 70EDAP: 113Sono: 104	HM3: 79EDAP: 82Sono: 79	HM3: 12EDAP: 13Sono: 9	HM3: 4EDAP: 42Sono: 26
18		Siemens Lithostar, Dornier HM4, Wolf Piezolith 2300, Direx Tripter X-L, Breakstone	Kidney and ureter	Multicenter	comparable between 2nd generation			All were deemed inferior to HM3 in terms of stone free rates
19		Medstone STS	Kidney	HM3: 5698Med: 8166	HM3: 70Med: 81.5	HM3: 3.1Med: 5.5	HM3: 4.4 Med: 5.2	Slightly better retreatment and need for auxiliary procedures with HM3
20		Lithotron	Kidney	38 matched pairs	HM3: 79Lithotron: 58	> for Lithotron	> for Lithotron	HM3 superior to Lithotron using matched pair analysis
11		Siemens Lithostar		Meta-analysis	HM3: 59-76 Siemens: 60-69			Using regression model, SFR better with HM3 across all stone sizes

Table 2. Acute and Chronic Injury with SWL

Acute	Chronic
Renal edema (swelling)	Hypertension (elevated blood pressure)
Hematuria (blood in urine)	Decreased renal function
Subcapsular hematoma	Accelerated stone formation (in animal models)
Decreased renal blood flow	Renal scar formation
Altered renal function:	
Impaired urine concentration	
Impaired control of electrolytes	

their formation in other locations (tissue, blood vessel lumen) is an unwanted end product that results in tissue injury.

Recent investigations have elucidated yet another potential mechanism of renal injury secondary to high energy shock waves. Evidence suggests that SWL exerts an acute change in renal hemodynamics (i.e., vasoconstriction) that occurs away from the volume targeted at F2, as measured by a transient reduction in both glomerular filtration rate (GFR) and renal plasma flow (RPF) (28). Prolonged vasoconstriction can result in tissue ischemia and permanent renal damage.

Vasoconstriction and cavitation both appear to injure the renal microvasculature. However, as the vasoconstriction induced by SWL abates, reperfusion of the injured tissue might also result in further tissue injury by the release of free radicals. These oxidants produced by the normal processes of cellular metabolism and cellular injury cannot be cleared and injure the cell membrane destroying cells. Free radical formation has been demonstrated in animal models (26).

It appears that the entire treated kidney is at risk of renal damage from SWL-induced direct vascular and distant vasoconstrictive injury, both resulting in free radical formation. Although previous studies have suggested that the hemodynamic effects are transient in nature in normally functioning kidneys, patients with baseline renal dysfunction may be at significant risk for permanent renal damage (28). Patients of concern may be pediatric patients, patients undergoing multiple SWL treatments to the same kidney, patients with solitary kidneys, vascular insufficiency, glomerulosclerosis, glomerulonephritis, or renal tubular insult from other causes.

SHOCK WAVE LITHOTRIPSY ADVANCES

Based on a better understanding of cavitation in stone fragmentation as well as the role of cavitation, vasoconstriction, and free radical formation in SWL-induced tissue injury, several groups are investigating ways in which SWL can be clinically more effective and safe. In general, these advancements involve changes to the shock wave itself, by modifying the lithotripter, alterations in treatment technique, improvements in stone fragmentation / passage or the reduction in tissue injury through medical adjuncts, and improved patient selection.

Changes to the Lithotripter

There are two major mechanical modifications that can improve stone comminution, based on our current understanding of acoustic physics. One is to enhance the compressive component of the shock wave. The original HM3 relies on a high energy output and thus the compressive component to achieve stone fragmentation. The downside of this effect, from clinical experience, is patient discomfort and potential renal tissue injury. Alternatively, one can improve stone comminution by altering the tensile component of the shock wave and thus better control cavitation. Below, several ways are describe in which investigators are modifying the shock wave to improve comminution, with decreased renal tissue injury.

Several investigators have modified lithotripters to alter the negative portion of the shock wave that is responsible for cavitation-induced stone fragmentation and tissue injury. In one study, a reflector insert is placed over the original reflector of an electrohydraulic lithotripter to create a second shock wave that arrives behind the original shockwave, thus partially canceling out the negative component of the shock wave. These investigators found that this modification reduced phantom blood vessel rupture, while preserving stone fragmentation *in vitro* (29). Similarly, an acoustic diode (AD) placed over the original reflector, has the same impact as this modified reflector (30).

However, because reducing the tensile component of the shock wave weakens that collapse of bubbles at the stone surface, two groups have designed piezoelectric inserts into an electrohydraulic lithotripter that send small, focused shock waves at the time of bubble collapse near the stone surface thus, intensifying the collapse of the cavitation bubble without injuring surrounding tissue (29).

Another way in which investigators have modified the shock wave is by delivering shock waves from two lithotripters to the same focal point, F2. Dual pulse lithotripsy has been evaluated by several investigators both *in vitro*, animal models and in clinical trials. Several investigators have demonstrated in an *in vitro* model that the cavitation effect became more localized and intense with the use of two reflectors. Also, the volume and rate of stone disintegration increased with the use of the two reflectors, with production of fine (< 2 mm) fragments (31). In both animal models and clinical studies, dual pulse lithotripsy has been shown to improve stone fragmentation with reduced tissue injury.

Modifications to Treatment Strategy

The original Dornier HM3 lithotripter rate was synchronized with the patient's electrocardiogram so that the shock rate did not exceed the physiologically normal heart rate. Experience with newer lithotripters has revealed that ungating the shock wave delivery rate results in few cardiac abnormalities. As a result, there has been a trend to deliver more shock waves in a shorter period of time. However, increasing doses of shock wave energy at a higher rate may have the potential to increase acute and chronic renal damage.

As a result, several investigators have evaluated ways in which the treatment strategy can be modified to optimize SWL treatment. One proposed strategy is altering the rate of shock wave delivery. Several investigators have reported that 60 shocks · min⁻¹ at higher intensities resulted in the

most efficient stone fragmentation than 120 shocks · min⁻¹. This has been confirmed *in vitro*, in animal models and also in randomized clinical trials. These studies speculate that at increased rates, more cavitation bubbles were formed in both the fluid and tissue surrounding the stone that did not dissipate between shocks. As a result, these bubbles scattered the energy of subsequent shocks resulting in decreased efficiency of stone fragmentation (32).

In order to acclimate patients to shock waves in clinical treatment, lower energy settings are typically used and gradually increased. A study investigating whether increasing voltage (and thus increasing treatment dose) impacted on stone fragmentation has been performed *in vitro* and in animal models. Stones fragmented into smaller pieces when they were exposed to increasing energy compared to decreasing energy. The authors speculate that the low voltage shock waves “primed” the stone for fragmentation at higher voltages (33). In addition, animals exposed to an increasing voltage had less tissue injury than those kidneys exposed to a decreasing or stable dose of energy. While this treatment strategy has not been tested clinically, it might be able to improve *in vivo* stone comminution while decreasing renal parenchymal injury (34).

In the same vein, several studies have reported that pretreating the opposite pole of a kidney with a low voltage dose of shock waves (12 kV), prior to treating a stone in the other pole of a kidney with a normal dosage of shock waves, reduced renal injury when as little as 100 low voltage shocks were delivered to the lower pole. It is believed that the low voltage shock waves causes vasoconstriction which protects the treated pole of the kidney from hemorrhagic injury (35).

Other SWL treatment modifications being tested include aligning the shock wave in front of the stone in order to augment cavitation activity at the stone surface or apply overpressure in order to force cavitation bubble collapse. While these techniques have only been investigated *in vitro*, these alterations in shock wave delivery, as well as the previous treatment strategies demonstrate how an improved understanding of the mechanisms of SWL can enhance stone comminution and potential reduce renal tissue injury (36,37).

Adjuncts to Improve SWL Safety and Efficacy

Antioxidants. A number of studies have investigated the role of antioxidants in protecting against free radical injury to renal parenchyma (38). Table 3 summarizes the results of various *in vitro* and *in vivo* studies on the use of antioxidants to protect against SWL-induced renal injury due to free radicals. While these studies are intriguing, further clinical trials will be needed to evaluate potential antioxidants for use in patients undergoing SWL.

Improving Stone Fragmentation. Another potential way to improve stone fragmentation is to alter the stone's susceptibility to shock wave energy. One group has demonstrated that after medically pretreating stone in an *in vitro* environment, one could achieve improved stone fragmentation. These data suggest that by altering the chemical environment of the fluid surrounding the stones it is possible to increase the fragility of renal calculi *in vitro* (49). Further studies are warranted to see if calculi can be

Table 3. Investigated Antioxidants Providing Protection against SWL-Induced Free Radical Injury

Reference	Study Type	Antioxidant
39	<i>In vitro</i>	nifedipine, verapamil, diltiazem
40	<i>In vitro</i>	Vitamin E, citrate
41	<i>In vitro</i> , animal	Selenium
42	Animal	Verapamil
43	Animal	Verapamil
26	Animal	Allopurinol
44	Animal	Astragalus membranaceus, verapamil
45	Human	Antioxidant vitamin
46,47	Human	Verapamil, nifedipine
48	Human	Mannitol

clinically modified, prior to SWL therapy, in the hopes of enhanced stone fragmentation.

Improving Stone Expulsion. Several reports have demonstrated that calcium channel blockers, steroids, and alpha blockers all may improve spontaneous passage of ureteral stones. (ref) Compared to a control group, investigators found improved stone clearance and shorter time to stone free in patients treated with nifedipine or tamsulosin following SWL compared to the control group. Additionally, retreatment rates were lower (31%) for the medical treatment group compared to the control group (51%). While expulsive therapy appears to offer improved outcomes following SWL for ureteral stones, confirmation with a randomized controlled study is needed (50). Another intriguing report from the same group involves the use of *Phyllanthus niruri* (Uriston) to improve stone clearance of renal stones following SWL. This medication is derived from a plant used in Brazilian folk medicine that has been used to treat nephrolithiasis. Again, stone free rates were improved with the administration of Uriston following SWL compared to a control group with apparently the greatest effect seen in those patients treated with lower pole stones (51).

Improving Stone/Patient Selection for SWL. Another way to enhance the efficacy of SWL is improve patient selection. Advances in computed tomography (CT) have allowed better determination of internal stone architecture (52). As a consequence, a few studies have demonstrated that determining the Hounsfield units (i.e., density unit of material on CT) of renal stones on pretreatment, noncontrasted CT could predict stone free rates of patients treated with SWL (53). Current micro-CT and newer multidetector CT scanners have the potential to identify stone composition based on CT attenuation. Therefore, stone compositions that are SWL resistant, such as calcium oxalate monohydrate or cystine stones, can be identified and those patients can be treated with endoscopic modalities, thereby avoiding additional procedures in these patients (54). Clinical trials utilizing this concept will need to be performed.

Other factors, such as the distance of the stone from the skin, weight of the patient, and other imaging modalities, are being investigated to help determine who is likely to benefit the most from SWL and which patients should be treated initially with other modalities.

CONCLUSIONS

Shock wave lithotripsy has revolutionized the way in which urologists manage urinary calculi. Patients can now be treated with minimal discomfort using an outpatient procedure. While all lithotripters rely on the same fundamental principles of acoustic physics, second and third generation lithotripters appear to have traded patient comfort and operator convenience for reduced stone free rates, as compared to the original HM3 lithotripter. In addition, mounting evidence demonstrates that SWL has both acute and chronic impact on renal function and blood pressure as a result of renal scarring.

Basic science research has provided insight into how SWL results in stone comminution as well as renal tissue injury. While the compressive component of the shock wave causes stone comminution, it is apparent that the tensile component plays a critical role in creating passable stone fragments. These same forces cause tissue injury by damaging the microvasculature of the kidney. This knowledge has resulted in several novel modifications to improve both stone free rates as well as SWL safety. Mechanical modifications to lithotripsy have focused on controlling cavitation. Preventing bubble expansion in blood vessels while intensifying bubble collapse near the stone surface has been demonstrated to achieve improved stone comminution with decreased tissue injury *in vitro* and in animal models. Many of these designs could be adapted to conventional lithotripters. Modification of treatment techniques have also stemmed from our better understanding of SWL. Slowing treatment rates may limit the number of cavitation bubbles that can interfere with the following shock wave. Voltage stepping and alternative-site pretreatment with low dose shock waves, may cause global renal vasoconstriction that prevents cavitation injury to small vessels during treatment. In addition, our understanding that free radicals may be the end culprit in parenchymal damage has suggested that pretreatment with antioxidants may prevent SWL-induced renal injury. Finally, improved CT imaging may allow us to predict which stones and patients are best suited for SWL versus endoscopic stone removal. Further advances will continue to make SWL a major weapon in the war against stone disease for years to come.

LIVER TRANSPLANTATION

PAUL J. GAGLIO
Columbia University College
of Physicians and Surgeons
New York, New York

INTRODUCTION

From a conceptual perspective, liver transplantation involves the replacement of a diseased or injured liver with a new organ. Historically, liver transplantation has emerged from an experimental procedure deemed “heroic” therapy for patients not expected to survive, to the treatment of choice with anticipated excellent long-term outcomes for patients with end stage liver disease. This article will outline the history of and indications for liver transplantation, delineate short- and long-term complications associated with the procedure, and discuss the role of immunosuppressive therapy, intrinsic to the long-term success of the procedure.

HISTORY

Historically, the most significant and persistent impediment to liver transplantation has been the availability of suitable organs. Up until the early 1960s, “death” was defined as cessation of circulation, and thus, donation from deceased donors was thought to be both impractical and impossible, as organs harvested from pulseless, nonperfusing donors would not function when transplanted, due to massive cellular injury. The concept of “brain death” and ability to harvest organs from individuals defined as such first occurred at Massachusetts General Hospital in the early 1960s, when a liver was harvested from a patient whose heart was beating despite central nervous system failure. This seminal event led to the development of a new concept; death was defined when cessation of brain function occurred, rather than the cessation of circulation. Thus, brain dead donors with stable blood pressure and the absence of comorbid disease could serve as potential organ donors. Improvements in the ability to preserve and transport organs dramatically increased organ availability, necessitating a

centralized system to facilitate procurement and allocation of organs to individuals waiting for transplantation. This was initially provided by SEOPF (the Southeast Organ Procurement Foundation), founded in 1968, from which UNOS (the United Network for Organ Sharing) arose. At present, UNOS operates the OPTN (Organ Procurement and Transplantation Network), providing a centralized agency that facilitates recovery and transportation of organs for transplantation, and appropriately matches donors and recipient.

LIVER TRANSPLANTATION: INITIAL RESULTS

The first reported liver transplantation occurred in 1955, in the laboratory of Dr. Stuart Welch (1). In a dog model, an “auxiliary” liver was transplanted into the abdominal cavity, leaving the native liver *in situ*. Between 1956 and 1960, various investigators initiated experiments in different animal models whereby “orthotopic” liver transplantation was performed, achieved by removal of the native liver and implantation of a “new” liver in its place, requiring anastomoses of the donor and recipient hepatic vein and artery, bile duct, and portal vein (see Fig. 1). These initial attempts at liver transplantation refined the surgical procedure, however, graft dysfunction and death of the animals occurred quickly, due to ineffective immunosuppression and eventual rejection of the liver mediated by the animal’s immune system (2).

The first human liver transplants were performed by Dr. Thomas Starzl in 1963, at the University of Colorado (3). These early attempts at transplantation highlighted the difficulties associated with extensive abdominal surgery in desperately ill patients, and were associated with poor outcomes, largely due to technical difficulties and the inability to effectively prevent rejection. Similar negative experiences at other centers led to a worldwide moratorium on liver transplantation. However, a major breakthrough in the ability to prevent rejection and prolong the survival of the transplanted liver occurred following the availability of Cyclosporine in 1972 (described below). With continued refinement of the surgical techniques required to perform liver transplantation, combined with the ability to minimize

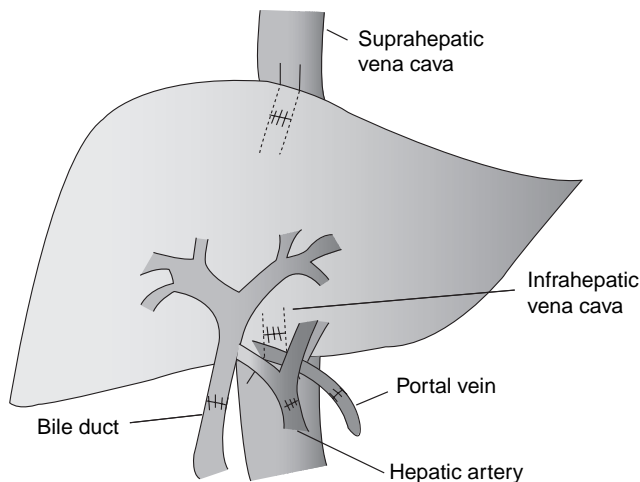

Figure 1. Schematic representation of an orthotopic liver transplant.

organ rejection, posttransplant outcomes improved significantly. From 1963 to 1979, 170 patients underwent liver transplantation at the University of Colorado; 56 survived for 1 year, 25 for 13–22 years, and several remain alive today 30 years after their surgery. Continued improvement in posttransplantation outcomes were achieved, and thus, in 1983, the National Institutes of Health (NIH) established that liver transplantation was no longer considered an “experimental” procedure, rather, as definitive therapy for appropriately selected patients with end-stage liver disease. Additional advances in immunosuppression (reviewed below) including the discovery of polyclonal and monoclonal antibodies to T-cells or their receptors, and other agents such as Tacrolimus, Mycophenolate Mofetil, and Sirolimus have further improved outcomes.

INDICATIONS FOR LIVER TRANSPLANTATION

Liver transplantation is an accepted therapeutic modality for complications of chronic liver disease, or acute liver failure. In general, liver transplantation is recommended when a patient with end stage liver disease manifests signs and symptoms of hepatic decompensation, not controlled by alternative therapeutic measures. This is evidenced by

1. Esophageal and/or gastric variceal bleeding, or bleeding from portal hypertensive gastropathy.
2. Hepatic encephalopathy.
3. Spontaneous bacterial peritonitis.
4. Significant ascites.
5. Coagulopathy.

Patients with liver disease complicated by early stage hepatocellular carcinoma (HCC), often defined as either a single lesion <5 cm or not more than three lesions, each <3 cm are also considered candidates for liver transplantation irrespective of evidence of concomitant hepatic decompensation (4).

If a patient meets these initial criteria, further requirements must be realized. It is generally accepted that liver transplantation is indicated if the patient is not moribund and the transplant is likely to prolong life with a >50% chance of 5-year survival. Furthermore, it is anticipated that the transplant will restore the patient to a range of physical and social function suitable for the activities of daily living. Patients who are suitable candidates should not have comorbid disease with involvement of another major organ system, which would preclude surgery or indicate a poor potential for rehabilitation.

Transplant candidates undergo a thorough psychological assessment prior to liver transplantation. Adequate family and social support must be demonstrated to ensure adherence to the difficult long-term medical regimen that will be required posttransplant. In addition, if a history of substance abuse is present, most transplantation programs require that the patient complete at least 6 months of documented rehabilitation with displayed freedom from alcohol and/or drug recidivism. “Psycho-social” assessment is usually performed by several individuals, including a Psychiatrist or Psychologist and an experienced social worker. In addition, living

Table 1. Diseases Associated with Fulminant Hepatic Failure

Viral Infection	Frequent	Hepatitis A, B, D, E, Hepatitis Non A-G	
	Rare	Hepatitis C Cytomegalovirus Epstein Barr virus Herpes simplex virus

	Miscellaneous		Hyperthermia Hellp SX

donor liver transplantation (LDLT), discussed in greater detail below, requires a detailed psychosocial assessment of both recipient and potential donor. In most transplantation centers, an independent donor advocate team consisting of a social worker, internist, and surgeon who are independent of the team evaluating the recipient performs the difficult task of educating a potential donor regarding the risks and benefits of LDLT, assessing motivation to be a donor, and determining if coercion is present.

Another indication for liver transplantation is fulminant hepatic failure, defined as hepatic encephalopathy (confusion) arising in the setting of massive liver injury in a patient without preexisting liver disease. This condition is rapidly fatal unless recovery of hepatic function occurs spontaneously, and thus, emergent liver transplantation may be required. Conditions associated with fulminant hepatic are listed in Table 1.

ETIOLOGY OF LIVER DISEASES REQUIRING LIVER TRANSPLANTATION

Diseases associated with hepatic dysfunction in adults and children are outlined in Tables 2 and 3, respectively. In general, any disease process in adults or children that induces either acute or chronic hepatocellular, biliary, or vascular injury may necessitate liver transplantation. The indications for liver transplantation in children are identical to those in adults, that is, liver transplantation is indicated in the presence of progressive liver disease in patients who fail medical management.

Table 2. Indications for Liver Transplantation

Diseases Effecting Hepatic Parenchyma	
	Viral hepatitis with cirrhosis (Hepatitis B with or without Delta Virus, Hepatitis C, Non A-E hepatitis)
	Autoimmune hepatitis
	Alcoholic cirrhosis
	Metabolic disorders (Wilson's disease, hemochromatosis, alpha 1 Antitrypsin, Tyrosinemia, protoporphyria, Cystic fibrosis, familial amyloidosis, Neiman-Pick disease)
	Fulminant hepatic failure due to any cause
	Drug induced liver disease
Diseases Effecting Biliary System	
	Primary and secondary biliary cirrhosis
	Sclerosing cholangitis
	Caroli's disease
	Relapsing cholangiohepatitis
	Choledochal cysts with obstruction and biliary cirrhosis
Hepatic Neoplasia/Malignancies	
	Patients with nonmetastatic primary hepatocellular carcinoma, with;
	A single tumor not > 5 cm
	No more than three lesions with the largest lesion < 3 cm
	No thrombosis of the portal or hepatic vein
	Hemangioendothelioma (confined to the liver)
	Neuro endocrine tumors with hepatic involvement
	Large hepatic Hemangioma
Miscellaneous Causes	
	Hepatic vein thrombosis (Budd-Chiari syndrome)
	Portal vein thrombosis
	Hepatic artery thrombosis
	Trauma

Many of the disease processes in adults that induce liver failure are recapitulated in children. However, specific disease states seen in children including metabolic diseases and congenital biliary anomalies represent additional indications for liver transplant. Moreover, liver transplantation is indicated in infants and children if the transplant will prevent or attenuate derangements in cognition, growth, and nutrition. Therefore, children should be considered for liver transplantation when there is evidence that hepatic decompensation is either unavoidable (based on knowledge of the history of the disease itself), imminent, or has already occurred. The clinical scenarios that determine when liver transplantation is required in children can include one or more of the following:

1. Intractable cholestasis.
2. Portal hypertension with or without variceal bleeding.
3. Multiple episodes of ascending cholangitis.
4. Failure of synthetic function (coagulopathy, low serum albumin, low cholesterol).
5. Failure to thrive or achieve normal growth, and/or the presence of cognitive impairment due to metabolic derangements, and malnutrition.
6. Intractable ascites.
7. Encephalopathy.
8. Unacceptable quality of life including failure to be able to attend school, intractable pruritis.
9. Metabolic defects for which liver transplantation will reverse life-threatening illness and/or prevent irreversible central nervous system damage.

Table 3. Additional Indications for Liver Transplantation in Infants and Children

Disease	Defect	Inheritance	Comments
Cholestatic Liver Disease			
Obstructive: Biliary Atresia (most common indication for liver transplantation in children)			
Intrahepatic: Alagille's Syndrome, Bylers disease, familial cholestatic symptoms			
Other			
Congenital hepatic fibrosis			
Metabolic Diseases			
Alpha 1 antitrypsin	Decreased serum A1AT	Codominant	May reverse both liver and lung disease
Wilson's Disease	Decreased Ceruloplasmin	Autosomal Recessive (AR)	
Tyrosinemia	Fumarylacetoacetate hydrolase	AR	Transplant in fulminant liver failure, or to prevent hepatic neoplasia
Urea cycle defects	Example: ornithine transcarbamylase	x-linked dominant	Prevent CNS injury
Galactosemia	Arginosuccinate synthetase	AR	
Glycogen storage Diseases	Galactose phosphate uridyl transferase	AR	Prevent development of cirrhosis and Hepatoma
	Glucose 6 phosphatase	AR	Consider transplant if dietary management not successful
Type 1A	Brancher enzyme		
Type IV			
Familial hypercholesterolemia	Type 2 A-LDL receptor deficiency	AR	Avoids ASHD
Gaucher's Disease	Glucocerebrosidase	AR	May need combined liver/bone marrow t-plant
Nieman-Pick disease	Sphingomyelinase	AR	
Crigler-Najjar type 1	Uridine diphosphate glucuronyl transferase	AR	prevents fatal Kernicterus
Cystic fibrosis	Chloride ion transfer gene	AR	May need combined liver/lung transplant
Hyperoxaluria type 1	Alanine glyoxalate aminotransferase	AR	Usually requires combined liver/kidney
Neonatal Fe storage	Unknown	Varies	Transplant as infant
Hemophilia A and B	Factor VIII/IX	x-linked	Transplant indication varies (?iron overload, factor inhibitor present)
Disorders of bile acid synthesis (Bylers disease)	Unknown	Varies	Transplant indicated if associated with end stage liver disease

10. Life threatening complications of stable liver disease (e.g., hepatopulmonary syndrome).

comes must be restrained by evidence that HCV recurrence in HIV-HCV coinfecting patients may be problematic (5).

CONTRAINDICATIONS TO LIVER TRANSPLANTATION (ADULTS AND CHILDREN)

At present, "absolute exclusion" criteria for liver transplantation are evolving. In general, patients with advanced cardiac or pulmonary disease, severe pulmonary hypertension, active substance abuse, coma with evidence of irreversible central nervous system injury, sepsis, or uncorrectable congenital abnormalities that are severe and life threatening are not transplant candidates. In addition, individuals with evidence of extrahepatic malignancy do not meet criteria for transplantation, unless the patient meets standard oncologic criteria for "cure". "Relative" exclusion criteria include renal insufficiency when renal transplantation is not feasible, prolonged respiratory failure requiring > 50% oxygen, advanced malnutrition, primary biliary malignancy, inability to understand the risk/benefits of the procedure, and inability to comply with medications and conform to follow-up regimens. Recent data indicates successful outcomes in HIV infected patients who undergo liver transplantation, a population formerly considered noncandidates for the procedure. However, initial enthusiasm regarding successful transplantation out-

RECIPIENT CHARACTERISTICS AND PRIORITIZATION FOR TRANSPLANTATION

Given the relatively stable number of available donor organs in the setting of a rapidly expanding pool of potential recipients, the timing of transplantation is critical. Liver transplantation in a stable patient who is anticipated to do well for many years while waiting for an available organ may not be appropriate, while liver transplantation in a moribund patient with a low probability of posttransplantation survival is similarly inappropriate. Prior to 1997, prioritization for liver transplantation was based on the location where patients received their care (i.e., home, hospital, intensive care unit) and waiting time on the transplant list. In 2002, several policies were instituted by UNOS in an attempt to produce a more equitable organ allocation scheme. Waiting time and whether the patient was hospitalized were eliminated as determinants of prioritization of organ allocation. The "MELD" score (Model for End Stage Liver Disease) a logarithmic numerical score based on the candidate's renal function (creatinine), total bilirubin, and INR (international normalized ratio for prothrombin time) has been shown to be the best predictor of

mortality among cirrhotic patients, including those on the transplant waiting list. It was therefore adopted by UNOS as a mechanism to prioritize waiting list candidates. MELD had been validated as a predictor of 3-month survival in diverse groups of patients with various etiologies and manifestations of liver disease (6). Presently, a patient's position on the liver transplantation waiting list is now determined by their MELD score; patients with highest MELD scores are ranked highest on the list. Prospective analysis of the impact of MELD indicates improvement in both the rate of transplantation, pretransplantation mortality, and short-term posttransplantation mortality rates (7). However, retrospective analysis has suggested that posttransplantation survival may be reduced in patients with very high pretransplantation MELD score, particularly in Hepatitis C infected patients (8). Conversely, MELD score effectively delineates when a patient is "too well" for transplantation. A recent review indicates that posttransplantation survival in patients transplanted with a MELD score of <15 is lower than a nontransplanted cohort with similar MELD score (9). Thus, it is clear that careful recipient selection, with attention to pressor and ventilatory requirements, need for dialysis, age, and MELD score are important factors in selecting appropriate candidates for liver transplantation.

LIVER TRANSPLANTATION: SOURCE OF ORGANS

At present, there are three potential types of organ donors specific to liver transplantation, identified as deceased, living, or non-heart beating. Deceased donors (DD) comprise the majority of liver donors. Either by self-identification while living, or after discussion with "next of kin" when donor brain death has been declared, individuals are acknowledged as potential organ donors. Recent data from UNOS indicate that 1- and 3-year patient survival in recipients of DD liver transplant is 81 and 71%, respectively (10). However, despite efforts to maximize utilization of organs acquired from DD including the use of older donors, steatotic (fatty) livers, and livers infected with Hepatitis C or B, a growing disparity exists between the number of available livers and the number of individuals waiting for transplantation. This critical shortage of organs has resulted in both an increase in the waiting time for liver transplantation and death rate among patients on the waiting list. In response, the modalities of adult-to-child and adult-to-adult LDLT have emerged as alternatives to deceased donor liver transplantation (11,12). Adult-to-child LDLT usually involves the removal of the left lateral segment of the liver (~20% of hepatic mass) from an adult donor for implantation into a child, while adult to adult living donor liver transplantation requires that the larger, right lobe of the liver (which accounts for ~50–60% of the hepatic mass) be removed from the donor to ensure adequate hepatic mass in the recipient. Rapid regeneration of the liver remnant in the donor and the partial allograft transplanted into the recipient occurs, to the extent that appropriate liver volume is restored within 1–2 months in both donor and recipient following surgery. Since most pediatric LDLT recipients are <2-years old, they receive a liver graft of

adequate or even excessive size, and thus liver insufficiency due to the receipt of inadequate liver mass is rare. In contradistinction, as the recipient of an adult-to-adult living donor liver transplantation receives a graft that must over time grow to an appropriate volume, selection of recipients best able to tolerate transplantation of a "partial" graft is necessary. In appropriately selected pediatric and adult recipients, 1- and 3-year graft and patient survival in individuals who undergo LDLT is similar or superior to DD (10). However, when comparing postoperative complications in recipients of DD versus LDLT, recipients of LDLT have a greater rate of biliary complications including bile leaks and biliary strictures, which occur in 15–32% of patients (13). In addition, the "small-for-size syndrome" manifested as prolonged posttransplantation cholestasis with or without portal hypertension may occur following LDLT, if the graft is of inadequate size (14). Fortunately, the majority of patients who experience this syndrome recover without the requirement of retransplantation.

Recently, significant interest in the utilization of "non-heart beating" donors (donation after cardiac death, DADC) as a potential modality to further increase the pool of available organs has emerged. In contrast to DD who are declared brain dead, DADC are critically ill patients who are not brain dead, but have no expectation of recovery and who based on their own prior wishes or families request are removed from life support. Following cardiac arrest and declaration of death, organs are harvested. There are two types of DADC, "controlled" and "uncontrolled". In the controlled DADC (Maastricht category 3 "death anticipated") the patient is removed from life support and death occurs in the operating room. Once death has been declared, organs deemed suitable for transplantation are rapidly perfused with preservation solution and removed surgically. The uncontrolled DADC (Maastricht category 1 and 2 "death not anticipated") is declared dead after cardiac arrest, rushed to the operating room, and organs are harvested. Uncontrolled DADC are usually not utilized for liver transplantation due to the high rate of primary nonfunction (defined below), usually due to prolonged ischemia of the graft. When utilizing controlled DADC for transplantation, emerging data indicates that recipient and graft survival are diminished when compared to deceased and living donor liver transplantation with a higher incidence of primary nonfunction, biliary injury, and requirement for retransplantation. However, several centers have reported acceptable outcomes when utilizing controlled DADC organs, particularly those without significant ischemia in well-selected recipients (15).

Finally, "domino" transplantation is an option for patients afflicted with familial amyloidotic polyneuropathy (FAP). Familial amyloidotic polyneuropathy is a fatal disease caused by an abnormal amyloidogenic transthyretin (TTR) variant generated by the liver. Liver transplantation in these patients removes the source of the variant TTR molecule, and represents the only known curative treatment. As no intrinsic liver disease exists in patients affected by FAP, the liver explanted from a patient with FAP may be transplanted into another patient, thus, allowing "domino" transplantation. Survival in both recipients of FAP livers and transplanted FAP patients has

been reported to be excellent and comparable to survival with OLT performed for other chronic liver disorders (16).

POSTTRANSPLANTATION MANAGEMENT

The complex nature of the surgical procedure utilized to both explant (remove) the diseased, cirrhotic liver and implant (transplant) the new allograft into the recipient make it intuitive that the majority of the early complications following liver transplantation are technical and related to the surgical procedure itself. However, following the first postoperative days, and as patients progress to the first month posttransplantation and beyond, the nature and variety of complications change. Early complications (within the first 2 months) and late complications (beyond 2 months) may negatively affect patient and graft survival (Table 4). Complications specific to the surgical procedure and those that directly affect the transplanted organ are discussed below.

EARLY COMPLICATIONS

Primary Nonfunction and Early Graft Dysfunction

A major threat to the newly transplanted liver is primary graft nonfunction (PNF). This syndrome defined as acidosis, rising INR, progressive elevation in liver transaminases and creatinine, and decreases in mentation occurs when the newly transplanted liver allograft fails to function normally. The mechanisms responsible for this phenomenon are complex, and relate to donor factors,

inadequate preservation of the liver, prolonged ischemia, extensive steatosis of the graft, hepatic artery thrombosis (see below) or immune response to the implanted organ (17). In the setting of PNF, a rapid assessment of hepatic artery flow needs to occur, as immediate surgical repair of a thrombosed hepatic artery may reverse PNF. In the absence of hepatic artery thrombosis, emergent retransplantation is required for PNF.

In contrast to PNF, early graft dysfunction (EGD) is manifested by an early rise in serum transaminases to values > 2000–3000 IU/L, cholestasis with rising Bilirubin levels, without marked coagulopathy or impairment in mental status and renal function. EGD may occur in the setting of ischemic injury or steatosis in the graft, and typically occurs within the first 24–48 h after the transplant. Unlike PNF, the manifestations of EGD usually improve with supportive care, and emergency retransplantation is not necessary.

Hepatic Artery Thrombosis

A potentially devastating posttransplantation complication is hepatic artery thrombosis (HAT). Hepatic artery thrombosis occurs more commonly in pediatric transplant recipients compared to adults due to the technical difficulties associated with the anastomosis of smaller size vessels. In HAT, the immediate postoperative period may be associated with graft failure, elevation in serum liver transaminases, bile leak, hepatic necrosis, and sepsis. Since the blood supply to the biliary tree in the early posttransplant period is principally from the hepatic artery, HAT is frequently associated with irreversible injury to the biliary tract (18). Thus, HAT in the first 7 days after liver transplantation is an indication for emergent artery repair or retransplantation.

Due to the potentially devastating consequences of HAT, most transplant centers screen for this complication with duplex-ultrasound (US) in the immediate posttransplant period. If duplex-US suggests HAT, angiography is usually performed to confirm the diagnosis, and if present, surgical revision of the hepatic artery is required. If surgical repair cannot be achieved, liver retransplantation may be necessary.

PORTAL AND HEPATIC VEIN THROMBOSIS

Though less common than HAT, thrombosis of the portal and/or hepatic veins in the immediate posttransplant period can also adversely affect patient and graft survival. Acute “Budd-Chiari” syndrome due to hepatic vein or vena cava thrombosis is associated with abdominal pain, peripheral edema, and the threat of graft failure, as hepatic congestion in the newly transplanted liver is poorly tolerated. In this circumstance, emergency thrombectomy and surgical revision is required. Acute portal vein occlusion may be associated with exacerbation of preexisting portal hypertension, associated with gastrointestinal bleeding from porto-systemic collateral vessels such as esophageal and gastric varices. Acute portal vein thrombosis is managed by surgical repair, while chronic portal vein thrombosis may be well tolerated. A potential alternative to surgical repair for both hepatic and portal vein stenosis or occlusion is thrombolysis and/or the placement of

Table 4. Early and Late Complications Following Liver Transplantation

Early

Graft Specific

- Primary nonfunction
- Early graft dysfunction
- Hepatic artery thrombosis
- Hepatic and portal vein thrombosis
- Preservation injury/Biliary complications: bile leak, biliary stenosis
- Acute cellular rejection

Other

- CMV infection
- Recurrent Hepatitis B and C

Late

Graft Specific

- Chronic rejection
- Recurrence of primary disease

Other

- Hypertension
- Hyperlipidemia
- Diabetes
- Obesity
- Cardiac disease
- Renal dysfunction
- Fungal infection (Cryptococcus, Aspergillus)
- CMV
- Posttransplant lymphoproliferative disorder
- Nonhepatic malignancy: i.e., skin cancer

endovascular stents by an experienced interventional radiologist (19).

ACUTE CELLULAR REJECTION

Rejection of any transplanted organ is a constant threat, as immunologic recognition of the graft as “foreign” may be associated with injury. However, compared to other organs, liver allografts are relatively privileged immunologically, and thus, the incidence and consequences of acute cellular rejection (ACR) are diminished when compared to other solid organs utilized for transplantation. The reported incidence of ACR within the first posttransplant year is 30–50%, in most cases, usually occurring within the first 2–3 weeks postoperatively. The clinical presentation is variable; ACR may be asymptomatic, or associated with fever or abdominal pain. Laboratory findings include elevation or failure of normalization of serum transaminases, usually in association with a rising alkaline phosphatase and/or bilirubin. The diagnosis of acute liver graft rejection is confirmed by liver biopsy and examination of liver histology (20). Conventional histologic criteria associated with ACR include the presence of periportal lymphocytic infiltrate, as well as bile duct and hepatic vascular endothelial cell injury. Most cases of ACR respond to treatment with intravenous bolus glucocorticoids. Approximately 10% of patients with ACR will not improve with intravenous glucocorticoids, requiring the administration of monoclonal or polyclonal anti-T cell antibodies (reviewed below). Mild and moderate ACR may also respond to either increasing the dose of the primary immunosuppressive agent, or switching to an alternate calcineurin inhibitor. This approach has been used with increasing frequency, particularly in patients transplanted for HCV and HBV due to concerns regarding the negative impact of over-immunosuppression on viral recurrence.

BILIARY COMPLICATIONS

Bile leaks and strictures generally occur at the anastomosis of the donor and recipient bile ducts, recognized by a rise in serum bilirubin and/or alkaline phosphatase or by the presence of bile in surgical drains in the immediate posttransplantation period. The incidence of biliary complications is between 5 and 15% following deceased donor liver transplantation. However, between 15 and 30% of patients who undergo living donor liver transplantation develop biliary complications, due to the complexity of the biliary reconstruction required (21). In both deceased and living donor recipients, the majority of bile leaks resolve spontaneously without the need for reoperation. As previously stated, the biliary tree receives the vast majority of its blood supply from the hepatic artery, and thus, the adequacy of hepatic artery blood flow needs to be evaluated in the setting of any biliary injury. If spontaneous resolution of the bile leak does not occur, endoscopic or radiologic placement of a biliary stent across the biliary anastomoses is often successful (22). In some cases, surgical exploration and revision of the biliary anastomoses with a Roux-en-Y choledochojejunostomy may be required.

Anastomotic biliary strictures require careful attention, as if left untreated, cholangitis, graft dysfunction, and eventually secondary biliary cirrhosis may occur. Techniques for management include dilatation and stenting via biliary endoscopy or percutaneous transhepatic cholangiogram by an interventional radiologist. If these modalities are unsuccessful, surgical revision of the biliary anastomosis with a Roux-en-Y choledochojejunostomy may be required. In rare cases with diffuse stricturing, retransplantation may be necessary.

ISCHEMIC AND PRESERVATION INJURY

The newly transplanted liver is always subjected to some degree of ischemic injury (23). Cold (or hypothermic) ischemia is unavoidable, as it occurs prior to transplantation while the liver is cooled in preservation solution, awaiting implantation. Warm (normothermic) ischemia occurs during the transplantation procedure itself, when hepatic blood flow is interrupted to minimize blood loss during transplantation, or when the formerly “cooled” liver is subjected to body temperature during transplantation. Cold ischemia is usually well tolerated, while in contrast, warm ischemia often leads to death of hepatocytes, with resultant elevation in serum transaminases, apoptosis and centrilobular necrosis. In the setting of significant warm ischemia, graft failure may result. Several investigators have noted improvement in ischemic injury and enhanced graft and patient outcomes by employing a technique described as “ischemic preconditioning” defined as a brief period of controlled ischemia followed by a short interval of reperfusion before the actual surgical procedure (24). This is accomplished during liver transplantation by transiently interrupting hepatic inflow by placing a vascular clamp or a loop around the portal triad (i.e., portal vein, hepatic artery, and bile duct), rendering the whole organ ischemic for 10–15 min, after which the clamp is removed and the liver is reperfused. This technique may be of particular benefit in organs with significant steatosis.

Complications Beyond Two Months

Progress in the surgical techniques required to perform transplantation, the treatment of postoperative complications and prevention of rejection have been associated with significant improvements in short-term morbidity and mortality following transplantation. Coincident with improvements in short-term outcomes has been a rise in long-term complications. These complications, including side effects of chronic immunosuppression, neoplasia, and infections are discussed in detail elsewhere. Long-term complications that affect the transplanted liver are discussed below.

CHRONIC REJECTION

Chronic allograft rejection or “vanishing bile duct syndrome” is rare, but in contradistinction to acute cellular rejection, a much more difficult to treat complication. Diagnostic criteria for chronic rejection include bile duct atrophy affecting the majority of bile ducts, with or without bile duct loss. Arterial and venous injury affecting the

large branches of the hepatic artery or portal vein (foamy arteriopathy) may also be present (24). Risk factors for chronic liver rejection include transplantation for primary sclerosing cholangitis, primary biliary cirrhosis, HLA mismatch between donor and recipient, and cytomegalovirus infection. Chronic rejection is usually a harbinger of poor outcomes, often resulting in the requirement for retransplantation; altering immunosuppression is rarely associated with improvement.

Recurrence of Primary Disease Following Liver Transplantation

A major challenge to the liver transplant community is recurrence of the primary disease that caused the patients native liver to fail. Diseases that do not recur following liver transplantation include congenital anatomic anomalies (e.g., biliary atresia, polycystic liver disease, Caroli's disease, Alagilles syndrome, congenital hepatic fibrosis) and metabolic diseases of the liver (e.g., Wilson's disease, alpha 1 antitrypsin deficiency). However, all other causes of liver disease including primary biliary cirrhosis, primary sclerosing cholangitis, autoimmune hepatitis, nonalcoholic fatty liver disease, hemochromatosis and alcohol related liver disease have been reported to recur after liver transplantation. In some cases, recurrent disease may lead to significant liver injury with resultant graft failure (26–30). Disease processes most commonly associated with recurrence include viral hepatitis B (HBV) and C (HCV). The recurrence of HBV is associated with uniformly poor outcomes with graft failure and death. Fortunately, recurrence of HBV after liver transplantation can be prevented by administering hepatitis B immune globulin (HBIG) at the time of transplantation and at regular intervals thereafter, with or without the use of antiviral agents such as Lamivudine and Adefovir. In contradistinction to HBV, HCV recurrence following liver transplantation remains a significant source of morbidity and mortality, with negative impact on post-transplantation outcomes. In patients with active HCV replication prior to transplantation, reacquisition of viremia following transplantation is universal, and histologic injury due to HCV occurs in up to 90% of patients followed for 5 years (31). Although histologic injury in the allograft due to HCV is exceedingly common, disease progression after the development of hepatitis is variable, with some patients experiencing indolent disease and others rapidly progressing to cirrhosis and liver failure. In patients that develop HCV associated cirrhosis posttransplantation, up to 42% will experience decompensation manifested as ascites, encephalopathy, or hepatic hydrothorax, and <50% of patients survive > 1 year after the development of decompensation (32). It is important to contrast the natural history of HCV before and after transplant; prospective and retrospective data are emerging which indicate that the progression of HCV following liver transplantation is accelerated when compared to the nonimmunosuppressed pretransplant patient population.

Whether HCV recurrence is more severe in recipients of LDLT than in DD recipients is controversial. Although several recent reports indicate that HCV recurrence may be more problematic in recipients of LDLT when compared to DD (33), particularly the cholestatic variant of HCV (34),

other authors have noted no differences in outcomes in HCV infected patients who undergo LDLT when compared to DD (35,36). At present, both the optimal timing for transplant in HCV patients and the therapy for recurrent HCV following liver transplantation are incompletely described. Theoretically, eradication of HCV prior to liver transplantation in patients with decompensated liver disease would be beneficial, although in practice, this strategy has been marred by exacerbation of encephalopathy, infections, and other serious adverse events, particularly in patients treated with high dose Interferon and ribavirin (37). A novel approach including initiating therapy with low dose interferon (including Pegylated interferon preparations) and ribavirin with slow escalation in dose may be associated with improved tolerability and efficacy (38). Following liver transplantation, both preemptive therapy prior to the development of histologic injury and directed therapy after the onset of liver injury have been attempted with varying degrees of success. It is important to note, however, that posttransplantation, tolerability of interferon preparations, and ribavirin is suboptimal. Significant leucopenia and anemia are common, likely due to drug induced bone marrow suppression and renal insufficiency potentiating ribavirin induced hemolysis (39).

Immunosuppressive Medications

A cornerstone to posttransplantation management is the ability to prevent or attenuate immunologic rejection of the transplanted graft, which when left untreated, can be associated with graft failure. From a conceptual standpoint, understanding how recognition of the newly engrafted liver as "foreign" occurs, how to modulate immune mediated injury, and at the same time prevent "overimmunosuppression" are critical to achieve optimal post transplantation outcomes. The various immunosuppressive medications and their mechanism of action currently utilized in liver transplant recipients are listed in Table 5. Unfortunately, all immunosuppressive therapy is associated with undesired effects, with the potential for additive effects when agents are combined. In general, most transplant centers utilize three agents to prevent allograft rejection in the immediate posttransplant period, utilizing a combination of a calcineurin inhibitor such as Cyclosporine (CYA) or Tacrolimus (TAC), a second agent such as Mycophenolate mofetil (MMF) or Azathioprine (AZA), and a glucocorticoid such as Prednisone. As patients achieve adequate liver function and freedom from rejection beyond 6-months posttransplantation, satisfactory immunosuppression can be achieved in many patients with monotherapy, usually with a calcineurin inhibitor, although in patients who are at increased risk of rejection such as those with autoimmune hepatitis, primary biliary cirrhosis, or sclerosing cholangitis, long-term immunosuppression is achieved with a combination of a calcineurin inhibitor with either low dose MMF or Prednisone (40).

Corticosteroids

Corticosteroids achieve their desired immunosuppressive effects by the suppression of leukocyte, macrophage, and cytotoxic T-cell activity, and diminution of the effect of

Table 5. Immunosuppressive Agents

Agent	Mechanism of Action	Side Effects
Antilymphocyte globulin	Depletes circulating lymphocytes	Flu-like symptoms Anaphylaxis
Antithymocyte globulin		Lymphoproliferative disorders
OKT3	Depletes circulating T cells	Flu-like symptoms Anaphylaxis Lymphoproliferative disorders
Basiliximab Daclizumab	IL-2 receptor blockade	Infections Gastrointestinal distress Pulmonary edema and bronchospasm (rare)
Cyclosporine	Inactivates calcineurin, decreases IL2 production, Inhibits T-cell activation	Hypertension Renal insufficiency Neuropathy Hyperlipidemia Gingival hyperplasia Hirsutism Insulin resistance
Prednisone	Suppression of leukocyte, macrophage, and cytotoxic T-cell activity Decrease cytokines, prostoglandins, and leukotrienes	Hypertension Dyslipidemia Glucose intolerance Bone abnormalities Peptic ulcers Psychiatric disorders
Azathioprine	Inhibits adenosine and guanine production Inhibits DNA and RNA synthesis in rapidly proliferating T cells	Leukopenia Anemia Thrombocytopenia Pancreatitis
Tacrolimus	Inactivates calcineurin, decreases IL2 production, Inhibits T-cell activation	Hypertension Renal insufficiency Insulin resistance Neuropathy Hyperlipidemia
Mycophenolate mofetil	Inhibits of inosine monophosphate dehydrogenase (IMPDH) Prevents T- and B-cell proliferation	Leukopenia Anemia Thrombocytopenia GI side effects
Sirolimus	inhibiting mTOR (target of Rapamycin) Prevents T-cell replication.	Hepatic artery thrombosis Bone marrow suppression Hyperlipidemia Pneumonitis Inhibits wound healing

cytokines, prostaglandins, and leukotrienes. However, hypertension, dyslipidemia, glucose intolerance, bone loss, peptic ulcers and psychiatric disorders are often associated with therapy. Therefore, a strategy to taper and discontinue glucocorticoids within the first 6 months–1 year following transplantation while maintaining adequate levels of calcineurin inhibitor is employed by many transplant centers. This tactic is often altered in patients who undergo liver transplantation secondary to an immunologic disorder such as autoimmune hepatitis, primary biliary cirrhosis and sclerosing cholangitis due to an enhanced risk of acute cellular rejection. In these patients, either long-term use of corticosteroids with an attempt to minimize doses is advocated, or chronic use of MMF or AZA in combination with a calcineurin inhibitor is required.

T-Cell Depleting Agents

In the past, “induction therapy” with antilymphocyte agents such as antilymphocyte globulin or antithymocyte

globulin or monoclonal antibody preparations such as OKT3 was utilized immediately after liver transplantation to rapidly induce an immune suppressed state via the rapid destruction of the host’s T cells. However, due to significant systemic side effects including fevers, allergic reactions, serum sickness, and thrombocytopenia, the use of these agents is now usually reserved for the treatment of glucocorticoid resistant rejection, or less commonly, in patients with severe renal insufficiency in an attempt to delay the use of either CYA or TAC, which may be associated with worsening of renal function (41).

IL-2 Receptor Blockers

T-cell activation and proliferation following presentation of a foreign antigen requires the induction of several cytokines, including IL-2 (interleukin 2). Antibodies directed against the interleukin (IL)-2 receptor are effective for initial immunosuppression, as IL-2 receptor blockade

down regulates IL-2 mediated T-cell proliferation. The IL-2 receptor antibodies such as Basiliximab and Daclizumab, given intravenously at the time of transplant and during the first posttransplantation week can reduce the incidence of acute liver graft rejection when utilized in combination with a calcineurin inhibitor, although these agents may not be sufficient to prevent rejection when utilized alone. The IL-2 receptor antibodies are generally well tolerated, although side effects may include infections, gastrointestinal distress, and rarely, pulmonary edema and bronchospasm. As these agents rarely induce renal dysfunction, many transplant programs utilize IL-2 receptor antibodies as “induction” therapy in individuals with renal insufficiency at the time of transplantation (42), in an attempt to delay initiation or diminish dose of calcineurin inhibitors, which may exacerbate renal insufficiency.

Calcineurin Inhibitors

IL-2 inhibition effectively suppresses T-Cell activation. Cyclosporine and TAC achieve this by binding to cytoplasmic receptors, forming complexes which inactivate calcineurin, a key enzyme in T-cell signaling. The major side effects of both CYA and TAC include hypertension, renal insufficiency, and neurologic complications. However, there is evidence to suggest that obesity, hyperlipidemia, hirsutism, and gingival hyperplasia occur more commonly in patients who receive CYA, while a higher rate of diarrhea, insulin resistance, and diabetes is seen in patients who receive TAC. In response to inconsistent absorption of standard Cyclosporine, the development of a microemulsified formulation of cyclosporine (e.g., Neoral) has allowed consistent blood levels (43). Given their efficacy and oral administration, calcineurin inhibitors have a central role in posttransplant immunosuppression.

Safety and efficacy of calcineurin inhibitors is generally assessed by monitoring blood levels drawn prior to the dose (trough), although several investigators describe that blood levels drawn 2 h after a dose of Cyclosporine (i.e., C2 levels) rather than trough levels more accurately indicate exposure to drug. At many transplantation centers, the definition of appropriate target level of calcineurin inhibitor is linked to the patients time posttransplantation; in general, higher levels are required in the first several months postoperatively while the threat of rejection is acute. The target levels for calcineurin inhibitors can be appropriately adjusted downward as patients achieve both normal liver function and freedom from rejection months to years following surgery. In addition, a philosophy of minimizing exposure to high levels of calcineurin inhibitors in HBV or HCV infected patients is adopted by many transplant centers, due to the negative impact of “overimmunosuppression” on viral replication and disease recurrence.

Antiproliferative Agents

Antiproliferative agents such as AZA and MMF prevent the expansion of activated T cells and B cells and regulate immune mediated injury. Azathioprine, a purine analogue, is metabolized in the liver to its active compound, 6-mercaptopurine, which inhibits adenosine and guanine production, thus inhibiting DNA and RNA synthesis in rapidly

proliferating T cells. Mycophenolate Mofetil is a potent noncompetitive inhibitor of inosine monophosphate dehydrogenase (IMPDH), an enzyme necessary for the synthesis of guanine, a purine nucleotide. Mycophenolate Mofetil, when used in combination with a calcineurin inhibitor and steroids has been shown to be associated with lower rejection rates in the first 6 months posttransplantation when compared to AZA (44). The major toxicities associated with the use of either MMF or AZA are bone marrow suppression with resultant leukopenia, anemia, and thrombocytopenia, though this is more marked with AZA. Mycophenolate Mofetil has been associated with a greater incidence of dyspepsia, peptic ulcers, and diarrhea when compared to AZA, while pancreatitis may occur in individuals prescribed AZA. These side effects usually abate by dose reduction or discontinuation. The majority of transplant centers utilize a combination of a Calcineurin inhibitor with either MMF or, less commonly, AZA for at least the first 3–6 months posttransplantation. Since AZA and MMF do not cause renal insufficiency, they can be utilized in a strategy to minimize or avoid calcineurin inhibitor use, particularly in patients with renal dysfunction.

Other Immunosuppressive Agents

The limitations and untoward effects of available immunosuppressive agents have induced research and development of alternative agents. Sirolimus (Rapamycin) (RAPA) and its derivative Everolimus represent a new class of compounds, which achieve their immunosuppressive effect by inhibiting mTOR (target of Rapamycin). Inhibition of mTOR diminishes intracellular signaling distal to the IL-2 receptor and prevents T-cell replication. As the lymphoproliferative pathways inhibited by RAPA and Everolimus are distinct from those affected by calcineurin inhibitors, investigators have utilized these agents in combination with calcineurin inhibitors to achieve synergistic effect. However, enthusiasm for RAPA has been tempered by recent data showing higher rates of hepatic arterial thrombosis in patients who receive RAPA in the weeks immediately following transplantation (45). In addition, impaired wound healing has been noted in patients who receive RAPA, potentially due to impairment of granulation mediated by inhibition of TGF- β . Leukopenia, thrombocytopenia, and hyperlipidemia are the principal toxicities associated with RAPA and Everolimus. Recent reports of pneumonitis in RAPA treated patients have also emerged. A positive attribute of both RAPA and Everolimus is the absence of renal toxicity; some data suggest that post transplantation renal insufficiency can be reversed when calcineurin inhibitors are withdrawn and RAPA is initiated (46). Newer immunosuppressive agents will continue to be developed; it is hoped that these agents will be associated with diminished short- and long-term toxicity and facilitate a state of “immune tolerance” of the graft that will ultimately allow minimization of the requirement for immunosuppressive medications.

SUMMARY

Liver transplantation is the treatment of choice for appropriately selected patients with end stage liver disease.

Over the last several decades, significant advances in surgical technique and immunosuppression, selection of appropriate donors, grafts, and recipients, and improved therapies to prevent and treat postoperative complications have greatly improved posttransplantation outcomes. Despite these impressive achievements, many challenges remain. It is becoming increasingly apparent that the growing disparity between the number of liver transplant candidates and available organs will be associated with escalating death rates on the transplant waiting list. Enhanced posttransplantation survival has led to the emergence of complications associated with patient longevity, including nonhepatic disease, complications of immunosuppression, infections, neoplasia, and recurrence of the primary disease for which the liver transplantation was indicated. Further progress in liver transplantation will be achieved by maximizing the use of available organs, refinement and exploration of alternatives to deceased donor liver transplantation, improvements in immunosuppression, and enhanced recognition and treatment of long-term complications, particularly recurrent liver disease.

LUNG SOUNDS

ROBERT G. LOUDON
RAYMOND L. H. MURPHY

INTRODUCTION

Medical devices and instrumentation have developed rapidly in the last few decades, yet the first diagnostic medical instrument, the stethoscope, is still the most widely used, and it has changed only superficially in design and function.

The lungs, as we breathe, produce sounds that are transmitted to the body surface and to the mouth. The characteristics of these sounds convey information about the sound-producing and -transmitting structures. This information often has diagnostic value. Auscultation of the lungs is therefore widely taught and practiced. Textbooks of physical diagnosis present a body of information that has been derived by careful workers since the introduction of the stethoscope by R.T.H. Laennec in 1819. Much of that information was indeed presented by Laennec himself in his remarkable treatise, *De l'Auscultation Mediate*(1,2).

In this article, the medical devices and instruments that have been applied to the study of lung sounds, including the traditional acoustic stethoscope are reviewed. This survey will include sound transducers and their placement, methods, and equipment used for the recording and analysis of lung sounds, results obtained by the use of these techniques, and their clinical meaning. Recent work on this subject helps in the understanding of what we hear with the stethoscope; some is aimed at answering specific questions in physiology or pathology, and some is designed to provide new diagnostic and monitoring tools. Much of this work has been done in the past three decades, reflecting the enormous increase in the availability and quality of sound recording and processing techniques during that period. Reviews of lung sounds (3–5) and the success of the International Lung Sounds Association and its annual meetings bear witness to the upsurge of interest in the subject. Recommended standards for terms and techniques used in computerized respiratory sound

analysis (CORSA) have been prepared by a Task Force of the European Respiratory Society and published in the European Respiratory Review series (6). Better understanding of the meaning of current and future observations promises a larger place in the future for clinical and research applications.

THE STETHOSCOPE

The introduction of the stethoscope is an interesting story, well described in a bicentenary appreciation of Laennec's birth (7). Laennec, a young physician practicing in Paris, had occasionally found it useful to listen directly to a patient's chest, as had been done by physicians at least since the time of Hippocrates. In 1816, he wished to listen to an obese young lady's heart, but was reluctant to do so. He recollected (and this part of the story may be apocryphal) having seen boys playing on a park bench, one listening to the wooden bench at one end with his ear, and the other scratching the other end. Laennec's own words were that "he happened to recollect a simple and well known fact in acoustics, that sound could be transmitted through solid material or along a tube. He rolled a quire of paper into a sort of cylinder", placed one end over her heart, and listened at the other end. He was "not a little surprised and pleased" to hear the sounds more clearly in this "mediate" fashion than he had ever been able to do by the immediate application of his ear (2). Over the next 3 years he amassed an enormous amount of information about the sounds heard over the chests of his patients. As he did all of the autopsies at the Hopital Necker in Paris where he worked, he could often relate these sounds to the underlying pathology.

The first edition of Laennec's book (1) cost 13 francs for the two volumes; for an extra 2.50 francs, one received a wooden stethoscope. This "cylinder" served its purpose well. Modifications were introduced over the years, such as earpieces, flexible tubing, binaural stethoscopes, and a diaphragm on the chest piece. The relative merits of diaphragm and bell, the effect of the length and bore of the tubing, and the convenience of different patterns have been debated over the years, and the design of modern stethoscopes has been largely empirical, better models surviving because of their popularity with auscultators. Some characteristics that acousticians might think of as defects may indeed be advantageous from the physician's point of view. Those using them tend to feel comfortable listening to sounds with which they are familiar and may reject a stethoscope that lets them hear too much.

The assessment of acoustical performance of stethoscopes is not as simple as it might seem, and approaches to this problem have been described by several authors (8-10). The value of the traditional stethoscope is in no way reduced by the recent introduction of devices and instruments that can record and analyze the sounds that we hear. Rather, its value is increased. Appropriate use on new medical devices and instrumentation adds science to art, measurement to impression, and recordings to memory. Better understanding of what lung sounds mean, and of how much the simple stethoscope can tell us and how much it cannot, will make the use of the simple stethoscope in

examining rooms or on clinical rounds more important than ever.

SOUND TRANSDUCERS

Microphones transform mechanical energy to electrical energy, in the sound frequency range. Mechanical movement at the chest wall, resulting from the transmission of vibrations representing lung sounds to the chest wall surface, may be detected by any one of several devices. The main categories are ceramic, condenser (capacitor), and electret microphones. Ceramic microphones use a piezoelectric ceramic element that produces voltage when it is stressed. They tend to be stable and rugged and do not need a bias voltage for operation. Condenser microphones of the conventional type act as a variable capacitor that requires a bias voltage. They have good sensitivity and frequency-response characteristics. Electret microphones are a more recent type; a permanent charge on the diaphragm and no free electrostatic charge on its surface relieve the need for a polarizing (bias) voltage and reduce sensitivity to humidity.

Most microphones are designed to receive sound transmitted through air. Air coupling has been used by several investigators recording sounds from the surface of the chest wall, or from the trachea, and it is not surprising that stethoscope chest-pieces have been used for this purpose. The sound transmitted through the air column in stethoscope tubing can be applied to a microphone just as it can to an auscultating eardrum. Direct mechanical coupling of the transducer to the signal site (chest wall or tracheal surface) is an alternative to air coupling.

Several authors have reviewed the relative advantages and disadvantages of the various types of microphones as lung sound transducers (11,12). Desirable characteristics include sensitivity, rejection of ambient noise and surface noise, appropriate frequency response, insensitivity to variation in pressure of application, ease of attachment, ruggedness, and low price. Sensitivity is necessary because of the low level of the sound signal. Vesicular breath sounds will on occasion be virtually inaudible, for example, when airflow rates at the mouth are <0.27 L/s (13).

It is not always possible to study lung sounds in ideal circumstances, and rejection of ambient noise is important for many applications. Microphone housing can be helpful in this regard. Heart sounds are often of greater amplitude than lung sounds and may obscure them. They can be made less troublesome by the frequency response of the microphone because heart sounds are in a lower frequency range. Air coupling or inherent microphone characteristics may help by increasing the high frequency response. Microphone placement can also reduce the interference from heart sounds, which are, of course, loudest over the front of the chest, particularly in the left lower zone, and are less obtrusive on the right side, especially at the base of the right lung posteriorly. One method that has been adopted to reduce contamination of lung sounds by the heart sounds is to record the electrocardiogram simultaneously and to use some form of gating to delete segments where the heart sounds are present (14). The periodicity of

the heart sound makes this an attractive alternative for some purposes. Muscle noise can also contaminate lung sounds; again the frequency content of muscle noise is considerably lower than that of lung sounds, and a microphone that is insensitive to low frequency noise, or subsequent filtration of the signal, can be helpful. Muscle noise has the disadvantage of being timed with respiration because it arises from respiratory muscle activity, and this prevents it from being gated out on a time base. Most investigators have found that the frequency range of most interest in the recording and analysis of lung sounds lies between 100 and 1000 Hz, well within the frequency range of most microphones.

Surface noise is another important source of difficulty that can arise in recording and interpreting lung sounds. The movements associated with respiration make it easy for the microphone to slide over the skin surface in phase with respiration, producing sounds that are in phase with respiration, may be in the same frequency range as lung sounds, and may be very difficult to distinguish from friction sounds such as a pleural friction rub. Surface noise is more likely to arise when the microphone is mechanically in contact with, but not firmly fixed to, the chest wall. Air coupling may have advantages over mechanical coupling in this respect, but not always if the chest piece is of the diaphragm type commonly used in stethoscopes. Respiratory movement may also cause changes in the pressure with which a microphone is applied to the chest wall; if the microphone is strapped to the chest by a circumferential band, pressure on the microphone will increase as inspiration occurs and the chest diameter increases. Variation in pressure of the microphone against the chest wall is liable to alter the acoustic coupling, particularly if mechanical coupling is used to transmit surface movement to the sensitive microphone element. If the pressure exerted is sufficient, the deformation of the sensitive element may approach the limit of its range, damping the signal. Air-coupled microphones are less sensitive to changes in pressure of application, provided that the air chamber between chest wall surface and microphone element is vented to the outside, usually by a small-bore needle; but too large a vent may increase the amount of ambient sound recorded (15).

For some purposes, the sound transducer is applied only briefly at a specific site on the chest wall while a few breaths are recorded. For monitoring purposes, attachment of a sound recording device for a period of hours or overnight may be necessary. Lightness and small bulk are important in this type of application, and in some cases two-sided adhesive tape or an adhesive patch similar to that used for electrocardiograph electrodes is adequate for attachment.

If chest wall surface movement is unimpeded, the vibrations that correspond to the lung sound do not involve actual mechanical displacement of the chest wall surface by more than a few micrometers. A sensor applied to the surface may measure displacement or, if it applies a load to the chest wall surface, it may measure pressure rather than displacement, or a combination of the two. Some sound transducers measure acceleration rather than actual physical displacement. In each case, the reaction

of the sensor to the signal being sensed will influence its characteristics. Inertia, rigidity, or counterpressure by the sensing element may cause distortion of the sound. Particularly in the case of accelerometers, the mass of the sensing element will determine its frequency response characteristics. It is not always clear what criteria are used in making a decision about microphone type. The human ear is remarkably good at separating out the different sounds that may be combined to form a mixed signal, and often the final judgment may be made by listening to replay of a recorded signal. The efficiency of a particular sound system depends on the purpose for which it is intended, but unless the signal is listened to with an educated ear it is easy to be misled by, for example, frequency components whose origin is not obvious from inspection of a graphic or calculated spectrum.

RECORDING AND DISPLAY SYSTEMS

Those using devices and instruments to study lung sounds will choose recording and display systems appropriate to their purpose. Audio tape and strip-chart recorders have now virtually all been replaced by computers or systems designed or modified for the purpose. The signals of interest may be presented to the observer audibly, visually, or in a variety of forms during and after analysis. Standard physical examination of the chest does, in a sense, present audible and visual displays to the clinician. The stethoscope presents an audible signal at the earpieces, and the clinician observes his patient breathe to get a visual display of respiratory movement.

For teaching purposes at the bedside, an electronic stethoscope or microphone may be connected to several headsets worn by students, by telemetry if preferred, giving the instructor an opportunity to share the sounds with them. In this way, a realistic learning experience is provided with less imposition on the patient's patience. Recording of sounds for teaching purposes usually involves a computer system, or an electronic stethoscope and audio tape recorder. Standard audiovisual equipment has been used for editing, for adding comments, and for preparation of cassettes or disks for distribution (16,17) for teaching purposes.

For research purposes, arrays of microphones are now available with computer recording, analysis, and display systems to show the distribution of sound signals over the surface of the chest (18–20). Brief differences in time of sound signals have clinical relevance by allowing comparison in timing of the same sound signal of a crackle or the start of a wheeze arriving at different surface sites in the same patient. And on a longer time base, in asthmatics, for example, the site, the frequency pattern, and the sound amplitude of wheezing may change during exercise, sleep, exposure to cold air or to inhalants such as pollen, or industrial exposure, or in response to drug treatment. Sleep disorders such as nocturnal asthma, the sleep apnea syndrome, and snoring, may be studied by sound monitoring. Nocturnal asthma and snoring are present in the same patient more often than would be expected as a result of chance alone, especially in asthmatics under the age of 40 (21). Snoring is a respiratory, but not a lung sound, as it

rises in the upper airways, at or above the larynx. Possible explanations for the association with asthma, and sound monitoring methods and devices, have been reviewed (22).

Comparisons over long periods of time were once made by recording the results of analyses of wheezes, rather than by comparing the actual recorded sounds. The development and proliferation of computers with rapidly increasing audiovisual capability and storage capacity are now, however, changing the situation to allow storage of original data on tape or disk together with derived values. Kraman et al. (23) evaluated minidisk recorders, with their considerable increase of storage capacity for music, for lung sound recording. They found no distortion of frequency or waveforms that would interfere with this use. For some studies, analyzing sound signals in real time as they are being acquired makes it simpler to monitor results as they accrue, and helps direct the course of an experiment.

An early example of audiovisual recording is in a paper by Krumpe et al. (24), in which the authors discuss the evaluation of bronchial air leaks by auscultation and phonopneumography. They describe three patients who develop air leaks from the bronchi after resectional lung surgery and in whom "videophonopneumography" provided more precise correlation of abnormal sounds with the underlying visibly leaking bronchial abnormalities. Audiovisual tapes or disks are useful for teaching or demonstration purposes, by providing examples of classical or of unusual sounds.

Simultaneous sound recordings at several sites have been used to study the spatial distribution of lung sounds. This has provided information on regional ventilation, and on the localization of abnormalities in disease such as pneumonia, airways obstruction, bullae, or small areas of infarction, atelectasis, fibrosis, or interstitial lung disease. Indeed, lung imaging by sound production provides a potential alternative to chest X rays and computed tomography (CT) scans, without the need to inject possibly damaging energy or drugs.

For research purposes, analysis of sound signals and any associated physiological measurements were formerly conducted off-line. The signals were recorded on tape or disk and replayed for analysis. This allowed editing for selection of relevant segments of data and for quality control and signal conditioning, such as amplification, filtering, or attenuation. The purpose of each study will determine the equipment needs, but most current lung sound research uses computers with high speed audiovisual capabilities. These can be adapted to record lung sounds along with physiological respiratory variables, such as airflow, lung volume, and esophageal pressure, measured simultaneously, which can then be related to the lung sounds. If relationships in time are to be studied with any precision, it is necessary to record signals together on one medium and it is necessary to know the frequency characteristics of the items of equipment used, and the time delays introduced by filters, envelope detectors, integrators, frequency analyzers, and other acquisition or processing devices.

SOUND ANALYSIS

Sound amplitude and frequency content are the two measurements that most commonly form the basis of lung

sound analysis systems. Early studies presented the sound signal as a time-amplitude plot. If such plots represent a respiratory cycle on a few centimeters of paper, the result is a compressed representation that superimposes many successive sound signal cycles to form an envelope. Simple integrating and rectifying circuits can provide the outline of the envelope as a single line, thus acting as an envelope detector, ac-dc converter, or sound-level meter. Filters incorporated in such circuitry can yield a method for comparing sound amplitude in different frequency bands (14,17) or to provide a signal believed to represent the important band range of vesicular sound from the ventilation point of view (25).

The sound spectrogram is really an extension of this principle, the signal of interest being passed repetitively through a narrow bandpass filter with slowly changing center frequency and the signals passed being assembled to present a graphic display of time on the horizontal axis, sound frequency on the vertical axis, and sound amplitude by the degree of blackening of the paper. Sound spectrograms of this type, used routinely in the speech sciences, were applied to heart and lung sounds extensively by McKusick et al. (26) and are still widely used to good effect.

The time-amplitude plot of a sound signal has been used to advantage in a different way by Murphy et al. (27). Features of the sound waveform cannot be studied in detail without using a rapid time sweep on an oscilloscope, and only a brief (a few milliseconds) segment can be viewed in this way. By digitizing a sound signal at a rapid rate and playing the signal back through a digital-to-analogue converter (DAC), a "time-expanded" waveform was prepared. This has proved of particular value in studying crackles (rales), the brief sounds heard over fibrotic, edematous, consolidated, or atelectatic lung. Measurable characteristics of these crackles, such as the initial or the largest deflection width, show diagnostic value and automatic methods for their measurement are now being applied.

The sound characteristics of rhonchi, as opposed to crackles (continuous versus discontinuous adventitious sounds) require an additional approach. Essentially, they are longer in duration, possessed of perceptible pitch, and have a repetitive waveform pattern. Waveform analysis is a rapidly moving field. Sound frequency spectrum analysis of lung sounds has most frequently been reported in terms of discrete Fourier analysis. Several workers have used a fast Fourier transform algorithm to measure frequency content of signal segments. One way of representing time-variant sound signals is to assemble a sequence of spectra with frequency on the horizontal axis, sound amplitude or power on the vertical axis, and time on an oblique axis. Usually, some overlapping of the sequential segments and appropriate windowing (e.g., Hanning) are used. The resulting "bird's-eye view" has proved to be readily related to sounds, providing a mental image that can evoke a mental image of the sounds represented. Individual peaks on a frequency spectrum may be related to individual wheezes coming from the chest, and peak detection programs have been used (28,29) to compare them statistically. The fast Fourier transform is the most frequently reported type of waveform analysis, but other techniques, such as those of linear predictive coding (LPC), the

maximal entropy method of waveform analysis, fractal-dimension analysis, wavelet networks, and artificial neural networks, are being explored. They are most likely to prove useful in brief sounds, in timing the onset or rapid changes in complex sounds, or in noting time relationships among sounds recorded at separate or at adjacent sensors. Any graphic form of waveform analysis is more readily interpreted when it can be combined with visual examination of a simultaneous time-amplitude plot.

RESULTS AND CLINICAL APPLICATIONS

Increasing attention and techniques for more exact representation have led to a rapid growth in information available about lung sounds. The meaning of these various items of information will emerge more slowly, as will clinical applications. The objective, quantitative study of lung sounds, is still at an interesting rapid growth phase of development. It is clear that a good deal of information is contained in the signals that we hear emerging from the chest (2) and that auscultation is one of the safest of diagnostic procedures, since no external energy or chemical is inserted into the body. It is also clear that some of the information conveyed would be difficult to obtain in any other way. Much of it is regional or local and may be able to tell us about mechanical events and structural characteristics at specific sites in the chest (30,31). The vesicular lung sounds have been studied in sufficient detail that we now know more about the probable general range of bronchial dimensions involved in the production of these sounds, but not the exact site; the effects of flow rate and lung volume, but not the exact nature of the relationships; and we know that there are relationships between vesicular lung sound intensity and regional ventilation, but not their exact nature. The roles of production and of transmission of these sounds are not always easy to distinguish from one another in the end-product, sensed at the site of their detection, but recent work by Kiyokawa and Pasterkamp (32) shows progress in this distinction.

We know that wheezing indicates airflow obstruction and roughly its levels in the bronchial tree. We know that several factors, such as airway dimensions, geometry, and compressibility, are important. Endobronchial surface characteristics and the presence and nature of secretions may also have some effect. We know that flow rates and intrathoracic pressure and volume history affect wheezes; but we do not know the relative importance of these factors and the extent of variation from one disease state to another. Crackles are known to be associated with certain diseases and not with other radiographically similar diseases, but we are not sure why. We know that crackles from different types of abnormal lungs have different characteristics, but a great deal of clinical observation will be needed to test their diagnostic value: and physiological or pathological studies to understand the basic mechanisms involved.

Laennec's stethoscope—and for that matter the stethoscope pulled currently from the pocket of a white coat—allows the user to consider the sound of one breath at one place at one time. Medical devices and equipment are now

being developed that can expand the observations in time, in space, in content, and in information; for example, from one or two breaths to hundreds of breaths, and from one specific point on the chest to the entire chest. From one breath described or remembered as vesicular, reduced in volume, with a few end-expiratory crackles the information may expand to an assembly of pages of tables and graphs showing a variety of measured features. These can include diagrams of the chest showing where and how the lungs and ventilation vary, where and how much airflow obstruction or lung collapse is present, and can offer a regional description of airways' diameters and other characteristics.

Que et al. (33) developed a system to measure tracheal flow from tracheal sounds, and to use this to estimate tidal volume, minute ventilation, respiratory frequency, mean inspiratory flow rate, and duty cycle. Careful observations and comparison of the results with simultaneously recorded pneumotachygraph-derived volumes in various postures allowed them to address the problems inherent in the adverse signal/noise ratio and the low level of the flow-derived sound at flow rates seen in quiet breathing. The system that they developed suggests that their method of phonospirometry measures overall ventilation reasonably accurately without mouthpiece, noseclip, or rigid postural constraints.

The study by Kiyokawa and Pasterkamp (32) in a sense complements this by measuring lung sounds at two closely spaced sensors on the chest surface. In five healthy subjects, volume-dependent variations in phase and amplitude of signals recorded over the lower lobe might reflect spatial variations of airways and diaphragm during breathing. These authors noted similar variations in phase and amplitude on passive sound transmission, suggesting that a difference in sound transmission was a more likely cause of the variations than a difference in sound generation. Their observations compare local sounds that reflect local circumstances; the observations discussed in the previous paragraph concern central sounds that reflect total ventilation.

Several systems are now available or under development that can record sound signals simultaneously from a number of sites, with or without associated physiological signals, and present the observations for read-out by the physician. Lung sound documentation and analysis can now be done on personal digital assistants (PDAs) as well as on laptop computers. Stethoscopes can be connected to these devices wirelessly or by a short cable. This allows objective quantification of these sounds at the bedside (34,35). A personal computer based "telemedicine" system has been described in which two remote hemodialysis sites were connected by high speed telephone lines to allow video and audio supervision of dialysis from a central site (36). Such equipment may eventually be used to supplement—or perhaps in some circumstances replace—other diagnostic devices such as fluoroscopy or other types of radiographic imaging. They have the great advantage of avoiding the subjection of a patient to any potentially harmful radiation or other energy, and can therefore be used over prolonged periods of time.

Transthoracic speed of sound introduced at the mouth or the supraclavicular space (35) can be mapped at several sites on the chest using sound input with specific

characteristics. This may allow noninvasive monitoring of conditions such as pneumonia, congestive heart failure, or pleural effusion that increase intrathoracic density. Chronic obstructive lung disease may be detected by reading lung sound maps showing time intensity plots at several sites over the chest; this appears to be more accurate than current clinical diagnostic methods. The ability to detect diaphragmatic movement by multichannel lung sound analysis suggests that it may prove to be an inexpensive bedside test. It may also have useful applications in ventilator management.

It seems clear that wider application of these new developments in lung sound analysis will lead to safe, useful, and rewarding forms of clinical and physiological information that can answer many imaging, diagnostic, and monitoring problems.

INTRODUCTION

The principle of nuclear magnetic resonance (NMR) was discovered by Felix Bloch and Edward Purcell independently in 1946. The two were awarded the Nobel Prize in Physics for the discovery, which had numerous applications in studying molecular structure and diffusion. Atomic nuclei with an odd number of protons or an odd number of neutrons behave like spinning particles, which, in turn, create a small nuclear spin angular momentum. This angular momentum of an electrically charged particle such as the nucleus of a proton leads to a magnetic dipole moment. In the absence of an external magnetic field, the orientation of these magnetic moments is random due to thermal random motion. These magnetic moments are referred to as spins, because the fundamentals of the phenomena can be explained using classical physics where the moments act similarly to toy tops or gyroscopes. The NMR phenomenon exists in several atoms and is used today to study metabolism via imaging. However, hydrogen is the simplest and most imaged nucleus in MR examinations of biological tissues because of its prevalence and high signal compared with other nuclei.

NMR imaging was renamed Magnetic resonance imaging (MRI) to remove the word nuclear, which the general public associated with ionizing radiation. MRI can be explained as the interaction of spins with three magnetic fields: a large static field referred to as B_0 , which organizes the orientation of the spins; a radio frequency (RF) magnetic field referred to as B_1 , which perturbs the spins so that a signal can be created; and spatially varying magnetic fields referred to as gradients, which encode the spatial location of the spins. These subsystems are shown in Fig. 1.

When an external magnetic field is present, the distribution of the magnetic moments is no longer random. Current technology allows large, homogenous static

magnetic fields to be created using superconducting magnets, whereas smaller fields are possible with permanent magnets. In most conventional systems, the static field is aligned along the longitudinal axis or the long axis of the body, as shown in the z axis in Fig. 1. Clinical MRI scanners have been built with static fields ranging from 0.1 to 7 T, but the vast majority of scanners are between 0.5 and 3.0 T.

THEORY

Creating Net Magnetization

Consider a static field oriented along the z axis with magnitude B_0 , or represented as a vector $\mathbf{B} = B_0\mathbf{k}$. Hydrogen protons have a quantum operator whose z component is quantized to $\pm\frac{1}{2}$. According to quantum mechanics, only two discrete sets of orientations exist for the magnetic dipole of each hydrogen nucleus. In the parallel energy state, the magnetic moment vector μ orients itself so that its projection on the z axis aligns with the direction of the main magnetic field B_0 . In the antiparallel energy state, this projection aligns in the opposite direction of the main field. It can be shown that the two allowed angles between magnetic dipoles and the static field are $\theta = \pm 54^\circ$ (1), and thus a population of spins will be oriented as in Fig. 2b.

The ratio of spins in the parallel state n^- to the spins in antiparallel state n^+ is given by the Boltzmann equation

$$\frac{n^-}{n^+} = e^{\frac{-\Delta E}{kT}} = e^{-\frac{\gamma^2 \hbar^2 B_0 k T}{kT}} \quad (1)$$

where γ is a nuclei-specific constant referred to as the gyromagnetic ratio, k denotes the Boltzmann constant, and T is the absolute temperature. There are only slightly more spins in the parallel state than in the antiparallel state because this state is of lower energy; however, the prevalence of water in biological tissue can create an adequate signal with this differential. This distribution of spin orientations in a small volume element results in an average or net magnetization \mathbf{M} , which aligns along the longitudinal or z axis, as shown in Fig. 2b. The entire process is referred to as polarization. The contributions in the transverse (x - y) plane sum to zero. As the argument of the exponential in Equation 1 is small and the difference in energy levels varies proportionally with field strength, the length of the net magnetization vector varies linearly with field strength. A quantum mechanics description of the spin distribution can be found elsewhere (2).

Signal Generation

The behavior of the net magnetization vector in an external field can be described by the classical model according to

Figure 1. Clinical 1.5T MRI scanner with static field oriented along long axis of the body (z). Patient's head lies in RF coil, which is used to both perturb and receive MR signal. Scanner bed will move patient into middle of cylinder before imaging begins. MR gradient coils for y dimension are shown, which have mirrored coils on the opposite side of the magnet. A portion of the z gradient, based on solenoid design, is also shown.

the Bloch equation.

$$\frac{d\mathbf{M}}{dt} = \gamma(\mathbf{M} \times \mathbf{B}) \quad (2)$$

A useful parallel description is a spinning toy top where the axis of the top is analogous to \mathbf{M} and gravity is analogous to \mathbf{B} . In the equilibrium state, the net magnetization \mathbf{M} and the static magnetic field \mathbf{B}_0 are parallel so that \mathbf{M} does not experience a torque and consequently the direction of \mathbf{M} does not change. Similarly, the axis of a spinning top oriented vertically remains vertical.

The second magnetic field in MRI is an RF field that is created using an RF amplifier that supplies oscillating current into a coil that surrounds the patient. The coil is designed to create a magnetic field, referred to as \mathbf{B}_1 field, oriented in the transverse plane and approximately on the order of 10 T. By having the RF energy oscillate at the resonant frequency of the nuclei, this relatively low field can perturb and rotate the net magnetization away from its orientation along the longitudinal axis. The resonant or Larmor frequency ω_0 is related to the static field strength such that $\omega_0 = \gamma B_0$. For protons, the gyromagnetic ratio $\gamma/2\pi = 42.57 \text{ MHz/T}$. The field created by the tuned RF coil, referred to as an excitation, can be

Figure 2. (a) shows the precession of a spin with a magnetic moment μ in a static field with magnetic flux density of B_0 . An assembly of spins in parallel and antiparallel states is shown in (b). The Boltzmann equation determines the ratio of the spins in the two states. As the components in x and y compensate each other, the net magnetization \mathbf{M} has a component in the z direction only (parallel to B_0). The coordinate system is shown with its unit vectors \mathbf{i} , \mathbf{j} , and \mathbf{k} along x , y , and z .

viewed as an applied torque that tips or flips spins away from the longitudinal axis by an angle referred to as the flip angle. The strength of the \mathbf{B}_1 field and the length of time it is applied determine the flip angle. The flip angle usually varies between 5° and 180° depending on the application.

Once the magnetization is no longer parallel to the static field, the right-hand side of Equation 5 is no longer zero and the direction of the net magnetization will change. In fact, it will begin to precess about the axis of the static magnetic field and at the Larmor frequency. In general, the precessional frequency is directly proportional to the magnetic field experienced by the spin, such that $\omega = \gamma B$. Similar to a toy top that is tipped an angle θ off its vertical axis, the top will maintain an angle of θ as it rotates about the vertical force supplied by gravity.

The net magnetization can be described by its longitudinal component M_z and its transverse component M_{xy} , a complex value whose magnitude describes the component's strength and whose angle describes the location of the component in the x - y plane. The rapid rotation of the transverse component will create a time-varying magnetic flux. A properly oriented receiver coil will detect this time-varying flux as a time-varying voltage, in agreement with Faraday's law of induction. Often, the same coil used for excitation can also be used for reception. This voltage signal, known as a Free Induction Decay, or FID, is shown after a 90° excitation in Fig. 3, which is the most basic form of a MR signal. Although the entire magnetization vector is tipped into the transverse plane in this example, smaller flip angles will also create a transverse magnetization and thus an FID.

Figure 3. Generation of a free induction decay after a 90° RF excitation.

The complex motion of the net magnetization, and thus the recorded FID signal, can be described in a simplified manner by using a rotating reference frame that rotates at the Larmor frequency about the static B_0 field. In this rotating frame, the FID will decay as a simple exponential. The causes of this decay, and its use as potential image contrast mechanism, will be described after spatial encoding is described. Most MR signals are demodulating using the Larmor frequency and, thus are effectively acquired in the rotating frame.

Spatial Encoding

The first two magnetic fields described above allow biological tissue to be polarized, perturbed, and measured. In terms of clinical imaging, however, these fields merely allow us to integrate the signal derived throughout the body, a measure of little value. The field of MRI developed only when a third spatially varying magnetic field, referred to as a gradient field, was invented to spatially encode the MRI signal. This method allows us to achieve sub-millimeter resolution while using RF energy whose wavelengths are on the order of tens of centimeters to meters.

Dr. Paul Lauterbur realized, in 1973, that, instead of working like others to build a more homogenous field for NMR spectroscopy, spatially varying the strength of the magnetic field could provide a means to build an imaging system. For this work, he won the Nobel Prize in Medicine along with Sir Peter Mansfield in 2003.

The three gradient coils in a cylindrical MRI system, two of which are shown in Fig. 1, are laid out concentrically on a cylinder. The cylinder surrounds the patient as he or she lies inside of the static B_0 field. The three coils are designed to create longitudinal magnetic fields in z that vary in strength linearly with the x , y , and z dimensions, respectively. The digital scanner hardware controls the current waveforms, which are amplified by three respective gradient amplifiers before being sent to the gradient coils. The strength of each component gradient field, G_x , G_y , or G_z , is measured in G/cm or mT/m and is directly proportional to the current supplied to the coil. Changing gradient strengths quickly on clinical scanners is possible with amplifiers capable of slew rates of approximately 200 mT/m/s.

As the resonant frequency of an MR spin is directly proportional to the magnetic field it experiences, a gradient coil allows us to linearly vary the frequency of spins according to their position within the magnet. For example, a gradient of strength G_x , which does not vary in time, causes the frequency of spins to vary linearly with the x coordinate.

$$w(x) = \gamma[B_0 + G_x x] \quad (3)$$

Spins to the left of the magnet center rotate slower, spins at the exact magnet center remain unchanged, and spins to the right rotate faster than they did without the gradient.

Gradients can be used to selectively excite only spins from a slice or slab of tissue. Slice thicknesses in 2D MRI range from 1 to 20 mm. To select a transverse slice, the z gradient can be applied during RF excitation, which will cause the resonant frequency to vary as a function of z in

the magnet, such that $w(z) = \gamma[B_0 + G_z z]$. Instead of exciting all the spins within the magnet, only spins whose frequency matches the narrow bandwidth of a pulsed-RF excitation will be excited within a slice at the center of the magnet. Modulating the frequency of the RF pulse up will move the slice superior in the body, whereas modulating it down will excite an inferior slice. Likewise, slices perpendicular to the x or y axis can be excited by applying a G_x or G_y gradient, respectively, simultaneously with RF excitation. In fact, an oblique slice orientation can be achieved with a combination of two or more gradients. The ability to control from which tissue signal is obtained, without any patient movement, is a major advantage of MRI.

Simplified MR Spatial Encoding. Once a slice of tissue is selected, the two remaining spatial dimensions must be encoded. A somewhat simplified method of visualizing encoding follows. For a transverse slice, receiver data could be obtained after RF excitation while a constant gradient was applied in the x direction. Tuning a receiver to select a very narrowband frequency range would determine which spins were present within a spatial range $x_1 < x < x_1 + \Delta x$. By repeating the experiment while changing the narrowband frequency range, a projection of the spin densities along the x axis could be determined. Likewise, the same experiment could be repeated while applying a constant y gradient to obtain a projection of spin densities along the y axis. Likewise, projections along arbitrary axes could be achieved by acquiring data while applying a combination of x and y gradients after RF excitation. In a matter very similar to computed tomography (CT) imaging, an image could be reconstructed from this set of acquired projections.

MR Spatial Encoding in the Fourier Domain. Although possible, the proposed method would be very slow because each sample point within each projection would require its own MR experiment or excitation. Time between excitations in MR vary in duration from 2 ms to 4 s depending on the desired image contrast. Even with the shortest excitation, each slice would require over 3 min of scan time. All the data for an entire projection can be acquired within milliseconds by considering how the phase of the transverse magnetization varies, instead of the frequency, with spatial position. This description also uses the concept that position in MR is encoding using an alternative Fourier domain where signal location is mapped onto spatial frequencies.

Integrating the frequency expression in Equation 3 indicates how the spin phase, or location of the transverse magnetization within the transverse plane, will vary with the x coordinate during a general time-varying gradient $G_x(t)$ applied after excitation. Ignoring the phase term due to the B_0 field, which will be removed during demodulation of the received signal, gives a phase term for each spin that varies with the spatial position x and the integral of the applied gradient at each point in time.

$$M_{xy}(x, t) = M_{xy}(x) e^{-j2\pi \frac{\gamma}{2\pi} \int_{t=0}^t [G_x(t')x] dt'} \quad (4)$$

The signal received by the MR coil can be expressed as an integration of all the excited spins in the x - y plane using the following equation:

$$S(t) = \int_y \left[\int_x M_{xy}(x,y)e^{-j2\pi k_x(t)x} dx \right] dy \quad (5)$$

where a Fourier spatial frequency, termed $k_x(t)$ in MR, has been substituted for $\frac{\gamma}{2\pi} \int_{t'=0}^t (G_x(t')x) dt'$. In this example, the coil simply integrates all the spins in the y dimension, and thus only spatial information in x is available. The received signal can be seen as a 1D Fourier transform of the projection of transverse magnetization $M_{xy}(x, y)$ onto the x axis. The corresponding coordinate in the Fourier domain at each point in time t is determined by the ongoing integral of the gradient strength. Thus, we can acquire an entire projection in one experiment rather than numerous MR experiments as in the simplified example with the narrow-band receiver.

The last spatial dimension for this 2D imaging example y has a corresponding Fourier dimension termed k_y , which can be similarly traversed by designing the integral of the G_y gradient current.

$$S(t) = \int_y \int_x M_{xy}(x, t) e^{-j2\pi k_x(t)x} e^{-j2\pi k_y(t)y} dx dy \quad (6)$$

where $k_y(t) = \frac{\gamma}{2\pi} \int_{t'=0}^t (G_y(t')y) dt'$. The integral of the gradients determines location in the Fourier space known as k space in MRI. Numerous strategies can be used to traverse and sample k space before transforming the data, often with a Fast Fourier Transform (FFT), into the image domain. The method can be extended to three dimensions by exciting a slab of tissue and using the G_z gradient to encode the third dimension.

As in the simplified example, a combination of G_x and G_y can be used to sample the 1D Fourier expression of projections of M_{xy} at arbitrary angles. This data can be transformed into the actual projections using 1D inverse Fourier transforms. Methods very similar to computed tomography can translate the projection data into an image. Although acquiring data in this manner, known as radial imaging, has interesting properties, by far the most popular method in clinical imaging traverses the Fourier space in a Cartesian raster pattern known as spin-warp imaging.

This sampling is typically completed in a series of experiments, where the time between consecutive

excitations is referred to as the repetition time TR. In many MR acquisition schemes, a complete k space line is acquired along k_x , known as the frequency-encoding or readout direction, for each TR. During each subsequent TR, a line parallel to the previous one is sampled after applying a short, pulsed G_y gradient. By changing the strength of the pulsed G_y gradient by equal increments during each MR experiment, a different phase shift is placed on spins depending on their position in y . In terms of the k space formalism, the area under the G_y gradient pulse causes a vertical displacement in k space such that a different horizontal line in k space is acquired in each MR experiment, as shown in Fig. 4. Here, the vertical direction in k space is known as the phase-encoding direction. By applying 1D Fourier transforms in the k_x direction, spin position is resolved based on their frequency during readout. An image is formed by following these horizontal transforms with 1D Fourier transforms in the k_y dimension. Here, the y position of spins is resolved due to the different phase shifts experienced in each experiment prior to the readout gradient.

The image coverage, or field of view, in MRI decreases as the sampling rate decreases. As MR samples in the frequency domain, failure to sample fast enough in k space leads to aliasing in the image domain. Higher resolution in MRI requires obtaining higher spatial frequencies or larger extents of k space. Achieving adequate resolution and coverage then increases the amount of k space sampling that is required and increases imaging time. Unlike other modalities where hundreds to thousands of detectors can be used at a time, encoding spatial position in this method only allows one point of data to be taken at a time, which explains MR's relatively slow acquisition speed. Industrial scanners have only recently determined how to partially bypass this limitation by using up to 32 different receivers who have different spatial sensitivities to different tissues. The differences of each receiver in proximity, and thus sensitivity to each spin, can be used to synthesize unacquired regions of k space.

Image Contrast Through Varying Decay Rates

Imaging the spatial density distribution of hydrogen often produces a very low contrast image, as the density of hydrogen is relatively consistent in soft tissue. However, the imaging experiments described above can be easily modified to exploit the differences in time for which the

Figure 4. 2D spin-warp imaging with one readout per TR. One complete line is sampled along the readout direction on a rectilinear grid in the Fourier domain (k space) with a resolution of Δk_x (circles on the arrow). The next line is acquired parallel at a distance of Δk_y on the grid by increasing the phase-encoding gradient. This scheme is repeated until the desired grid is sampled. Images are reconstructed by an inverse 2D Fourier transform (FT).

Figure 5. The regrowth of the longitudinal magnetization M_z (a) and the decay of the transverse magnetization M_{xy} (b) after an RF excitation.

MR spins remain perturbed. The differences account for the vast majority of image contrast in standard clinical MRI.

After the spins are perturbed, the transverse magnetization decays toward zero, whereas, the longitudinal magnetization returns toward its equilibrium magnetization. As more mechanisms exist for the loss of transverse magnetization than for the regrowth of longitudinal magnetization, the length of the magnetization vector \mathbf{M} does not remain constant after excitation. Although related, the rate of longitudinal relaxation time, termed T_1 , is always larger than the rate of transverse relaxation time, termed T_2 .

If the magnetization has been completely tipped in the transverse plane with a flip angle of 90° , then the longitudinal magnetization recovers as

$$M_z = M_0[1 - e^{-t/T_1}] \quad (7)$$

T_1 is also called the spin–lattice relaxation time, because it depends on the properties of the nucleus and its interactions with its local environment. The transverse relaxation time T_2 is also referred to as the spin–spin relaxation time, reflecting dephasing due to interactions between

neighboring nuclei.

$$M_{xy} = M_{xy}(0)e^{-t/T_2} \quad (8)$$

where $M_{xy}(0)$ is the initial transverse magnetization ($M_{xy}(0) = M_0$ for a 90° pulse). The temporal evolution of the longitudinal and transverse magnetization is shown in Fig. 5. In general, hydrogen protons in close proximity to macromolecules have lower relaxation times than bulk water that is freer to rotate and translate its position.

Delaying the encoding and acquisition of the transverse magnetization until some time after RF excitation generates T_2 image contrast. As injured and pathological tissues generally have higher T_2 relaxation rates, T_2 -weighted images have positive image contrast. T_1 -weighting can be achieved by using an interval between MR experiments, the TR parameter, which does not allow enough time for tissue to fully recover its longitudinal magnetization. Thus, tissues with shorter T_1 relaxation rates will recover more quickly and thus have more signal present in the subsequent experiments used to build the image than tissues with longer T_1 . In general, T_1 -weighting provides negative contrast for pathological tissue. An example is shown in Fig. 6 for a human brain tumor. The differing rates of

Figure 6. The flexibility of MR to image in different planes with different types of image contrast is shown in these sagittal and axial brain tumor (arrows) images.

Table 1. Longitudinal (T_1) and Transverse (T_2) Proton Nuclear Magnetic Resonance Relaxation Times for Several Tissues and Blood at 1.5 T

Tissue	T_1 /ms	T_2 /ms
Gray brain matter (3)	950	100
White brain matter (3)	600	80
Cerebrospinal fluid (CSF) (3)	4500	2200
Muscle (3)	900	50
Fatty tissue (3)	250	60
Oxygenated blood	1200	220
De-oxygenated blood	1200	120

recovery can also be used to null out an unwanted tissue, such as fat, by inverting all the spins 180° prior to imaging. As the point where unwanted tissue passes through the null of the recovery phase, an imaging experiment is begun. This technique is referred to as inversion recovery magnetization preparation or simply inversion recovery. Table 1 lists representative relaxation times for some tissues (3). Extensive reviews of the relaxations times (4) and methods for their measurement (3,4) are available.

Spin Echoes

Ideally, the transverse magnetization decays according to T_2 . However, the signal dephasing in the transverse plane is significantly accelerated by field inhomogeneities due to difference in magnetic susceptibility between tissue types or the presence of paramagnetic iron. The largest inhomogeneities occur at air/tissue interfaces, such as near the sinuses or near the diaphragm. These effects lead to different precession frequencies and loss of coherence that are described by a T_2^* relaxation time

$$\frac{1}{T_2^*} = \frac{1}{T_2} + \frac{1}{T_2'} \tag{9}$$

where T_2' represents the decay due to the effects described above.

A method to reverse these often undesirable dephasing effects uses a 90° pulse followed by a 180° spin refocusing pulse after a time delay τ_d , as shown in Fig. 7b. The first pulse rotates the longitudinal magnetization into the transverse plane as in the case of the FID. Prior to the second pulse, the magnetization dephases in the transverse plane due to T_2^* effects, with some spins

Figure 7. Generation of a (a) free induction decay and (b) a spin echo. In (a), other local factors dephase signal faster according to a T_2^* decay rate. If a second RF pulse is applied at time $\tau_d = TE/2$ to flip the magnetization by 180° , the spins will refocus and form an echo at $TE = 2\tau_d$, which is only subject to T_2 decay.

rotating faster than the Larmor frequency and others spinning slower. The second pulse flips all magnetic moments about an axis in the transverse plane, effectively inverting the phase accruals due to different rotational frequencies. Over the second interval τ_d , the faster spins will catch up with the slower spins. As a result, a spin echo is said to form at the time $2\tau_d$, also known as the echo time or TE time. The amplitude of the signal at time TE is only decreased due to T_2 decay whereas the T_2^* effects have been reversed. A simplified pulse sequence for the generation of a spin echo is shown in Fig. 7b without the gradient waveforms necessary for spatial encoding.

Signal-to-Noise Ratios

Signal in MR is generally proportional to the number of nuclei and, thus, to the volume of the image voxel. Noise in MR is caused by the random fluctuations of electrons in the patient, and thus the source of noise is independent from the signal generating sources. The data acquisition system is designed such that the noise level from properly designed MR electronics will be dominated by patient noise. Overall, $SNR = \text{voxel volume} * \sqrt{\text{total data sampling time}}$.

Imaging Sequences

Ideally, all MRI would be performed with high spatial resolution, a high signal-to-noise ratio (SNR), ultrashort imaging time, and no artifacts. The difficulty in achieving all of these properties simultaneously has led to the development of many acquisition methods that differ in image contrast, acquisition speed, SNR, susceptibility to and type of artifacts, energy deposited in the imaged patient, and suppression of unwanted signal such as fat. Their corresponding images represent a combination of tissue-specific parameters T_1 , T_2 , proton density ρ , and scan-specific parameters such as repetition time (TR), echo time (TE), flip angle, field of view (FOV), spatial resolution, and magnetization preparation.

Gradient Recalled Echo (GRE) Imaging

Spin-echo imaging is desirable because signal voids due to magnetic field inhomogeneity are avoided that could mask pathological tissue or injury. Long repetition times, and thus long scan times, are necessary in spin-echo imaging to allow longitudinal magnetization to return after the relatively high flip angles used. Long scan times hinder the capture of dynamic processes such as the beating heart, cause discomfort to the patient, and limit the number of patients who can be imaged with this expensive resource. Thus, other methods of imaging have been developed. In gradient recalled echo (GRE) imaging, the echo is formed by dephasing and rephasing of the signal with gradient fields as shown in Fig. 8. In these diagrams, known as pulse sequence diagrams, plots of the time-varying gradient and RF waveforms are shown as function of time. Compared with the spin-echo sequences, gradient recalled echo imaging does not have a refocusing RF pulse. The absence of this pulse allows for a reduced minimal repetition time and echo time compared with spin-echo imaging, but the signal becomes susceptible to T_2^* decay rather than T_2 decay.

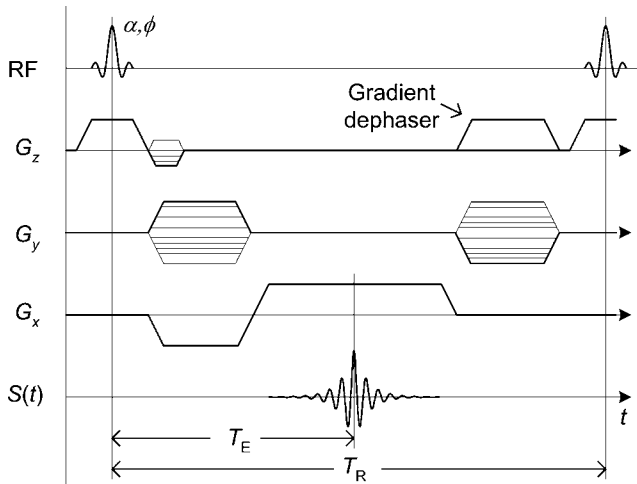

Figure 8. Basic 2D gradient echo pulse sequence. First, the magnetization is tipped into the transverse plane by an angle α during the application of a slice select gradient G_z . Then, the gradients G_y and G_x are used for phase encoding and the readout gradient. An echo forms at $t = T_E$ when the area under the readout gradient is zero. This experiment is then repeated every T_R with a different phase encode.

After RF excitation, the signal is dephased along the readout direction x with a prewinding gradient lobe. The amplitude of this gradient is then inverted to rephase the spins. When the area under the readout gradient is zero, the trajectory passes through the origin of k space and the echo forms with maximum amplitude. During the prewinder along the x axis, a gradient in y is played out to produce y depending on phase shifts for phase encoding.

By using a flip angle less than 90° , significant amounts of transverse magnetization are available without the need for long repetition times needed for recovering longitudinal magnetization. For example, after a single 30° excitation, the transverse magnetization contains $\sin(30^\circ)$ or one-half of the available magnetization. Meanwhile, the longitudinal magnetization still contains $\cos(30^\circ)$ or nearly 87% percent of the equilibrium magnetization. In fast GRE imaging, the repetition time is significantly reduced and generally less than the T_2 values of biological tissues. Under this condition, the transverse magnetization from preceding RF pulses is not completely dephased and generally results in a complex superposition of echoes from multiple RF pulses. Under certain conditions, a steady-state can be reached from repetition to repetition for one or more components of the magnetization (6).

GRE sequences can be used to generate T_1 , T_1/T_2 , T_2 , T_2^* , and proton density-weighted contrast, depending on the choice of TR , TE , the flip angle α , and the phase ϕ of the RF pulse. By altering the phase of the RF transmit pulse in a pseudo-random method, the steady state of the transverse magnetization can be scrambled while the beneficial aspects of the longitudinal steady state are maintained. Although the signal from the transverse steady state is lost and only the signal from the current RF pulse is available, strongly T_1 -weighted images are available with this technique, known as RF spoiling or spoiled gradient recalled

(SPGR) imaging. This technique is popular with contrast-enhanced MR angiography, where an intravenously injected paramagnetic contrast agent significantly decreases the T_1 of blood while the T_1 of static tissues remains unchanged.

In an opposite approach, known as steady-state free precession (SSFP), the maximum amount of the transverse magnetization is maintained by rewinding all gradients prior to each RF pulse. The method provides T_2 -like contrast very quickly and has proven very popular when fast imaging is essential such as in cardiac imaging.

Other Rapid MR Imaging Methods

In many applications, a short scan time is required to reduce artifacts from physiological motion or to observe dynamic processes. Many techniques exist to reduce the scan time while preserving high spatial resolution. One way to decrease spin-echo imaging time is to acquire multiple or all k space lines after a single preparation of the magnetization as explored with RARE (Rapid Acquisition with Relaxation Enhancement) (7). Also referred to as fast or turbo spin echo, the method works by creating a train of spin reversal echoes for which one line of k space is acquired for each. In echo-planar imaging (EPI) (8), an oscillating G_x gradient is used to quickly create many gradient echoes. By adding small blip gradients in between the negative and positive pulses of G_x , different horizontal lines in k space can be acquired.

Although the first MRI method proposed the acquisition of projections (9) as in CT, acquiring k space data on a Cartesian grid is fairly robust to magnetic field inhomogeneities and other system imperfections. Although spin-warp imaging (10) is predominant today, k space can be sampled along numerous 2D or 3D trajectories. The PROPELLER technique (11) acquires concentric rectangular strips that rotate around the origin, as shown in Fig. 8c. This method offers some valuable opportunities for motion correction due to the oversampling of the center of k space. K space can be sampled more efficiently with fewer echoes using spiral trajectories (12), as shown in Fig. 8d. Here, the amount of k space that can be acquired in one excitation is limited only by T_2 decay and possible blurring due to off-resonance spins. In nonCartesian acquisitions, phase errors due to off-resonance spins cause blurring. The sampling trajectories for these acquisitions schemes are shown in Fig. 9.

Applications

MRI is quickly moving beyond morphological and anatomical imaging. The advent of new functional image contrast mechanisms is making MR a tool for a much wider group of people than radiologists. Psychology, psychiatry, neurology, and cardiology are just some of the new areas where MR is being applied. A description of application areas in functional brain, diffusion-weighted brain, lung, MR angiography, cardiac, breast, and musculoskeletal imaging follows.

Functional Magnetic Resonance Imaging (fMRI). Functional Magnetic Resonance Imaging (fMRI) is a method of

Figure 9. 2D k space sampling trajectories. Shown are the spin-warp (a), radial sampling (b), PROPELLER (c), and interleaved spiral imaging (d) examples.

measuring the flow of oxygenated blood in the brain (13–15). fMRI is based on the blood oxygen-level-dependent, or BOLD, effect. BOLD MRI is accomplished by first exposing a patient or volunteer to a stimulus or having them engage in a cognitive activity while acquiring single-shot images of their brain. The region of the brain that is responding to the stimulus or is engaged in the activity will experience an increase in metabolism. This metabolic increase will require additional oxygen. Therefore, an increase in oxygenated blood flow will occur (oxyhemoglobin) to the local brain area that is active. Oxyhemoglobin differs in its magnetic properties from deoxyhemoglobin. Oxyhemoglobin is diamagnetic like water and cellular tissue. Deoxyhemoglobin is more paramagnetic than tissue, so it produces a stronger MR interaction. These differences between oxyhemoglobin and deoxyhemoglobin in BOLD imaging are exploited by acquiring images during an

“active” state (more oxyhemoglobin) and in a “resting” state (more deoxyhemoglobin), which creates a signal increase in the “active” state and a signal decrease in the resting state. Figure 10 shows a typical BOLD time course (shown in black) where four “active” states and four “resting” states exist. With prior knowledge of the activation timing (shown in red), we can perform a statistical test on the data to determine which areas of the brain are active. This statistical map (shown in color) is superimposed on a high resolution MR image so that one can visualize the functional information in relation to relevant anatomical landmarks.

Diffusion Imaging. The random motion of water molecules may cause the MRI signal intensity to decrease. The NMR signal attenuation from molecular diffusion was first observed more than a half century ago by Hahn (1950) (16).

Figure 10. Color brain activation map is superimposed on high resolution MR image. Signal levels of the activated pixels are shown to increase during cognitive activity periods, whereas they fall off during periods of rest.

Figure 11. Temporal schematic of a diffusion-weighted, spin-echo pulse sequence with an EPI readout. The diffusion gradient pulses are shown as gray boxes on the gradient axes. The direction of diffusion-weighting can be changed by changing the relative weights of the diffusion gradients along G_x , G_y , and G_z .

Subsequently Stejskal and Tanner (1965) described the NMR signal attenuation in the presence of field gradients (17). More recently, field gradient pulses have been used to create diffusion-weighted MR images (18).

Diffusion-Weighted Pulse Sequences. Typically, diffusion-weighting is performed using two gradient pulses with equal magnitude and duration on each side of a 180° refocusing pulse, as shown in Fig. 11. The first gradient pulse dephases the magnetization as a function of position, and the second pulse rephases the magnetization. For stationary (e.g., no flow or diffusion) molecules, the phases induced by both gradient pulses will completely cancel, no signal attenuation will occur. In the case of motion in the direction of the applied gradient, a net phase difference will occur, $\Delta\phi = \gamma v G \delta \Delta$, which is proportional to the velocity v , the area of the gradient pulses defined by the amplitude G , and the duration δ , and the spacing between the pulses Δ . For the case of diffusion, the water molecules are also moving, but in arbitrary directions and with variable effective velocities. Thus, in the presence of diffusion gradients, the signal from each diffusing molecule will accumulate a different amount of phase, which, after summing over a voxel, will cause signal attenuation. For simple isotropic Gaussian diffusion, the signal attenuation for the diffusion gradient pulses in Fig. 11 is described by $S = S_0 e^{-bD}$ where S is the diffusion-weighted signal, S_0 is the signal without any diffusion-weighting gradients (but otherwise identical imaging parameters), D is the apparent diffusion coefficient, and b is the diffusion-weighting described by the properties of the pulse pair $b = (\gamma G \delta)^2 (\Delta - \delta/3)$.

Diffusion Tensor Imaging. The diffusion of water in fibrous tissues (e.g., white matter, nerves, and muscle) is anisotropic, which means the diffusion properties change as a function of direction. A convenient mathematical model of anisotropic diffusion is using the diffusion tensor (19), which uses a 3×3 matrix to describe diffusion using a general 3D multivariate normal distribution. The diffusion

tensor matrix describes the magnitude, anisotropy, and orientation of the diffusion distribution. In a diffusion tensor imaging (DTI) experiment, six or more diffusion-weighted images are acquired along noncollinear diffusion gradient directions. Maps of the apparent diffusivity for each encoding direction are calculated by comparing the signal in an image without diffusion-weighting and the signal with diffusion-weighting. The diffusion tensor may then be estimated for each voxel, and maps of the mean diffusion, anisotropy, and orientation may be constructed, as shown in Fig. 12.

The primary clinical applications of diffusion-weighted imaging and DTI are ischemic stroke (20,21) and mapping the white matter anatomy relative to brain tumors and other lesions (22). DTI is also highly sensitive to subtle changes in tissue microstructure and, therefore, has become a popular tool for investigating changes or differences in the microstructure as a function of brain development and aging, as well as disease.

Vascular Imaging. Magnetic Resonance Angiography (MRA) describes a series of techniques that can be used to image vascular morphology and provide quantitative blood flow information in high detail. Two widely used techniques, phase contrast angiography and time-of-flight angiography, use the inherent properties of blood flow in the MR environment to create angiograms. A third technique, contrast-enhanced angiography, uses the injection of a

Figure 12. Representative diffusion tensor images. The images are (top-left): a T_2 -weighted (or nondiffusion-weighted) image; (bottom-left): a mean diffusivity map (note similar contrast to T_2 -weighted image with cerebral spinal fluid appearing hyperintense); (top-right): a fractional anisotropy map (hyperintense in white matter); and (bottom-right) the major eigenvector direction indicated by color (red = R/L, green = A/P, blue = S/I) weighted by the anisotropy (note that specific tract groups can be readily identified).

paramagnetic contrast agent into the vascular system to specifically alter the magnetic properties of the blood in relation to the surrounding tissue.

Phase-contrast (PC) angiography (23) usually uses a pair of gradient pulses of equal strength and opposite polarity, placed in the MRI sequence between the RF excitation pulse and the data acquisition window. During the imaging sequence, stationary nuclei accumulate phase during the first gradient pulse, and accumulate the opposite phase during the second gradient pulse, resulting in zero net phase. Moving nuclei accumulate phase during the first gradient pulse, but during the second pulse are in different positions, and accumulate phase different from that obtained during the first pulse. The net accumulated phase is proportional to the strength of the gradient pulses and the velocity of the nuclei. From the resulting data, images can be formed of both blood vessel morphology and blood flow.

TOF angiography techniques (24) (more accurately called “inflow” techniques) typically use a conventional gradient-echo sequence to acquire a thin 3D volume or a series of 2D slices. The nuclei in stationary tissue are excited by many consecutive slice-selective RF pulses. As a short TR is used, the longitudinal magnetization is not able to return to equilibrium, resulting in saturation of magnetization and low signal. Moving nuclei in the blood flow into the slice during each TR period, having been excited by zero or very few RF pulses. As these nuclei arrive in the imaging slice at or near full equilibrium magnetization, high signal is obtained from blood. Figure 13 shows a projection image of a 3D TOF dataset acquired in the head. The TOF technique can produce high

Figure 13. Time-of-flight (TOF) angiography in the head uses inflow of fresh blood to produce contrast between blood and the surrounding tissue. A Maximum Intensity Projection (MIP) reformatted image is used to compress the acquired volume data into a single slice for display.

quality MRA images in many situations, but slow or in-plane blood flow can result in blood signal saturation and reduced the quality of the images.

Contrast-enhanced MRA (CE-MRA) is performed using an injection of a paramagnetic contrast agent into the intravenous bloodstream (25). Although several transition and rare-earth metal ions can be used, the most common is Gadolinium (Gd^{+3}) chelated to a biologically compatible molecule. The compound is paramagnetic, having a strong dipole moment and generating strong local magnetic field perturbations, which increase the transfer of energy between the excited hydrogen nuclei and the lattice, promoting T_1 relaxation and return to equilibrium of the longitudinal magnetization.

The contrast agent is injected intravenously in a limb away from the area of interest and circulates into the arterial system. The longitudinal relaxation rate is typically enhanced by a factor of 15 to 25 during this initial arterial phase, resulting in a much shorter T_1 for blood compared with the surrounding tissue. As the longitudinal magnetization in blood is much higher after each TR period, background tissue is suppressed in a manner similar to TOF imaging, and blood vessels have a comparably bright signal on the resulting images. Imaging is typically performed so that the central k space lines, which contain most of the image contrast information, are acquired while the contrast agent is distributed in the arteries of interest, but before it can circulate into the neighboring veins.

MRA data consist of large volumetric sets of image data, which are stored in the format of contiguous image slices. Specialized image display techniques are used to display the data in a manner that can be interpreted by the radiologist. Maximum Intensity Pixel (MIP) projections are widely used and are formed by projecting the volume set of data onto a single image plane. Here, each image pixel is obtained as the maximum value along the corresponding projection, as shown in Fig. 13. Volume rendering is beginning to be used more often to display MR angiograms. The individual slices of data are always available for detailed review by the radiologist and can be reformatted into any plane on the computer workstation to optimally display the vasculature of interest.

Cardiac MRI. Cardiac magnetic resonance (CMR) imaging is an evolving technique with the unprecedented ability to depict both detailed anatomy and detailed function of the myocardium with high spatial and temporal resolution. The past decade has seen tremendous development of phased array coil technology, ultra-fast imaging sequences, and parallel imaging techniques, all of which have facilitated ultra-fast imaging methods capable of capturing cardiac motion during breath-holding. The ability to perform imaging in arbitrary oblique planes, the lack of ionizing radiation, and the excellent soft tissue contrast of MR make it an ideal method for cardiac imaging. Comprehensive cardiac imaging is performed routinely in both in-patient and out-patient settings across the country and is widely considered the gold standard for clinical evaluation of many cardiac diseases (26).

Ischemic heart disease caused by atherosclerotic coronary artery disease (CAD) is the leading cause of mortality,

morbidity, and disability in the United States, with over 7 million myocardial infarctions and 1 million deaths every year (27). Consequently, ischemic heart disease is the primary indication for CMR. Accurate visualization of wall thickness and global function (ejection fraction), as well as focal wall motion abnormalities, is performed with retrospectively ECG-gated ultra-fast short TR pulse sequences, especially steady-state gradient recalled echo imaging (28), as shown in Fig. 14. Breath-held cinemagraphic or CINE images have high SNR, excellent blood to myocardial contrast, and excellent temporal resolution (< 40–50 ms) capable of detecting subtle wall motion abnormalities. Areas of myocardial infarction (nonviable tissue) are exquisitely depicted with inversion recovery (IR) RF-spoiled gradient echo imaging, acquired 10–20 minutes after intravenous injection of gadolinium contrast (29), as shown in

Fig. 14. Areas of normal myocardium appear dark, whereas regions of nonviable myocardium appear bright (delayed hyper-enhancement). Accurate depiction of subtle myocardial infarction is possible because of good spatial resolution across the heart wall. The combination of motion and viability imaging is a powerful combination. Areas with wall motion abnormalities but without delayed hyper-enhancement may be injured or under-perfused from a critical coronary artery stenosis but are viable and may benefit from revascularization.

Cardiac “stress testing” using CMR has seen increasing use for the evaluation of hemodynamically significant coronary artery stenoses (30). Imaging of the heart during the first pass of a contrast bolus injection using rapid T_1 -weighted RF-spoiled gradient echo sequences is a highly sensitive method for the detection of alterations

Figure 14. End-diastolic (a), mid-systolic (b), and end-systolic (c) short axis CINE images of the heart in a patient with a myocardial infarction in the anterior wall and septum, demonstrated by decreased wall thickening (arrows in b, c). The corresponding T_1 -weighted RF-spoiled gradient recalled echo first-pass perfusion image (d) shows a fixed perfusion deficit (darker myocardium) in the corresponding territory (arrows). Finally, an inversion recovery RF-spoiled gradient echo image acquired at the same location (e) demonstrates a large region of delayed hyper-enhancement (arrows) indicating a full wall thickness region of nonviable myocardium that corresponds to the region of decreased perfusion and decreased contraction.

in myocardial blood flow (perfusion). Perfusion imaging during both stress (pharmacologically induced) and rest can reveal “reversible” perfusion defects that reflect a relative lack of perfusion during stress. In this way, coronary “reserve” can be evaluated and CAD can be uncovered, leading to further evaluation with coronary catheterization and possible angioplasty and stenting. Direct imaging of coronary arteries with CMR has shown tremendous technical advances, but is not commonly used, except for imaging of proximal coronary arteries in the evaluation of anomalous coronary arteries.

Other important indications of CMR include congenital heart disease, primarily, but not exclusively, in the pediatric population (31). Accurate diagnosis of a wide variety of congenital abnormalities requires high resolution, high contrast imaging that permits depiction of complex anatomical variants seen with congenital heart disease. Although anatomic imaging can be performed accurately with cardiac-gated CINE sequences, conventional sequences such as cardiac-gated black-blood fast spin-echo (FSE) and T_1 -weighted spin-echo imaging are invaluable tools. Equally important to accurate anatomical imaging is functional imaging. With altered anatomy comes radically altered hemodynamics, requiring visualization of myocardial function with CINE imaging. Phase-contrast velocity imaging permits flow quantification through the heart, including the great vessels (pulmonary artery, aorta, etc.). An important example includes quantification of left-to-right “shunts” with resulting over-circulation of the pulmonary circulation. With a wide variety of pulse sequences, flexible scan plane prescription and the lack of ionizing radiation, CMR is ideally suited for evaluation of congenital heart disease.

Other important applications of CMR include visualization of valvular disease, pericardial disease, valvular disease, and cardiac masses. The latter two are particularly well evaluated with CMR; however, they are relatively uncommon and will not be discussed here.

Hyperpolarized Contrast Agents in MRI. Conventional MR imaging measures the resonant signal from the hydrogen nuclei of water, the most ubiquitous and highly concentrated component of the body. However, many other nuclei exist with magnetic dipole moments that produce MR signals. Many of these nuclei, such as phosphorous-31 and sodium-23, are biologically important in disease processes. However, these species typically exist at a very low concentration in the body, making them difficult to image with sufficient signal. One approach is to align, or polarize, the nuclei preferentially using physical processes other than the intrinsic magnetic field of the MR scanner. In some cases, these polarization processes can align many more nuclei than otherwise possible. These hyperpolarized nuclei can then act as contrast agents to better visualize blood vessels or lung airways on MRI. For example, helium-3 and xenon-129 are inert gases whose magnetic dipole moments can be hyperpolarized using spin-exchange optical pumping—a method of generating a preferred alignment of the nuclear dipoles using polarized laser light (32). As they are inert gases, polarized helium-3 and xenon-129 are used as inhaled contrast

agents for visualizing the lung airspaces (upper-right panel) using MRI (33),(34). Unlike other parts of the body, conventional MRI of the lungs suffers from poor signal due to low water proton density and the multiple air-tissue interfaces that further degrade the MR signal in the upper left of Fig. 15. Hyperpolarized gas MRI has been particularly useful for depicting airway obstruction in several lung diseases including asthma (lower panel of Fig. 15) (35), emphysema (36), and cystic fibrosis (37). Additional techniques based on this technology show promise for MR imaging of blood vessels using injected xenon-129 dissolved in lipid emulsion (38), gas-filled microvesicles (39) and liquid-polarized carbon-13 (40). Hyperpolarized carbon-13 agents are of particular interest because of the wide range of biologically active carbon compounds in the body. Another important advantage of this technology is its ability to maintain high signal using low magnetic field (0.1–0.5 T) scanners (41). These systems are much cheaper to purchase and maintain than the high field (1.5–3.0 T) MRI scanners in common clinical use today.

Breast MRI. Breast MRI is presently used as an adjunct to mammography and ultrasound for the detection and diagnosis of breast cancer. Dynamic contrast-enhanced (DCE) MRI has been shown to have high sensitivity (83%–96%) to breast cancer but has also demonstrated variable levels of specificity (37–89%) (42). DCE-MRI requires an injection of a contrast agent and acquisition of a subsequent series of images to enable the analysis of the time course of contrast uptake in suspect lesions. Lesion morphology is also important in discerning benign from malignant lesions in breast MRI. Standard in-plane spatial resolution is sub-millimeter. A typical clinical breast MRI includes a spoiled gradient echo (SPGR) T_1 -weighted sequence both precontrast (Fig. 16a) and, at minimum, at 30 second intervals postcontrast (Fig. 16b). Along with their morphologic characteristics, lesions can be further described by the shape of their contrast uptake curve. The three general categories of contrast uptake are (1) slow, constant contrast uptake (2) rapid uptake and subsequent plateau of contrast, and (3) rapid uptake and rapid washout of contrast (43). Although the slowly enhancing lesions are usually benign and fast uptake and washout is a strong indication of malignancy, time course lesion characterization is not absolute. The ambiguity of time course data for certain classes of lesions drives the investigation into higher temporal resolution imaging methods. A standard clinical breast MRI also includes acquisition of a T_2 -weighted sequence for the identification of cysts (Fig. 16c). Present research in breast DCE-MRI is focused on development and application of pulse sequences that provide high temporal and spatial resolution. Also, investigation is ongoing into more specific characterization of uptake curves. Diffusion-weighted MRI, blood-oxygen-level-dependent imaging, and spectroscopy are also being investigated as possible methods to improve the specificity of DCE-MRI in the breast. In some circumstances, the high sensitivity of breast DCE-MRI outweighs the variable specificity leading to the present use of DCE-MRI to determine the extent of disease, with equivocal mammographic findings, and for the screening of high risk women.

Figure 15. Upper left shows normal lack of signal in parenchyma of lungs in MRI. Ventilated areas are clearly seen after imaging inhaled hyperpolarized helium. Rapid imaging during inhalation and exhalation shows promise for capturing dynamic breathing processes.

Figure 16. Fat-suppressed (a) pre-contrast T_1 -weighted image (b) postcontrast T_1 -weighted image (c), and noncontrast T_2 -weighted image. Images are from different patients.

MRI of Musculoskeletal Disease. Musculoskeletal imaging studies traumatic injury, degenerative changes, tumors, and inflammatory conditions of the bones, tendons, ligaments, muscles, cartilage, and other structures of joints. Although X-ray imaging is the work-horse imaging modality for many musculoskeletal diseases, MRI plays a critical role in several aspects of diagnosis, staging, and treatment monitoring.

Fast spin-echo (FSE) pulse sequences are typically used to acquire T_1 , T_2 , and proton density-weighted images of the joints. For the assessment of joint structures, images are acquired in multiple planes to ensure adequate spatial resolution in all dimensions. These MR images can be used to evaluate tissues including ligaments, bone, cartilage, meniscus, and labrum. As a result of their high spatial resolution and excellent soft tissue contrast, MR images can provide accurate diagnosis that can prevent unnecessary surgeries and can facilitate pre-operative planning when surgical intervention is required.

Osteoarthritis is a degenerative disease that affects approximately 20 million Americans and countless others around the world. Currently, this debilitating disease is often not detected until the patient experiences pain that can be reflective of morphologic changes to joint cartilage. MR can be used to accurately measure cartilage

thickness and volume. New MR techniques are also under development that may provide insight into biochemical changes in cartilage at the earlier stages of osteoarthritis that precede gross morphologic changes and patient pain.

Fortunately, primary bone tumors are relatively rare. However, bone is a common site for metastatic disease, which is especially true for breast, lung, prostate, kidney, and thyroid cancers. MR is a sensitive test for metastatic bone disease and is being adopted as a standard of care in some parts of the world, replacing nuclear scintigraphy. A typical approach employs inversion recovery pulse sequences to generate fat-suppressed, T_2 -weighted images. Diffusion-weighted imaging also shows promise to detect hematologic cancers such as multiple myeloma, leukemia, and lymphoma.

Inflammatory diseases include infection and inflammatory forms of arthritis. Infection of the foot is a common complication of microvascular disease often seen with diabetes, a disease afflicting 18 million Americans. MR can be used to assess the vasculature of the foot as well as diagnose infection and evaluate treatment efficacy. Two million Americans have rheumatoid arthritis, a common form of inflammatory arthritis. Inflammation from a condition known as synovitis, which often occurs in rheumatoid arthritis patients, is shown in Fig. 17. New MR methods

Figure 17. Axial knee image in a patient with inflamed synovium shows excellent soft tissue contrast available in MRI. The thickened intermediate signal intensity for synovium (arrowheads) is well distinguished from the adjacent high signal intensity of joint fluid (arrow).

are being developed to detect rheumatoid arthritis earlier and to gauge treatment success.

MAMMOGRAPHY

PEI-JAN PAUL LIN
Beth Israel Deaconess
Medical Center
Boston, Massachusetts

INTRODUCTION

It has been shown that reduced breast cancer mortality in the past decade can be attributed to the high sensitivity of screening mammography in detecting nonpalpable lesions (1,2). There has been a wide variety of equipment and imaging modalities employed in the breast cancer detection and imaging; ranging from ultrasound imager, X-ray mammography, computed tomography scanner (CT), to magnetic resonance imager (MRI). Additionally, thermography, light diaphanography, electron radiography, and microwave radiometry have also been utilized, experimentally, to detect breast cancer without much success. Brief explanations of these imaging modalities have been described in the first edition of this Encyclopedia, NCRP Report No.85, and in a review article by Jones (3–5). Among those modalities; ultrasound, X-ray mammography, CT, and MRI, X-ray mammography is the most practical and relatively inexpensive, and is the only main stream of equipment available for breast cancer detection. At present, the ultrasound imager is often employed as an adjunct to the X-ray mammography and is not the primary screening imaging device. However, when mammography is mentioned, it is normally meant to say “X-ray mammography”. For these reasons, this article will devote all of its effort to X-ray mammography.

THE MAMMOGRAPHY QUALITY STANDARDS ACT OF 1992 (MQSA), (PUBLIC LAW 102–539)

Breast cancer was a major public health issue in the early 1990s; U.S. Congress enacted MQSA “to ensure that all women have access to quality mammography for the

detection of breast cancer in its earliest, most treatable stages”. Thus, it is required by law that facilities providing mammography services be properly accredited and be certified by the U.S. Food and Drug Administration (FDA). “Accreditation and Certification” of mammography facilities are beyond the scope of this article, and interested readers are requested to refer to the FDA’s WEB Site (6), and the American College of Radiology (ACR) WEB Site (7).

X-RAY MAMMOGRAPHY

Conventional X-ray equipment was initially employed for breast cancer imaging with industrial (thick) emulsion film, or portal imaging film for use in radiation therapy as the image receptor in order to visualize the small microcalcifications, prior to, as late as 1970s. The breast entrance dose of this imaging process exceeded well over 85 mGy per film (~ 10 R per film) and the radiographic techniques were typically in the range of 45–55 kVp, and ~ 1000 mAS with a radiation beam quality of half-value layer (HVL) = 1.0–1.5 mm of aluminum (mmAl) (8). The X-ray beam spectrum produced by a conventional X-ray tube, equipped with tungsten anode, is not necessarily optimized for breast cancer detection. The mammography images obtained in this manner had the desired spatial resolution (~ 20 lp \cdot mm $^{-1}$), but had a less than desirable radiographic contrast. This combination of “high entrance dose” with “low radiographic contrast” was not an acceptable approach. The radiology community was searching for a new breast imaging solution. In the 1970s, xeromammography imaging plates provided the much needed improvement in image quality and lowered the breast entrance dose by a factor of two thirds to one half compared to using the thick emulsion industrial type film (9).

Due to its unique patient positioning of breast imaging, the geometrical arrangement of dedicated mammography units should be pointed out. As shown in Fig. 1, with the

Figure 1. Geometric arrangement of conventional radiography. The X-ray system, the anatomy of interest, and the screen-film cassette are centered and aligned for exposure.

Lateral View of Mammography Examination Setup

Figure 2. Geometry of dedicated mammography systems. On the left side of (a), the geometrical arrangement of a dedicated mammography unit is correctly setup where the center of the radiation beam is aligned to the chest wall of the patient with the compression cone pressing down on the breast being imaged. On the right side (b), improper setup for mammography examination is evident. The “black” triangular area is not included in the image captured by the image receptor, potentially missing the suspected cancer site.

conventional radiography system, the X-ray tube is setup in the center of the anatomy of interest. The radiation field is a projection of diverging X rays restricted by the collimator, centered to the area of interest. The geometry of a dedicated mammography system on the other hand is off-set so as to maximize inclusion of breast tissue close to the chest wall (see Fig. 2a). If the geometry were setup in the same manner as the conventional radiography as depicted in Fig. 2b, the black triangular area of the breast would not be included in the imaging field possibly missing a suspected cancer site.

THE PHYSICS OF MAMMOGRAPHIC IMAGING

Considering that various tissues in the breast are radiologically similar, but not identical, the task of differentiating the fibrous, ductal, and glandular tissues is extremely difficult. This is due to the fact that (1) water; the main ingredient of human tissue, has a density of $\rho = 1.0 \text{ g}\cdot\text{cm}^{-3}$ and effective atomic number of $Z_{\text{eff}} = 7.4\text{--}7.6$, and (2) fat has a density of $\rho = 0.9 \text{ g}\cdot\text{cm}^{-3}$ and effective atomic number of $Z_{\text{eff}} = 5.9\text{--}6.5$ (10). Thus, various breast tissues with varying degrees of fat and water contents are very similar from radiological point of view.

The development of screen-film mammography was, in reality, paired with the redesigning of dedicated X-ray equipment for breast imaging. Breasts are relatively thin (physical thickness and X-ray attenuation property) compared to other body parts. Radiographs of extremities, for example, are obtained with X-ray tube potential in the

range of 50–60 kVp. Breast tissues contain no high attenuation anatomy, such as bones, a lower tube potential ($< 35 \text{ kVp}$) would be more suitable for breast imaging (11). Use of lower tube potential has a potential benefit of taking advantage of the photoelectric effect in differentiating the subtle differences of breast tissues.

It should be pointed out that there are five basic ways that X-ray photons interact with matter; they are (1) coherent scattering, (2) photoelectric effect, (3) Compton effect, (4) pair production, and (5) photodisintegration (12). Of these five interactions, photoelectric effect and Compton effect predominantly contribute to the image formation in diagnostic radiology. The probabilities of photoelectric effect and the Compton effect can be expressed as following;

$$\text{Photoelectric effect} \sim Z^3/E^3 \quad (1)$$

$$\text{Compton effect} \sim E * Z \quad (2)$$

In equations (1) and (2), E is the photon energy, and Z is the atomic number. Clearly, from Eq. 1, the lower the X-ray photon energy, and the higher the atomic number the probability of the photoelectric effect will be higher. Since the photoelectric effect is proportional to the “cube” of (Z/E) , the differential of breast tissues in Z_{eff} is “enhanced” in the image formation. Thus, a better approach to differentiate and image the breast tissues is to employ a lower X-ray tube potential for imaging. While this approach is “good” for imaging, the radiation dose absorbed by the breast would still be a major concern.

Conventional X-ray tubes employ tungsten as the target material and produce a broad X-ray spectrum through the bremsstrahlung process. At X-ray tube potential of 35 kVp and lower, the tube potential used on most dedicated mammography systems, the tungsten target X-ray tubes would produce broad energy spectrum that contribute less to the image formation and more to the radiation dose. Tungsten, rhodium, and molybdenum are ideal for use in X-ray production due to their relatively high melting points than other metallic elements. Typically, dedicated mammography equipment is equipped with molybdenum target X-ray tube with beryllium window (port), and 30- μm thick molybdenum filter. The X rays, generated at 25–30 kVp tube potential, produced by the molybdenum target X-ray tube contain a large fraction of characteristic X rays at energies $\sim 17\text{--}20 \text{ keV}$ (13,14). It is, therefore, quite natural to optimize and utilize these characteristic X rays for image formation and, consequently, patient exposure reduction at the same time. Most dedicated mammography equipment employ a combination of molybdenum target with aluminum, molybdenum, or rhodium filters. The characteristic X rays generated at the molybdenum target have X-ray photon energies of 17.4 and 19.6 keV, just below the K-absorption edge of 20 keV, thus are quite transparent to the molybdenum filter. This is illustrated in Fig. 3. On the left of Fig. 3a, is a schematic drawing of the X-ray spectrum generated at 30 kVp with a molybdenum target and aluminum filter. In the middle of Fig. 3b, is the same system with 30 μm thick molybdenum filter. Notice that the K-absorption edge curve (dashed curve) of molybdenum shows that the X-ray photons with energies just above

Figure 3. The spectrum of X rays generated with molybdenum and rhodium. On the far left (a) is the X-ray spectrum generated by a molybdenum target at 30 kVp and filtered with aluminum filter. The characteristic X rays K_{α} (17.4 keV), and K_{β} (19.6 keV) appear as the two peaks in the graph. In the middle (b) is the X-ray spectrum generated by the same X-ray system in part a, but is filtered with 30 μm thick molybdenum. The K-absorption edge curve is shown in dashed line. On the far right (c) is an X-ray spectrum generated by a rhodium target at 30 kVp and filtered with 20 μm thick rhodium. The general shapes of middle figure and far right figure are similar with differences in the peak energies of K-characteristic X rays (K_{α} = 20.2 keV, and K_{β} = 22.7 keV), and the K-absorption edge energy (23.2 keV).

20 keV would be preferentially absorbed than those just below 20 keV. Similarly, the same can be said for the rhodium target with rhodium filter as shown in Fig. 3c. Figure 3b and c are graphically speaking quite similar. It is noteworthy to point out that a careful study of Fig. 3b, and c will reveal that X-ray beams generated from rhodium target X-ray tube “must not” be filtered with molybdenum! The intensity of rhodium K-characteristic X rays (K_{α} , and K_{β}) would be in the energy range where the molybdenum K absorption is high. Taking advantage of the spectral information, in 1991, GE introduced the Senographe DMR unit equipped with a dual track and dual filter (molybdenum and rhodium) X-ray tube for mammography applications. Some of the physical characteristics and the spectral energy data of molybdenum, rhodium, and tungsten are summarized in Table 1.

For illustration purposes and descriptions of imaging components, following this paragraph, the screen-film mammography (SFM) system manufactured by GE, the Senographe DMR mammography unit, is shown in Fig. 4. The photograph in Fig. 4 represents the overall external

and mechanical design of a typical “dedicated” X-ray mammography unit. It represents “the overall” design with respect to the tilting gantry with the X-ray tube housing at the top and the image receptor at the bottom. And, the gantry is attached to a column (or stand), which houses the elevation mechanism of entire gantry.

THE SCREEN-FILM MAMMOGRAPHY

The screen-film mammography employs the same basic image receptor system as conventional radiographic imaging. While conventional radiography employs a double-emulsion film sandwiched between two intensifying \ screens yielding a spatial resolution of (up to) 8 lp-mm⁻¹ for a detailed screen (15), a typical SFM image receptor consists of a single-emulsion film and a single thin rare-earth phosphor intensifying screen yielding a spatial resolution of ~ 20 lp-mm⁻¹ (16).

In order to optimize the efficiency of the SFM, manufacturers including Agfa, Kodak, Konica, and Fuji, have produced matching pairs of the intensifying screen and film specifically for use with mammography. And, to further improve the sensitometric characteristics of the screen-film, the processing chemistry, particularly the developer, have also been carefully prescribed along with its development conditions. Note that the sensitometric characteristics of screen-film system refers to the “photographic effect or blackening effect” of the screen-film system in response to the X-ray absorption (17). An example of this matching pair of intensifying screen and film is depicted in Fig. 5, the emission and absorption

Table 1. K-Characteristic X Rays and K-Absorption Edge of Molybdenum, Rhodium, and Tungsten

	Molybdenum	Rhodium	Tungsten
Atomic Number	42	45	74
K_{α} ^a	17.4	20.2	59.3

The figure shows the light-emitting spectrum of the AD Mammo Screens, the spectral sensitivity curve of the AD-M film, and the transmittance spectrum of SLG-8U safety light filter. (Courtesy of Fujifilm Medical Systems USA, Inc.)

In order to accommodate the varying size of breasts, two imaging cassette sizes are available with dedicated mammography equipment, they are 18 × 24 cm (8 × 10 in.), and 24 × 30 cm (10 × 12 in.). The film is loaded on the topside of the cassette with the emulsion side facing the intensifying screen. Figure 6 is a schematic drawing showing the cross-section of a typical screen-film mammography cassette (the single emulsion film, single intensifying screen) with enlarged views of the film (top, right), and the screen (bottom, right). The “sponge”, in the cassette, is employed to assure good screen-film contact.

THE ANTISCATTER GRID

The antiscatter grid is placed between the breast holder, and the cassette slot, refer to Fig. 4. Scattered radiation is one of the main causes of degrading the image quality in X-ray imaging. The antiscatter grid is employed to minimize the scattered radiation from reaching the screen-film system while allowing the primary radiation to pass through. Although, mammography examinations are typically conducted with X-ray potentials <30 kVp, would still require a moving (reciprocating) antiscatter grid to cleanup the scattered radiation. Typically, the antiscatter grid used in mammography has a grid ratio of 5 : 1, or 4 : 1. While the exposure time in X-ray mammography imaging is relatively long (~1 s), the speed of the moving grid must be

carefully adjusted to avoid artifact associated with grids. For the antiscatter grids, the grid line rate must be sufficiently high, or the attenuation material structure must be so designed to avoid being imaged as grid artifacts on the mammograms. The honeycomb design antiscatter grid; Cellular (HTC) Grid utilized in LoRad mammography systems and marketed by Hologic is well known for its high transmission of useful primary radiation with increased absorption of scattered radiation (18).

THE COMPUTED RADIOGRAPHY FOR MAMMOGRAPHY

Computed radiography was introduced to radiology in 1981 and the “digitization” of routine radiographic examinations had started in earnest. The CR image plate housed in cassette replaced, directly, the screen-film cassette in routine radiography applications. This direct replacement design required no mechanical modifications on the existing radiographic equipment. With the introduction of CR, a whole new set of technology including the optical CR readers, image processing software programs, image display subsystems, and so on, made the filmless radiology department within an achievable reality (19).

The difference between the routine CR and the CR for mammography (CR-M) is largely due to the optical response of the CR phosphor; thus, the radiation dose required to reduce the image noise, and the spatial resolution capability for mammography applications. In 2001, Fuji introduced the FCR 5000MA, which was used in the America College of Radiology Imaging Network (ACRIN); Digital versus Screen-Film Mammography (DMIST) study (20,21). While the study had already been concluded, the official results are in the final preparation stage, and have not been released yet. The FCR 5000MA differentiated itself from the previous generation of CR products by utilizing a 50 μm pixel spot size for the laser and introduced dual side IP reading to the market.

In January 2004, Fuji introduced the Profect CS, or “ClearView-CS” in the United States. Clear View CS is pending FDA approval and not yet commercially available in the United States. Fuji recently finished the Premarketing Approval (PMA) application to FDA, and the approval is anticipated sometime during the second half of 2005 (22). Note, however, that the 100 μm pixel spot size digital mammography system has been in use for the past few years in Europe, Australia, and Japan. The mechanism in which “how” the IP and the CR reader work together to produce an image is beyond the scope of this article and readers are suggested to turn to publications available (23,24), or corresponding articles in this Encyclopedia.

The obvious advantage of CR-M, and the full field digital mammography (FFDM) systems, is its wide dynamic range and its linear response to radiation. In screen-film mammography, over-or underexposure was one of the main causes of “repeat” examinations. Such exposure related repeats can be minimized due to the wide latitude in exposure acceptable for imaging. Furthermore, the images are no longer “fixed” or “limited”; the subject contrast and the overall image brightness can be adjusted for image interpretation by adjusting the display window “level”, and

Figure 7. Comparison of dynamic range of CR and screen-film image receptors. (Courtesy of Fuzifilm Medical Systems, USA, Inc.) The image plate (IP) has wider linear response to radiation extends over four decades of dose and eliminates the inherent limitations of the “toe” and “shoulder” portions of the film’s H&D Curve. (Courtesy of Fujifilm Medical Systems USA, Inc.)

“width”. The display “window level” corresponds to the film optical density in SFM, and the “widow width” corresponds to the contrast. In digital imaging systems, both window level and width may be adjusted to optimize the image rendered on the monitor. Figure 7 shows the response differences of these two image receptor systems to the radiation exposure. The exposure range for the CRs “Image Plate” is wider than that of a typical screen-film combination by an order of 2 to 3 in magnitude.

THE STEREOTACTIC BREAST BIOPSY MAMMOGRAPHY

Breast biopsy is often required when an area of suspicious malignancy site is revealed after a mammography is obtained. In order to accurately extract the specimen, a stereo mammogram may be obtained so that the biopsy needle can be accurately inserted to the site where it is suspected of malignancy; core biopsy (25). Most dedicated mammography equipment are designed to perform routine (screen-film, or FFDM) mammography, and with an attachment to perform stereotactic mammography and core biopsy in an “up right” posture; either the patient is standing or sitting on a chair.

From a pair of stereo images separated by 30° ($\pm 15^\circ$ from the centerline), using the triangulation technique, the three-dimensional (3D) coordinates of the suspicious site can be calculated within an accuracy of 1 mm (25), see the schematic diagram of stereotactic imaging geometry in Fig. 8. It is essential that the patient remain still before and after the acquisition of the stereo images. The core biopsy can be localized accurately only if the patient positioning remain the same.

Stereotactic mammography requires that the breast being examined is compressed (just as in routine mammography), but the patient should remain standing still while the mammogram is being processed. The processing time alone takes at least 90 s with typical automatic film processor. Thereafter, the best location of the biopsy needle entrant site, and the coordinates of the sampling must be determined. The prolonged time represents substantial

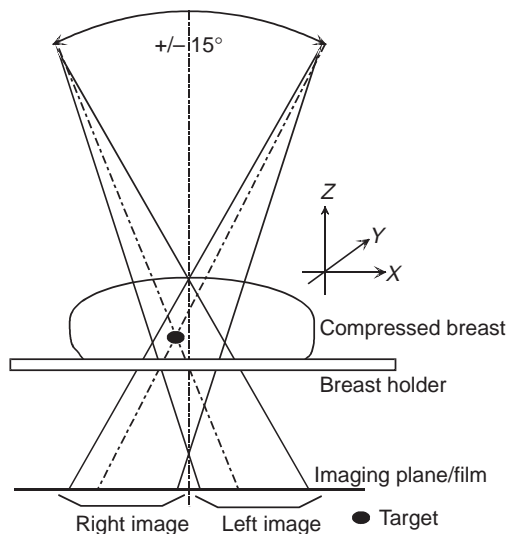

Figure 8. Schematic drawing of geometrical setup for stereotactic mammography. From the stereo images, with known geometry and the X - Y coordinates, the depth in Z direction is calculated via triangulation.

discomfort on the part of the patient not to mention the anxiety of fear for the possibility of being diagnosed and confirmed as having breast cancer.

DIGITAL SPOT MAMMOGRAPHY

Before the introduction of FFDM, in order to ease the discomfort of undergoing the biopsy process, a small detector with imaging area of 5×5 cm had been developed by LoRad, for example, so that the stereo images of the breast can be displayed immediately after exposures are made. This is one of the successful biomedical applications that have resulted from collaborative technology transfer programs between the National Aeronautics and Space Administration (NASA), the National Cancer Institute (NCI), and the U. S. Department of Health and Human Services Office on Women's Health (OWH) (26). Since the imaging area is only 5×5 cm, it is referred to as Digital Spot Mammography. The biopsy coordinate is then calculated via the built-in software program with a shorter overall examination time.

In addition, dedicated breast biopsy systems have been developed where the patient would be lying on her stomach (recumbent). The breast under examination is positioned through a hole in the examination table and aligned with the X-ray equipment and the biopsy needle gun. The recumbent core biopsy mammography unit manufactured by LoRad is depicted in Figs. 9 and 10. LoRad is now one of the brand names sold under Hologic. A similar recumbent core biopsy unit, called Mammo Test Biopsy System, is available from Fisher Imaging.

FULL FIELD DIGITAL MAMMOGRAPHY

The CR-M is a direct replacement of the screen-film cassette. In other words, the IP cassette replaced the screen-

Figure 9. The recumbent stereotactic core biopsy system. A recumbent design provides a stable patient positioning to acquire a pair of stereo images for accurate localization of biopsy site while the patient lays flat on her stomach with comfort during the entire examination. (Courtesy of Hologic.)

film cassette. Therefore, no major mammography equipment modification would be necessary. In DR on the other hand, just as in conventional radiography and fluoroscopy applications, the image receptor system may be built into the image receptor compartment as an integral part of the imaging assembly (27,28). Manufacturers had attempted to physically fit the DR detector assembly, or more accurately; the Flat Panel (FP) detector assembly, into the space occupied by the SFM cassette. To date, no commercial product of FP detector assembly has been fitted as a *direct physical replacement* of the SFM cassette is available (29). In other words, due to technical difficulties, there is no FP detector assembly that is sufficiently compact to fit into the space designed to accommodate the SFM cassette. The image acquired with FP detector is transmitted to and processed by the image processing chain thereafter.

While there are a hand full of FFDM systems either under development or manufactured for clinical applications, three FFDM units are currently available in the United States, and are described here (27). The fact that

Figure 11. Schematic drawing of an amorphous silicon digital detector. (Courtesy of GE Healthcare.)

these three systems are designed to cover an imaging field of at least (\sim) 18×24 cm, the smaller cassette size of SFM, the name; FFDM was assigned. This is to signify the full size imaging field coverage as opposed to the small field detector of LoRad's Digital Spot Mammography, or Fischer Imaging's Mammo Test Biopsy System.

There is a trend that mammography equipment is being transformed to "digital" format. One reason of the slow pace of this transformation is the large initial capital expenditure of FFDM. Both, analog and digital formats are expected to coexist for many more years to come. The impact of Fuji's CR-M cannot be ignored due to the fact that it is possible to convert and replace the screen-film cassette directly. Any of the existing SFM units will be able to join the "digital era".

Currently, there are three FFDM systems that have received FDA approval and are sold in the United States. The GE Senographe 2000D was approved by FDA on January 28, 2000 and "accredited" by ACR in February, 2003. Fischer Senoscan received its FDA approval on September 25, 2001 with subsequent ACR accreditation in August, 2003. Hologic/LoRad's Selenia received FDA approval and ACR accreditation, respectively, on October 2, 2002, and in September of 2003 (27).

GEs FFDM: SENOGRAPHE 2000D, AND SENOGRAPHE DS

Figure 11 depicts the FP detector developed by General Electric Medical Systems, and the photo inset (top left) shows the Cesium-Iodide (CsI) scintillator crystals. The incident X rays are absorbed by the CsI crystals, which in turn, convert the X-ray photon energy to light. The CsI crystals are deposited in columnar shape so as to minimize the scatter, and optical diffusion of scintillation lights from one column to the other. The underlying photodiode-transistor amorphous Silicon (a-Si) arrays is connected to control data lines, then, converts the light to electrical signals for further processing (30).

GEs FP detector is an indirect-conversion digital detector system. The detective quantum efficiency (DQE) of this FP detector system has been shown to be $\sim 60\%$ at Zero Frequency (31,32). Essentially, being the first FFDM system introduced to the commercial market, GEs Senographe

2000D ushered in the digital mammography era to the radiology community. Depicted in Fig. 12 is the second-generation FFDM unit, Senographe DS, with the X-ray gantry set to $+15^\circ$ with the stereotactic biopsy needle assembly attached. Both Senographe systems (2000D and DS) are equipped with CsI scintillator on an a-Si photodiode-transistor arrays with pixel size of $100 \mu\text{m}$ and an image matrix size of 1920×2304 , covering a field of view 19×23 cm.

FISCHER IMAGING'S SENOSCAN FFDM

On the other hand, Fischer Imaging Corporation's answer to the FFDM is the Senoscan FFDM unit. The unique feature of Senoscan unit is that it employs a slot mechanism for the X-ray field collimation that is synchronized to the detector as the slot and detector assembly sweeps across the imaging field, see Fig. 13. The detector of

Figure 12. Photograph of GE FFDM unit; Senographe DS with stereotactic attachment installed. The gantry is tilted to $+15^\circ$ and prepped for Stereotactic imaging. Note, this is the FFDM version of similar unit shown in Fig. 1, but with zoomed up view for the stereotactic attachment. (Courtesy of GE Healthcare.)

Figure 13. A schematic drawing of the scanning mechanism of Fischer Senoscan FFDM. (Adapted from Fisher Imaging Senoscan user's manual with permission. Courtesy of Fisher Imaging.)

Senoscan unit consists of a layer of thallium activated CsI scintillator connected to charge-coupled-device (CCD) chips via fiber optics (33). Hence, this is also an indirect-conversion digital detector system.

The use of slot mechanism also means "restricting" the X-ray beams for exposure. It offers an advantage of less scattered radiation for improved image contrast (34). Therefore, no antiscatter grid is necessary with Senoscan unit. The absence of the antiscatter grid compensate for a less efficient use of the available X rays. In addition, a tungsten anode X-ray tube (35) is employed with this unit, since the tungsten anode X-ray tube would produce X rays more efficiently than a molybdenum or rhodium target. Senoscan is equipped with CCD chips having pixel size of (1) 27 μm , covering a field of view 11×15 cm under the high resolution mode, and (2) pixel size of 54 μm , covering a field of view 19×29 cm for the normal mode. The image matrix size of this system is 4096×5625 .

HOLOGIC/LORAD'S FFDM; SELÉNIA

Selenia's image receptor is a 250 μm thick amorphous Selenium (a-Se) photoconductor. Underneath a layer of a-Se photoconductor is a thin-film transistor (TFT) arrays that serves as an active readout mechanism. The TFT arrays are typically deposited onto a glass substrate, which provides a physical support for the entire detector components. Selenia uses a 250 μm thick a-Se photoconductor to capture the X-ray photons impinging on the detector sur-

face without the aid of a scintillator. It is said that a thickness of 250 μm a-Se photoconductor is adequate to stop 95% of the X-ray photons in the mammographic energy range (36). The photon energy is converted to a pair of electron, which is negatively charged, and a positively charged "hole". With bias voltage applied, the signal is read off by the TFT arrays. Thus, this is a direct-conversion digital detector system. The detector is an a-Se photoconductor and TFT arrays with pixel size of 70 μm , covering a field of view 24×29 cm, resulting in an image matrix size of 3328×4096 . A summary of the detector characteristics for these three FFDM systems is given in Table 2, (37).

READING MAMMOGRAPHY IMAGES

Initially, the FFDM images were printed on dry laser printers and read on high luminance view boxes (ACR accreditation required of a luminance of >3000 $\text{cd}\cdot\text{m}^{-2}$) (38). All three FFDM systems are equipped with workstations where images are soft-copy read. The workstations are commonly equipped with two 5-megapixel high resolution monitors. With the soft-copy reading, an assortment of image manipulation are possible including, but not limited to, basic window width and window level adjustments, zooming, image reversal, and so on for viewing the details of the pathology. More importantly, the impact of image processing in transforming the acquired raw data set to the image displayed for soft-copy reading should be recognized (39). For example, as can be seen in Fig. 14, substantial differences not only in the brightness and contrast of the image but also in the impression of pathology in the images can be noticed. While all three images are acceptable and diagnostic, the two enhanced images are easier to recognize various details.

SUMMARY

A brief history of mammography was described as the introduction to the X-ray mammography. The SFM continues to play its major role in breast cancer detection while FFDM is gaining its installed base. Upon the anticipated FDA approval, the CR-M is poised for introduction for clinical applications in the second-half of 2005. However, all three modalities employed in breast cancer detection, namely; the SFM, FFDM, and the CR-M are expected to

Table 2. Summary of Imaging Characteristics of FFDM Units

Manufacturer	Model Name	Scintillator	Detector	Pixel Size, μm	Image Matrix Size	Imaging Size, $L \times W$ cm
GE	Senographe 2000D, DS	CsI (Tl) ^a	TFT	100	1920×2304	19×23
Fisher Imaging	Senoscan	CsI (Tl)	CCD	24/48	4096×5625	22×30

play their roles in contributing to reduction of breast cancer deaths through the early detection of mammography screening.

Display of FFDM images and its workstations are important components of the total picture of FFDM (40,41). However, monitors and workstations associated with diagnostic radiology imaging including mammography are in a domain of their own and no attempt is made to include these subjects in this article. Such subject matters belong to digital image processing and display. Finally, archiving of the acquired digital images is also a very important aspect of digitized diagnostic images in the overall operation of radiology. However, this subject is better handled in Picture Archiving and Communication Systems (PACS), and readers are referred to articles under PACS for additional information.

ACKNOWLEDGMENT

The information and materials presented here had been provided by numerous numbers of representatives and scientists from respective manufacturers mentioned in the main text. The author would like to express his thanks and sincere appreciation by listing the manufacturers here, (in alphabetical order) in lieu of listing the individuals who had provided their supports: General Electric Healthcare, Fischer Imaging Corporation, Fujifilm Medical Systems USA, Inc., and Hologic Inc. (LoRad).

MEDICAL EDUCATION, COMPUTERS IN

ARIE HASMAN
Maastricht
The Netherlands

INTRODUCTION

The amount of knowledge is increasing rapidly in many disciplines. Medicine is not an exception. Because of scientific research new knowledge comes available at such a pace, that physicians should read 19 articles a day, every day of the week, to keep up to date. Since that is not possible the results of scientific research often are applied clinically only years later. Computers can support physicians in finding relevant recent information. In the next section, the reasons for using computers in medical education are presented. Then the roles computers can play in medical education are reviewed. Since health professionals increasingly use computer systems for their work, they need to know the benefits and limitations of these systems. The discipline of medical informatics is responsible for developing these systems and therefore is discussed. The next sections discuss the use of Internet and electronic patient records. Also, it is discussed why knowledge of information systems is important for health professionals.

THE REASONS FOR USING COMPUTERS IN MEDICAL EDUCATION

The goal of academic medical education is to educate students to become physicians. During the study knowledge, skills and attitudes have to be mastered. Students are taught academic skills like critical reading, they are acquainted with the principles of research methods, and they should know the scientific background of the basic disciplines (like anatomy, molecular cell biology and genetics, endocrinology and metabolism, immunology and inflammation, growth, differentiation and aging) as far as they are related to the study of abnormalities and to diagnosis and therapy. Because of the explosive growth of biomedical knowledge, it is not possible anymore to teach all the currently available knowledge. This does not have to be a problem since part of the knowledge presented to medical students during their formal education may be more or less obsolete by the time they are in their main professional practice. Moreover, it is difficult to teach medicine for the coming era, since most of the future's

technology is probably nonexistent today. Students therefore must be taught how to become life-long learners. Computers can support this process.

Computers play an increasing role in the practice of medicine too. No doctor—whether a general practitioner or a specialist in advanced or social care—will be able to escape the confrontation with some form of information processing. The work of health professionals is dominated by information collection, storage, retrieval, and reasoning. Health professionals both use individual patient data and general medical or nursing knowledge. The amount of medical and nursing knowledge increases so quickly that health professionals cannot stay fully up to date. Tools are therefore needed to acquire relevant knowledge at the time it is needed.

Computer systems are installed in many hospital departments and physician offices. Hospital information systems support, for example, financial, administrative, and management functions. Clinical departmental systems are used to collect, store, process, retrieve, and communicate patient information. Clinical support systems are used in function laboratories [for electroencephalogram (EEG), electrocardiogram (ECG), electromyogram (EMG), and spirometry analysis], for imaging [magnetic resonance imaging (MRI), computerized tomography (CT), nuclear medicine, ultrasound], and in clinical laboratories (analysis of electrolytes, etc.). The results of clinical support systems are increasingly stored in so-called electronic patient records, together with the medical history, results of physical examination, and progress notes. Electronic patient records gradually replace the paper patient record. Apart from the fact that electronic paper records are better readable they also support functions (like decision support) paper records cannot provide. Students must learn the benefits and limitations of these kinds of systems.

Decision support systems are used to support clinicians during the diagnostic or therapeutic process and for preventive purposes to prevent either errors of omission (when, eg, the physician does not order a mammography when indicated) or commission (when, eg, the physician prescribes the wrong drug).

Clinical patient data are increasingly stored in the above mentioned electronic patient records (EPRs), from which they can be later retrieved by physicians or nurses who are in need of the data. Also, information systems can retrieve relevant data from the electronic patient record when a suitable interface between system and EPR is available. When a standard vocabulary is used for representing data values in the EPR, decision support systems can interpret these data and remind, alert, or critique the physician or provide access to relevant knowledge, based on patient data available in the EPR. Health professionals should have insight in and knowledge of the principles, concepts, and methods underlying electronic patient records.

Also, patients become active players in the field and increasingly demand access to the EPR.

Patient management increasingly has become the combined task of a group of healthcare workers. Therefore the memory-aid role of the patient record more and more changes into a communication role. Paper records have

several limitations in this respect. In addition, since the appearance of the report "To err is human" of the IOM (1) it is apparent that due to miscommunication (among which are problems with reading handwritten information, with incomplete information, etc.) medical errors are made that even may lead to the death of patients. Electronic patient records and order entry systems can reduce the number of errors because they are not only more readable, but because they can also be interfaced with decision support systems when standardized terminology is used.

Decision support can be passive in the sense that the decision support system contains information that has to be searched by the physician. In this case, the healthcare professional takes the initiative to search for information, for example, via PubMed or the Cochrane Library. Decision support can also be active. In this case, the decision support system volunteers advice based on information it can retrieve from the EPR. Decision support systems can either proactively suggest the next step in a diagnostic or treatment process or reactively remind the healthcare professional that a (preventive) procedure was not performed or a step in the protocol was not carried out.

ROLES FOR COMPUTERS IN MEDICAL EDUCATION

What roles can computers play in medical education? In the first place, information systems can be used to manage the learning process. Students can get access to the curriculum via so-called learning environments (e.g., Blackboard or WebCT), can get overviews of their marks, can access computer aided instruction programs, can access PowerPoint presentations of their teachers, and so on. Computers provide access to the internet so that they can search for content knowledge.

Computer-aided instruction can be used to teach students certain subjects. For example, computers are used to simulate regulatory mechanisms occurring in the human body. With a simulation program, students can treat "patients" without risking their patient lives. The simulation is often based on models that present (patho)physiologic processes in the form of mathematical equations. When the models become increasingly accurate they can even be used in patient care. Also, patient management problems can be simulated. In this case, usually no mathematics is involved, but the patient's signs and symptoms as they develop as a function of time are expressed as text.

There are simulation tools that allow users to evaluate, plan, or redesign hospital departments, or parts of other healthcare systems. Physicians will be confronted with the results of simulations. The model that is used in the simulation has to be checked for validity. Some tools present the modeled processes visually so that physicians or nurses can easily determine the correctness of the model. An example is the modeling of a phlebography service. On the screen, the cubicles and other rooms are displayed and the movements of patients, physicians, and nurses can be followed. In this way, the users can judge whether the model represents the situation of a phlebography service in an adequate way.

Note that computers should not be considered as surrogate teachers controlling students' learning. Computers should enrich the learning environment by expanding the student's control over their self-learning and by providing a better learning environment as a supplement to traditional methods of learning. The effectiveness of CAI has always been a subject of controversy. Studies have claimed both that CAI is superior and that CAI is inferior to traditional methods. The majority of the publications, however, support the notion that CAI is as effective as traditional educational methods (2).

Although decision making is the pre-eminent function of a physician, hardly anywhere is the student confronted with a systematic exposition of procedures of good decision making. The use of computers can facilitate the teaching of these procedures. Computer support offers new possibilities to teach problem solving techniques and analytical methods that are presently learned by the student through practice and the observation of mentors.

MEDICAL INFORMATICS

Education concerning the advantages and limitations of the use of computers for supporting the work of health professionals is the responsibility of medical informatics departments. Medical informatics can also be instrumental in developing computer-aided instruction programmes and simulation packages. Medical informatics is the discipline that deals with the systematic processing of data, information, and knowledge in the domains of medicine and healthcare. The objects of study are the computational and informational aspects of processes and structures in medicine and healthcare (3). Medical informatics is a very broad discipline covering subjects like applied technology (bioinformatics, pattern recognition, algorithms, human interfaces, etc.) and services and products (quality management, knowledge-based systems, electronic patient records, operations-resource management, etc.). Also human and organizational factors (managing change, legal issues, needs assessment, etc.) should be taken into account.

Informatics can be either a systems-oriented discipline in which computer systems, operating systems and programming languages are the object of study or a methods-oriented discipline in which the methods are studied that can be used to create algorithms that solve problems in some application domain. In the case of the methods-oriented approach, a problem is studied and formalized solutions are determined. Medical informatics is an example of this approach: it studies the processing of data, information, and knowledge in medicine and healthcare. Medical informatics focuses on the computational and informational aspects of (patho)physiological processes occurring in the patient, cognitive processes going on in the brain of physicians, and organizational processes that control healthcare systems.

The resulting knowledge can be used to design information systems that can support healthcare professionals. It is clear that healthcare professionals need to have some medical informatics knowledge in order to optimally use

information systems. Medical informatics education should therefore be part of the medical curriculum.

Various groups of professionals with quite different backgrounds can be identified who carry out medical informatics tasks ranging from the use of IT to developing information systems. Users of information systems naturally need less medical informatics knowledge than health informatics experts who develop health information systems or support other healthcare workers in designing terminology servers, coding systems, and so on.

There exists a wide range of job opportunities in the field of medical informatics. These jobs require various medical informatics capabilities. In addition to medical informatics, students (and graduate students) with other backgrounds may prefer a job in the field of medical informatics. In order to obtain the relevant capabilities these students have to learn additional subjects depending on their previous education and the type of specialization they want to achieve. These students can be graduates from healthcare related programs or from informatics-computer science programs. Graduates from healthcare related programs possess the relevant medical knowledge, but need to increase their medical informatics knowledge. Graduates with an informatics or computer science background must learn how the healthcare system is organized and how healthcare professionals are working in order to develop systems that are appreciated by healthcare professionals. Medical informatics is therefore taught in different ways (4) depending on the type of students and the type and extent of specialization that they want to achieve.

USE OF THE INTERNET

Much knowledge can be found on the internet. Browsers allow health professionals and patients to access sites containing (references to) medical knowledge. PubMed is an example. It contains references to the medical literature. The web contains a lot of information of which the quality is not always guaranteed. Especially in the medical arena, this is a big disadvantage. The internet has become one of the most widely used communication media. With the availability of Web server software, anyone can set up a Web site and publish any kind of data that is then accessible to all. The problem is therefore no longer finding information, but assessing the credibility of the publisher as well as the relevance and accuracy of a document retrieved from the net. The Health On the Net Code of Conduct (HONcode) has been issued in response to concerns regarding the quality of medical and health information (5). The HONcode sets a universally recognized standard for responsible self-regulation. It defines a set of voluntary rules to make sure that a reader always knows the source and the purpose of the information they are reading. These rules stipulate, for example, that any medical or health advice provided and hosted on a site will only be given by medically trained and qualified professionals unless a clear statement is made that a piece of advice is offered from a nonmedically qualified individual or organization. Another guideline states that support for the Web site should be clearly identified, including the identities of

commercial and noncommercial organizations that have contributed funding, services or material for the site. Students searching for information should be introduced to these guidelines.

Searching can be carried out by entering keywords. These keywords can be connected by Boolean operators like AND, OR, and NOT. A user can for example enter: Diuretics and Hypertension to search for documents that discuss the use of diuretics in hypertension. The NLM (National Library of Medicine) uses the Medical Subject Headings (MeSH) vocabulary for indexing most of their databases. Students should be taught how to efficiently search in bibliographic databases using, for example, the MeSH vocabularies.

We speak of e-learning when content is accessible via Web browsers. Some characteristics of e-learning follow: Internet is the distribution channel. Access to the content is possible 24 h/7 days a week. It is learner-centered. The student determines the learning environment, the speed of learning, the subjects to consider, the learning method. A mix of learning methods can be used (blended learning): for example, virtual classroom, simulations, cooperation, communities, and "live" learning.

Virtual learning environments aim to support learning and teaching activities across the internet. Blackboard and WebCT are examples of such environments. These environments offer many possibilities. New or modified educational modules can be announced or teachers can give feedback regarding the way a module is progressing. Also general information about a module can be provided. Staff information can be presented with photo, email address, and so on. Assignments can be posted, and so on. The virtual classroom allows students to communicate online, whereas discussion boards allow asynchronous communication. Also, links to other websites can be provided. The internet is a source of information for patients. They can retrieve diagnostic and therapeutic information from the internet. Increasingly, patients present this information to their care providers. Health professionals must know how to cope with this new situation and must be able to assess the quality of the information.

KNOWLEDGE OF INFORMATION SYSTEMS

Information systems are increasingly used in healthcare. They not only support administrative and financial, but also clinical and logistic processes. Since healthcare workers have to use information systems they should know the possibilities, but also the limitations, of information systems. Since in information systems, for example, data can be easily retrieved, the quality of entered data determines the quality of the results: garbage in, garbage out. In addition, they should have the skills to work with information systems. Information systems relevant for healthcare professionals include hospital information systems, departmental systems, electronic patient record systems, order entry and result reporting systems, and so on. But healthcare workers should also be proficient in the use of productivity tools like word processing systems, bibliographic search systems, and so on.

Logistics is becoming more important these days. Hospitals have to work not only effectively, but also more efficiently, thereby taking the preferences of patients into account. Planning systems can reduce the time that ambulatory patients have to spend in the hospital for undergoing tests, but also the length of stay of hospitalized patients can be reduced by planning both the patients and the needed capacity (6).

It is important for healthcare workers to know what support they can expect from information systems and to know which conditions have to be satisfied in order that information systems can really be of help. Optimal use of information systems therefore does not only depend on acquired skills, but also on the insight in and knowledge of the principles, concepts, and methods behind information systems. This is true for all types of healthcare professionals. When hospitals or physicians consider the purchase of information systems they must be able to specify their requirements so that they will not be confronted with systems that do not perform as expected.

ELECTRONIC PATIENT RECORDS

Physicians store information about their patients in patient records. The patient record frequently is a paper record in which the physician writes his notes. Paper records have several advantages because they are easy to use, easy to carry, and so on. But there are also limitations: they may be difficult to read and are totally passive: the physician records the information with little support (e.g., headings in a form) and therefore the recordings are often incomplete. Not only are the data incomplete, they also contain errors, for example, due to transcription or because the patient gave erroneous information. The readers of patient records can interpret the data in the patient record incorrectly. The fact that data are recorded in chronological order makes the retrieval of facts sometimes difficult: such data are not recorded on standard positions in the record. A study showed that because of the constrained organization of paper records, physicians could not find 10% of the data, although these data were present in the paper record (7). The patient data are usually stored in more than one type of record, because each department uses its own records, each with a different lay-out. Paper records are not always available at the time they are needed. Paper records are passive: they will not warn the physician if he overlooks some results. If the results of a lab request are unexpectedly not yet available, the paper record will not indicate that. Despite these drawbacks physicians are usually very positive about the use of the paper record, because they do not recognize their shortcomings.

Electronic patient records have some advantages over paper records. The legibility of electronic patient records is per definition good. Data can be presented according to different views (time-, source-, and problem-oriented), making the data easier to access. Electronic patient records, when interfaced with decision support systems, can provide reminders when a physician forgets something.

The use of computers in medical education is diverse. They can be used for managing the learning process, for distributing content, for assessing the student's knowledge or skills, and so on. In this case, they can be regarded as educational tools. As is clear from the above information systems are extensively used in the practice of health professionals. Students should be taught the benefits, but also the limitations of the use of information systems. Finally the information systems have to be developed. To be able to do so students need additional education in medical informatics.

MEDICAL ENGINEERING SOCIETIES AND ORGANIZATIONS

ARTHUR T JOHNSON
University of Maryland
College Park, Maryland
PATRICIA I HORNER
Landover, Maryland

INTRODUCTION

Modern technology has transformed the practice of medicine. We can now see where we could not before, conduct surgery with minimal trauma, intervene at the genetic level, replace whole natural organs with functional artificial ones, make rapid diagnoses, and peer into the workings of the brain. More patients are surviving, and those who do are living better. Much of the credit for these advances goes to the engineers, physicians, and physiologists who together decided what needed to be done, the science required to support it, and how it could be made practical. Medical engineers are now very much involved in the process of developing medical advances. They bring to medicine the abilities of conceptualization, computation,

and commercialization. They use varied tools such as biophysics, applied mathematics, physiological modeling, bioinstrumentation and control, imaging, and biomechanics to accomplish their advances.

The result is that there are nearly as many subspecialties of medical engineering as there are medical specialties. Tissue engineers, for instance, grow bioartificial tissues and organs as replacements; metabolic engineers find means to adjust cellular metabolic pathways to produce greater quantities of biochemicals and hormones; and rehabilitation engineers design new prostheses or modify existing units to reestablish adequate function in patients who have lost ability usually as the result of trauma. There are medical engineers working with biosensors, bioprocess optimization, multiple imaging modes, pancreatic function, vascular replacement, and drug delivery. Biomaterials engineers have produced materials that can function in different regional corporal environments. Indeed, there is no part of the human body that has not been studied by medical engineers to improve or replace lost function.

As the body of medical knowledge has increased overall and has been repeatedly split more and more finely into specialties, there has been a concomitant proliferation of organizations to communicate, share, and advocate action related to their particular specialties. Some of these would be recognized as chiefly engineering organizations with application interests in medicine; some are medical societies with significant engineering contributions. There is almost no significant human disease, physiological system, organ, or function without a group or organization representing associated interests. There is even a group interested in developing synthetic biological forms that, although it is too premature to link with medicine, may someday have a profound effect on medicine. All of these groups can be found by searching the Internet, and any attempt to enumerate them here would be outdated very quickly.

DEFINITIONS

Progress in biological science and engineering has not been made with a clear distinction between medical and non-medical applications. Advances in human medicine often find applications as well in veterinary medicine. Genetic coding techniques have been applied equally to humans and fruit flies. Prospective biomaterials are modeled on computer without regard for the ultimate specific application, and they are tested in animals, plants, or fungi before approval for human use. Progress toward better nutrition through science, and toward purer environments through improved pollutant detection monitoring, have resulted in better human health for most humans living in the developed world. Biology is biology, whether applied to human health care or not, so a convergence of basic knowledge and methods between medical and biological engineers is expected to continue.

Several relevant definitions attempt to distinguish among various fields where engineers have and will continue to contribute.

The U.S. National Institutes for Health (NIH) has the following definition of bioengineering:

Bioengineering integrates physical, chemical, mathematical, and computational sciences and engineering principles to study biology, medicine, behavior, and health. It advances fundamental concepts; creates knowledge from the molecular to the organ systems levels; and develops innovative biologics, materials, processes, implants, devices, and informatics approaches for the prevention, diagnosis, and treatment of disease, for patient rehabilitation, and for improving health.

The U.S. National Science Foundation program in Biochemical Engineering and Biotechnology (BEB) describes its program in the following way:

Advances the knowledge base of basic engineering and scientific principles of bioprocessing at both the molecular level (biomolecular engineering) and the manufacturing scale (bioprocess engineering). Many proposals supported by BEB programs are involved with the development of enabling technologies for production of a wide range of biotechnology products and services by making use of enzymes, mammalian, microbial, plant, and/or insect cells to produce useful biochemicals, pharmaceuticals, cells, cellular components, or cell composites (tissues).

The Whitaker Foundation definition of biomedical engineering is as follows:

Biomedical engineering is a discipline that advances knowledge in engineering, biology, and medicine, and improves human health through cross-disciplinary activities that integrate the engineering sciences with the biomedical sciences and clinical practice. It includes: 1) The acquisition of new knowledge and understanding of living systems through the innovative and substantive application of experimental and analytical techniques based on the engineering sciences, and 2) The development of new devices, algorithms, processes, and systems that advances biology and medicine and improve medical practice and health care delivery.

And, finally, the Institute of Biological Engineering (IBE) defines biological engineering as follows:

Biological engineering is the biology-based engineering discipline that integrates life sciences with engineering in the advancement and application of fundamental concepts of biological systems from molecular to ecosystem levels. The emerging discipline of biological engineering lies at the interfaces of biological sciences, engineering sciences, mathematics and computational sciences. It applies biological systems to enhance the quality and diversity of life.

HISTORICAL DEVELOPMENTS

In 1948, in New York City, a group of engineers from the Instrument Society of America (ISA) and the American Institute of Electrical Engineers (AIEE), with professional interests in the areas of X-ray and radiation apparatus used in medicine, held the First Annual Conference on Medical Electronics. Soon thereafter the Institute of Radio Engineers (IRE), joined with the ISA and AIEE, and the

series of annual meetings continued. Subsequent years witnessed a remarkable growth of interest in biomedical engineering and participation by other technical associations. By 1968 the original core group evolved into the Joint Committee on Engineering in Medicine and Biology (JCEMB), with five adherent national society members: the Instrument Society of America (ISA), the Institute of Electrical and Electronics Engineers, Inc. (IEEE), the American Society of Mechanical Engineers (ASME), the American Institute of Chemical Engineers (AIChE), and the Association for the Advancement of Medical Instrumentation (AAMI), who jointly conducted the Annual Conference on Engineering in Medicine and Biology (ACEMB).

Professional groups responded vigorously to the demands of the times. Attendance at the annual conference by natural scientists and medical practitioners grew to approximately 40% of the total; medical associations requested formal participation with their technical counterparts on the JCEMB. New interdisciplinary organizations were formed. New intrasociety and intersociety groups, committees, and councils became active; meetings filled the calendar; and publications overflowed the shelves.

In 1968, a document was prepared that read as follows: WHEREAS:

1. Common interdisciplinary purposes cannot be well served by individual groups working independently from each other;
2. Certain associations have developed in attempts to meet the need;
3. Conferences and publications have proliferated in attempts to meet the needs;
4. At present, no mutually satisfactory mechanism exists for the coordination of the relevant groups and functions;
5. There does exist an annual meeting and proceedings publication sponsored by a limited number of societies through the Joint Committee on Engineering in Medicine and Biology (JCEMB);
6. The JCEMB is formally structured with a constitution, plural societal representation, and an established pattern of operation. This structure and pattern of operation, however, are not deemed adequate to fulfill present and future needs. To the best of our knowledge, there exists no other single organization that seems capable of fulfilling these needs.

THEREFORE, it is appropriate that a new organization be established.

On July 21, 1969, at the 22nd ACEMB in Chicago, Illinois, representatives of 14 national engineering, scientific, and medical associations founded the Alliance for Engineering in Medicine and Biology (AEMB). It was incorporated on December 24, 1969, in Washington, D.C. Lester Goodman, Ph.D., served as Founder President in

1970–1971; Arthur C. Beall, MD(1972); Alan R. Kahn, MD(1973); Harry S. Lipscomb, MD(1974); Anthony Sances, Jr., Ph.D. (1975); Charles Weller, MD(1976–1977); Edward J. Hinman, MD MPH(1978–1979); Paul W. Mayer, MD(1980–1982); Francis M. Long, Ph.D., (1983–1984); Arthur T. Johnson, PE, Ph.D. (1985–1988); and Alfred R. Potvin, PE Ph.D. served as the final President in 1989–1990.

The Alliance operations were determined by an Administrative Council composed of delegates from each of its affiliates. Later the Alliance was to consist of more than 20 such organizations:

Aerospace Medical Association (ASMA)
 American Academy of Orthopaedic Surgeons (AAOS)
 American Association of Physicists in Medicine (AAPM)
 American College of Chest Physicians (ACCP)
 American College of Physicians (ACP)
 American College of Radiology (ACR)
 American College of Surgeons (ACP)
 American Institute of Aeronautics and Astronautics (AIAA)
 American Institute of Biological Sciences (AIBS)
 American Institute of Chemical Engineers (AIChE)
 American Institute of Ultrasound in Medicine (AIUM)
 American Society for Artificial Internal Organs (ASAIO)
 American Society for Engineering Education (ASEE)
 American Society for Hospital Engineers of the American Hospital Association (ASHE)
 American Society for Testing and Materials (ASTM)
 American Society of Agricultural Engineers (ASAE)
 American Society of Civil Engineers (ASCE)
 American Society of Heating, Refrigerating and Air Conditioning Engineers (ASHRAE)
 American Society of Internal Medicine (ASIM)
 American Society of Mechanical Engineers (ASME)
 Association for the Advancement of Medical Instrumentation (AAMI)
 Biomedical Engineering Society (BMES)
 Institute of Electrical and Electronics Engineers (IEEE)
 Instrument Society of America (ISA)
 National Association of Bioengineers (NAB)
 Neuroelectric Society (NES)
 RESNA—Rehabilitation Engineering & Assistive Technology Society of North America
 Society for Advanced Medical Systems, now American Medical Informatics Association (AMIA)
 Society for Experimental Stress Analysis (SESA)
 SPIE—International Society for Optical Engineering
 Alpha Eta Mu Beta—National Biomedical Engineering Student

Honor Society, established under the auspices of A EMB.

The Alliance headquarters office opened on November 1, 1973. John H. Busser served as the first Executive Director. Patricia I. Horner served as Assistant Director, as Administrative Director, and succeeded Busser as the Executive Director. Among its goals, is the following excerpted in part from its constitution, bylaws, and recorded minutes:

to promote cooperation among associations that have an active interest in the interaction of Engineering and the physical sciences with medicine and the biological sciences in enhancement of biomedical knowledge and health care.

to establish an environment and mechanisms whereby people from relevant various disciplines can be motivated and stimulated to work together

to respond to the needs of its member societies, as expressed by their delegates, rather than to seek authoritative preeminence in its domain of interest...

to support and enhance the professional activities of its membership...

The 23rd ACEMB in Washington, D.C., in 1970, was the first held under the aegis of the Alliance. From 1979 to 1984, the IEEE Engineering in Medicine and Biology Society (EMBS) held their conferences immediately preceding the ACEMB. The Society for Advanced Medical Systems, later to become AMIA, and the Biomedical Engineering Society also held their meetings for several years in conjunction with the ACEMB.

The accomplishments of the Alliance far outstripped the expectations of its founders. The Alliance more than fulfilled responsibilities for the annual conference inherited from the predecessor JCEMB, but the Alliance made important contributions through a variety of studies and publications ranging from a 5-year ultrasound research and development agenda to a guideline for technology procurement in health-care institutions:

- First International Biomedical Engineering Workshop Series held in Dubrovnik, Yugoslavia, under the sponsorship of the National Science Foundation. This project was in cooperation with AIBS and the International Institute of Biomedical Engineering in Paris. Five workshops were held, and planning handbooks were completed.
- Assessment of selected medical instrumentation; Tasks 1–4, ultrasonic diagnostic imaging; Task 5, radiologic and radionuclide imaging technology.
- Summary guidelines and courses on technology procurement; practices and procedures for improving productivity in research and health-care institutions.
- Information exchange and problem assessments in medical ultrasound, including preparation and distribution of a directory of federal activities, conducted instrumentation conferences, delineated training needs, assessed technology transfer potential, and prepared guidelines for the establishment of clinical ultrasound facilities.

- Joint U.S.–Egypt international technology transfer project in medical diagnostic ultrasound, including international workshops and the design and support of a focus laboratory for ultrasonic diagnosis at Cairo University Medical School.
- Short courses for continuing education at the annual conference on engineering in medicine and biology.
- International directory of biomedical engineers.

Before long, the proliferation of medical engineers, and competing interests among societies, led to a fragmentation of the field. It became clear that the Alliance no longer represented positions of the entire field. No organized group could speak for the entire profession, and the spirit of unity that had led to the development of AEMB no longer existed. It was time for a new beginning.

AMERICAN INSTITUTE FOR MEDICAL AND BIOLOGICAL ENGINEERING

In 1988, the National Science Foundation funded a grant to develop an infrastructure for bioengineering in the United States. The AEMB, jointly with the U.S. National Committee on Biomechanics (USNCB), was to develop a unifying organization for bioengineering in the United States. The co-principal investigators were Robert M. Nerem and Arthur T. Johnson, and Patricia Horner served as Project Director. The AEMB/USNCB Steering Committee consisted of Robert M. Nerem, Arthur T. Johnson, Michael J. Ackerman, Gilbert B. Devey, Clifford E. Brubaker, Morton H. Friedman, Dov Jaron, Winfred M. Phillips, Alfred R. Potvin, Jerome S. Schultz, and Savio L-Y Woo. The Steering Committee met in January and March 1989, and the first workshop was held in August 1989. Two more Steering Committee meetings were held in December 1989 and March 1990, and the second workshop was held in July 1990. The outcome of these two workshops was to establish the American Institute for Medical and Biological Engineering (AIMBE). All AEMB members voted to cease operation of the Alliance for Engineering in Medicine and Biology in 1990 and to transfer the AEMB assets and 501(c)3 status to AIMBE in 1991.

AIMBE opened an office in Washington, D.C., in 1995 with Kevin O'Connor as Executive Director. He was succeeded by Arthur T. Johnson in 2004 and Patricia Ford-Roegner in 2005. AIMBE Presidents have been as follows: Robert Nerem (1992–1993), Pierre Galletti (1994), Jerome Schultz (1995), Winfred Phillips (1996), Larry McIntire (1997), William Hendee (1998), John Linehan (1999), Shu Chien (2000), Peer Portner (2001), Buddy Ratner (2002), Arthur Coury (2003), Don Giddens (2004), Thomas Harris (2005), and Herbert Voigt (2006).

Representing over 75,000 bioengineers, the AIMBE seeks to serve and coordinate a broad constituency of medical and biological scientists and practitioners, scientific and engineering societies, academic departments, and industries. Practical engagement of medical and biological

engineers within the AIMBE ranges from the fields of clinical medicine to food, agriculture, and environmental bioremediation.

AIMBE's mission is to

- Promote awareness of the field and its contributions to society in terms of new technologies that improve medical care and produce more and higher quality food for people throughout the world.
- Work with lawmakers, government agencies, and other professional groups to promote public policies that further advancements in the field.
- Strive to improve intersociety relations and cooperation within the field.
- Promote the national interest in science, engineering, and education.
- Recognize individual and group achievements and contributions to medical and biological engineering.

AIMBE is composed of four sections:

- The College of Fellows—1000 Persons who are the outstanding bioengineers in academic, industry, and government. These leaders in the field have distinguished themselves through their contributions in research, industrial practice, and/or education. Most Fellows come from the United States, but there are international Fellows.
- The Academic Council—Universities with educational programs in bioengineering at the graduate or undergraduate level. Currently there are approximately 85 member institutions. Representative to the Council generally are chairs of their departments. Many also are members of the College of Fellows. The Council considers issues ranging from curricular standards and accreditation to employment of graduates and funding for graduate study.
- The Council of Societies—The AIMBE's mechanism coordinating interaction among 19 scientific organizations in medical and biological engineering. The purposes of the Council are to provide a collaborative forum for the establishment of society member positions on issues affecting the field of medical and biological engineering, to foster intersociety dialogue and cooperation that provides a cohesive public representation for medical and biological engineering, and to provide a way to coordinate activities of member societies with the activities of academia, government, the health-care sector, industry, and the public and private biomedical communities.
- The Industry Council—A forum for dialog among industry, academia, and government to identify and act on common interests that will advance the field of medical and biological engineering and contribute to public health and welfare. Industrial organizations may be members of the Industry Council if they have substantial and continuing professional

interest in the field of medical and biological engineering.

Current members of the Council of Societies are as follows:

American Association of Physicists in Medicine
 American College of Clinical Engineering
 American Institute of Chemical Engineers; Food, Pharmaceutical and Bioengineering Division
 American Medical Informatics Association
 American Society of Agricultural and Biological Engineers
 American Society for Artificial Internal Organs
 American Society for Biomechanics
 American Society of Mechanical Engineers, Bioengineering Division
 Biomedical Engineering Society
 Controlled Release Society
 IEEE Engineering in Medicine and Biology Society
 Institute of Biological Engineering
 International Society for Magnetic Resonance in Medicine
 Orthopaedic Research Society
 Rehabilitation Engineering and Assistive Technology Society of North America
 Society for Biomaterials
 SPIE: The International Society for Optical Engineering
 Surfaces in Biomaterials Foundation

Current members of the Industry Council are as follows:

Biomet, Inc.
 Boston Scientific Corporation
 Genzyme Corporation
 Medtronic, Inc.
 Pequot Ventures
 Smith + Nephew
 Vyteris, Inc.
 Wright Medical Technology, Inc.
 Zimmer, Inc.

The AIMBE Board of Directors oversees the work of the College of Fellows and the three councils. The Board consists of a President who is assisted by two Past Presidents, the President-Elect, four Vice-Presidents at Large, a Secretary-Treasurer, and the Chair of the College of Fellows—all of whom are elected by the Fellows. The Board also includes chairs of the other councils and chairs of all standing committees. AIMBE's day-to-day operations are supervised by the Executive Director in the Washington headquarters.

AIMBE's Annual Event each winter in Washington, D.C., provides a forum on the organization's activities and is a showcase for key developments in medical and

biological engineering. The annual event includes a 1-day scientific symposium sponsored by the College of Fellows, a ceremony to induct the newly elected Fellows, and a 1-day series of business meetings focused on public policy and other issues of interest to AIMBE's constituents. For additional information about AIMBE's mission, memberships, and accomplishments, visit <http://www.aimbe.org>.

The AIMBE has focused on public policy issues associated with medical and biological engineering. The AIMBE enjoys high credibility and respect based on the stature of its Fellows, support from constituent societies, and its intention to be a forum for the best interests of the entire field. The AIMBE has taken positions on several important issues and advocated that they be adopted by various agencies and by Congress. A few of the AIMBE'S public policy initiatives that have met with success are as follows:

- National Institute of Biomedical Imaging and Bioengineering (NIBIB)—Created in 2000 with the help of AIMBE advocacy, the NIBIB has received strong support from the AIMBE and other institutions that value the role of technology in medicine, particularly the Academy of Radiological Research. The NIBIB has experienced rapid growth and development in all areas, including scientific programs, science administration, and operational infrastructure. The prognosis for the near future is continued growth and development especially in bioengineering, imaging, and interdisciplinary biomedical research and training programs.
- FDA Modernization Act (FDAMA)—Enacted in 1997, this legislation amended the Federal Food, Drug, and Cosmetic Act relation to the regulation of food, drugs, devices, and biological products. FDAMA enhanced the FDA's mission in ways that recognized the Agency would be operating in a twenty-first century characterized by increasing technological, trade, and public health complexities.
- Biomaterials Access Assurance Act—The 1998 legislation provides relief for materials suppliers to manufacturers of implanted medical devices by allowing those suppliers to be dismissed from lawsuits in which they are named if they meet the statutory definition of a "biomaterials supplier."
- National Institutes of Health Bioengineering Consortium (BECON)—This is the focus of bioengineering activities at the NIH. The Consortium consists of senior-level representatives from all NIH institutes, centers, and divisions plus representatives of other Federal agencies concerned with biomedical research and development. The BECON is administered by NIBIB.

The AIMBE Hall of Fame was established in 2005 to recognize and celebrate the most important medical and biological engineering achievements contributing to the quality of life. The Hall of Fame provides tangible evidence of the contributions of medical and biological engineering during the following decades:

1. *1950s and earlier*

- Artificial kidney
- X ray
- Cardiac pacemaker
- Cardiopulmonary bypass
- Antibiotic production technology
- Defibrillator

2. *1960s*

- Heart valve replacement
- Intraocular lens
- Ultrasound
- Vascular grafts
- Blood analysis and processing

3. *1970s*

- Computer-assisted tomography (CT)
- Artificial hip and knee replacement
- Balloon catheter
- Endoscopy
- Biological plant/food engineering

4. *1980s*

- Magnetic resonance imaging (MRI)
- Laser surgery
- Vascular stents
- Recombinant therapeutics

5. *1990s*

- Genomic sequencing and micro-arrays
- Positron emission tomography
- Image-guided surgery

The AIMBE has now turned its attention to Barriers to Further Innovation. It is providing forums and platforms for identification and discussion of obstacles standing in the way of advances in medical and biological engineering. Barriers could be procedures, policies, attitudes, or information and education, anything that can yield when AIMBE constituents apply pressure at appropriate levels.

OTHER SOCIETIES

These are other general biomedical engineering societies that operate within the United States. Among these, the Biomedical Engineering Society (BMES), Engineering in Medicine and Biology Society (EMBS), and the Institute for Biological Engineering (IBE) are probably the most inclusive. Others direct their attentions to specific parts of the discipline. There are trade organizations that have an

industry perspective (such as AdvaMed for the medical device industry and the Biotechnology Industry Organization (BID) for the biotech industry), and there are peripheral organizations that deal with public health, the environment, and biotechnology. Many of these organizations publish excellent journals, newsletters, and information sheets. Those from trade organizations are often distributed free of charge, but they do not include peer-reviewed articles. Information about these can be found on the Internet.

Internationally, an organizational hierarchy exists. National and transnational organizations can belong to the International Federation for Medical and Biological Engineering (IFMBE), and that confers membership privileges to all AIMBE members and constituent society members. The IFMBE and the International Organization for Medical Physics (IOMP) together jointly sponsor a World Congress on Medical Physics and Biomedical Engineering every 3 years. The IOMP and IFMBE are members of the International Union for Physical and Engineering Sciences in Medicine (IUPESM), and the IUPESM, in turn, is a member of the International Council for Science (ICSU). ICSU members are national and international scientific unions and have a very broad and global outreach.

THE FUTURE

At least for the foreseeable future, new groups will be formed representing medical engineering specialties. Whether these groups organize formally and persist will depend on the continuing importance of their areas of focus. The organizations with a more general foci will continue to function and may spawn splinter groups. Given the political importance of concerted effort, organizations such as the AIMBE will continue to be active in promoting policy. Competitive pressures among different organizations, especially when expectations of continuing growth cannot be sustained, will always be a threat to the current order. Given that the cycle of competition and disorder leading to a realization that some ordered structure is preferable has been repeated at least once, there will continue to be some undercurrent of turmoil within the community of medical engineering organizations.

U.S. PROFESSIONAL SOCIETIES AND ORGANIZATIONS

Biomedical Engineering Associations and Societies

AdvaMed. 1200 G Street NW, Suite 400, Washington, D.C. 20005. 202-783-8700, <http://www.advamed.org>. Stephen J. Ubl, President. 1300 Members.

Represents manufacturers of medical devices, diagnostic products, and medical information systems. AdvaMed's members manufacture nearly 90% of the \$80 billion of health-care technology purchased annually in the United States. Provides advocacy, information, education, and solutions necessary for success in a world of increasingly complex medical regulations.

Alpha Eta Mu Beta. 8401 Corporate Drive, Suite 140, Landover, MD 20785. 301-459-1999, <http://www.ahmb.org>.

Herbert F. Voigt, National President; Patricia I. Horner, Executive Director. 20 chapters.

Alpha Eta Mu Beta, the National Biomedical Engineering Honor Society, was founded by Daniel Reneau at Louisiana Tech University in 1979. This organization was sponsored by the AEMB. The AEMB was established to mark in an outstanding manner those biomedical engineering students who manifested a deep interest and marked ability in their chosen life work to promote an understanding of their profession and to develop its members professionally.

American Institute for Medical and Biological Engineering. 1901 Pennsylvania Ave NW, Suite 401, Washington, D.C. 20006. 202-496-9660, <http://www.aimbe.org>. Patricia Ford Roegner, Executive Director. 1000 Fellows; 18 Scientific Organizations; 85 Universities.

Founded in 1991 to establish an identity for the field of medical and biological engineering, which is the bridge between the principles of engineering science and practice and the problems and issues of biological and medical science and practice. The AIMBE comprises four sections. The College of Fellows with over 1000 persons who are the outstanding bioengineers in academia, industry, and government. The Academic Council is 85 universities with educational programs in bioengineering at the graduate or undergraduate level. The Council of Societies is 18 scientific organizations in medical and biological engineering. The Industry Council is a forum for dialog among industry, academia, and government. Principal activities include participation in formulation of public policy, dissemination of information, and education. Affiliated with the International Federation for Medical and Biological Engineering. Annual event each winter in Washington, D.C.

American Association of Engineering Societies. 1828 L Street NW, Suite 906, Washington, D.C. 20036. 202-296-2237, <http://www.aaes.org>. Thomas J. Price, Executive Director. 26 Engineering Societies.

Founded in 1979 in New York City. Member societies represent the mainstream of U.S. engineering with more than one million engineers in industry, government, and academia. The AAES has four primary programs: communications, engineering workforce commission, international, and public policy. Governance consists of two representatives from each of 26 member societies. Convenes diversity summits, publishes engineering and technology degrees, and holds annual awards ceremony.

American Academy of Environmental Engineers. 130 Holiday Court, Suite 100, Annapolis, MD 21401. 410-266-3311, <http://www.aeee.net>. David A. Asselin, Executive Director.

The American Sanitary Engineering Intersociety Board incorporated in 1955 became the American Academy of Environmental Engineers in 1966; and in 1973, it merged with the Engineering Intersociety Board. Principal purposes are improving the practice, elevating the standards, and advancing public recognition of environmental engineering through a program of specialty certification of qualified engineers.

American Academy of Orthopaedic Surgeons. 600 North River Road, Rosemont, IL 60018. 847-823-7186, <http://www.aaos.org>. Karen L. Hackett, Chief Executive Officer. 24,000 Members.

Founded in Chicago in 1933. Provides education and practice management services for orthopedic surgeons and allied health professionals. Maintains a Washington, D.C., office. Annual spring meeting.

American Academy of Orthotists and Prosthetists. 526 King Street, Suite 201, Alexandria, VA 22314. 703-836-0788, <http://www.oandp.org>. Peter D. Rosenstein, Executive Director. 3000 Members.

Founded in 1970 to further the scientific and educational attainments of professional practitioners in the disciplines of orthotics and prosthetics. Members have been certified by the American Board for Certification in Orthotics and Prosthetics. Annual spring meeting.

American Association of Physicists in Medicine. One Physics Ellipse, College Park, MD 20740. 301-209-3350, <http://www.aapm.org>. Angela R. Keyser, Executive Director. 4700 Members.

Founded in Chicago in 1958 and incorporated in Washington in 1965. Promotes the application of physics to medicine and biology. Member society of the American Institute of Physics. Annual summer meeting.

American Chemical Society. 1155 Sixteenth Street NW, Washington, D.C. 20036. 800-227-5558, <http://www.chemistry.org>. Madeleine Jacobs, Executive Director, and CEO. 159,000 Members.

Founded in 1877 in New York City. Granted a national charter by Congress in 1937. Encourages the advancement of chemistry. Semiannual spring and fall meetings.

American College of Nuclear Physicians. 1850 Samuel Morse Drive, Reston, VA 20190. 703-326-1190, <http://www.acnponline.org>. Virginia M. Pappas, Executive Director. 500 Members.

Established in 1974, the organization provides access to activities that encompass the business and economics of nuclear medicine as they impact nuclear medicine physicians. Semiannual meetings fall and winter.

American College of Physicians. 190 N. Independence Mall West, Philadelphia, PA 19106. 215-351-2600, <http://www.acponline.org>. John Tooker, Executive Vice President. 119,000 Members.

Founded in New York City in 1915. Merged with the Congress of Internal Medicine in 1923 and merged in 1998 with the American Society of Internal Medicine. Patterned after England's Royal College of Physicians. Members are physicians in general internal medicine and related subspecialties. Maintains a Washington, D.C., office. Annual spring meeting.

American College of Radiology. 1891 Preston White Drive, Reston, VA 20191. 703-648-8900, <http://www.acr.org>. Harvey L. Neiman, Executive Director. 30,000 Members.

Founded in 1923 in San Francisco and incorporated in California in 1924. Purpose is to improve the health of patients and society by maximizing the value of radiology and radiologists by advancing the science, improving patient service, and continuing education. Annual fall meeting.

American College of Surgeons. 633 N. St. Clair Street, Chicago, IL 60611. 312-202-5000, <http://www.facs.org>. Thomas R. Russell, Executive Director. 64,000 Fellows, 5000 Associate Fellows.

Founded in 1913 and incorporated in Illinois. U.S. member of the International Federation of Surgical Colleges. Members are Fellows who must meet high standards established by the College. Purpose is to improve the quality of care for the surgical patient by setting high standards for surgical education and practice. Annual fall clinical congress.

American Congress of Rehabilitation Medicine. 6801 Lake Plaza Drive, Suite B-205, Indianapolis, IN 46220. 317-915-2250, <http://www.acrm.org>. Richard D. Morgan, Executive Director. 1700 Members, 15 Companies.

Founded in 1923 as the American College of Radiology and Physiotherapy. Name changed in 1926 to American College of Physical Therapy and in 1930 to American Congress of Physical Therapy. Changed again in 1945 to American Congress of Physical Therapy and in 1953 became American Congress of Physical Medicine and Rehabilitation. Adopted its current name in 1967. Provides education for professionals in medical rehabilitation. Fall annual meeting.

American Institute of Biological Sciences. 1444 I Street NW, Suite 200, Washington, D.C. 20005. 202-628-1500, <http://www.aibs.org>. Richard O'Grady, Executive Director. 80 Societies, 6000 Members.

Founded in 1947 as part of the National Academy of Sciences. Incorporated as an independent nonprofit since 1954. Absorbed America Society of Professional Biologists in 1969. Represents more than 80 professional societies with combined membership exceeding 240,000 scientists and educators. Also more than 6000 individual members. Purpose is to better serve science and society. Annual meeting in August.

American Institute of Chemical Engineers. 3 Park Avenue, New York, NY 10016. 212-591-8100, <http://www.aiche.org>. John Sofranko, Executive Director. 40,000 Members.

Organized in 1908 and incorporated in 1910. Member of Accreditation Board for Engineering and Technology, American National Standards Institute, American Association of Engineering Societies, and other related organizations. Purpose is to advance the chemical engineering profession. Annual meeting in November.

American Institute of Physics. One Physics Ellipse, College Park, MD 20740. 301-209-3131, <http://www.aip.org>. Marc H. Brodsky, Executive Director, and Chief Executive Officer. 10 Societies and 24 Affiliates.

Chartered in 1931 to promote the advancement of physics and its application to human welfare. Federation of 10 Member Societies representing spectrum of physical sciences.

American Institute of Ultrasound in Medicine. 14750 Sweitzer Lane, Suite 100, Laurel, MD 20707. 301-498-4100, <http://www.aium.org>. Carmine Valente, Chief Executive Officer.

Began in 1951 at a meeting of 24 physicians attending the American Congress of Physical Medicine and Rehabilitation. Membership includes biologists, physicians, and engineers concerned with the use of ultrasound for diagnostic purposes. Provides continuing education, CME tests, and accreditation of ultrasound laboratories. Annual fall meeting.

American Medical Informatics Association. 4915 St. Elmo Avenue, Suite 401, Bethesda, MD 20814. 301-657-1291, <http://www.amia.org>. Don Detmer, President, and CEO. 3000 Members.

Founded in 1990 through a merger of three existing health informatics associations. Members represent all basic, applied, and clinical interests in health-care information technology. Promotes the use of computers and information systems in health care with emphasis on direct patient care. Semiannual meetings: spring congress in the West and fall annual symposium in the East.

American Society for Artificial Internal Organs. P.O. Box C, Boca Raton, FL 33429. 561-391-8589, <http://www.asaio.net>. 1400 Members.

Established in 1955 in Atlantic City, NJ. Annual June conference.

American Society for Engineering Education. 1818 N Street NW, Suite 600, Washington, D.C. 20036. 202-331-3500, <http://www.asee.org>. Frank L. Huband, Executive Director. 12,000 Members, 400 Colleges, 50 Corporations.

Founded in 1893 as the Society for Promotion of Engineering Education. Incorporated in 1943 and merged in 1946 with Engineering College Research Association. Members include deans, department heads, faculty members, students, and government and industry representatives from all disciplines of engineering and engineering technology. Member of the American Association of Engineering Societies, Accreditation Board for Engineering and Technology, American Institute for Medical and Biological Engineering, and American Council on Education. Participating society of World Federation of Engineering Associations. Purpose is to further education in engineering and engineering technology. Annual June meeting.

American Society for Healthcare Engineering of the American Hospital Association. One North Franklin, 28th Floor, Chicago, IL 60606. 312-422-3800, <http://www.ashe.org>. Albert J. Sunseri, Executive Director.

Affiliate of the American Hospital Association. Annual June meeting.

American Society for Laser Medicine and Surgery. 2404 Stewart Avenue, Wausau, WI 54401. 715-845-9283, <http://www.aslms.org>. Dianne Dalsky, Executive Director. 3000 Members.

Founded in 1980 to promote excellence in patient care by advancing laser applications and related technologies. Annual spring meeting.

American Society of Agricultural and Biological Engineers. 2950 Niles Road, St. Joseph, MI 49085. 269-429-0300, <http://www.asabe.org>. Melissa Moore, Executive Vice President. 9000 Members.

Founded in 1907 as the American Society of Agricultural Engineers and changed its name in 2005. Dedicated to the advancement of engineering applicable to agricultural, food, and biological systems. Annual meeting in July.

American Society of Civil Engineers. 1801 Alexander Bell Drive, Reston, VA 20191. 703-295-6000, <http://www.asce.org>. Patrick J. Natale, Executive Director. 137,500 Members.

Founded in 1852 as the American Society of Civil Engineers and Architects. Dormant from 1855 to 1867, but it revived in 1868 and incorporated in 1877 as the American Society of Civil Engineers. Over 400 local affiliates, 4 Younger Member Councils, 230 Student Chapters, 36 Student Clubs, and 6 International Student Groups. Semi-annual spring and fall meetings.

American Society of Heating, Refrigerating and Air-Conditioning Engineers, Inc. 1791 Tullie Circle NE, Atlanta, GA 30329. 404-636-8400, <http://www.ashrae.org>.

Incorporated in 1895 as the American Society of Heating and Ventilating Engineers, known after 1954 as American Society of Heating and Air-Conditioning Engineers. Merged in 1959 with American Society of Refrigerating Engineers to form American Society of Heating, Refrigerating and Air-Conditioning Engineers. Annual summer meeting.

American Society of Mechanical Engineers. Three Park Avenue, New York, NY 10016. 212-591-7722, <http://www.asme.org>. Virgil R. Carter, Executive Director. 120,000 Members.

Founded in 1880 and incorporated in 1881. Focuses on technical, educational, and research issues of engineering and technology. Sets industrial and manufacturing codes and standards that enhance public safety. Conducts one of the world's largest technical publishing operations. Semi-annual summer and winter meetings.

American Society of Neuroradiology. 2210 Midwest Road, Suite 207, Oak Brook, IL 60523. 630-574-0220, <http://www.asnr.org>. James B. Gantenberg, Executive Director/CEO. 2700 Members.

Founded in 1962. Supports standards for training in the practice of neuroradiology. Annual spring meeting.

American Society of Safety Engineers. 1800 E. Oakton Street, Des Plaines, IL 60018. 847-699-2929, <http://www.asse.org>.

Fred Fortman, Executive Director. 30,000 Members.

Founded in 1911 as the United Association of Casualty Inspectors and merged with the National Safety Council in 1924, becoming its engineering section. Became independent again in 1947 as the American Society of Safety Engineers and incorporated in 1962. There are 13 practice specialties, 150 chapters, 56 sections, and 64 student sections. Annual spring meeting.

Association for Computing Machinery. 1515 Broadway, New York, NY 10036. 212-626-0500, <http://www.acm.org>. John R. White, Executive Director. 80,000 Members.

Founded in 1947 at Columbia University as Eastern Association for Computing Machinery and incorporated in Delaware in 1954. Affiliated with American Association for Advancement of Science, American Federation of Information Processing Societies, Conference Board of Mathematical Sciences, National Academy of Sciences-National Research Council, and American National Standards Institute. Advancing the skills of information technology professionals and students. Annual fall meeting.

Association for the Advancement of Medical Instrumentation. 1100 North Glebe Road, Suite 220, Arlington, VA 22201. 703-525-4890, <http://www.aami.org>. Michael J. Miller, President. 6000 Members.

Founded in 1967, the AAMI is an alliance of over 6000 members united by the common goal of increasing the understanding and beneficial use of medical instrumentation and technology. Annual spring meeting.

Association of Biomedical Communications Directors. State University of New York at Stony Brook, Media Services L3044 Health Sciences Center, Stony Brook, NY 11794. 631-444-3228. Kathleen Gebhart, Association Secretary. 100 Members.

Formed in 1974 as a forum for sharing information; adopted a Constitution and Bylaws in 1979, and incorporated in April 1979 in North Carolina. Members are directors of biomedical communication in academic health science settings. Annual spring meeting.

Association of Environmental Engineering and Science Professors. 2303 Naples Court, Champaign, IL 61822. 217-398-6969, <http://www.aeesp.org>. Joanne Fetzner, Secretary. 700 Members.

Formerly, in 1972, the American Association of Professors in Sanitary Engineering. Professors in academic programs throughout the world who provide education in the sciences and technologies of environmental protection. Biennial conference in July.

Biomedical Engineering Society. 8401 Corporate Drive, Suite 140, Landover, MD 20785. 301-459-1999, <http://www.bmes.org>. Patricia I. Horner, Executive Director. 3700 Members.

Founded in 1968 in response to a need to give equal representation to both biomedical and engineering interests. The purpose of the Society is to promote the increase of biomedical engineering knowledge and its use. Member

of American Institute for Medical and Biological Engineering. Annual fall meeting.

Biophysical Society. 9650 Rockville Pike, Bethesda, MD 20814. 301-634-7114, <http://www.biophysics.org>. Ro Kampman, Executive Officer. 7000 Members.

Founded in 1957 in Columbus, OH, to encourage development and dissemination of knowledge in biophysics. Annual winter meeting.

Health Physics Society. 1313 Dolley Madison Boulevard, Suite 402, McLean, VA 22101. 703-790-1745, <http://www.hps.org>. Richard J. Burk, Jr, Executive Secretary. 7000 Members.

Founded in 1956 in the District of Columbia and reincorporated in Tennessee in 1969. Society specializes in occupational and environmental radiation safety. Affiliated with International Radiation Protection Association. Annual summer meeting.

Human Factors and Ergonomics Society. P.O. Box 1369, Santa Monica, CA 90406. 310-394-1811, <http://www.hfes.org>. Lynn Strother, Executive Director. 50 Active Chapters and 22 Technical Groups.

Founded in 1957, formerly known as the Human Factors Society. An interdisciplinary organization of professional people involved in the human factors field. Member of the International Ergonomics Association. Annual meeting in September-October.

Institute for Medical Technology Innovation. 1319 F Street NW, Suite 900, Washington, D.C. 20004. 202-783-0940, <http://www.innovate.org>. Martyn W.C. Howgill, Executive Director.

The concept was developed in 2003 by leaders in the medical device industry, and the Institute was incorporated and opened its offices in 2004. Purpose is to demonstrate the role, impact, and value of medical technology on health care, economy, and society, for the benefit of patients.

Institute of Electrical and Electronics Engineers. 3 Park Avenue, 17th Floor, New York, NY 10016. 212-419-7900, <http://www.ieee.org>. Daniel J. Senese, Executive Director. 365,000 Members.

The American Institute of Electrical Engineers was founded in 1884 and merged in 1963 with the Institute of Radio Engineers. Three Technical Councils, 300 local organizations, 1300 student branches at universities, and 39 IEEE Societies including the Engineering in Medicine and Biology Society with 8000 members and meets annually in the fall. Maintains Washington, D.C. office.

Institute of Environmental Sciences and Technology. 5005 Newport Drive Suite 506, Rolling Meadows, IL 60008. 847-255-1561, <http://www.iest.org>. Julie Kendrick, Executive Director.

Formed by a merger of the Institute of Environmental Engineers and the Society of Environmental Engineers in 1953. Annual spring meeting.

Instrument Society of America. 67 Alexander Drive, Research Triangle Park, NC 27709. 919-549-8411, <http://www.isa.org>. Rob Renner, Executive Director. 30,000 Members.

Founded in Pittsburgh in 1945. Charter member of American Automatic Control Council, affiliate of American Institute of Physics, member of American Federation of Information Processing Societies, member of American National Standards Institute, and U.S. representative to the International Measurement Confederation. Develops standards, certifies industry professionals, provides education and training, publishes books and technical articles, and hosts largest conference for automation professionals in the Western Hemisphere. Annual meeting in October.

International Biometric Society ENAR. 12100 Sunset Hills Road, Suite 130, Reston, VA 22090. 703-437-4377, <http://www.enar.org>. Kathy Hoskins, Executive Director. 6500 Members.

Founded in September 1947. Became the International Biometric Society in 1994. Annual March and June meetings.

International College of Surgeons. 1516 North Lake Shore Drive, Chicago, IL 60610. 312-642-3555, <http://www.icsglobal.org>. Max C. Downham, Executive Director. 10,000 Members.

Founded in Geneva, Switzerland, in 1935 and incorporated in the District of Columbia in 1940. Federation of general surgeons and surgical specialists. Annual spring meeting of U.S. section and biennial international meetings.

International Society for Magnetic Resonance in Medicine. 2118 Milvia Street, Suite 201, Berkeley, CA 94704. 510-841-1899, <http://www.ismrm.org>. Roberta A. Kravitz, Executive Director. 6,000 Members.

Formed as a merger of the Society for Magnetic Resonance Imaging and Society of Magnetic Resonance in Medicine in 1995. Promotes the application of magnetic resonance techniques to medicine and biology. Annual meetings in April/May.

Medical Device Manufacturers Association. 1919 Pennsylvania Avenue NW, Suite 660, Washington, D.C. 20006. 202-349-7171, <http://www.medicaldevices.org>. Mark B. Leahy, Executive Director. 140 Companies.

Created in 1992. Supersedes Smaller Manufacturers Medical Device Association. Represents manufacturers of medical devices. Annual May meeting.

Radiation Research Society. 810 East 10th Street, Lawrence, KS 66604. 800-627-0629, <http://www.radres.org>. Becky Noordsy, Executive Director. 2025 Members.

Founded in 1952 as a professional society of persons studying radiation and its effects. Annual spring-summer meetings.

Radiological Society of North America. 820 Jorie Boulevard, Oak Brook, IL 60523. 630-571-2670, <http://www.rsna.org>.

www.rsna.org. Dave Fellers, Executive Director. 37,577 Members.

Founded as Western Roentgen Society and assumed its current name in 1918. Members are interested in the application of radiology to medicine. Holds the largest medical meeting in the world annually in November with more than 60,000 in attendance.

RESNA—Rehabilitation Engineering & Assistive Technology Society of North America. 1700 N. Moore Street, Suite 1540, Arlington, VA 22209. 703-524-6686, <http://www.resna.org>. Larry Pencak, Executive Director. 1000 Members.

Founded in 1979 as the Rehabilitation Engineering Society of North America. In June 1995, the name was changed to the Rehabilitation Engineering and Assistive Technology Society of North American—RESNA. Twenty-one special interest groups and seven professional specialty groups. Annual meeting in June.

SPIE—International Society for Optical Engineering. P.O. Box 10, Bellingham, WA 98227. 360-676-3290, <http://www.spie.org>. Eugene G. Arthurs, Executive Director. 14,000 Members, 320 Companies.

Founded in 1956 in California as the Society of Photographic Instrumentation Engineers, it later became the Society of Photo-Optical Instrumentation Engineers and assumed its current name in 1981. Members are scientists, engineers, and companies interested in application of optical, electro-optical, fiber-optic, laser, and photographic instrumentation systems and technology. Semiannual meetings.

Society for Biological Engineering of the American Institute of Chemical Engineers. 3 Park Avenue, New York, NY 10016. 212-591-7616, <http://www.bio.aiche.org>.

Established by the AIChE for engineers and applied scientists integrating biology with engineering.

Society for Biomaterials. 15000 Commerce Parkway, Suite C, Mt. Laurel, NJ 08054. 856-439-0826, <http://www.biomaterials.org>. Victoria Elliott, Executive Director. 2100 Members.

Founded in 1974. Promotes biomaterials and their uses in medical and surgical devices. Annual spring meeting.

Society for Biomolecular Screening. 36 Tamarack Avenue, #348, Danbury, CT 06811. 203-743-1336, <http://www.sbsonline.org>. Christine Giordano, Executive Director. 1080 Members, 230 Companies.

Supports research in pharmaceutical biotechnology and the agricultural industry that use chemical screening procedures. Annual fall meeting.

Society for Modeling and Simulation International. P.O. Box 17900, San Diego, CA 92177. 858-277-3888, <http://www.scs.org>. Steve Branch, Executive Director.

Established in 1952 as the Simulation Council and incorporated in California in 1957 as the Simulation Councils. Became Society for Computer Simulation in 1973 and later changed its name to the current one. A founding

member of the Information Processing Societies and National Computer Confederation Board, and affiliated with American Association for the Advancement of Science. Holds regional simulation multiconferences.

Society of Interventional Radiology. 3975 Fair Ridge Drive, Suite 400 North, Fairfax, VA 22033. 703-691-1805, <http://www.sirweb.org>. Peter B. Lauer, Executive Director.

Society of Nuclear Medicine. 1850 Samuel Morse Drive, Reston, VA 20190. 703-709-9000, <http://www.interactive.snm.org>. Virginia Pappas, Executive Director.

Society of Rheology. Suite 1N01, 2 Huntington Quadrangle, Melville, NY 11747. 516-2403, <http://www.rheology.org>. Janis Bennett, Executive Director.

Permanent address is at the American Institute of Physics and is one of five founding members of the AIP. Members are chemists, physicists, biologists, and others concerned with theory and precise measurement of flow of matter and response of materials to mechanical force. Annual meeting held in October or November.

Professional Societies and Organizations of Other Countries

MEDICAL GAS ANALYZERS

TADEUSZ M. DRZEWIECKI
JERRY M. CALKINS
Defense Research Technologies,
Inc.
Rockville, Maryland

INTRODUCTION

Medical gas monitoring has been so successful in improving patient safety and reducing patient risk that it has become standard medical practice today in every part of medical practice from hospital to home. The argument for providing additional patient safety will continue to be a powerful incentive to improve and enhance the methods and techniques to provide increased knowledge of the monitoring of respiratory and anesthetic gases. Research on gas markers to aid in diagnosis is an equally important application, and with the capability to measure gases at parts per billion or even trillion, heretofore unobserved gases can point to early diagnosis of such nearly always fatal neonatal diseases as necrotizing enterocolitis and other difficult-to-diagnose states.

Medical gas analyzers are used to sample and measure gases of medical importance, such as anesthesia and respiratory monitoring, and detection of trace gases for diagnostic purposes. This article predominantly discusses these two cases. The estimation of arterial blood gases is considered only in terms of measurement of respired gases. Two basic categories of sensor/analyzers exist: continuous and batch. Gas analyzers are further broken down by their sensing mechanisms into two fundamental modes of operation, specific and analytic.

Continuous devices are used where real-time information is needed. Batch systems operate on a bolus of gas, usually when real-time information is not needed. Many applications may have to live with the offline, longer duration of a batch test because nothing else is available.

Specific-type sensors rely on particular physical phenomena that are activated in the presence of a particular gas. Electrochemical devices, for example, are representative of a specific sensor wherein a voltage is developed by a chemical reaction between the sensor material and the gas being analyzed in some identified or known proportion to the amount of gas present. The same is true of fuel cells and other galvanic devices where an electric potential is developed in the presence of a difference in partial pressures across a conducting medium.

Specificity is a major issue and is of particular importance to the medical community. At this point in time, no truly specific sensors exist. All sensors exhibit some form of cross-sensitivity to a variety of gases, some in the same family, some with similar physical properties, and some for extraneous reasons not always obvious to the user. Nitrous oxide (N_2O) and carbon dioxide (CO_2) have practically the same molecular weight, 44.0128 versus 44.0098. Consequently, they have near-identical physical characteristics such as specific heat and viscosity. Interestingly, they also have almost exactly the same absorption wavelengths, although not necessarily because the atomic weights are

the same but rather because the orbital electron transition energetics are similar. Thus, it is difficult to distinguish the two with most conventional techniques, and a carbon dioxide sensor that is based on absorption at 4.3 μm will be affected by the presence of nitrous oxide with its peak absorption at 4.5 μm . Unless a very narrow wavelength light source is used, such as a laser, the nitrous oxide will absorb some of the energy and make it appear that more carbon dioxide is present than there really is.

Analytic devices imply an ability to assay a gas or gas mixture and tell the user not only how much of a particular gas is present, but also which gases or elements are present and in what relative quantities, of which optical spectroscopy is a good example where a large number of absorption lines exist for different gases, so one can scan the entire spectrum from ultraviolet (UV) to far infrared (IR) and compare absorption lines to see what is present. This example is interesting because IR spectroscopy can also be the basis for a specific sensor when only a single or a particular wavelength of light is monitored looking only for a gas at that absorption line. Gas chromatography (GC) is also a batch process where a bolus of gas to be assayed is separated into its constituent parts in time by a molecular sieve and the binary pairs (the carrier and the separated gas) are detected and quantized upon exiting the GC column.

Perhaps the most common use of and need for continuous gas analysis or sensing is in real-time respiratory applications where inspired and expired (end-tidal) concentrations of respiratory gases are measured to validate that the appropriate standards of care are being applied and that proper ventilation and oxygenation of a patient is being achieved. An example would be monitoring of a ventilated patient in the ICU or recovery room. In addition, the monitoring of anesthetic gases during and immediately following anesthetic administration in the operating room is a critical application that can mean the difference between life and death. Too much can lead to brain damage or death, and too little can result in unnecessary pain and memory recall. And, of course, the detection and warning of the presence of toxic gases such as carbon monoxide released from desiccated soda lime CO_2 scrubbers due to interactions between the anesthetic agents and various scrubbers, or the production of the highly toxic Compound A, is critical to patient safety.

Continuous medical gas monitoring provides the clinician with information about the patient's physiologic status, estimates of arterial blood gases, verifies that the appropriate concentrations of delivered gases are administered, and warns of equipment failure or abnormalities in the gas delivery system. Monitors display inspired and expired gas concentrations and sound alarms to alert clinical personnel when the concentration of oxygen (O_2), carbon dioxide (CO_2), nitrous oxide (N_2O), or volatile anesthetic agent falls outside the desired set limits.

Medical gas analysis has been driven by a need for safety and patient risk reduction through respiratory gas analysis and identification and quantification of volatile anesthetic vapors. Perhaps one of the earliest anesthetic agent sensors was the Drager Narkotest, which comprised a polymer rubber membrane that contracted and moved a needle as it absorbed agent. It did not require

an electrical power supply and its slow response was not any slower than the rate of change of gas composition. Much has transpired since those early days.

Currently, numerous methods and techniques of gas monitoring are in place, and new techniques and paradigms are constantly being developed to meet a new need or to serve the community with better performance or lower cost. In this review, many of the intrinsic advantages and disadvantages of these methods and techniques are discussed. A brief comparison, which includes stand-alone and multioperating room gas monitors that can determine concentrations of anesthetic and respiratory gases in the patient breathing circuit during anesthesia, is also presented.

Much of the research and development of these monitors have followed the long use of similar detector principles from analytical chemistry. As a result of the fast pace of sensor development, to a great extent driven by the need for hazardous gas sensors in the face of terrorist threats and being spearheaded by agencies such as the Defense Department's Defense Advanced Research Projects Agency (DARPA), an attempt is made to cover the most common systems and provide insights into the future based on solid technological developments.

The current development of gas analyzers is described in the extensive anesthesia and biomedical engineering literature. Complete and specific historical information about the principles and applications of these devices is well reviewed in several texts [e.g., Ref. (1)], manufacturers' and trade publications [(2) (ECRI)], and an extensive open literature describing equipment and operating principles, methods, and techniques that is available on the Internet. Societies and professional associations also exist that deal with just one method of gas analysis that can provide in-depth information about their particular interests. The Chromatographic Society is one such organization. It is the purpose of this article to concisely summarize such a large selection of information sources to a manageable few, but with enough references and pointers to allow even the casual reader to obtain whatever relevant information at whatever level is required.

CURRENT GAS MONITOR METHODS AND TECHNIQUES

As a result of the chemically diverse substances to be measured, medical gas analyzers commonly combine more than one analytical method. Methods of interest to the medical practitioner, clinician, researcher, or operator include, in alphabetical order:

- Colorimetry
- Electrochemistry
 - Fuel cells
 - Polarography
- Gas chromatography
 - Flame ionization
 - Photoionization Detectors
 - Thermal conductivity

- Infrared/Optical Spectroscopy
- Luminescence/fluorescence
- Mass spectrometry
- Nuclear Magnetic Resonance
- Paramagnetism
- Radioactive ionization
- Raman Laser Spectroscopy
- Solid-state sensors
 - Semiconductor metal oxides
 - ChemFETs
 - Solid-state galvanic cells
 - Piezoelectric/Surface Acoustic Wave

Each of these methods will be described in the following text. Illustrative examples of typical devices may be mentioned.

COLORIMETRY

Colorimetry is one of the oldest methods of gas analysis that is typically used to detect the presence of carbon dioxide in a breath as a means of determining if proper tracheal intubation has been performed. Basically, it works on the principle of changing the color of a material such as paper or cloth impregnated with a reagent in the presence of a known analyte. An example is the changes in litmus paper from purple to red in the presence of an acid and blue in the presence of a base. Carbon dioxide (CO₂) in the presence of water vapor in the exhaled breath produces carbonic acid, which turns the litmus paper toward red, usually some shade of pink. The degree of color change can be quite subjective, but a color scale usually accompanies most devices so that a coarse estimate, roughly $\pm 0.5\%$ CO₂ by volume, can be made. More expensive, sophisticated devices offer an electronic colorimetric analyzer that does the comparison automatically and can even provide a digital output.

Reagents may be tuned to a variety of specific gases and are quite commonly used in the semiconductor business to monitor levels of hydride gases to include arsine and phosphene. Hydrogen sulfide (H₂S) is also a common analyte for colorimetric sensors (1).

Cross-sensitivity can be additive or subtractive with colorimetric devices. For example, a colorimetric capnometer (CO₂ sensor) may register false-positives and false-negatives. Color may change in the presence of acidic reflux or the ingestion of acidic liquids (lemonade, wine, etc.). Conversely, the presence of bases could negate the acid response, which is true in other applications as well. For example, in hydrogen sulfide detection, the presence of methyl mercaptan (CH₄S) compounds can cancel out any reading of H₂S. Clearly, any chemical reactions between the selected analyte and a reactive contaminant can affect readings one way or another.

Figure 1 shows a photograph of one of the newer colorimetric capnometers on the market manufactured by Mercury Medical (www.mercurymed.com). A color-changing tape used in this device turns yellow in the

Figure 1. Mercury medical colorimetric end tidal CO₂ detector.

presence of CO₂, but returns to green when no CO₂ is present. The same piece of paper will register changes as the patient breathes. As the tape is consumed, it can be pulled through the device, and a fresh piece exposed to the breath.

ELECTROCHEMISTRY

Electrochemical gas sensors operate on the principle that a current is generated when the selected gas reacts at an electrode in the presence of an electrolyte, not unlike a battery. For this reason, these devices are often called amperometric gas sensors or microfuel cells. Electrochemical gas sensors are found ubiquitously in industry because of their excellent sensitivity to toxic gases (often low parts per million, ppm) and relatively low cost. They are, however, consumable devices and have a limited operating and shelf life, typically a few years. They are not particularly susceptible to poisoning, that is, being contaminated or degraded by absorption of particular contaminant gas species. Gases of medical importance that can be sensed with electrochemical devices are ammonia, carbon monoxide, nitric oxide, oxygen, ozone, and sulfur dioxide. The most prominent medical use is in the measurement of oxygen.

Three basic elements exist in any electrochemical gas sensor. The first is a gas-permeable, hydrophobic membrane, which allows gas to diffuse into the cell but keeps the liquid or gel electrolyte inside. It is the slow diffusion process that limits the time response of these sensors, although, if they are made very small, they can be quite responsive. Typically, however, an oxygen sensor may take as long as 20 s to equilibrate, making these devices impractical for real-time monitoring of respiration other than monitoring some average oxygen level.

The second element is the electrode. Selection of the electrode is critical to the selectivity of an appropriate reaction. Typically, electrodes are catalyzed noble metals such as gold or platinum. Gases such as oxygen, nitrogen oxides, and chlorine, which are electrochemically reducible, are sensed at the cathode while those that are electrochemically oxidizable, such as carbon monoxide, nitrogen dioxide, and hydrogen sulfide, are sensed at the anode.

The third element is the electrolyte that carries the ions between the electrodes. The electrolyte must be kept encapsulated in the cell as leakage would cause dysfunction.

In many cases, a fourth element exists which is a filter/scrubber mounted across the face of the sensor and the permeable membrane, which helps with the specificity by eliminating some interfering gases. In an oxygen sensor, this element is often an activated charcoal molecular sieve that filters out all but carbon monoxide and hydrogen. Other filters can be tailored to allow only the selected analyte through.

An oxygen fuel cell gas detector uses a lead anode that is oxidized during operation. It is powered by the oxygen it is sensing with a voltage output proportional to the oxygen concentration in the electrolyte. In this case, the electrolyte is potassium hydroxide (KOH) solution. With the recent explosion in research on fuel cells, they have become almost ubiquitous in medical practice, supplanting the Clark electrodes to a great extent.

Among the most recognizable oxygen-sensing devices are the Clark electrodes (Ag/AgCl anode, Pt cathode). One of the first applications of this device was monitoring oxygen concentrations in the inspiratory limb of the breathing circuit of an anesthesia machine. Clark electrodes differ slightly from the above-described fuel-cell-type devices. Clark electrodes require an external voltage source to generate a bias voltage against which the oxygen-induced potential operates. These devices are, therefore, called polarographic because of the bias voltage that is required for its operation, contrasting with a galvanic or amperometric cell, which produces current on its own proportional to the amount of analyte present. Oxygen from the sample fluid equilibrates across a Teflon membrane with a buffered potassium chloride (KCl) solution surrounding a glass electrode. The electrode has a platinum cathode and a silver/silver chloride anode. With between 0.5 V and 0.9 V applied across the electrodes, the consumption of O₂ at the cathode, and hence the current in the circuit, is dependent on the O₂ concentration in the solution, which rapidly equilibrates with the sample. In practice, 0.68 V is used. Performance is adversely affected by the presence of N₂O and halogenated anesthetic agents such as halothane. Protection of the platinum

Figure 2. Datex-Ohmeda Smart Vent 7900 ventilator monitor uses a galvanic cell O₂ sensor.

cathode and the need for semipermeable membranes reduces their effectiveness.

Fuel cell and polarographic devices both require temperature and pH compensation and, as indicated before, have limited life spans because of the consumable nature of the reaction and the propensity of the permeable membranes to eventually lose the effectiveness of the Clark electrodes.

Datex-Ohmeda, one of the largest manufacturers of anesthesia equipment, sells many of their systems, included with which is a galvanometric fuel cell oxygen sensor. Figure 2 shows a Smart Vent 7900TM (3) display showing the level of oxygen being delivered. The oxygen sensor life is specified at 18 months.

GAS CHROMATOGRAPHY

Gas chromatography (GC) is an analytic tool that provides the user with an assay of what is in the gas sample of interest. It consists of two parts: (1) separation of different species by differential travel times through a separation column and (2) analytic detection of the quantity of each analyte at the end of the column using any one of a variety of methods. That is, GC provides a quantification of the constituent gases as well as an identification of what the constituent gases are. It is actually a very simple process, and, were it not for the relatively long analysis time, usually on the order of several minutes to as long as an hour, and its batch nature, it would be used more frequently.

GC requires the separation of a gas sample into its constituent gases, which is accomplished by mixing the sample with a carrier gas, usually some inert gas like helium or nitrogen, which is not adsorbed by the GC column, and passing it through a column or long impermeable, nonreacting (e.g., stainless steel) capillary filled with a zeolite, molecular sieve, or other material that separates the sample gases according to their physical or chemical properties. The different gas constituents travel through the column at different speeds and exit as binary

pairs (a constituent and the carrier) in order of their adsorption properties. The time it takes for a constituent to exit the column identifies the constituent. The capillary columns can be as short as a few centimeters to tens and even hundreds of meters long. The capillary columns are heated to maintain a constant temperature, as the transport characteristics tend to be temperature-dependent.

Calibration is required to determine the transit times for each analyte, which is done by injecting known gas samples at the start of the column and physically timing them at the exit. At the exit of the column, a gas detector exists usually a flame ionization or thermal conductivity detector that measures the amount of constituent relative to the carrier. After all the constituents have been accounted for, the assay of the original sample can be made by summation of the relative amounts of each constituent and then taking the ratio of each constituent relative to the summation, which then gives the concentrations and the final assay.

Usually, this summation is accomplished by summing the areas under the detector output peaks and then ratioing the areas under the individual peaks relative to the total area. The choice of gas chromatographic detectors depends on the resolution and accuracy desired and includes (roughly, in order from most common to the least): the flame ionization detector (FID), thermal conductivity detector (TCD or hot wire detector), electron capture detector (ECD), photoionization detector (PID), flame photometric detector (FPD), thermionic detector, and a few more unusual or expensive choices like the atomic emission detector (AED) and the ozone- or fluorine-induced chemiluminescence detectors.

The Flame Ionization Detector (FID) is widely used to detect molecules with carbon-hydrogen bonds and has good sensitivity to low ppm. Basically, in operation, the analyte is injected into a hydrogen carrier and ignited inside a grounded metal chamber. Hydrogen is used because it burns clean and is carbon-free. The latter is important because output is proportional to the ionized carbon atoms. An electrode is situated just above the flame and a voltage potential is applied. The current produced is proportional to the number of carbon atoms in the analyte. When applied at the exit of a GC, very accurate measures of hydrocarbon gases can be made.

Photoionization Detectors (PIDs) are used to detect the volatile organic compound (VOC) outputs of GCs but are also widely used in industry and science to detect environmental and hazardous gases. They operate on a similar principle to that of the FID, but use ultraviolet light (UV) as opposed to a flame to ionize the flowing gas between insulated electrodes. As UV energy is a much higher frequency (lower wavelength) than IR or visible light, it can be larger and, consequently, can readily ionize gases. The ionization potentials of the analyte gases are matched by adjusting the frequency of the emitted light. The output power of the lamp is roughly the product of the number of photons and the energy per photon divided by the area and time, although changing the output frequency will change the photon energy ($E = h\nu$), thereby changing the power. The output power can be changed independently by increasing the fluence of photons.

Figure 3. Seito ToxiRae personal PID gas monitor.

An inert gas lamp provides the UV light, (e.g., xenon lamps emit UV light at 147.6 nm, krypton at 123.9 nm, and argon at 105.9 nm). An advantage is that the sensitivity to particular species or groups of compounds can be adjusted by adjusting the output power to match the distinct ionization potentials of analyte gases. Consequently, different sensor sets can be achieved. For example, amines, aromatic compounds, and benzene are highly detectable at 9.5 eV. Disease and other anomaly marker gases often found in the breath, such as acetone, ammonia, and ethanol, are detectable at 9.5 eV as well as 10.6 eV. Other, more complex, marker gases such as acetylene, formaldehyde, and methanol can be detected at 10.6 eV and 11.7 eV. Typically, the PID devices are fairly responsive, on the order of a few seconds, and do well with moderately low concentrations (e.g., 0.1 ppm isobutylene).

One of the nice things about PIDs is that they can be made very small in size, as shown in Fig. 3, which shows the Rae Systems, Inc. ToxiRae personal gas monitor (www.raesystems.com). Depending on the UV source, CO, NO, SO₂, or NO₂ can be read. It works with rechargeable batteries.

Thermal Conductivity Detectors (TCD) are used to detect and quantify gases that have large variations in thermal conductivity. Gases that are discriminated well are sulfur dioxide and chlorine, which have roughly one-third the conductivity of air to helium and hydrogen, which have six and seven times the conductivity of air. As heat transfer depends on three mechanisms, radiation, convection, and conduction, the actual TCD sensor itself must be designed in such a way that conduction dominates, which implies a very slow, constant, moving flow to minimize or stabilize convection effects and a radiation-shielded enclosure. Most arrangements use two identically heated coils of wire comprising two legs of a Wheatstone bridge, one coil in a reference gas tube and the other in the sample tube. When the thermal conductivity of the sample increases, the sample coil is cooled more than the reference, and its resistance changes (usually decreases), thereby generating a voltage difference across the bridge. TCDs are usually used in high concentration applications, as they do not have the sensitivity of other techniques. TCDs do very well when mounted at the exit of a GC where the separated gas analytes are expected to have large variations in thermal conductivity.

Gas chromatographs have come a long way over the last decade as far as size and cost are concerned. Although laboratory-grade devices such as the HP stand-alone system shown in Fig. 4 still are fairly common, portability is being stressed in order to get the almost incomparable

Figure 4. An HP/Agilent laboratory-grade gas chromatograph.

detectibility of the GC to where the real gas problems exist, such as in the emergency or operating rooms, in the field, and at sites where toxins and suspected hazardous gases may be present. Bringing the GC to the patient or taking data without having subjects come into the lab has spawned systems such as Mensanna's VOC (volatile organic compound) GC system that uses a PID (Fig. 5) to check trace gases in the breath, and HP's has introduced a briefcase-sized micro-GC (Fig. 6). Lawrence Livermore National Laboratory has taken the recent developments in micromachining, MEMS (micro-electromechanical systems), and microfluidics and developed a real micro-GC. Researchers at LLNL (4) have micro-machined a very long capillary on a silicon chip, which serves as the separating column.

Figure 5. Mensanna portable GC for measuring breath VOCs.

Figure 6. Agilent (formerly HP) Micro-GC.

Figure 7 shows the implementation of this device that is reported to have a response time of less than 2 min.

INFRARED/OPTICAL SPECTROSCOPY

Gases absorb light or photon energy at different wavelengths depending on the complexity of their molecular structure. When a molecule is subjected to light energy of a particular frequency, the atoms involved in the atomic bonds will vibrate at the light frequency. If the frequency matches their resonant frequency, or a harmonic, they will resonate, thereby becoming highly absorbent as more of the light energy is used to feed the motion of the resonating molecules. The more complex a molecule, the greater number of different atomic bonds it will have and, consequently, the more absorption frequencies it will have. Table 1 provides some guidelines for absorption for different molecules.

Most infrared analyzers measure concentrations of volatile fluorocarbon halogenated anesthetic agents, carbon dioxide, and nitrous oxide using nondispersive infrared (NDIR) absorption technology. The transduction means may differ. Most use an electronic IR energy detector of one sort or another, such as a bolometer, solid-state photon detectors, and thermopiles; however, one monitor uses

Figure 7. LLNL MEMS-based micro-GC.

Table 1. Infrared Absorption Bands for Gases of Medical Interest

Wavelength (microns)	Elements of Atomic Bonds	Typical Gases
2.7–4 μm	X-H (X = C, N, O, S)	H ₂ O, CH ₄ ,
4.3–5 μm	C-X (X = C, N, O)	CO ₂ , N ₂ O
5.26–6.6 μm	C-X (X = C, N, O)	fluorocarbons
7.7–12.5 μm	C-X (X = C, N, O)	fluorocarbons

another IR detection principle, photoacoustic spectroscopy, based on the level of sound produced when an enclosed gas is exposed to pulsed/modulated IR energy.

Infrared analyzers have been used for many years to identify and assay compounds for research applications. More recently, they have been adapted for respiratory monitoring of CO₂, N₂O, and halogenated anesthetic agents.

Dual-chamber NDIR spectrometers pass IR energy from an incandescent filament through the sample chamber and an identical geometry but air-filled reference chamber. Each gas absorbs light at several wavelengths, but only a single absorption wavelength is selected for each gas to determine the gas concentration. The light is filtered after it passes through the chambers, and only that wavelength selected for each gas is transmitted to the detector. The light absorption in the analysis chamber is proportional to the partial pressure (concentration) of the gas. Most manufacturers use a wavelength range around 3.3 μm , the peak wavelength at which the hydrogen-carbon bond absorbs light, to detect halogenated anesthetic hydrocarbons (halothane, enflurane, isoflurane, etc.).

In one monitor that identifies and quantifies halogenated anesthetic agents, the analyzer is a single-channel, four-wavelength IR filter photometer. Each of four filters (one for each anesthetic agent and one to provide a baseline for comparison) transmits a specific wavelength of IR energy. Each gas absorbs differently in the selected wavelength bands so that the four measurements produce a unique signature for each gas. In another monitor, potent anesthetic agents are assessed by determining their absorption at only three wavelengths of light. Normally, only one agent is present so this process reduces total agent ID. However, the use of “cocktails,” mixtures of agents, usually to reduce undesired side effects of one or another agent, require very special monitoring because of the possibility of accidental overdosing.

The Datex-Ohmeda Capnomac (www.us.datex-ohmeda.com), a multigas anesthetic agent analyzer, is based on the absorption of infrared radiation. This unit accurately analyzes breath-to-breath changes in concentrations of CO₂, NO₂, and N₂O and anesthetic vapors. It is accurate with CO₂ for up to 60 breaths/min, and 30 breaths/min for O₂ (using a slower paramagnetic sensor), but N₂O and anesthetic vapors show a decrease in accuracy at frequencies higher than 20 breaths/min. The use of narrow wave-band filters to increase specificity for CO₂ and N₂O makes the identification of the anesthetic vapors, which are measured in the same wave band more difficult. It is interesting to note that IR spectroscopy can also be used on

liquids, as exemplified by the Inov 3100 near-infrared spectroscopy monitor that has been offered as a monitor for intracerebral oxygenation during anesthesia and surgery. Studies with this monitor indicate that it needs a wide optode separation and the measurements are more likely those of the external carotid flow rather than the divided internal carotid circulation (5).

A subset of NDIR is photoacoustic spectroscopy, which measures the energy produced when a gas expands by absorption of IR radiation, which is modulated at acoustic frequencies. A rotating disk with multiple concentric slotted sections between the IR source and the measurement chamber may be used to modulate the light energy. The acoustic pressure fluctuations created occur with a frequency between 20 and 20,000 Hz, producing sound that is detected with a microphone and converted to an electrical signal. Each gas (anesthetic agent, CO₂, N₂O) exhibits this photoacoustic effect most strongly at a different wavelength. This method cannot distinguish which halogenated agent is present, however. The microphone detects the pulsating pressures from all four gases simultaneously and produces a four-component magnetic signal. A monitor using IR photoacoustic technology has been developed that can quantify all commonly respired/anesthetic gases except N₂ and water vapor. Similarly, a microphone detects the pulsating pressure changes in a paramagnetic oxygen sensor (magnetoacoustics).

The Bruel & Kjaer Multigas Monitor 1304 (6) measurements use photoacoustic spectroscopy and also incorporate a pulse oximeter. It has some advantages over the Datex Ohmeda Capnomac because it uses the same single microphone for detection of all gases, displaying gas concentration in real-time.

With the development of both fixed frequency and tunable solid-state lasers, a revolution in IR spectroscopy has occurred with new technical approaches appearing every year. Tuned diode laser spectroscopy, and Laser-induced Photo Acoustic Spectroscopy (a DARPA initiative) are developments that bear close watching as they mature. The ability to produce IR energy at extremely narrow bandwidths allows discrimination of very closely related gas species such as CO₂ and N₂O. In addition, most of the volatile anesthetic agents such as halothane, desflurane, isoflurane, and sevoflurane can also be thus distinguished.

An advantage of NDIR is that the sensing mechanism does not interfere or contact the sample, thus minimal chance exists that the sample would be affected. The costs of these devices have continued to decrease, with numerous companies competing to keep the prices low and attractive. Disadvantages are the susceptibility to dirt and dust in the optical path and cross-sensitivities to interfering gases.

Companies marketing anesthesia and respiratory mechanics monitors are involved in either development or promotion of NDIR. Figure 8 shows a Datex-Ohmeda Capnomac Ultima that uses NDIR for CO₂, N₂O and anesthetic analysis, and agent identification. The top waveform is the plethysmograph, the next down is the O₂ (measured with a fast paramagnetic sensor), and the bottom waveform is the capnographic CO₂ waveform. As an added capability beyond gas analysis, to the right of the

Figure 8. A Datex-Ohmeda Capnomac Ultima multiple gas analyzer.

capnogram is the pressure-volume loop that is used to assess the lung compliance.

Another limitation of NDIR is its relatively low sensitivity due, for the most part, to the short path length over which the IR energy is absorbed. The short path length and small chamber size is dictated by the need for fast response in order to be able to monitor human physiological and respiratory response.

Breath rates are normally about 10 breaths per min (bpm) but, under acute hyperventilation conditions, can reach 100 bpm and higher. Also, neonates and small animals naturally exhibit high breathing rates, which requires a sensor with a millisecond response in order to be able to detect breath-by-breath variations. However, in cases where a fast response is not the driving factor, the sampling chamber may be lengthened or the path length increased.

Notwithstanding this limitation, the recent invention of Cavity Ring-Down Spectroscopy (CRDS) by Princeton chemist Kevin Lehmann (7,8) is based on absorption of laser energy over huge path lengths but is extremely fast. By bouncing laser energy between near-perfect mirrors in a sample or test chamber, the light can pass through the gas of interest multiple times, often for total distances of up to 100 km, which creates the opportunity to detect miniscule trace amounts of the gas species of interest. The time it takes for the light energy to get attenuated to zero provides a measure of the amount of the gas species present. The shorter the Ring-Down time, the more of the gas is present. These times are, however, on the order of only milliseconds. In fact, Tiger Optics of Warrington, PA, the company that has licensed Dr. Lehmann's technological development, claims that trace gases can be detected in the hundreds of parts per trillion. The LaserTrace multi-point, multi-species, multi-gas analyzer (shown in Fig. 9) is capable of detecting many species such as H₂O, O₂, CH₄, H₂, CO, NH₃, H₂S, and HF. The O₂ module measures down to 200 parts-per-trillion (ppt), in milliseconds, noninvasively and can readily be adapted to respiratory breath measurements. Methane can be detected at the parts per billion level.

Figure 9. Tiger Optics Cavity Ring-Down Spectrometer.

Although of interest in the detection and quantification of oxygen, spectroscopy has not been widely considered for this application. However, an oxygen absorption line exist in the center of the visible spectrum at 760 nm. Often neglected because of the problems associated with the narrowness of the absorption band (0.01 nm versus 100 nm for CO₂ in the IR) as well as with spurious interference from visible light, it is nonetheless an opportunity because no interference exists from any other gases of medical interest. The development of low cost, very narrow-band lasers has resulted in the successful introduction of Laser-based Absorption Spectroscopy from Oxigraf (www.oxigraf.com). With 100 ms response and $\pm 0.02\%$ resolution traces, such as that shown in Fig. 10, are possible. Cost is relatively low in comparison with other technical approaches with similar capabilities.

LUMINESCENCE/FLUORESCENCE

Gas sensors that use luminescence or fluorescence basically take advantage of the phenomenon of excitation of a molecule and the subsequent emission of radiation. Photoluminescence implies optical excitation and re-emission of light at a different, lower frequency. Chemiluminescence implies the emission of light energy as a result of a chemical reaction. In both cases, the emitted light is a function of the presence of the gas species of interest and is detected by optical means. Most industrial sensors use photomultiplier tubes to detect the light, but the needs of the medical community are being met with more compact fiber-optic systems and solid-state photodetectors.

Fluorescence quenching is a subset of luminescence-based sensors, the difference being that the presence of the analyte, rather than stimulating emission of light,

Figure 10. Oxigraf Fast Oxygen Sensor trace of respired O₂.

actually diminishes the light output. Fundamentally, fluorescence occurs when incoming light excites an electron in a fluorescent molecule to a higher energy state, and, in turn, when the electron returns to its stable state, it releases energy in the form of light.

Two important characteristics of fluorescence are that the light necessary to excite a fluorescent molecule has a shorter wavelength than that of the fluorescent emission, and that the fluorescence of a particular molecule may be suppressed (quenched) or enhanced (dequenched) by the presence of one or more specific molecules. Consequently, the presence of such other molecules (called analytes) may be detected.

A few companies exist that use one form or another of luminescence sensing, in particular, of oxygen in the medical arena, although the sensors are ubiquitous for other gases. For example, Ocean Optics (www.oceanoptics.com) FOXY Fiber Optic Oxygen Sensors use the fluorescence of a ruthenium complex in a sol-gel to measure the partial pressure of oxygen. First, a pulsed blue LED sends light, at ~ 475 nm, to and through an optical fiber, which carries the light to the probe. The distal end of the probe tip consists of a thin layer of a hydrophobic sol-gel material. A ruthenium complex is trapped in the sol-gel matrix, effectively immobilized and protected from water. The light from the LED excites the ruthenium complex at the probe tip and the excited ruthenium complex fluoresces, emitting energy at ~ 600 nm. When the excited ruthenium complex encounters an oxygen molecule, the excess energy is transferred to the oxygen molecule in a nonradiative transfer, decreasing or quenching the fluorescence signal. The degree of quenching is a function of the level of oxygen concentration pressure in the film, which is in dynamic equilibrium with oxygen in the sample. Oxygen as a triplet molecule is able to efficiently quench the fluorescence and phosphorescence of certain luminophores. This effect is called “dynamic fluorescence quenching.” When an oxygen molecule collides with a fluorophore in its excited state, a nonradiative transfer of energy occurs. The degree of fluorescence quenching relates to the frequency of collisions and, therefore, to the concentration, pressure, and temperature of the oxygen-containing media. The energy is collected by the probe and carried through an optical fiber to a spectrometer where an analog-to-digital (A/D) converter converts the data to digital data for use with a PC.

MASS SPECTROSCOPY

Mass spectroscopy provides, what many consider, the best accuracy and reliability of all of the gas analyzing/assaying schemes. The basic concept is to assay the analyte by reducing it into ionized component molecules and separating them according to their mass-to-charge ratio. By this technique, the constituents of the sample gas are ionized. The resulting ions are accelerated through an electrostatic field and then passed through a deflecting magnetic field. The lighter ions will deflect more than the heavier ions. Detecting the displacement and counting the ions can achieve the assay of the gas sample.

Ion detectors usually comprise an electric circuit where the impinging ions generate a current, which can be measured with a conventional circuit. The more current, the more ions are impinging. In practice, the ionization must be conducted in a high vacuum of the order of 10^{-6} torr. The gas is ionized with a heated filament, or by other means as have been discussed before.

A number of different mass spectroscopic configurations have been developed over the years. Time-of-flight (TOF) systems differ from the magnetically deflected devices in that the ions are free to drift across a neutrally charged evacuated flight chamber after having been accelerated electrostatically by a series of gratings that separate the ions. The time it takes for the ions to travel across the chamber is a function of their mass. An output not unlike that of a GC is developed. Quadrupole mass spectrometers focus the ions through an aperture onto a quadrupole filter. The ion-trap mass spectrometer traps ions in a small volume using three electrodes. An advantage of the ion-trap mass spectrometer over other mass spectrometers is that it has a significantly increased signal-to-noise ratio because it is able to accumulate ions in the trap. It also does not require the same kind of large dimensions that the TOF and magnetically deflected devices need, so, as a consequence, it can be made in a fairly compact size. Finally, the Fourier-transform mass spectrometer takes advantage of an ion-cyclotron resonance to select and detect ions. Single-focusing analyzers use a circular beam path of 180° , 90° , or 60° . The various forces influencing the particle separate ions with different mass-to-charge ratios. Double-focusing analyzers have an electrostatic analyzer added to separate particles with difference in kinetic energies.

A particular advantage of the mass spectrometer is that it can operate with an extremely small gas sample and can detect minute quantities. Response was long compared with most continuous sensors, but with the development of high speed microprocessors, analysis times have steadily decreased to where, today, it is not unusual to have assays in less than one minute. With the development of MEMS TOF devices, the time-of-flight is measured in microseconds.

Mass spectrometers have always tended to be bulky and expensive and, thus, rarely used on a single patient basis. Multiplexing up to 30 patients using a complex valving switching system has been shown to be feasible and has made the system much more cost-effective. Figure 11 shows a conventional ThermoElectron laboratory-grade mass spectrometer setup.

The move to miniature mass spectrometers has been rapid over the last decade, from a suitcase-sized miniature TOF mass spectrometer, developed at Johns Hopkins Applied Physics laboratory (Fig. 12) (9), to a micro-electro-mechanical system (MEMS) device smaller than a penny, developed in Korea at the MicroSystems Lab of Ajou University (Fig. 13) (10).

Mass spectroscopy is often used as the detector in combination with gas chromatography to enhance the sensitivity down to ppb, because in a GC, detection limits the capability.

Figure 11. A ThermoElectron laboratory-grade quadrupole mass spectrometer.

Figure 12. JHU Teeny mass spectrometer.

NUCLEAR MAGNETIC RESONANCE

Nuclear Magnetic Resonance (NMR) is the process by which a relatively low intensity radio-frequency (RF) signal at the resonant frequency of the species of gas of interest interacts with the atoms in a gas and aligns them momentarily, which requires some energy. When the RF

Figure 13. MEMS TOF mass spectrometers developed at Ajou University in Korea.

signal is removed, the atoms release the energy that had been stored in the alignment resonance, return to their chaotic orientations, and re-emit an RF signal at the same resonant frequency at which they were excited. Each atomic bond has its own characteristic frequency so that a spectroscopic analysis can be made by scanning through a large number of frequencies. A variant of NMR, nuclear quadrupole resonance (NQR) is used for detecting explosive vapors, which could be very useful in military medicine where explosives in clothing during triage pose a major hazard. The hydrogen bonds in TNT have a resonance at ~ 760 kHz and the vapors of plastic explosives have resonances at low MHz frequencies. NMR is very attractive because gas analysis can be performed without having to physically take a sample of the analyte in question. As the initiating and re-emitted RF signals can pass through most nonferrous materials with little attenuation, gas, liquid, and solid chemical species can be interrogated noninvasively. By summing the returns from a number of signals, sensitivity to the low ppm can be achieved.

In dirty environments where optical or infrared devices suffer significant degradation of performance, NMR is particularly useful. Compared with chromatographic approaches, NMR eliminates the need for solvents, columns, carrier gases, or separations. Also, NMR analysis can be performed in real-time because typical atomic relaxation times, the time it takes for the atomic spin axes to return to their original orientations, is on the order of milliseconds for many gases of interest.

PARAMAGNETISM

Many gases exhibit magnetic sensitivity, paramagnetism, due to their polar nature, which means that they are attracted to a magnetic field. For oxygen, its paramagnetic sensitivity is due to its two outer electrons in unpaired orbits. Most of the gases used in anesthesia are repelled by a magnetic field (diamagnetism).

Paramagnetic sensors are typically used specifically for measuring oxygen concentration. The high degree of sensitivity of oxygen (compared with other gases) to magnetic forces reduces the cross-sensitivity to other gases of paramagnetic sensors. Sensors come in two variants, the older balance type and the newer pressure type. The balance types of sensors are relatively frail and have been replaced by the pressure types. Nevertheless, some of these older devices are still being used. The balance type of sensor uses a mechanical approach that has a dried gas sample flowing through a chamber in which a nitrogen-filled dumbbell is balanced in a magnetic field. The paramagnetic force on the oxygen in the sample puts a torque on the dumbbell. The output can be read either as a spring-loaded displacement or, in newer devices, electronically by measuring the current required to keep the dumbbell centered.

Most modern paramagnetic oxygen sensors consist of a symmetrical, two-chambered cell with identical chambers for the sample and reference gas (often air or nitrogen). These cells are joined at an interface by a responsive differential pressure transducer or microphone. Sample and reference gases are pumped through these chambers

in which a strong, usually varying, magnetic field surrounding the region acts on the oxygen molecules and generates a static pressure or a time-varying (acoustic) difference between the two sides of the cell, causing the transducer to produce a DC or AC voltage proportional to the oxygen concentration. When the magnetic field is modulated at acoustic frequencies, these devices may sometimes be referred to as magnetoacoustic.

Paramagnetic oxygen analyzers are very accurate, highly sensitive, and responsive, often with a step response of 200 ms to 90% of maximum. However, they require calibration, usually with pure nitrogen and oxygen. A major drawback is that they are adversely affected by water vapor and, consequently, require a water trap incorporated into their design. The frequency response makes them useful for measurement of oxygen on a breath-by-breath basis. The Datex Ohmeda Capnomac Ultima that was previously shown in Fig. 8 uses a paramagnetic oxygen sensor, as do many of the other mainline medical gas monitor manufacturers.

RADIOACTIVE IONIZATION

The ubiquitous smoke detector found in every house, hospital, and facility has spawned detectors for other gases such as carbon monoxide, a very important marker gas in medical diagnosis. Although usually used as devices that are set to alarm when a preset level is detected, they are also used as calibrated sensors. A very low level radioactive alpha particle source (such as Americium-241) can ionize certain gases so that, in the presence of an analyte, a circuit can be completed and current caused to flow in the detector circuit.

Ionization detectors detect the presence of invisible particles (less than 0.01 micron in size) in the air. Inside the detector, a small ionization chamber exists that contains an extremely small quantity of radioactive isotope. Americium-241 emits alpha particles at a fairly constant rate. The alpha particles, which travel at an extremely high rate of speed, knock off an electron from the oxygen and nitrogen molecules in the air passing through the ionization chamber. The free electron (negative charge) is then attracted to a positively charged plate, and the positively charged oxygen or nitrogen is attracted to a negatively charged plate, which creates a very small but constant current between the plates of a detector circuit, which in itself is a gas detection mechanism much in the same way that the other ionization detectors operated. However, when particles, such as soot particles, dust, fumes, or steam, enter the ionization chamber, the current is disrupted. If the current decreases too much, an alarm is triggered.

The disadvantage of these devices is clearly the health hazard associated with the presence of the radioactive material. However, because the detector contains only a tiny amount of radioactive material, exposure is unlikely with proper care in handling. Another disadvantage of these sensitive detectors is the false-positive alarms that can be triggered by spurious dust and other nontoxic fumes. However, the big advantage is that ionization detectors are very sensitive and, given that false alarms

are tolerable, should be considered in most alarm situations.

Another form of radioactive detector is the electron capture detector, which uses a radioactive Beta emitter (electrons) to ionize some of the carrier gas and produce a current between a biased pair of electrodes. When organic molecules that contain electronegative functional groups, such as halogens, phosphorous, and nitro groups, pass by the detector, they capture some of the electrons and reduce the current measured between the electrodes.

RAMAN LASER SPECTROSCOPY

In the 1980s, Raman scattering was first heralded as an improvement to mass spectrometry (11), although some individuals had reservations (12). Although no longer manufactured but still serviced, Ohmeda Rascal II multi-gas analyzer uses a Raman scattering of laser light to identify and quantify O₂, N₂, CO₂, N₂O, and volatile anesthetic agents. It is stable and can monitor N₂ directly and CO₂ accurately for a wide range of concentrations. One of the acknowledged disadvantages is that a possibility of some destruction of volatile anesthetic agent exists during the analysis because the concentration of halothane does appear to fall when recirculated and as much as 15% must be added. Some concern exists over the reliability of the hardware, software, and laser light source (13) that is currently being addressed by others.

Raman scattering occurs when a gas sample is drawn into an analyzing chamber and is exposed to a high intensity beam from an argon laser. The laser energy is absorbed by the various molecules in the sample and are then excited into unstable vibrational or rotational energy states, which is the Raman scattering. The low intensity Raman scattered, or re-emitted, light signals are measured at right angles to the laser beam, and the spectrum of Raman scattering lines can be used to identify various types of gas molecules. Spectral analysis allows identification of known compounds by comparison with their Raman spectra. This technique is of similar accuracy to mass spectrometry.

SOLID-STATE SENSORS

At least four types of solid-state gas sensors exist: semiconductor metal oxide (SMO) sensors; chemically sensitive field effect transistors (ChemFETs); galvanic oxide sensors; and piezoelectric or surface acoustic wave (SAW) crystal sensors.

Semiconductor metal sensors are an outgrowth of the development of semiconductor devices. Early in the development of transistors and integrated circuits, it was observed that the characteristics would change in the presence of different gases. Recalling that a transistor is basically a voltage-controlled resistor, it was discovered that the p-n junction resistance was being changed by chemical reaction with the semiconductor materials (14). Commercially available Taguchi Gas Sensors (TGS) tin oxide sensors have found a niche as electronic noses. Walmsley et al. (15) used arrays of TGS sensors to develop

patterns for ether and chloroform and other vapors of medical interest.

Hydrocarbons were among the first gases to be detected, and later, hydrogen sulfide was found to be detectable. Since the first tin oxide sensors appeared in the late 1960s, it has been found that by doping transition metal oxides, such as tin and aluminum, with other oxides, that as many as 150 different gases could be specifically detected (1) at ppm levels. The heated oxide adsorbs the analyte and the resistance change is a function of the concentration of the analyte. The semiconducting material is bonded or painted in a paste to a nonconducting substrate and mounted between a pair of electrodes. The substrate is heated to a temperature such that the gas being monitored reversibly changes the conductivity of the semiconducting metal oxide material. When no analyte is present, the current thinking is that oxygen molecules capture the free electrons in the semiconductor material when they are absorbing on the surface, thereby preventing the mobility of the electron flow. Analyte molecules replace the oxygen, thereby releasing the free electrons and, consequently, reducing the SMO resistance between the electrodes.

The ChemFET is derived from a field effect transistor where the normal gate metal has been replaced with a catalytic metal or chemically sensitive alloy. The gaseous analyte interacts with the gate metal and changes the FET characteristics to include gain and resistance.

Solid-state galvanic cells are based on the semiconductor galvanic properties of certain oxides or hydrides. The zirconium oxide galvanic cell oxygen sensor is probably one of the most ubiquitous sensors in daily life. It is the sensor mounted in every automobile catalytic converter to measure its effectiveness. Zirconium oxide, when heated to a temperature of about 700 °C, becomes an oxygen ion conductor, so that, in the presence of a difference in partial pressure on either side of a tube with metallized leads coming off each side, a voltage potential (Nernst voltage) is developed. These devices are commonly called fugacity sensors. As the process is reversible, a voltage applied will cause oxygen ions to flow. This process may also be applicable to the hydrogen ions in hydrides. An advantage of these oxygen sensors over other types is that no consumable exists. Hence, life is long. However, the need for heating tends to make these devices difficult to handle and they, as well as SMOs, require significant power to power the heating elements. However, because these sensors can be very small, they can have fast response times, often less than 100 ms, which makes them suitable for use for respiration monitoring. The electronics associated with the detection circuits is simple and should be very reliable.

Piezoelectric sensors use the change in a crystal vibrational frequency or propagation of surface acoustic waves to measure the concentration of a selected analyte. Most often, an analyte sample is passed through a chamber containing two piezoelectric crystals: a clean reference crystal and a second crystal that has been coated with a compound that specifically adsorbs specific analyte gases. Organophillic coatings are used for hydrocarbons such as anesthetic vapors. The resulting increase in mass changes the coated crystal's resonant frequency or the speed of propagation in direct proportion to the concentration of

anesthetic gas in the sample. Using either some form of beat frequency measurement or detection of the phase shift between the two crystals, a detection circuit can generate a signal that can be processed and displayed as a concentration.

EMERGING TECHNOLOGIES—MEMS— MICROFLUIDICS—NANOTECHNOLOGY

The development of a variety of microfluidic labs-on-a-chip is leading the charge in the state-of-the-art in gas sensing. It was noted in the gas chromatography section that microfluidic channels are being used as GC columns and in the mass spectrometry section that microfluidics plays a major role in the TOF passages and chambers. The ability to miniaturize classic technologies has opened the door to mass production as well as the ability to mix-and-match sensors and technologies. The development of electronic noses that can discriminate between thousands of different chemicals and gases is driving the need to detect odors and minute quantities of dangerous or toxic gases.

Patient safety in medicine continues to be a major driver. MEMS (micro-electromechanical systems) and nanotechnology have become the enabling technologies for placing thousands of sensors in microdimensional arrays that can be placed inside a capsule and swallowed or implanted to monitor physiological and metabolic processes. IR bolometers that can sense incredibly small temperature differences as low as 0.02 °C are already a part of today's inventory (Fig. 14), and in the future, nanotechnology elements that are merely one molecule thick and dust particle-sized may provide IR spectroscopic capability in implantable or inhaled micro-packages.

A new paradigm for gas analysis that has been enabled by the development of microfluidics was originally suggested in the 1960s by Mapleson (16), who suggested measuring a physical gas property as a way of inferring binary gas mixture composition. This concept has been extended and implemented for ternary and quaternary gas mixtures with a microfluidic gas multiple gas property analyzer (17–20). Ternary mixtures are assayed with a chip that measures viscosity with a microcapillary viscometer and density with a micro-orifice densitometer. An early prototype microfluidic lab-on-a-chip showing the microcapillaries is shown in Fig. 15. By measuring properties possessed in common by all gases, such as density, viscosity, and specific heat, a single chip can be used to

Figure 14. 25 micron wide longwave IR microbolometer detector.

Figure 15. Microfluidic chip that measures the density and viscosity of three-component respired gases from which the constituent gas concentrations of oxygen, nitrogen, and carbon dioxide are deduced.

analyze mixtures of any four gases. The concentrations of the constituents can be determined by simultaneously solving the equations that relate the mixture properties to the concentrations, thereby determining the relative concentrations of the mixture gases required to produce the measured properties. The only limitation to such an approach is that one must know what at least all but one of the constituents are. Microfluidic property sensors such as capillary viscometers, orifice densitometers, and speed-of-sound calorimeters can provide real-time simultaneous assays of respiratory gases (O_2 , CO_2 , and N_2), the simultaneity of which then enables the reduction to practice of a variety of physiologic analyzers such as metabolic rate, cardiac output, and cardio-pulmonary function that had been postulated back in the 1960s (21) but never practically implemented.

Advances in optics and optical fiber technology, greater expansion of solid-state sensing, and the revolutionary aspects of nanotechnology will provide gas analysis and sensing with new capabilities, provided that the lessons learned from the past are appropriately heeded.

OTHER CONSIDERATIONS IN GAS ANALYSIS

Most continuous gas analysis devices are side-stream monitors that acquire gas samples from a breathing circuit through long, narrow-diameter tubing lines. These lines may incorporate moisture removal to allow moisture to pass through the sampling line and into the atmosphere, as is the case with Nafion tubing. A water trap or filter may also be used to remove condensation from the sample in order to reduce water vapor before the gas sample reaches the analysis chamber. Gas samples are aspirated into the monitor at either an adjustable or a fixed-flow rate, typically from 50 to 250 ml/min. Lower rates minimize the amount of gas removed from the breathing circuit and, therefore, from the patient's tidal volume; however, lower sampling flow rates increase the response time and typically reduce the accuracy of conventional measurements.

Gas monitors have to eliminate the exhaust gas through a scavenging system or back to the patient's breathing circuit.

DISPLAYS, ALARMS, CALIBRATION, AND CONTROLS

Many gas monitors provide a graphic display of breath-by-breath concentrations and a hardcopy of trends of gas concentrations from the beginning to the end of an event (e.g., anesthesia delivery during an operation). The user typically calibrates or verifies calibration of the sensors with a standard gas mixture from an integral or external gas cylinder. Gas monitors are usually microprocessor-controlled and have user-adjustable alarms that typically include factory-preset default alarms or alarm-set programs for both high and low concentrations of the gases measured. Some monitors also have alarms for system malfunctions, such as disconnection from a gas source, and leaks can often be identified from trending of O₂ and CO₂. Occlusion, apnea, or inadvertent rebreathing can also be identified. Most monitors typically have a method for temporarily, but not indefinitely, silencing audible alarms for low O₂, high N₂O, and high agent, whereas other, less critical audible alarms can be permanently silenced. Most monitors typically display real-time waveforms and long-term trends. They have integral display capability and are also commonly equipped with output jacks to interface with computerized record-keeping systems or with additional analog or digital display units such as chart recorders and printers.

PATIENT SAFETY

A review of the background and significance of medical gas sensors and monitors would be incomplete without an expression of the context that patient safety has had on the impetus for recent gains in technology and the need for additional improvements. Clearly the intrinsic dangers in the conduct of anesthesia have been long understood. It became evident in the early 1980s that patient safety and reduction to risk was possible if respiratory and anesthetic gas monitoring was routinely available and used. As a result of improved and increased availability of medical gas monitoring technology and professional activity lead by the Anesthesia Patient Safety Foundation (APSF) with the support of the American Society of Anesthesiologists (ASA), a standard for monitoring has been adopted and is routinely used in today's clinical practice. This standard requires assessment of the patient's ventilation and oxygenation in addition to circulation and temperature. The use of such monitors has resulted in a significant decrease in the risk of anesthesia-related deaths and morbidity in the ICU and other critical care situations.

CONCLUSION

Medical gas monitoring has been so successful in improving patient safety and reducing patient risk that medical malpractice liability insurance companies have lowered

their risk liabilities and premiums to anesthesiologists who guarantee the routine implementation of these standards whenever possible (22). The argument for providing additional patient safety will continue to be a powerful incentive to improve and enhance the methods and techniques to provide increased knowledge of the monitoring of respiratory and anesthetic gases.

The availability of gas sensors and monitors is a boon to the medical profession from both a clinical as well as a research point of view. In addition to patient safety, new diagnostic capabilities are emerging every year. In research, new gas-sensing capabilities are enhancing the discovery of markers for all kinds of disease states and metabolic functions.

Looking to the future, MEMS, microfluidics, and nanotechnology will provide growth in our understanding of physiologic processes at levels of detail never before conceived of, from inside the body as well as supplanting today's conventional techniques.

MEDICAL PHYSICS LITERATURE

COLIN ORTON
Harper Hospital and Wayne
State University
Detroit, Michigan

INTRODUCTION

Medical physicists are responsible for the application of physics to the diagnosis and treatment of disease and other disabilities although, in some countries, the treatment of patients with disabilities is a separate field, often referred to as “biomedical engineering” or words to that effect. Here, we restrict ourselves to applications in the diagnosis and treatment of disease.

The major applications in diagnosis are the use of X-rays for imaging (diagnostic radiology, including computerized tomography (CT), etc.); radioactive isotopes for imaging and uptake measurements [nuclear medicine, single photon emission computed tomography (SPECT), positron emission tomography (PET), etc.]; magnetic resonance imaging (MRI) and spectroscopy (MRS); ultrasound (ultrasonography).

Applications of physics to the treatment of disease include the following: external beams of X-rays, gamma-rays, or electrons for the treatment of cancer radiation oncology, including stereotactic radiosurgery, intensity

modulated radiation therapy (IMRT), total body irradiation (TBI), etc.; external beams of heavy particles for the treatment of cancer (neutrons, protons, heavy ions); internal radioisotope treatments for cancer (brachytherapy, systemic radiotherapy, and radioimmunotherapy) and other problems (intravascular brachytherapy, hyperthyroidism, etc.); hyperthermia for the treatment of cancer.

Other topics of major interest for medical physicists include various medical applications of light and lasers, radiation protection, radiation measurements, radiation biology, and the applications of computers to all of the above.

Throughout the world there are medical physics organizations that represent medical physicists and provide information to help them in their profession. Most of these are national associations, with about 70 of these represented by the International Organization for Medical Physics (IOMP). In terms of publications, by far the two most prolific organizations are the Institute of Physics and Engineering in Medicine (IPEM) in the United Kingdom, and the American Association of Physicists in Medicine (AAPM) in North America. These two organizations between them have published hundreds of reports, monographs, and meeting proceedings that are used as reference materials throughout the world. From the IPEM many of these are published by the Institute of Physics Publishing (IOPP) in Bristol, UK, and from the AAPM many are published by either the American Institute of Physics (AIP) or Medical Physics Publishing (Madison, WI).

JOURNALS

Several national and international organizations and independent publishers publish journals used by medical physicists. Some of these journals are used extensively for medical physics papers in which at least 25% of the manuscripts are medical physics articles. These are categorized as “Primary” journals below. Others contain some medical physics articles (<25%) and are categorized as “Secondary”.

PRIMARY MEDICAL PHYSICS JOURNALS

Australasian Physical & Engineering Sciences in Medicine, Australasian College of Physical Scientists and Engineers in Medicine and the College of Biomedical Engineers.

Journal of Applied Clinical Medical Physics, American College of Medical Physics (<http://www.jacmp.org>).

Journal of Medical Physics, Association of Medical Physicists of India.

Medical Dosimetry, American Association of Medical Dosimetrists (Elsevier).

Medical Physics, American Association of Physicists in Medicine (AIP).

Physica Medica, Istituti Editoriali e Poligrafici Internazionali Casella Postale n.1, Succursale n.8, 56123 Pisa, Italy (<http://www.iepi.it>).

Physics in Medicine and Biology, Institute of Physics and Engineering in Medicine (IOPP).
 Polish Journal of Medical Physics and Engineering, Polish Society of Medical Physics.
 Zeitschrift für Medizinische Physik, Deutschen, Österreichischen und Schweizerischen Gesellschaft für Medizinische Physik (Elsevier).

SECONDARY MEDICAL PHYSICS JOURNALS

Acta Radiologica, Scandinavian Society of Radiology (Taylor & Francis).
 American Journal of Roentgenology, American Roentgen Ray Society.
 Applied Radiation and Isotopes (Elsevier).
 Australasian Radiology, Royal Australian and New Zealand College of Radiologists (Blackwell).
 Biomedical Imaging and Interventional Journal (University of Malaya: <http://www.bijj.org>).
 Biomedical Instrumentation & Technology, Association for the Advancement of Medical Instrumentation.
 Brachytherapy, American Brachytherapy Society (Elsevier).
 British Journal of Radiology, British Institute of Radiology.
 Canadian Association of Radiologists Journal, Canadian Association of Radiologists.
 Cancer Radiothérapie, Société Française de Radiothérapie Oncologique (Elsevier).
 Cardiovascular and Interventional Radiology, Cardiovascular and Interventional Radiological Society of Europe, Japanese Society of Angiography and Interventional Radiology, and British Society of Interventional Radiology (Springer).
 Cardiovascular Radiation Medicine (Elsevier).
 Clinical Imaging (Elsevier).
 Clinical Radiology, Royal College of Radiologists (Elsevier).
 Critical Reviews in Computed Tomography (Taylor & Francis).
 Computerized Medical Imaging and Graphics, Computerized Medical Imaging Society (Elsevier).
 Computers in Biology and Medicine (Elsevier).
 Current Problems in Diagnostic Radiology (Mosby).
 European Journal of Nuclear Medicine and Molecular Imaging, European Association of Nuclear Medicine (Springer).
 European Journal of Radiology (Elsevier).
 European Journal of Ultrasound, European Federation of Societies for Ultrasound in Medicine and Biology (Elsevier).
 European Radiology, European Congress of Radiology (Springer).
 Health Physics, Health Physics Society (Lippincott Williams & Wilkins).
 IEEE Transactions on Medical Imaging, IEEE.
 International Journal of Radiation Biology (Taylor & Francis).
 International Journal of Radiation Oncology, Biology, Physics, American Society of Therapeutic Radiology and Oncology (Elsevier).
 Investigative Radiology (Lippincott Williams & Wilkins).
 Journal of Biomedical Optics, International Society for Optical Engineering (SPIE).
 Journal of Cardiovascular Magnetic Resonance, Society for Cardiovascular Magnetic Resonance (Taylor & Francis).
 Journal of Clinical Ultrasound (Wiley).
 Journal of Computer Assisted Tomography (Lippincott Williams & Wilkins).
 Journal of Diagnostic Radiography and Imaging, Royal Society of Medicine.
 Journal of Digital Imaging, Society for Computer Applications in Radiology (Springer).
 Journal of Electronic Imaging, International Society for Optical Engineering (SPIE).
 Journal of Labelled Compounds and Radiopharmaceuticals (Wiley).
 Journal of Magnetic Resonance Imaging, International Society for Magnetic Resonance Medicine (Wiley).
 Journal of Neuroimaging, American Society of Neuroimaging (Sage Publications).
 Journal of Nuclear Cardiology, American Society of Nuclear Cardiology (Elsevier).
 Journal of Nuclear Medicine, Society of Nuclear Medicine.
 Journal of Nuclear Medicine Technology, Society of Nuclear Medicine.
 Journal of Radiological Protection, Society for Radiological Protection (IOPP, Bristol, U.K.).
 Journal of the Acoustical Society of America, Acoustical Society of America (American Institute of Physics, New York).
 Journal of the American Society of Echocardiography, American Society of Echocardiography (Mosby).
 Journal of Thoracic Imaging, Society of Thoracic Radiology (Lippincott Williams & Wilkins).
 Journal of Ultrasound in Medicine, American Institute of Ultrasound in Medicine.
 Journal of Vascular and Interventional Radiology, Society of Interventional Radiology (Lippincott Williams & Wilkins).
 Journal of X-Ray Science and Technology (IOS Press, Amsterdam).
 Lasers in Medical Science (Springer).
 Lasers in Surgery and Medicine, American Society for Laser Medicine and Surgery (Wiley).
 Medical Engineering & Physics (Elsevier).
 Magnetic Resonance Imaging (Elsevier).

Magnetic Resonance in Medicine, International Society for Magnetic Resonance in Medicine (Wiley).

Medical Engineering & Physics, Institute of Physics and Engineering in Medicine (Elsevier).

Medical Image Analysis (Elsevier).

Molecular Imaging and Biology, Academy of Molecular Imaging (Springer).

Neuroradiology, European Society of Neuroradiology (Springer).

NMR in Biomedicine (Wiley).

Nuclear Medicine and Biology, Society of Radiopharmaceutical Sciences (Elsevier).

Pediatric Radiology, European Society of Pediatric Radiology, Society for Pediatric Radiology, Asian and Oceanic Society for Pediatric Radiology (Springer).

Photomedicine and Laser Surgery, World Association for Laser Therapy (Mary Ann Liebert, Inc.).

Physiological Measurement, Institute of Physics and Engineering in Medicine (IOPP).

Progress in Nuclear Magnetic Resonance Spectroscopy (Elsevier).

Radiation Measurements (Elsevier).

Radiation Physics and Chemistry (Elsevier).

Radiation Research, Radiation Research Society.

Radiographics, Radiological Society of North America.

Radiography, College of Radiographers (Elsevier).

Radiology, Radiological Society of North America.

Radiotherapy and Oncology, European Society for Therapeutic Radiology and Oncology (Elsevier).

Seminars in Interventional Radiology (Thieme).

Seminars in Nuclear Medicine (Elsevier).

Seminars in Radiation Oncology (Saunders).

Seminars in Roentgenology (Elsevier).

Seminars in Ultrasound, CT and MRI (Elsevier).

Techniques in Vascular and Interventional Radiology (Elsevier).

Topics in Magnetic Resonance Imaging (Lippincott Williams & Wilkins).

Ultrasound in Medicine & Biology, World Federation for Ultrasound in Medicine and Biology (Elsevier).

Ultrasound in Obstetrics and Gynecology (Wiley).

Year Book of Diagnostic Radiology (Elsevier).

Year Book of Nuclear Medicine (Elsevier).

BOOKS AND REPORTS

As with journals, books and reports are published by both medical physics organizations, especially the AAPM and the IPEM, and independent publishers. Most of the books and reports in the following lists can be purchased directly

from the publishers or, alternatively, through bookstores using the ISBN number provided.

MEDICAL AND RADIOLOGICAL PHYSICS

General

A Century of X-Rays and Radioactivity in Medicine: With Emphasis on Photographic Records of the Early Years, Richard F. Mould, ISBN 0-7503-0224-0, 1993, 236 pp, IOPP, Bristol (UK).

Essentials of Radiology Physics, Charles A. Kelsey, ISBN: 0875273548, 1985, 467 pp, W.H. Green.

Introduction to Radiological Physics and Radiation Dosimetry, Frank Herbert Attix, ISBN: 0-471-01146-0, 1986, 640 pp, Advanced Medical Publishing, Madison (WI).

Meandering in Medical Physics: A Personal Account of Hospital Physics, J.E. Roberts, N.G. Trott, ISBN: 0750304944, 1999, 181 pp, IOPP, Bristol (UK).

Medical Physics and Biomedical Engineering, Brown BH, Smallwood RH, Barber DC, Lawford PV; Hose DR, ISBN: 0750303670, 1998, 768 pp, IOPP, Bristol (UK).

Medical Physics Handbook of Units and Measures, Freim J, Jr, ISBN: 0944838308, 1992, 47 pp, Medical Physics Publishing, Madison (WI).

Medical Radiation Physics: Roentgenology, Nuclear Medicine & Ultrasound, Hendee WR, ISBN: 0815142404, 1979, 517 pp, Year Book Medical Publishers.

Physics in Medicine and Biology Encyclopedia (2 Volume Set), T.F. McAinsh, (editor), ISBN: 0080264972, 1986, Pergamon, Elmsford (NY).

Physics and Engineering in Medicine in the New Millennium, Sharp PF, Perkins AC editors., ISBN: 0904181952, 2000, 156 pp, IPEM, York, (UK).

Physics of Radiology, 4th ed., Johns H E, John Robert Cunningham, ISBN: 0398046697, 1983, 796 pp, Charles C. Thomas.

Physics of Radiology, second edition, Wolbarst A B, ISBN: 1-930524-22-6. Published: 2005, 660 pp, Medical Physics Publishing, Madison (WI).

Physics of the Body, Cameron JR, Skofronick JG, Grant RM, ISBN: 094483891X, 1999, 394 pp, Medical Physics Publishing, Madison (WI).

Principles and Practice of Clinical Physics & Dosimetry, Michael L.F. Lim, ISBN: 1-883526-11-6, 2005, 500 pp, Advanced Medical Publishing, Madison (WI).

Principles of Radiological Physics, 4th ed., Graham D, Cloke P, ISBN: 0443070733, 2003, 576 pp, Churchill Livingstone.

Radiation Biophysics, Alpen EL, ISBN: 0120530856, 1998, 484 pp, Academic Press.

Radiation Physics Handbook for Medical Physicists, Ervin B. Podgorsak, ISBN: 3540250417, 2005, 360 pp, Springer, New York.

Review of Radiological Physics, Walter Huda, Richard M. Slone, ISBN: 0781736757, 2002, 350 pp, Lippincott Williams & Wilkins, Philadelphia.

Topical

How the Body Works, Lenihan J, ISBN: 0944838-48-0, 1995, 200 pp, Medical Physics Publishing, Madison (WI).

Physics of the Body 2nd ed., Cameron J, et al., ISBN: 0-944838-91-X, 1999, 394 pp, Medical Physics Publishing, Madison (WI).

Medical Applications of Nuclear Physics, Bethge K, Kraft G, Kreisler P, Walter G, ISBN: 3540208054, 2004, 208 pp, Springer.

Progress in Medical Radiation Physics, Orton CG, ISBN: 0306417898, 1985, 248 pp, Plenum, New York.

RADIATION ONCOLOGY PHYSICS

General

AAPM Monograph No. 15, Radiation Oncology Physics, Kereiakes J, Elson H, Born C, editors, ISBN: 0-883185-33-4, 1986, 812 pp, Medical Physics Publishing, Madison (WI).

AAPM Monograph No. 26, General Practice of Radiation Oncology Physics in the 21st Century, Almon Shiu & David Mellenberg, ISBN: 0-944838-98-7, 2000, 368 pp, Medical Physics Publishing, Madison (WI).

Applied Physics for Radiation Oncology, Robert Stanton & Donna Stinson ISBN: 0-944838-60-X, 1996, 375 pp, Medical Physics Publishing, Madison (WI).

Biomedical Particle Accelerators, Scharf WH, Siebers JV, ISBN: 1563960893, 1994, 480 pp, Springer.

Blackburn's Introduction to Clinical Radiation Therapy Physics, Benjamin Blackburn ISBN: 0-944838-06-5, 1989, 218 pp, Medical Physics Publishing, Madison (WI).

Clinical Radiotherapy Physics, 2nd ed., Jayaraman S, Lanzl LH, Lanzl EF, ISBN: 3540402845, 2004, 523 pp, Springer.

Handbook of Radiotherapy Physics: Theory and Practice, Mayles P, Nahum A, Rosenwald J-C, ISBN: 0750308605, 2005, 700 pp, IOPP, Bristol (UK).

Modern Technology of Radiation Oncology, Van Dyk J, ISBN: 0-944838-38-3, 1999, 1072 pp, Medical Physics Publishing, Madison (WI).

Practical Radiotherapy: Physics and Equipment, Cherry P, Duxbury A, ISBN: 1900151065, 1998, 224 pp, Cambridge University Press, New York.

Radiation Therapy Physics, Hendee WR, Ibbott GS, Hendee EG, ISBN: 0471394939, 2004, 450 pp, Wiley, New York.

Radiotherapy Physics and Equipment, Morris S, Williams A, ISBN: 0443062110, 2001, 176 pp, Churchill Livingstone.

Radiotherapy Physics: In Practice, Williams JR, Thwaites DI, editors, ISBN: 0-19-262878-X, 2000, 362 pp, Oxford University Press, New York.

Review of Radiation Oncology Physics, Prasad SC, ISBN: 1-930524-08-0, 2002, 95 pp, Medical Physics Publishing, Madison (WI).

Study Guide for Radiation Oncology Physics Board Exams, Berman B, ISBN: 0-944838-94-4, 2000, 112 pp, Medical Physics Publishing, Madison (WI).

The Physics of Radiation Therapy, Hardbound 3rd ed., Khan F, ISBN: 0-7817-3065-1, 2003, 511 pp, Wiley, New York.

Walter & Miller's Textbook of Radiotherapy Radiation Physics, Therapy and Oncology, 6th ed., Bomford CK et al., ISBN: 0443062013, 2003, 660 pp, Elsevier.

Topical

3-D Conformal and Intensity Modulated Radiation Therapy: Physics and Clinical Applications, Purdy JA, Grant W III, Palta JR, Butler EB, Perez CA, editors, ISBN: 1-883526-10-8, 2001, 650 pp, Advanced Medical Publishing, Madison (WI).

A Practical Guide to 3-D Planning and Conformal Radiation Therapy, Purdy JA, Starkschall G, ISBN: 1-883526-07, 1999, 400 pp, Advanced Medical Publishing, Madison (WI).

A Practical Guide to Intensity-Modulated Radiation Therapy, Memorial Sloan-Kettering Cancer Center, ISBN: 1-930524-13-7, 2003, 450 pp, Medical Physics Publishing, Madison (WI).

AAPM Manual No. 2: Workbook on Dosimetry and Treatment Planning for Radiation Oncology Residents, Wu RK, Gerbi BJ, Doppke KP, editors, ISBN: 0-88318-916-X, 1991, 32 pp, Medical Physics Publishing, Madison (WI).

AAPM Monograph No. 2, Practical Aspects of Electron Beam Treatment Planning, Orton CG, Bagne F, editors, ISBN: 0-88318-247-5, 1978, 109 pp, Medical Physics Publishing, Madison (WI).

AAPM Monograph No. 7, Recent Advances in Brachytherapy Physics, Shearer DR, editors, ISBN: 0-88318-285-8, 1981, 202 pp, Medical Physics Publishing, Madison (WI).

AAPM Monograph No. 8, Physical Aspects of Hyperthermia, Nussbaum GH, editors, ISBN: 0-88318-414-1, 1982, 656 pp, Medical Physics Publishing, Madison (WI).

AAPM Monograph No. 9, Advances in Radiation Therapy Treatment Planning, Wright AE, Boyer A, editors, ISBN: 0-883184-23-0, 1982, 626 pp, Medical Physics Publishing, Madison (WI).

AAPM Monograph No. 16, Biological, Physical and Clinical Aspects of Hyperthermia, Paliwal BR, Hetzel FW, Dewhirst M, editors, ISBN: 0-88318-558-X, 1988, 483 pp, Medical Physics Publishing, Madison (WI).

AAPM Monograph No. 28, Intravascular Brachytherapy/Fluoroscopically Guided Interventions, Balter S,

- Chan RC, Shope TB Jr, editors, ISBN: 1-930524-10-2, 2002, 930 pp, Medical Physics Publishing, Madison (WI).
- AAPM Monograph No. 29, Intensity-Modulated Radiation Therapy: The State of the Art, Palta JR, Rockwell Mackie T, editors, ISBN: 1-930524-16-1, 2003, 904 pp, Medical Physics Publishing, Madison (WI).
- AAPM Proceedings No. 2, Proceedings of the Symposium on Electron Dosimetry and Arc Therapy, Paliwal BR, editor, ISBN: 0-88318-404-4, 1981, 384 pp, Medical Physics Publishing, Madison (WI).
- AAPM Proceedings No. 3, Proceedings of a Symposium on Quality Assurance of Radiotherapy Equipment, Starkschall G, editor, ISBN: 0-88318-422-2, 1982, 242 pp, Medical Physics Publishing, Madison (WI).
- AAPM Proceedings No. 5, Optimization of Cancer Radiotherapy, Paliwal BR, Herbert DE, Orton CG, editors, ISBN: 0-88318-483-4, 1984, 556 pp, Medical Physics Publishing, Madison (WI).
- AAPM Proceedings No. 12, Biological & Physical Basis of IMRT & Tomotherapy, Paliwal BR, Herbert DE, Fowler JF, Mehta M, editors, ISBN: 1-930524-11-0, 2002, 390 pp, Medical Physics Publishing, Madison (WI).
- AAPM Report No. 7, Protocol for Neutron Beam Dosimetry, Radiation Therapy Committee Task Group 18; ISBN: 0-88318-276-9, 1980, 51 pp, Medical Physics Publishing, Madison (WI).

INTRODUCTION

Computers play a vital role in almost every aspect of modern medical science. If we begin with a primitive definition of a computer, as a system with a processor unit capable of performing arithmetic and logical operations and a memory unit to store programs and data, then almost every sophisticated piece of modern medical equipment comes with a computer. Most standard medical procedures [e.g., magnetic resonance imaging (MRI), computed tomo-

graphy (CT), positron emission tomography (PET), ultrasonography] use computers to record and to process data. Computer-based medical records would seem a natural choice for documentation of the recorded data. Moreover, the association of this data with computers presents numerous advantages including easy and random access to the data by multiple distributed users, globally searchable databases, and automated batch processing. However, the use of computer-based medical records is not as prevalent in today's medical community as one would expect. In this article, we explain the reasons for this anomaly, and we present methods to circumvent the problems associated with computer-based medical records and to allow medical practitioners to achieve the real potential of computer-based systems.

PAPER-BASED MEDICAL RECORD SYSTEMS

Medical records chronicle the transactions between health-care professionals and their patients. They record every detail of a patient's visit to a hospital, clinic, or office from the time of the patient's arrival to the time the patient is discharged. Details recorded include the condition of the patient at the time of examination, procedures and medications administered to the patient, symptoms and observations, diagnoses and test results, together with the exact time of each relevant activity.

Traditionally, medical records have consisted of handwritten documents called *charts*. This remains the most prevalent form of recording patient information, especially in small hospitals and clinics. These charts typically record every piece of information that is judged potentially relevant to a patient's case. When a patient visits a hospital or a primary care physician for the first time, a new chart is made, and the patient name and contact information are recorded on it. When the patient is discharged from the hospital, a discharge note is made on the chart. During subsequent visits, new charts are added. All patient charts are maintained in a labeled file bearing the patient's name and other information to enable easy identification and retrieval.

However, paper-based records exhibit shortcomings in six important areas that are necessary to ensure adequate long-term care to patients and easy preservation of treatments administered.

1. *Accessibility*: Accessibility refers to the immediate availability of patient-related information at all times to all parties with a need to know. It is important to review a patient's medical history before commencing any new treatment. If a patient decides to visit a specialist, emergency room, clinic, or hospital other than the primary care physician, a request may be made for the patient's medical history to be faxed or couriered to the second facility. This information transfer may take between hours to days to complete, depending on the distance and arrangements between the two locations, available modes of communication, availability of authorized personnel to promptly respond to the request, and so on. During

emergencies, a delay of just a few minutes in administering the correct treatment to a patient could have very serious ramifications. A situation in which adverse reactions to particular medications known by a primary care physician simply are not made available in a timely fashion to emergency room personnel is all easy to imagine. The delay in disseminating accurate detailed background information is perhaps the biggest drawback of paper-based medical record systems.

2. *Legibility*: Paper-based records are generally handwritten documents, and one person's handwriting is often not readily understood by another. The fact that entries may be made by many different people makes understanding a chart even more difficult. Furthermore, paper-based records are subject to wear and tear, accidental immersion in water or other liquids due to leaks, misfortune or negligence, smudging of ink, and so on. These factors lead to reduced legibility of the entries on the charts and consequently make interpreting the charts more subjective.
3. *Bulkiness*: Paper-based records for a single patient initially consist of just a few charts, but they can quickly become a thick file with subsequent visits. Assuming that a small clinic sees ~ 10 new patients daily, that the physicians in the clinic take rotating holidays and that it is not a leap year, ~ 3650 new files will be added over a period of 1 year. The files of many of the existing patients also become bulkier and subsequently occupy more space. All of this paper forces the addition of storage space in the clinic for these new records, even though the space could often be better utilized for clinical purposes through the addition of much more profitable and useful treatment or diagnostic capabilities.
4. *Data Dimensionality*: Data dimensionality refers to the ability to interpret the available information in multiple, complementary fashions. The data contained in paper-based records simply provide information about the medical history of a particular patient. In order to obtain trends, distributions or statistical patterns about a particular patient or even groups of people in a geographical area, the required information has to be manually compiled from each record. This can be extremely laborious and time consuming. Furthermore, even a simple text search for a particular word or phrase can take impractically long if the search must be conducted visually through paper-based handwritten records.
5. *Integrity*: A patient will have multiple medical files, maintained simultaneously at every hospital or clinic ever visited, yet none of these records contain the complete medical history of the patient. Usually, the patient's primary care physician is the one who has the records that will provide the most accurate long-term information, and during times of emergency the primary care physician will frequently be the first one contacted for patient records. However, medical facilities rarely have in place any mechanism to update the primary care physician. If, for example, during a visit

to a specialist it was found that a patient was allergic to a particular class of medications, the primary care physician's records will often not be updated to show this information. Even if the patient records from multiple sources were summoned, there will still remain a very realistic chance of missing one or more sources, leaving the completeness of paper-based records questionable. Paper-based systems also risk inadvertent loss or misfile of complete pages in copying, transporting, photocopying, faxing, and handling of records.

6. *Replication*: Paper-based medical records are prone to destruction by natural disasters, fires, leaks, and pests in storage areas. Because paper-based records are bulky, it is both expensive and tedious to replicate them and store back-up copies. Hence, if they are destroyed, patient medical histories can be completely lost.

Several research papers have been devoted to explaining the shortcomings of paper-based medical records (1,2). Nevertheless, paper-based records are still the most widely used method for maintaining patient information. The process of recording information in charts is a natural process of making notes, and it requires little specialized training. Once recorded, the information is relatively permanent and cannot be distorted easily. Furthermore, the chart often bears the signatures of both the patient and the appropriate medical personnel who treated the patient, which may be an important legal requirement. Such legal issues are a significant reason that many organizations resist wholesale changes to their paper-based record systems.

COMPUTER-BASED MEDICAL RECORD SYSTEMS

Paper-based records were the only method of storing patient medical information in use until ~ 25 years ago. Since that time, computer technology has experienced exponential growth, creating endless possibilities for developments within allied fields. The fields of medicine in general and medical records in particular have been no exception. Computer-based records were introduced to overcome the inherent limitations and problems of paper-based records and to alter patient medical record keeping in order to incorporate advancements in computer technology. The computer-based medical record is commonly given several names within differing environments, including Computer-based Patient Record (CPR), Electronic Health Record (EHR), and Electronic Medical Record (EMR). Throughout this article, we will use the name computer-based patient record and the abbreviation CPR to refer to computer-based medical records. The CPRs are fundamental to the role of computers in medical records, and a significant portion of this article deals with them.

A CPR is an electronic patient record that resides in a computer-based information system. Such systems are often specifically designed to augment medical practitioners by providing accessibility to complete and accurate long-term data, alerts, reminders, clinical decision support

systems, links to medical knowledge databases, and other aids (3,4). The CPRs are essentially digital equivalents of paper-based records. Because this patient information is stored digitally, the enormous information processing and networking capabilities of computers can be utilized to drastically increase the efficacy of patient treatment. They easily overcome the shortcomings of paper-based records on the six key issues outlined in the previous section, and they provide several other fascinating features exclusive to them.

1. *Accessibility*: With the advent of the Internet and the World Wide Web, information on virtually any topic can be quickly and easily obtained. CPR databases can be stored in networked servers, which can be searched from any properly networked location. With properly designed databases and network systems, the complete medical history of a patient can be retrieved in a matter of seconds. This helps in ensuring the most prompt and accurate treatment possible, which is one of the fundamental reasons for maintaining a medical record.
2. *Legibility*: The information recorded on CPRs is presented using digitally reproduced fonts, which are then independent of the handwriting of the person entering the data into the system. Anytime patient information is required, it can be readily visualized on a viewing device, such as a CRT monitor or PDA, which does not introduce any wear and tear in the record itself. If a paper copy of a patient record is required for a particular activity, a new printout can be generated every time. Thus there is no subjective element in understanding the information.
3. *Bulkiness*: CPRs can be stored on a variety of media, including Compact Disc (CD), Digital Versatile Disc (DVD), and Hard Disk Drive (HDD). A single CD, 11.4 cm in diameter and weighing ~15 g, can store 700 megabytes (MB) of data. This translates into >100,000 pages of raw text or two hundred 500-page books, which would occupy >10 m of shelf space. The DVDs have >10 times the density of CDs, and HDDs offer >100 times the information content of a CD. This means that with proper database design, all of the medical records of all of 1 year's new patients at the aforementioned small clinic can now be stored on a single CD, and several years of patient data for all ongoing patient activities can be stored on just one DVD.
4. *Data Dimensionality*: Data on CPRs can be exploited and interpreted in many more ways than can a simple paper-based record. Entire databases can be subjected to automated search, and specific information from a single record or a collection of records can be retrieved in a matter of seconds. Trends and patterns in disease occurrence and treatment administration and effectiveness can readily be extracted and processed for limited or wide-ranging populations. Database Management System (DBMS) software can be used to plot the available information on graphs and pie charts, which greatly simplify the

contents of medical records into a form that can be interpreted by laymen. All these operations can be done automatically using state-of-the-art software and require little, if any, human intervention. Techniques in data mining, for example, allow automated determination and analysis of data correlations among very large numbers of variables.

5. *Integrity*: CPRs are generally stored on local systems within hospitals, clinics, and physician offices, which means that medical records of a particular patient could be distributed across many systems throughout the world. Using modern networking techniques, these systems can be easily yet securely networked, and widely dispersed CPRs can be located and made available for inclusion in patient diagnosis and treatment. It would also be practical to develop a system in which all patient records are stored in a central repository, and any time new records of the patient are created or updated, they can be added to this central repository. Using either of these methods in a well-designed system, the complete medical history of a patient can be very rapidly retrieved from any of the authorized locations connected to the network.
6. *Replication*: Due to the high densities for computerized storage of data, CPRs occupy very little space when compared to paper-based systems. It is very easy and inexpensive to create back-up copies and to store these copies in geographically diverse locations. In a well-designed computer-based system with automated, networked backup, the complete medical history of every patient can still be retrieved even if a record storage facility is completely destroyed.

Exclusive Features of CPR

With considerable manual effort, the performance of paper-based records can be made comparable to that of CPRs within the six major requirements of a medical record outlined above. The efficiency advantages of computer-based medical record systems will nevertheless offer significant cost advantages over paper-based systems in achieving comparable performance levels. Significant improvements in patient treatment can result when CPRs are incorporated into expert systems and DBMS frameworks that engender an entirely new set of features for medical records.

1. *Content-Based Data Retrieval*: If a large hospital system is informed that a popular drug has been determined to cause serious side effects and that the manufacturer has consequently issued an immediate recall, the hospital system may hesitate to issue a broad public warning, because that action would lead to unnecessary panic and to patients flooding the system seeking confirmation on their prescriptions, even when their medications are completely unrelated to the recall. If the hospital maintained only paper-based records, it would take weeks to pore through patient charts to obtain the names

and locations of the patients to whom the drug was prescribed. Such a situation presents a perfect case for content-based data retrieval. With properly constructed CPRs, the same information can be much more rapidly retrieved through querying the database to fetch all patient records with the name of the recalled drug in the 'Drugs Prescribed' field. Then, only the patients who actually have been prescribed the recalled medication can be individually contacted with explicit instructions by a qualified staff member. This data search technique is known as Content-Based Data Retrieval (CBDR).

2. *Automatic Scheduling*: With CPR-based systems, routine periodic check-up or follow-up visits can be automatically scheduled, and e-mail reminders or automated telephone recordings can be sent directly to the patients. This automation will relieve healthcare professionals of a significant administrative burden.
3. *Knowledge-Based Systems*: Every physician attempts to solve a particular condition to the best of his limited knowledge (5). It is reported that there are >5,000,000 medical facts, which are constantly being appended, updated and questioned by over 30,000 medical journal publications each year (6). It is humanly impossible to remember all of these facts and to reproduce them accurately as needed. However, CPR databases all over the world can be rapidly and effectively searched in order to find information about patients who were previously diagnosed with the same condition, how they were treated and the end result. While the presiding doctor still makes the decisions and retains responsibility, he can have experimental evidence and experiential knowledge from other experts to assist his analysis (7). Diagnostic decision support systems like Quick Medical Reference (QMR) and Massachusetts General Hospital's DXplain provide instant access to knowledge bases of diseases, diagnoses, findings, disease associations and lab information.
4. *Expert Systems*: Human errors in recording information can be greatly reduced by programming the data-entry interface to reject anomalous values and to restrict the input to a finite set of possible choices. For example, a pulse rate of 300 beats min^{-1} would be highly unlikely. Potentially dangerous spelling mistakes in generating a prescription can be identified. Dates for follow-up activities can be checked against reasonable parameters. A well-designed interface would prompt a message to recheck such entries.
5. *In situ Data Access*: A medical records system in which a physician accesses a wireless PDA while conversing with a patient could allow direct bidirectional communication between a physician and a pharmacy, a laboratory, or a specialist. Collaborators on a complex case can simultaneously access each other's progress, even when the collaborators are geographically separated.

In 1991, the United States Institute Of Medicine (IOM) conducted a study on the advantages and disadvantages of CPRs and published its findings (3). The IOM concluded that CPRs greatly enhance the health of citizens and greatly reduce costs of care, and it called for widespread implementation of CPRs by 2001. However, 4 years past that deadline, widespread implementation still remains only a concept. Figures for CPR adoption rates in hospitals range from 3% to 21%, while CPR adoption rates for physician offices range from 20% to 25% (8). It is safe to say that these figures are not representative of the popularity that one would reasonably expect from the benefits of CPRs. The following section is devoted to explaining this anomaly.

ROADBLOCKS IN CPR IMPLEMENTATION

Recording and processing of information with CPRs requires installation of computer systems and software, and, in general, more training of healthcare professionals is required to get them acquainted with CPR systems than with paper-based record systems. Furthermore, realizing the full potential of CPR systems requires not only that patient records issued in the future should be CPRs but also that previously taken paper-based records should be converted into CPRs. Some of the important factors affecting this onerous large-scale conversion will now be discussed.

1. *Cost*: Expense is usually the major obstacle to the full-fledged incorporation of CPRs. Depending on whether the application is for the office of a single physician or for a large hospital, the basic infrastructure needed to establish a CPR system could vary from a single PC to a complete network of workstations and servers loaded with expensive network, database and records management software. Both hardware and software computer technologies become outmoded very quickly, and these technologies require constant update, increasing maintenance and operation costs. There is also a significant cost factor involved in hiring data-entry operators to convert existing paper-based records to CPRs and in training healthcare professionals to then operate the new systems and software. Although several studies have shown that CPRs are effective in the long run (9,10), both hospitals and physician offices remain apprehensive about investing many thousands of dollars on a new technology while the tried and tested paper-based records work reasonably effectively.
2. *Abundance of Choices and Lack of Standards*: There are > 100 CPR management software systems available in the market today, and additional entries arrive in the marketplace annually. Each software approach will have its advantages and disadvantages, and it is never easy to decide which one is best suited for a particular application. Furthermore, different software interfaces use different templates for the patient record, recording slightly different patient data within very different structures. A

standardized CPR format independent of the specific hardware and software running on a particular system is yet to be developed. This lack of standardization in CPR formats severely cripples cross-system interaction and comprehensive integration of CPR systems. The marketplace has, to date, failed to produce a clear market leader or an industrial body with the ability to enforce such standards. A customer contemplating a purchase and the subsequent investments in training and maintenance may have serious reservations concerning the ability to change from the products of one manufacturer to another.

3. *Confidentiality*: The United States government passed the Health Insurance Portability and Accountability Act (HIPAA) in 1996, protecting a patient's right to confidentiality and specifying the information on a medical record that can be shared and the information that must be considered confidential. A record can be made available only on a "need to know" basis, wherein only personnel who absolutely need to know the data are granted access. For example, physicians participating in the diagnosis and treatment process of a specific patient are granted complete access to the entire medical record, while health agencies involved in conducting demographic studies are granted access only to information that does not and can not reveal the identity of the patient.
4. *Security*: In the case of paper-based records, it is relatively easy to control access and to ensure security by keeping those records under lock and key. The security of CPRs will be constantly threatened by hackers, trying to break into a system in order to retrieve confidential patient information. Unless properly protected, CPRs are also vulnerable to being compromised during transmission across a network. Unlike paper-based records, CPRs can be easily manipulated, intentionally or unintentionally, in fashions that do not appear obvious. These vulnerabilities represent an enormous security problem, and effective solutions are required before CPRs can be put to widespread use. Furthermore, efforts to provide network security have significant costs, requiring manpower, equipment, and frequent software upgrades.
5. *Apprehension Among Patients*: Even in developed countries like the United States, considerable uneasiness exists among patients about the use of computers to maintain patient medical records. While some of this phenomenon can be ascribed to the reluctance of the older generation in accepting new technology, the most important reason for this apprehension is the lack of clear understanding by patients about the benefits of CPRs. One of the easiest ways to overcome this fear is for healthcare professionals to directly reach out to the patients and explain the long-term advantages of CPRs.
6. *Legal Issues*: The validity of CPRs in a court of law is still questionable. The Millennium Digital Commerce Act, otherwise known as the Electronic Signature Act, was passed in 2000 (although the portion

relating to records retention was passed in 2001). The act established that the electronic signature and electronic records cannot be denied legal effect simply because they are electronic and are not signed in ink on paper. However, legal implications in CPR transactions extend far beyond this act. For example, if it is found that the software system used to manage CPRs does not comply with stipulated security requirements, the validity of a CPR can be questioned in court, even if no indication of tampering can be identified. The CPR systems are also prone to computer viruses, worms and Trojans, which exploit loopholes in the computer security defenses to gain unauthorized access to sensitive data and/or to maliciously corrupt the information.

Despite significant progress toward overcoming these hurdles, complete transition from paper-based records to CPRs is a time-consuming and capital-intensive process, and during the midst of this transition, the benefits are unlikely to be immediately apparent. In the following section, some of the options available to healthcare professionals in implementing a CPR system, and several technologies available to ensure secure storage and transmission of confidential medical information are reviewed.

FEATURES OF CPR SYSTEMS

A complete CPR system can consist of individual workstations, data input devices (keyboards, mice, light pens, scanners, cameras), output devices (printers, plotters, and display monitors), Database Management System (DBMS) software, text, image and video processing hardware and software, and the networking infrastructure for intra- and intersystem communication. The security and reliability requirements of these systems should never be understated. With so many factors involved, there is always room for improvement, and a universally perfect combination has yet to be implemented. Nevertheless, a wide variety of CPR systems have been successfully implemented, tested and put to everyday use, with most such systems working successfully in the environment for which they were designed. We will now explore some of the general features of CPR systems and their components, and we will present advantages and disadvantages of the choices available.

System Architecture

A fundamental decision that must be made before implementing a CPR system is the choice of the system architecture to be used. There are two broad choices, which we now discuss.

1. *Centralized Architecture*: A block schematic of a centralized architecture as implemented in CPR systems is shown in Fig. 1. A CPR system based on the centralized architecture has a central server that contains complete medical records of all patients in the system. Any modification to a record must be

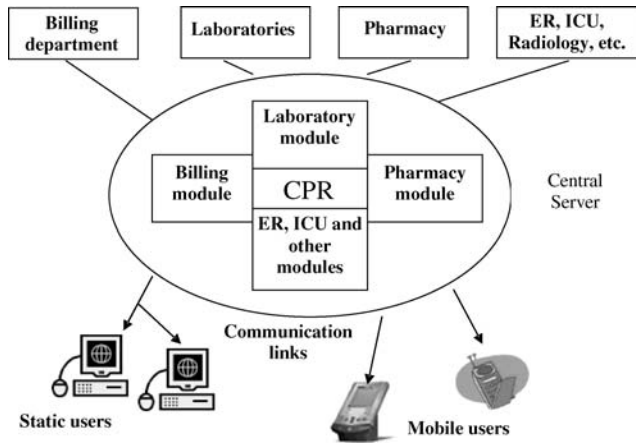

Figure 1. Centralized Architecture (Reprinted with permission from (The Computer-Based Patient Record: An Essential Technology for Health Care, Revised Edition) © (1997) by the National Academy of Sciences, courtesy of the National Academies Press, Washington, D.C.)

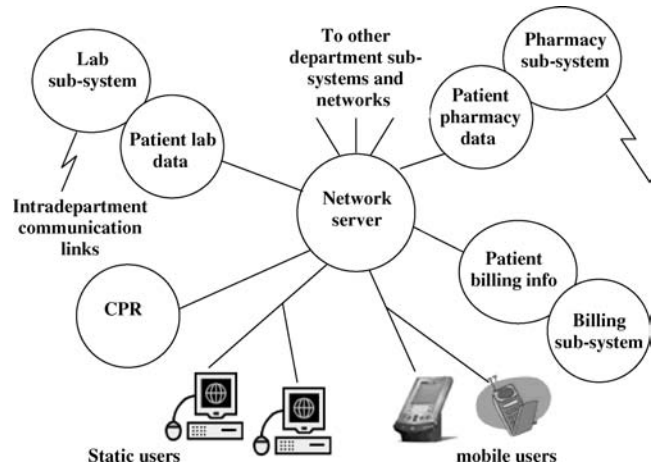

Figure 2. Distributed Architecture (Reprinted with permission from (The Computer-Based Patient Record: An Essential Technology for Health Care, Revised Edition) © (1997) by the National Academy of Sciences, courtesy of the National Academies Press, Washington, D.C.)

done to the CPR stored in this central repository to have any lasting effect. Communication links may be provided to other departments that will immediately communicate any new information to the server, thereby keeping the CPR on the central server fully updated. The principal advantage of this architecture lies in the immediate availability of the complete record for use elsewhere within the system. It is also easier to manage and to maintain the resources of the system, because they are located in one single location. However, a poorly designed system can be prone to server overloading, leading to delayed responses. Server or network failures can bring the system to a complete standstill, and if the data on the server is corrupted or destroyed, the medical record activity subsequent to system backup may be completely lost. These issues can be resolved, but the solutions can be expensive.

2. *Distributed Architecture:* The alternative to the centralized approach is the distributed architecture. A block schematic is shown in Fig. 2. In this approach, the load of the server is distributed among smaller subsystems, distributed through many departments. No department contains the complete medical record of all patients. The records are completed “on demand”, that is, when a user at a system workstation must obtain complete information, the workstation sends requests to each individual subsystem, receives data back from them, and arranges them into a record. This system continues to function even if one or more of the subsystems become inoperative. However, the response time, defined as the time elapsed between the user request to fetch a record and the arrival of the complete record back to the requesting workstation, might become significant if even one of the subsystems is overloaded. The architecture also provides more opportunities for security breaches than the centralized approach. There may

also be difficulties related to each subsystem using different data structures to manage and to store records, making the design of an effective DBMS potentially quite complex. These issues have been successfully addressed in specific implementations of distributed CPR systems.

DBMS and Media Processing

The general components of a CPR are shown in Fig. 3. An ideal DBMS would be able to seamlessly integrate different media formats (text, images, three-dimensional (3D) models, audio and video). Four important types of DBMS commercially available are hierarchical, relational, text-and object oriented. Each of these is better suited for one or more different media and system architectures than the others. Many modern CPR systems, especially those based on a distributed architecture, use a combination of commercial DBMSs or utilize a custom DBMS.

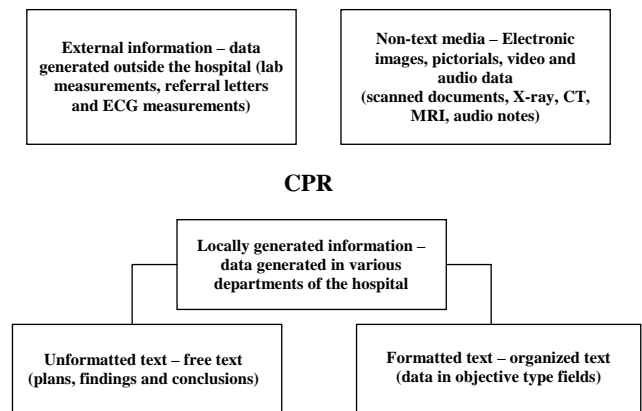

Figure 3. Components of a CPR.

An important aspect of a DBMS is the mechanism that it uses for data retrieval. The details of record construction can play a significant role in creation of databases that can be efficiently and accurately searched. Entries in formatted fields can be searched much more easily than scanned documents, images or nonformatted text. A DBMS should also provide organization of the data in a manner that is sensible and easy to comprehend. Well-organized databases will prove easier to manage and faster to search.

Security and Legal Issues

A core issue in the design of CPR systems is security. A single security breach could be used to access thousands of complete CPRs, which are then vulnerable to many malicious activities. Thus, it is extremely critical to protect individual CPRs from unauthorized access, as well as to protect the CPR system itself from hackers attempting to access the system or attempting to cause it to fail. In addition, the CPR data must be protected before it can be sent across a network, due to potential communication leaks that can land sensitive information in the wrong hands. Tools such as network packet sniffers are extremely powerful if an unauthorized party can achieve physical access to network interconnection hardware or cabling. In general, five conditions must be satisfied before patients or health care personnel are granted access to the records on a network (11):

1. The patient must not have recorded an explicit prohibition of CPR transmission across the network.
2. The patient must have consented to the transfer of the partial or complete CPR to the recipient institution.
3. The identity of the patient must be accurately verified and authenticated.
4. The identities of the healthcare provider and the recipient institution must be accurately verified.
5. It must be verified that the patient is mentally competent. If the patient is found to be mentally incompetent, then the need for the patient record must be sufficiently urgent that if it is not made available immediately, serious harm could result to the patient's health.

For a CPR produced by a CPR system to be a legally valid document, the CPR should be able to answer the following questions (12).

1. *Who Wrote It?* A single CPR is frequently handled by many different people, with several healthcare providers entering, updating, or removing information. A CPR must include the identities of all the people who have modified the record, together with the information that they have modified. This involves secure access control using smart cards, PINs, fingerprints, passwords, etc. to verify the identity of requestors before they will be allowed to access or to modify the information on the records.

2. *When Was It Written?* Time and date information is maintained by automatically attaching timestamps to the CPRs. The system must be designed to ensure that unauthorized personnel cannot change the system time or any timestamp in any CPR.
3. *What Does It Say?* Computer technology is reinvented roughly every 5 years. Data storage and retrieval media become obsolete very quickly. For example, the magnetic tapes that were very popular 25 years ago can be found only in museums today. It is thus important for CPR systems to incorporate these technological developments, and yet not become outmoded too quickly, so that the contents of current CPRs and archived CPRs can both be read and processed to obtain the same information.
4. *Has the Information Been Altered?* Undocumented alteration of information will prove to be the most important legal issue, and hence, the most difficult one to solve. A CPR system must be designed to allow determination of whether the information is indeed as originally recorded or whether it has been subsequently modified in a manner that would affect possible legal proceedings. Several effective solutions, based on cryptographic techniques, exist.

A very reliable solution to ensure that a particular CPR provides answers to all of these four questions is to attach digital signatures to them. Just as an ink-based signature provides legal acceptability for paper-based records, digital signatures can ensure the legal acceptability of a CPR. Digital signatures offer both signatory and document authentication, and they have been proven to be more effective than the ink-based signature (13). Signer authentication provides the capability to identify the person who signed the document, while document authentication offers the capability to determine whether a document was altered after it was signed.

Digital signatures use public-key encryption schemes to provide this functionality. In public-key encryption schemes (14), every user gets a pair of *keys*: a public key, which everybody is allowed to know, and a private key, which is kept as a secret known only by the individual and the authority that issues and verifies the keys. A digital signature is computed using the data bytes of the document and both the private and public keys and attached to the document. Consider that person A creates a CPR and attaches a digital signature to it using his public and private keys. Anybody with access to A's public key can verify that the CPR was actually created by A using the CPR, the digital signature and A's public key. If the result is correct, according to a straightforward mathematical relationship, A is authenticated as the signatory of the CPR, and the CPR is authenticated as accurate. Any alteration of the CPR after the calculation and attachment of the digital signature would corrupt the digital signature and would then cause the CPR to be identifiable as modified. In this case, the CPR would be considered fraudulent, although the source of the fraud would not necessarily be identifiable.

Public-key encryption can also be used to secure CPRs before transmitting them across a network. Consider that person A desires to send a CPR to person B. Person A looks up the public key of B and encrypts the CPR using B's public key. The CPR can only be decrypted using B's private key. Since only B has access to his private key, only he can decrypt the CPR. The principle of public-key encryption can be extended to CPRs to protect the authenticity of the information, to identify malicious alterations of the CPR, and to secure transmission across a network.

POINTERS TO THE FUTURE

Much of this article has been devoted to explaining the benefits of the CPRs and the factors hindering their widespread implementation. Despite their tremendous potential, the development of commercial CPR systems has not reflected the progress made in many related fields in computer technology. In this section, some of these related technologies that, in the future, the authors feel will have great potential to broaden the range of advantages of computer-based medical record services and to make them sufficiently secure are presented.

Radio Frequency Identification Tags

Radio Frequency (RF) identification (RFID) refers to an automatic ID system that uses small RF devices to identify and to track individual people, pets, livestock, and commercial products. These systems are used to automatically collect highway tolls and to control access to buildings, offices and other nonpublic sites. An RFID tagging system includes the tags themselves, a device to write information to the tags, one or more devices to read the data from the tags, and a computer system with appropriate software to collect and to process information from the tag. Many applications can use the same devices to both read and write the RFID tags. While the physical layout of the tag may vary according to the application, its basic components will include an intelligent controller chip with some memory and an antenna to transmit and receive information. According to its power requirements, an RFID tag will be classified into one of two types. Active tags have their own power source and hence provide greater range. Passive tags will be powered by RF pulses from the tag reader (or writer) and thus exhibit no shelf life issues due to battery exhaustion.

While plans are underway to replace bar codes with RFID tags on virtually every single commercial product, the field of medical informatics has found some unique applications for RFID tags. The U.S. Food and Drug Administration (FDA) recently approved the implantation of RFID tags on humans (15). These tags are similar to the tags being used on animals, and they are implanted under the skin in the triceps area. The chip contains a 16-digit number that can be readily traced back to a database containing the patient's information. One such chip made by VeriChip costs ~\$125, exclusive of the cost of implantation. This technology is expected to be a boon to individuals with life-threatening medical conditions and to lower medical costs by reducing errors in medical treatment.

Testing of replacement of bar codes with RFID tags in patient bracelets is ongoing. Unlike bar codes, RFID tags do not require clear line of sight between the bar code and the bar code reader, nor do they require active operator intervention. This ensures that healthcare workers will not fail to scan a patient ID bracelet. One such successfully tested system is Exavera's eShepherd, which combines RFID tags with Wireless Fidelity (Wi-Fi) networks and Voice over IP (VoIP) to implement a single system that will track patients, staff and hospital assets (16). The Wi-Fi routers can deliver patient information directly to a physician's handheld PDA every time any RFID transceiver detects a patient. Physicians and hospital staff can have the patient information whenever and wherever they want, and they do not have to refer repeatedly to a secure physical filing area to retrieve patient records.

A major factor impeding widespread implementation of RFID tags is the legal and ethical issue of keeping such detailed records of people, their activities, and all the things they buy and use, without their consent. However, once this issue has been resolved, RFID tags will change the way patient records are processed.

Biometrics

Biometrics refers to automatic recognition of people based on their distinctive anatomical and behavioral characteristics including facial structure, fingerprint, iris, retina, DNA, hand geometry, signature, gait and even the chemical composition of sweat (17). Biometric systems have been used in wide ranging applications like user authentication before entry into buildings and offices, criminal investigation, and identification of human remains.

Biometric systems will also find an excellent application in management of medical records. Individual traits of people who are authorized to access the record can be stored along with the record. When the system receives a request from a user to retrieve the record, the system will attempt to match the biometrics of the user to the database of biometrics of all the people who are authorized to access the record. The record is fetched only if the match is positive. In this manner, a CPR can be viewed and modified only by authorized personnel. This is potentially an effective application for biometric systems, because the system can be trained with as many samples as needed from authorized personnel. Biometric system applications where a strong need exists to verify the authenticity of claimed membership in a preidentified population have been successfully tested with almost 100% accuracy. Such systems also offer a deterrent to would-be intruders because the biometric information associated with an unsuccessful access attempt can be retained and used to identify the intruder.

Generally, the biometric information of a user is encoded on a smart card that the user must use to gain access into the system. This provides a far better authentication solution than using just a user name and a password, because both of these can be forged fairly easily. Most current biometric systems are based on the uniqueness of human fingerprints, and systems based on more complicated biometric features are currently undergoing

investigation. The development of superior biometric systems holds the key to more secure CPR authentication.

Content-Based Image Retrieval

Content-Based Image Retrieval (CBIR) is the process of retrieving images from a database based on the degree of similarity in content between an example image (the query image) and the various images contained in the database. Traditional non-CBIR data retrieval mechanisms apply text-based methods, in which a string query is matched to user-generated descriptions of documents or to contents of specific fields in a record. When patient images are integrated into patient records, simple text-based searches will not serve the same purpose. Text descriptions of images are very subjective and require data entry by a knowledgeable user. If that same image is to be added to a different database, the accompanying description also must be added if the image is to be retrievable.

These techniques utilize both global properties, such as image statistics and color distributions, and local properties, such as position and texture, to retrieve images that appear "similar" to the query image. This is a powerful tool for physicians, because CBIR enables them to compare the image of a current patient (query image) to similar images of other patients in the database, to examine descriptions attached to those images in their corresponding CPRs, and to study the treatment administered in those cases, all in a matter of seconds.

More and more frequently, scanned documents such as referral letters and scanned paper-based records are being added to CPRs. These documents can be treated as images, and CBIR systems based on character recognition technologies can search for text descriptions on these documents, making these documents compatible with text-based searches. This technology can save a great deal of time, money and errors in converting historical or ongoing paper-based records to CPRs, because the records can simply be scanned and need not be entered again into the CPR system. As more and more visual aids are added to medical diagnostics, CBIR will become indispensable to CPR management.

Steganography and Watermarking

Steganography and cryptography are related but distinct methods that are used to ensure secure transmission and secure archival of information. In cryptography, messages are encrypted in such a manner that unauthorized recipients may not decrypt the messages easily, using long, secure passwords and complex mathematical algorithms to drastically alter the data. Often, however, the encrypted messages themselves may be obtained fairly easily, because they are transmitted over insecure networks and archived on insecure servers. In steganography, the very presence of secure information is masked by hiding that information inside a much larger block of data, typically an image.

If an oncologist wishes to get a second opinion from a gynecological specialist concerning a diagnosis of cervical cancer, he might elect to send a digital image of the cervix of the patient. He would also include his diagnosis, relevant

patient details including other complications the patient may have, and a referral letter, all of which are sensitive and confidential information. The traditional method to send the supplemental information electronically would be to encrypt the information using public-key encryption techniques and to transmit it as separate files together with the image. If the transmission is intercepted by a malicious party seeking private data, the transmission would garner interest, because it would be quite obvious that any encrypted information following the image information would likely be related to that image. The data thief must still work to decrypt the transmission and to reveal the confidential information. Decryption itself is difficult without extensive computational capacity, but data thieves will often find getting the necessary password to be a much easier method to access the data. The disadvantage of encryption is that the data thief knows what to try.

An alternate data transmission method would use steganography. The sensitive information can be embedded in inconspicuous areas of the image (18). Thus, no additional information or files are transmitted, and the image will raise less suspicion that associated sensitive data can be located. Although the embedded data is computationally easier to decode than the encrypted messages, it will only be decoded by people with foreknowledge that there is information embedded in the image. Furthermore, the embedded data can be encrypted before it is embedded, so that the data thief has another level of barrier. The information is much more difficult to locate, and the thief still has to decrypt or to steal the password.

Usually, the clinically important sections of the image will be identified, and only the remaining regions will be used for embedding the secret information. Several sophisticated steganography techniques, like BPCS, ABCDE, and modified ABCDE (19–21) have been successfully implemented. These methods can hide significant amounts of information without clinically altering the image, although hiding too much data leaves evidence that can be detected mathematically using tools from the field of steganalysis. Figure 4 shows an example of data hiding using the

Figure 4. Steganography. (a) Original digital image of the cervix. (b) Section of clinically unimportant segment of image in a. (c) Section in b encoded with secret information.

modified ABCDE scheme. Figure 4a is a digital image of a cervix, and Fig. 4b shows the bottom right section of this image, which contains no clinically important information. This section forms an 864×432 RGB image, which requires 1,119,744 bytes to represent directly or 295,727 bytes to represent when losslessly compressed to PNG format. Figure 4c is the section in Fig. 4b after 216,326 bytes of sensitive information have been embedded. This hidden data corresponds to >40 pages of pure text, at 5000 characters per page. Figure 4c visually appears very similar to the section in Fig. 4b, even with this extensive additional data embedded. An even more secure solution would encrypt the sensitive information before embedding it inside the carrier image. This way, even if steganalysis methods detected that the carrier image contains embedded information, the decryption problem still remains.

Watermarking techniques are similar to digital signatures in the sense that they can provide owner and document authentication for digital media. They are usually nonvisibly detectable signals embedded into the media that can be checked, by authorized personnel, to verify the validity of the media and to trace its copyright holders. Watermarking and steganography techniques can also be used to identify times, dates, locations, and information that could be used to cross-reference to a patient, so that misidentification or misfiling of image data under the wrong patient file can be detected and corrected. It is the opinion of the authors that both these technologies will provide valuable solutions for secure CPR systems.

CONCLUDING REMARKS

This article attempted to provide a brief overview of the applications of computers in medical records, the benefits of computerization, and issues concerning widespread deployment of computer-based medical record systems. The computerization of medical records is a vast area of research, employing many people from diverse fields of medicine, science and engineering. While we have attempted to summarize and present the material from our own perspective, the topic itself is explored in great detail by several worthy publications. There are literally thousands of publications that attempt to explain or to solve one or more of the issues presented in this article and to provide much greater detail than is possible in this article. Thus, the authors felt it appropriate to leave the reader with a few resources, both in print and on the World Wide Web (WWW), to obtain more information about computers in medical records.

Much of the material in this article has been inspired from the extensive discussions in Refs. 3 and 22. These books provide interesting observations and refer to a wealth of references that pioneered the computer revolution in the medical field. Two more recent books, (23 and 24), also provide excellent insight into the various aspects of using computers to manage medical records. The WWW contains many websites that provide solid insight into various aspects of medical records management. Ref. 6 is one such site that is constantly updated with information

about upgrading to CPR systems, cost benefit calculators, software vendor surveys, and from basic tutorials on every aspect of CPR management. Refs. 25 and 26 provide excellent evaluations of commercially available software for CPR management.

ACKNOWLEDGMENT

The authors would like to thank Mr. Rodney Long at the U.S. National Library of Medicine, Bethesda, Maryland, for providing the images of the cervix used in the example on steganography.

MICROARRAYS

NEIL WINEGARDEN
University Health Network
Microarray Centre, Toronto
Ontario, Canada

INTRODUCTION

Microarrays allow for the simultaneous, parallel, interrogation of multiple biological analytes. Originally, microarrays were devised as a method by which gene expression could be measured in a massively parallel manner (all the genes in the genome at once), however, recent advances have demonstrated that microarrays can be used to interrogate epigenetic phenomena, promoter binding, protein expression, and protein binding among other processes. The overall process is reliant upon the manufacture of a highly ordered array of biological molecules, which are typically known entities. The features of this array behave as probes, which react with and bind to the unknown, but complimentary material present in a biological sample. Here we will focus specifically on gene expression (deoxyribonucleic acid, DNA) microarrays, which can be used to assay the activity of thousands of genes at a time.

In 1993, Affymetrix published a novel method of using light directed synthesis to build oligonucleotide arrays that could be used for a variety of biological applications (1). Shortly thereafter, a group lead by Patrick Brown and Ron Davis at Stanford University demonstrated that robotically printed cDNA arrays could be used to assay gene expression (2). Now, more than a decade after this initial work was made public, both types of DNA array are commonly found in genomics laboratories.

BASIC PRINCIPLES

A DNA microarray contains a highly ordered arrangement (array) of several discrete probe molecules. Generally, the

Figure 1. Watson–Crick base pairing interactions. During hybridization, specific base-pairing interactions occur by which Thymine (T) binds specifically to Adenine (A) and Cytosine (C) binds specifically to Guanine (G). The binding of these bases to one another is mediated by hydrogen bonding as shown. The GC base pairs are stronger by virtue of the three hydrogen bonds formed compared to only two for AT.

identity of these probes, be they cDNA or oligonucleotides, is either known or can be determined readily. The probes are deposited by some means (see the section Fabrication of Microarrays) onto a solid-support substrate such as glass or silicon. DNA microarrays take advantage of a basic characteristic of DNA, namely, the ability of one strand of DNA to find its complementary strand in solution and bind (hybridize) to it. This hybridization event is highly specific following standard Watson–Crick base pairing rules (Fig. 1).

Gene Expression

With some exceptions, the genetic makeup of every cell in an organism is the same. Each cell has the same complement of genes, which comprise the organism's genome. The subset of genes that are active in a particular cell dictate that cell's function. When we say a gene is active or *expressed*, we mean that particular gene is being transcribed. Transcription is the process by which ribonucleic acid (RNA) polymerase II (an enzymatic complex) reads a gene and creates a complementary copy of messenger RNA (mRNA). The more a gene is transcribed, the more copies of mRNA will be present in a cell. Thus genes that are highly active in the cell will be represented by multiple copies of mRNA, whereas genes that are inactive in the cell will have very few or no copies of mRNA in the cell. Microarrays function to measure the amount of mRNA present in the cells of a biological sample such as a tumor biopsy. The activity of the genes is inferred from this measure.

Gene Structure

In higher eukaryotes, somatic cells (diploid) have two copies of every gene: one maternally and the other

paternally derived. In the context of the diploid cell, each copy is termed an allele. In the case where both inherited alleles are the same for a given gene, that gene is said to be homozygous. If the two alleles are different, then the gene is heterozygous. Alleles may be either dominant (phenotypically manifested regardless of what the other allele is), or recessive (phenotypically manifested only in the absence of a dominant allele). In the case of a heterozygous gene, the dominant allele will be phenotypically manifested and the recessive allele will not. If both alleles are different, but dominant, they are termed codominant and both alleles will elicit a phenotype. The gene is comprised of DNA, which is double stranded. One strand is the sense strand or the strand that encodes the information, which will be ultimately represented in mRNA. The other strand is said to be anti-sense and is the strand of DNA that is actually read by the RNA polymerase to generate the mRNA. DNA has directionality: A gene is transcribed starting at the 3' end of the antisense strand of the DNA and is read toward the 5' end. The resultant mRNA is made from the 5' to the 3' end.

Genes are regulated by specific sequences of DNA that lie outside the coding region of the gene. The first such sequence is the promoter. Promoters bind the transcriptional machinery (RNA polymerase II) that performs transcription. Promoters are found 5' (upstream) of the gene and are proximal to the transcription start site. An additional class of regulatory sequence called an enhancer may be associated with the gene. Enhancers may lie upstream, downstream, or internal (usually in noncoding regions termed introns) to the gene (3). Specific transcription factors bind enhancers and promote recruitment or activation of the basal transcriptional machinery. It is the coordinated function of the promoter and enhancer, with the transcription factors that bind them, that control if a gene is active or not within the cell. Thus, genes are regulated, and can be turned on, off, or modulated up or down by the regulatory mechanisms of the cell.

RNA Isolation

Ribonucleic acid must be isolated from cells in order to prepare the material for hybridization to the array. A cell contains three major species of RNA: mRNA, transfer RNA (tRNA), and ribosomal RNA (rRNA). Together they are referred to as total RNA. For the purpose of gene expression experiments with microarrays, the mRNA is the species we are interested in and represents ~1% of total RNA. In order to isolate total RNA from cells, one of two main modalities is used: solution- or solid-phase extraction. In solution-phase methods, cells are lysed in the presence of isothiocyanate in order to inactivate any RNases (naturally occurring enzymes that nonspecifically degrade RNA). The lysate is then extracted with an acidified phenol:chloroform:isoamyl alcohol solution. The RNA selectively partitions to the aqueous phase of this mixture away from proteins and DNA. The aqueous phase is removed and RNA is precipitated out of solution using isopropyl alcohol at high salt concentrations. Solid-phase methods make use of the variable binding activity of RNA to a silica matrix at high and low salt conditions. Cells are again lysed in the

presence of isothiocyanate. The high concentration of isothiocyanate used in this methodology not only inactivates the RNases, it also selectively precipitates proteins out of solution. The lysate is applied to a column containing a silica filter at the bottom. The lysate is pulled through the column via vacuum or centrifugation, thereby removing the proteins and cellular debris. In this method, DNA may also bind to the column, and as such contaminating DNA is removed by the application of DNase. The column is washed to remove any further contaminants, and then the RNA is eluted from the filter using water.

mRNA Structure

In eukaryotic cells, mRNA has a unique feature that allows researchers to either purify it away from the rest of the RNA or to direct enzymes to it specifically while avoiding the other RNA species. This feature is the polyA tail. The polyA tail is a long stretch of adenine nucleotides found at the 3' end of mRNA, which is added post-transcriptionally. Such stretches of adenine nucleotides do not typically occur naturally in genes or other RNA species. The polyA tail will hybridize to an artificially generated oligonucleotide made up of a series of deoxythymine nucleotides (oligo-dT). If the oligo-dT is coupled to a support matrix (e.g., beads) the mRNA can be pulled out of solution thereby purifying it away from the rest of the total RNA. While some researchers prefer to include this step in their process, it is generally not a requirement for microarray analysis. Rather than purify the mRNA, the oligo-dT can be used as a primer for creating an enzymatically labeled complement of the mRNA.

Labeling

In order to render the RNA visible to a detection system, it is necessary to label it in some manner. While some laboratories choose a direct methodology of chemically labeling the mRNA itself, it is most common to work via a cDNA or crRNA intermediate that is labeled enzymatically.

The simplest methodology involves creating labeled cDNA. In this technique, the RNA is reverse-transcribed (DNA is made from an RNA template) by an enzyme named reverse transcriptase (RT) (for sample protocols, see Ref. 4). Reverse transcriptase requires a small oligonucleotide primer that binds to the RNA creating a short double-stranded region (an RNA:DNA hybrid). In order to ensure that the RT enzyme reads only the mRNA, the polyA tail of mRNA is exploited by using a primer made of a stretch of several (usually 20–25) thymine residues. The resultant DNA is the complement of the RNA and it is thus referred to as complementary DNA (cDNA). The RT reaction requires that free nucleotides (each of A, C, G, and T) are present to create the DNA. If one of these nucleotides is chemically modified with some detectable molecule (such as a fluorophore), then it will be incorporated into the cDNA strand, and that cDNA will be detectable with a fluorescent reader. Alternatively, it is possible to use a reactive molecule (such as amino-allyl) in place of a fluorescent molecule. After incorporation into the DNA, the DNA is then coupled to a reactive form of a fluorophore

(usually a reactive ester). This latter implementation of the method has an advantage in that the amino-allyl modifier is a much smaller chemical group that is incorporated much more efficiently into DNA than a bulky fluorescent moiety.

Often the amount of RNA available is limiting and cannot be detected by standard means. In this case, it is generally necessary to amplify the amount of material present. A typical microarray experiment usually requires 5–10 μg of total RNA in order to be able to obtain useful data. When researchers are working with diminishingly small samples, such as from a needle biopsy or a fine needle aspirate, it is often not possible to obtain this amount of total RNA. To overcome this limitation, various amplification strategies have been adopted. The most popular method of amplification is based on the protocols of Dr. James Eberwine from the University of Pennsylvania (5). In this technique, RNA is converted into cDNA using the same method described above with two key differences: (1) there is no labeled nucleotide incorporated and (2) the oligo-dT primer has another short sequence of DNA appended to it that represents a T7 promoter region. The T7 promoter is a bacteriophage-derived sequence that initiates transcription by T7 polymerase. After the cDNA is created, a second strand is generated creating a double-stranded artificial gene with a T7 promoter on one end. This artificial gene is then transcribed by the addition of T7 polymerase, which is allowed to make numerous transcripts of the gene. The transcripts that are obtained can either be labeled directly, or they in turn can be turned into labeled cDNA using standard methodologies described above. The resultant RNA is now actually the opposite sequence of the original mRNA, so it is said to be cRNA (complementary RNA).

The Affymetrix GeneChips utilize an amplification system based on T7 transcription as described above. During the production of cRNA, biotin modified nucleotides are incorporated. Posthybridization (see the section on Hybridization) the arrays are stained with a streptavidin bound fluorophore. Streptavidin is a protein that specifically and tightly binds to biotin molecules, allowing the fluorophore to be attached to the cRNA.

A clean-up step is required to remove any free, unbound detection molecules. This step helps to ensure that background signal is kept to a minimum. There are two main methods by which such purification is performed, one is based on standard nucleic acid purification systems, similar to the RNA isolation method described earlier, and the other is based on size exclusion. For the first method, a nucleic acid purification column is utilized. The cRNA or cDNA binds to the silica filter, but the less charged free nucleotides flow through. After a series of washes, the cRNA or cDNA is eluted from the column. The second methodology utilizes a membrane filter (usually incorporated into a column) that has a defined pore size. The large cRNA and cDNA molecules are retained on the membrane; where as the small free nucleotides flow through. The column is then inverted and the cDNA or cRNA is then eluted off the column by flowing wash buffer in the opposite direction. This purified labeled material is then ready for hybridization to the array.

Hybridization

Microarray technology relies on the natural ability of single-stranded nucleic acids to find and specifically bind complementary sequences. Purified labeled material is exposed to the spotted microarray and the pool of labeled material “self-assembles” onto the array, with each individual nucleic acid (cDNA or cRNA) species hybridizing to a specific spot on the array containing its complement. The specificity of this interaction needs to be controlled, as there may be several similar and related sequences present on the array. The control of hybridization specificity is accomplished through the adjustment of the hybridization stringency. Highly stringent conditions promote exact matches where as low stringency will allow some related, but nonexact matches to occur. In a microarray experiment, stringency is typically controlled by two factors: the concentration of salt in the hybridization solution and the temperature at which hybridization is allowed to occur.

High salt concentrations tend to lead to lower stringency of hybridization. Both strands of nucleic acid involved in the hybridization event contain a net negative charge. As such, there is a small repulsion between these two strands, which needs to be overcome to bring the labeled nucleic acid into proximity of the arrayed probe. The salt ions cluster around the nucleic acid strands creating a mask and shielding the electrostatic forces. Higher salt concentrations have a greater masking effect, thus allowing hybridization to occur more easily. If salt concentrations are high enough, the repulsion effects are completely masked and even strands of DNA that have low degrees of homology may bind to one another.

Temperature is another important factor. Every double-stranded nucleotide has a specific temperature at which the two strands will “melt” or separate. The temperature at which exactly 50% of a population of pure double-stranded material separates is termed the melting temperature (T_m). The T_m of a nucleic acid is controlled partially by the length of the strand and partially by the percentage of G and C residues (termed the GC content). The G and C residues bind to one another as a Watson–Crick base pair. This pairing interaction is the result of three hydrogen bonds forming. The other potential base pair in a DNA hybrid, A:T, only has two such hydrogen bonds and thus the greater the GC content of the nucleotide, the more stable the hybrid. At very low temperatures, nonstandard Watson–Crick base pair interactions can also occur causing noncomplementary sequences or sequences that are <100% matched to form hybrids. It is necessary therefore to find a temperature that will prevent or melt nonspecific hybrids, but allow the specific interactions to occur. For a microarray, this presents a challenge as there are thousands of specific interactions that must be accommodated. In the case of oligonucleotide arrays, the design of the oligonucleotides to be spotted takes this issue into account and probes are designed that tend to fall within a narrow window of potential melting temperatures. cDNA arrays are more difficult because the sequences spotted vary greatly in both GC content and length. In such cases, it is often true that conditions that represent somewhat of a “compromise” are necessary.

Hybridization kinetics can generally be modeled as shown in Eq. 1(6). The change in the amount of hybridization product LS over time is a function of the decrease in the concentration of labeled target L and free spotted DNA S over time. To simplify the equation, the rate of hybridization is equal to some rate constant k multiplied by the product of the concentrations of L and S. Thus hybridization rate is a direct function of the concentrations of the labeled target molecule and the DNA probe in the spot.

$$\frac{d[LS]}{dT} = -\frac{d[L]}{dT} - \frac{d[S]}{dT} = \frac{d[L-S]}{dT} = k[L][S] \quad (1)$$

In the case of an oligonucleotide microarray, it is often the case that the number of spotted DNA molecules is in great excess to the number of target molecules. As such, the concentration of the spotted DNA probe remains fairly constant and can be considered part of the constant k . Thus the equation for hybridization can be simplified as shown in Eq. 2 (6), where the rate of hybridization is typically driven by the concentration of the labeled target molecules alone.

$$\frac{d[LS]}{dT} = k'[L] \quad (2)$$

In the case of two color oligonucleotide arrays, the two labeled samples compete for hybridization to the probe that remains in excess and thus hybridization is simply a reflection of the concentrations of each of the two labeled targets L_1 and L_2 [Eq. 3(6)].

$$\frac{d[L_1S]}{d[L_2S]} = \frac{k'_1[L_1]}{k'_2[L_2]} \quad (3)$$

The situation becomes somewhat more complex when the probe molecules are not in excess of the target molecules. This is often the case with cDNA arrays. In these cases, the concentration of the spotted probe does change significantly as hybridization occurs and thus each of the labeled targets L_1 and L_2 hybridize in a manner described by Eqs. 4 and 5 (7).

$$\frac{d[L_1S]}{dT} = k_1[S][L_1] = k_1((S^0) - [L_1S] - [L_2S])([L_1^0] - [L_1S]) \quad (4)$$

$$\frac{d[L_2S]}{dT} = k_2[S][L_2] = k_2((S^0) - [L_2S] - [L_1S])([L_2^0] - [L_2S]) \quad (5)$$

In such a case, the rate of hybridization is affected by the change in the concentrations of the spotted probe from the initial concentration S^0 , where S^0 changes as the probe molecules are bound by either L_1 and L_2 .

When looking at differential hybridization between the two targets, we can represent the kinetics as shown in Eq. 6 (7).

$$\frac{d[L_1S]}{d[L_2S]} = \frac{k_1([L_1^0] - [L_1S])}{k_2([L_2^0] - [L_2S])} \quad (6)$$

If one is to assume that the two fluorescent molecules used in a two-color experiment behave similarly, and that the rate of hybridization of the two labeled targets is the same, we can say $k_1 = k_2$. It has been demonstrated that under ideal conditions and when the hybridization reaction

is allowed to continue to equilibrium that the ratio of the concentrations of each possible hybrid L_1S and L_2S is equivalent to the ratio of the original concentrations of the two targets L_1 and L_2 [Eq. 7 (7)]. This point is important because it is the basis for microarrays to work, assuming that the ratios read from the scans during data analysis are reflective of an actual biological condition.

$$\frac{[L_1S]}{[L_2S]} = \frac{[L_1^0]}{[L_2^0]} \quad (7)$$

The goal of microarray hybridization is to produce a result for which the signal obtained from specific hybridization is very strong when compared to any background signal that may be obtained by a nonspecific adsorption of labeled material to the substrate, or nonspecific binding to spotted elements. To reach this goal, it is common to use certain nonspecific blocking reagents in the hybridization solution. Frequently, nucleic acids from sources known not to contain any sequences that will interfere with specific hybridization are used. For example, in a hybridization of a human sample to an array, one might use yeast tRNA and salmon sperm RNA as competitors to bind any regions of the substrate or probes that have a generic nucleic acid binding capacity. These nucleic acids are nonlabeled and will therefore not contribute any signal when the array is scanned.

Washing

Unlike traditional northern blots, the majority of the stringency of a microarray assay is accomplished at the hybridization step. The washing step of a microarray experiment is a critical operation, but is important more as a means to remove unbound material in order to reduce background signal than it is to control the specificity of the signal obtained.

Wash buffers generally contain two components: a salt solution and a detergent. The salt solution, frequently sodium chloride sodium citrate (SSC), is set to a concentration that supports the maintenance of the hybridized molecules. This concentration most frequently falls in the $1 \times$ to $2 \times$ concentration range with some labs using as low of a concentration as $0.1 \times$ ($1 \times$ SSC contains $0.15 M$ NaCl and $0.015 M$ Na-citrate).

The detergents used in wash buffers help to remove the unbound fluorescent molecules that would normally stick to the surface of the slide. The detergent acts as a surfactant and helps to isolate and remove the unbound fluorescent material. Typically, an anionic detergent such as sodium dodecyl sulfate (SDS) is used for this purpose.

The temperature for the washes varies depending on the stringency of the wash solution being used. As with hybridization, the combination of temperature and salt concentration determines the overall stringency of the washes.

After washing the microarrays, it is generally necessary to perform a rinse. The rinse is typically a solution similar to the wash solutions without the detergent. If detergent remains on the slide after drying, the solution may fluoresce particularly if the labeled material has been trapped in detergent micelles.

Scanning

It is necessary to use an imaging device to detect the fluorescent labels present on the hybridized microarray. In general, the imaging device must contain an excitation light source, an emission filter, and a light gathering device.

During scanning, the labeled material, be it fluorescent or some other form of detectable molecule, is imaged and the resultant data is converted to a digital image. The optimal resolution at which the image is scanned is dependent on the size of the features and on their interspot spacing. A general rule of thumb is that the resolution of the image should be such that the pixels represent one-tenth of the diameter of the spot. For spotted arrays, for example, the features tend to be on the order of 100 μm in diameter and thus 10 μm resolution is frequently used. Affymetrix's technology, however, can generate features that are 11 μm square; in this case, a much higher resolution of down to 1 μm is required.

Most commonly, the image that is generated is a 16-bit grayscale TIFF (Tagged Image File Format) image (Fig. 2). The 16-bit depth of the image provides a total of 65,536 gray levels providing a possibility of more than five orders of magnitude range. The TIFF format is important because it is a universally accepted format that is LOSSLESS; that is, even with compression, this format retains all image information. The images can then be imported into the appropriate image quantification software.

Image Quantification

After scanning, it is necessary to extract data from the images. Image quantification generally starts with segmentation. Segmentation is the process by which pixels that represent the signal are isolated from those that represent background. During segmentation, the discrete areas of the image that represent the spotted DNA material are identified and digitally isolated from the remainder of the image. The intensities of all of the

pixels in the individual spot are averaged to determine the overall spot intensity. This spot intensity is proportional to the amount of material hybridized to that region, with higher intensities resulting from increased numbers of hybridized molecules. Each spot, for each channel (in the case of two color microarrays) is quantified, and the resultant data are tabulated. Other data may also be extracted at this stage. It is common to also obtain intensity data for the area outside of the individual spots. This value represents the background of the image and indicates the amount of signal that would have been obtained regardless of a specific hybridization event. It is common, however, not universal, to subtract the background values from the signal intensities of the spots.

There are several means by which segmentation can be carried out. In the most basic setup, a fixed shape (usually a circle) is placed over each spot. The entire complement of pixels lying within the circle is used to determine the average intensity. Pixels lying outside of one of these circles are deemed to be background signal. More advanced segmentation algorithms attempt to account for the fact that most of the spotted features on a microarray are in fact not perfectly uniform. Spots may deviate from a true circular shape, or may have regions within the circle in which DNA was not attached (creating a spot that is reminiscent of a doughnut). In addition, it is not uncommon for each of the spots to have some degree of variance in their diameter. The more advanced methods utilize various algorithms and statistics to determine which pixels actually represent signal and which are more representative of background.

Image quantitation software then processes the entire image and produces a table of results that represents the signal, and the background for each feature on the array. These packages may also export various other data, which can be used in quality control analysis such as standard deviations, coefficients of variance, circularity, or uniformity of the spot, and so on. This data table can then be processed as part of the data analysis.

Figure 2. Arrays imaged on a microarray scanner are presented as 16-bit grayscale TIFF images. The picture shown represents a small subsection of a larger array. Each spot is 100 μm in diameter and the spot-to-spot spacing is 200 μm in this image. The image was scanned at 10- μm resolution.

Data Analysis

An exhaustive description of the process of DNA microarray data analysis is far beyond the scope of this article (for an excellent review see Ref. 8). The exact process followed depends greatly on the experimental design and the question being addressed. There are, however, some basic principles that tend to be fairly common in dealing with microarray data: statistical analysis of data, supervised and/or nonsupervised data mining, data visualization, and validation are all key components.

Statistical analysis of microarray data comes into play in two main areas. The first is to determine which spots are reliable and provide sufficient data. Spots that have a high degree of variance across replicates, for example, are likely not able to provide reliable data. These hypervariable genes or signals need to be filtered from the data so as to not skew the results of data mining. Statistics may also play a role in supervised data analysis.

There are two major categories of data mining: supervised and nonsupervised. Supervised data mining utilizes algorithms in which the user imparts restrictions on how the data is grouped. For example, in an experiment where a cohort of patients was tested in which one group was healthy and the other group was afflicted with a particular disease, one would indicate to the algorithm which arrays were from the healthy patients and which were from the patients with disease. The algorithm then tests the data to find genes that are markers for the diseases. Specifically, each gene is tested to see if the expression levels for that gene are statistically significantly different in each of the two patient groups. The goal is to find a series of genes that can act as markers that are diagnostic of the disease.

In nonsupervised clustering, the algorithm is not given any indication as to how the individual samples are related. In true nonsupervised clustering, the algorithm is not even told how many groups exist. The data are analyzed and the samples are grouped based on similarity metrics. The classical methods of nonsupervised clustering include hierarchical clustering and principal components analysis (PCA). The algorithms generally display the data via some visualization pattern such as the canonical "plaid" expression patterns seen from hierarchical clustering. The researcher then overlays the grouping information onto the patterns provided to see if the individual groups naturally separate from one another. In other cases, this methodology may be being used to determine how many groups there truly are, as the researcher may not have this information a priori. In such cases, the groups can then be further examined to see if there are differences in treatment response, survival, or any other characteristic desired. Generally, after this technique is performed one will attempt to look for clusters of genes in the patterns that distinguish between the different groups and again use these genes as markers.

Regardless of the methodology utilized, it is extremely important to validate the data. Cross-validation strategies are various, but in their most basic form, one obtains a cohort of patients to profile. A subset of this cohort is used to look for potential markers. Once the markers have been

identified, the remaining patients are tested and only the identified markers are used to try and group the patients. If the markers are able to stratify the patients into their appropriate groups, then the markers are considered to be viable and may provide beneficial diagnostic ability. On occasion, however, the validation set is not properly grouped. In such cases, the markers are only useful for the narrow set of patients used in the initial tests and more testing is required to find a viable set of markers.

FABRICATION OF MICROARRAYS

There are two main methodologies for manufacturing microarrays, which differ in the means by which the probe material spotted onto the arrays is prepared. In one methodology, the DNA to be spotted is generated *in situ* using either standard or modified phosphoramidite chemistry. (Phosphoramidites are reactive forms of each of the nucleotides that make up DNA. Phosphoramidite chemistry is a well-defined process by which moderate length stretches of DNA can be created with any specific sequence.) This method is used by Affymetrix and Agilent, the two largest commercial suppliers of microarrays, although both groups use a different approach to the *in situ* synthesis.

Other groups use *ex situ* synthesis, whereby the DNA material is either prepared as PCR products (cDNA) or oligonucleotides manufactured using standard phosphoramidite synthesis. Once this material is prepared it is spotted onto the array substrate using either contact or noncontact printing methodologies. Amersham (now GE Healthcare) and Applied Biosystems use this methodology to make microarrays as do almost all of the "homebrew" laboratories that make microarrays in house.

Fabrication of DNA Arrays *In Situ*

There are two main approaches to the generation of microarrays by *in situ* synthesis of DNA: photolithography and inkjetting. Affymetrix, the industry leader uses a proprietary photolithography process to mask off areas of the array, protecting some areas, and leaving others available for the DNA synthesis reaction to occur (1). This is a multistep process requiring several masks per array to be made. Each synthesis reaction is performed sequentially. For each nucleotide position, there are four possible masks (one for each of A, G, C, and T). Thus, an array comprised of 25-mer oligonucleotides would require ~100 masks to complete the process (typically ~70 are required for an array due to the sequences used). Affymetrix uses a modified phosphoramidite chemistry for synthesis of the oligonucleotide chains; whereas standard phosphoramidite chemistry uses acid labile protection groups, the Affymetrix technology utilizes groups that can be removed by ultraviolet (UV) light. The Affymetrix technology allows for extremely high density arrays of hundreds of thousands of features to be prepared on very small substrates of <1 cm².

Other groups have developed technologies that allow them to get around the need for multiple masks to be made for each array design. The pioneer in this area was Nimblegen, who uses digital light processor (DLP)

micromirrors to create the masks (9). Each of these DLP units (used typically in AV projectors and large screen televisions) comprises thousands of tiny ($10\ \mu\text{m}^2$) micromirrors. The micromirrors can be individually addressed and the angle of the mirrors changed to allow light to pass through. In the “open state”, the micromirror directs light onto the surface of the microarray, allowing DNA synthesis to occur. In the “closed state”, the micromirror reflects light away from the surface, disallowing DNA synthesis. A computer controls the mirrors and thus each DLP unit has a near infinite number of combinations that can each be controlled, and as such, a single unit can create any pattern desired on the array. Nimblegen uses the same chemistry as Affymetrix, using light activated deprotection of the phosphoramidites. A somewhat newer entry into this area is Xeotron (now part of Invitrogen). Xeotron also uses micromirror DLPs to address the masks, however, they have also incorporated small microfluidic channels on their chips. Each feature is placed in a microscopic well on the chip. Rather than using the modified phosphoramidite chemistry of Affymetrix and Nimblegen, Xeotron uses standard chemistry, but has instead employed a caged acid that can be freed by light (10,11). As such, the acid that controls deprotection of the nascent oligonucleotide can be directed to specific locations by light. The Nimblegen and Xeotron technologies have the advantage of being highly amenable to custom array generation, however the Affymetrix technology is particularly well suited to mass production of a standard array. Each of these approaches has found customers in the marketplace.

A third approach to *in situ* synthesis of the oligonucleotides involves ink-jet spotting. Agilent uses this technology (developed by Rosetta Inpharmatics) in which each of the reactive phosphoramidites (A, G, C, and T) are loaded in to a separate “ink-cartridge” to allow for control of which nucleotide is added to each spot during the synthesis stage (12,13). This methodology eliminates the need for masks, but does require very high precision robotics as the print head must return to the same spot many times, within micron accuracy, during the course of synthesis. This technology draws from the strength of each of the others mentioned in that it is relatively easy to customize the design of arrays, and yet, mass production of arrays is possible using a large robotic system.

Fabrication of DNA Arrays *Ex Situ*

Some of the commercial vendors and nearly all of the “homebrew” microarray centers utilize and approach of spotting DNA that was prepared *ex situ*. In the case of cDNA arrays, the spotted material is prepared by polymerase chain reaction (PCR), whereas oligonucleotide arrays are generated using oligos created via high throughput oligo synthesis. The DNA material is purified and placed into a specific spotting buffer that is compatible with the substrates being used.

The DNA is typically aliquoted out into multiwell plates (96, 384, or 1536 wells /plate) to facilitate transfer by the arraying robot. The buffer that the DNA is placed in has several functions. First, the buffer stabilizes the DNA to prevent it from degradation. Second, the buffer must

provide an appropriate surface tension to ensure that the spots that are placed on the substrate are of a controllable size and uniform in shape. Of similar importance, however, is that the buffer must provide conditions that are compatible with the attachment chemistry that is going to be utilized.

The DNA may either be coupled to the slide through rather simple electrostatic interactions or via a specific coupling reaction. Electrostatic interactions are mediated by using a uniform positively charged substrate that attracts the negatively charged DNA. Often the substrates used are silylated to provide reactive amine groups on the surface. Alternatively, one may coat the slides with a chemical such as poly-L-lysine, which simply adsorbs onto the substrate and provides a net positive charge. This type of interaction is mass based. As such, there is a maximum mass of DNA that can bind to any one spot on the substrate. Longer DNAs will be represented by fewer copies than shorter DNAs. To overcome this, it is possible to use more specific interactions by using modifiers on the DNA that will react with certain groups on the slide. The two most common such modalities involve aldehyde or epoxide chemistry. In this method, the DNA is modified with a primary amine group. The substrate has reactive aldehydes or epoxides that will react specifically with the primary amine to form a covalent bond (Fig. 3). This type of interaction is molarity based, and as such, with the exception of steric effects, the number of DNAs that bind per spot is relatively equivalent regardless of length.

EQUIPMENT

The manufacture of microarrays, and their subsequent use requires some very specialized equipment. Generally, a facility that produces microarrays will require some advanced robotics for fabrication. A laboratory that uses arrays will require scanning devices to read the arrays. Due to the relatively high costs of these pieces of equipment it is common for many people to rely on core facilities for some or all of the process.

Arraying Robots

Ex situ prepared DNAs are spotted onto the microarray substrates via robotics (Fig. 4). Robotics are required to accurately position the printing devices over the slides to create the arrays. The majority of systems utilize pins and direct contact to deposit the DNA material. In this system, a printhead with several spotting pins in a defined arrangement is used to dip into the multiwell plates and pick up the material to be spotted. The typical operation sequence of an arrayer robot may include:

1. Dipping the printing applicators (pins) into a source plate to pick up DNA samples. Each applicator picks up a separate DNA sample from an individual well in the plate. Typically 32–48 pins are used at one time.
2. Movement to a blot-station to preprint from the pins. This step removes excess solution from the pins to ensure that the spots that are printed onto the arrays

Figure 3. Covalent attachment of amino-modified DNAs to aldehyde (a) or epoxide (b) slides is possible. An amino-modified DNA reacts with an aldehyde surface by a Schiff's base reaction. The resultant Schiff base must be reduced with an agent such as sodium borohydride (NaBH₄) to prevent reversal of the reaction.

- are uniform in size and do not run into one another causing contamination.
3. Movement to the slide platform. The print head then moves over the slide platform taking position over the first slide.
4. Printing onto the arrays. The print head moves down bringing the pins in contact with the slide. The DNA solution held in the pins by capillary action is spotted onto the slide. The printhead then moves to the next slide position and again spots onto the slide. This

- process is repeated until all of the slides on the platform have been printed.
5. Washing the pins. The print head then moves the pins to a wash station. Although there are many configurations possible, the basic principle is to use water or some other solution to remove the excess liquid from the pins and then to dry the pins (under vacuum or stream of air). This process may be repeated several times to make sure there is no carryover.

Figure 4. A microarraying robot. The robotic arrayer prints DNA onto glass slides with very high precision. Robots such as this have extremely high accuracy, on the order of 10 μm or less.

6. Loading the next sample. The print head returns to the source plate to pick up the next set of samples.

In a typical high throughput system, such as those offered by Bio-Rad, BioRobotics, GeneMachines, Genetix, and Telechem International, 48 pins are used at one time. The entire operation sequence described above may take 3–4 min to complete for 100 arrays. Often arrays may contain 20,000–40,000 spots. As such, a typical print run may require 600 or more cycles through the operation sequence, which can take as long as 30 h or more to complete.

Hybridization and Fluidics Stations

Certain array platforms require that a specific hybridization and/or fluidics station be utilized. In the case of spotted arrays (home-brew in particular), this is usually an option and often a case of personal preference. In these cases, a hybridization station may be utilized to improve mixing of the hybridization solution over the array. The rate of diffusion of a labeled nucleic acid in solution is actually very low, and as such, some researchers prefer to use an automated station that performs mixing of the solution.

In the case of Affymetrix GeneChip technology, a specific hybridization and fluidics station are required. The hybridization station is simply a rotating incubator in which the chips are placed. A bubble that is introduced into the sealed array cartridge moves around during

rotation creating a mixing effect. The fluidics station is a more advanced system that is required to introduce the various labeling components and wash solutions required. This station allows the user to keep the cartridge sealed without having to attempt to pipette solutions in and out.

Scanners

While some microarray imagers such as the Perkin Elmer ScanArray and GeneFocus DNAScope are confocal scanners, this is not a strict requirement. Confocal imaging serves to eliminate extraneous signals, but reduces the light gathering ability of the device. There are >10,000 commercial microarray scanners in the field capable of reading standard glass microarrays. The leading scanner makers include Agilent, Axon, Bio-Rad, GeneFocus, PerkinElmer, and other vendors. The laser scanner uses one or more lasers with wavelengths appropriate to the fluorophores being used. The most commonly used fluorophores for microarrays are cyanine 3 and cyanine 5 (or fluors with equivalent spectra). Cyanine 3 has an absorbance maximum of 550 nm and emission maximum of 570 nm. There are 2 main lasers used in scanners to excite this fluorophore: “Gre-Ne” (green neon) gas lasers and Nd:YAG (neodymium doped yttrium aluminum garnet) frequency doubled solid-state diode lasers. Cyanine 5 has an absorbance maximum of 650 nm and an emission maximum of 670 nm. There are two main lasers used in scanners to excite this fluorophore: standard He–Ne gas lasers and red diode lasers. Table 1 shows some of the characteristics of these two dyes, along with two other popular dyes, Alexa 555 and Alexa 647, which have spectra that are very similar to those of Cy3 and Cy5 respectively (Fig. 5).

Cyanine 3 and 5 have some important features that make these dyes particularly suitable for use in microarray analysis. The spectra of these dyes have little overlap and can generally be separated from one another with little to no cross-talk. In addition, these fluors have a somewhat unique property in that they are brighter when dry than when wet. Most fluorophores have the opposite behavior, which is impractical for microarrays because the scanners generally cannot handle wet preparations.

The other major class of microarray imager is a CCD (charge coupled device) based system. In general, these imagers use a white light source to excite the fluorophores. The fluorescent light that is emitted is captured by the CCD and converted into a digital image. Rather than scanning the slide, a CCD based imager tiles together several sections of the slide to create an image of the entire surface. This tiling can create a stitching effect whereby the “seams” of the images may not be completely smooth.

Table 1. Key Characteristics of the Most Commonly Used Fluorophores for Microarray Analysis

Fluorophore	Excitation Max, nm	Emission Max, nm	Molar Extinction Coefficient	Molecular Weight
Cy3	550	570	150,000	766
Cy5	649	670	250,000	792
Alexa555	555	565	150,000	1,250
Alexa647	650	668	239,000	1,250
Phycoerytherin	566	575	19,600,000	240,000

Figure 5. Representative spectra of the fluors commonly used in spotted microarray experiments. Alexa Fluor 555 and Cy3 are excited by green wavelengths of light whereas Alexa Fluor 647 and Cy5 are excited by red wavelengths of light. One green excited and one red excited fluor may be used at the same time as there is little overlap in their excitation spectra.

This problem can be overcome with advanced lighting systems and software.

Affymetrix arrays use a different labeling chemistry for detection relying on the naturally occurring fluorescent protein phycoerythrin. Phycoerythrin is a naturally occurring pigment protein from light harvesting algae that absorbs strongly at 566 nm and has an emission peak at 575 nm. It is a very bright fluorophore having a molar extinction coefficient that is 80 times as high as the standard Cy3 and Cy5 molecules. The limitation of this molecule is that it is also 200 times larger, making the number of molecules that can be incorporated per sequence much less. As such, this molecule can only be applied to the DNA posthybridization for fear that it would create steric interference.

MICROARRAYS AS MEDICAL DEVICES

To date, microarrays have mostly found use in basic research applications, and have yet to make a strong impact on the diagnostic market. [During the preparation of this text, Roche received FDA clearance for the first ever array based diagnostic chip. The AmpliChip CYP450 based on the Affymetrix platform was approved in January of 2005 (see <http://www.roche.com/med-cor-2005-01-12>).] Microarrays have indeed been used to study many diseases including various cancers, cardiovascular disease, inflammatory disease, psychiatric disorders and infectious disease. This basic research will ultimately lead to the identification of potential therapeutic markers for drugs for diagnostics. The potential of microarrays extends beyond target discovery, however, and will eventually impact on the way that medical care is performed.

Target Discovery

The use of microarrays in basic research laboratories has often focused on target discovery. In these applications, microarrays are used to profile a particular

disease where disease tissues are compared to healthy tissues either from the same patient or from a separate test population. In such experiments, the goal is to find genes that are differentially regulated (either up or down) in the disease state compared to a healthy tissue. Such genes are thought to be involved in the disease state or in the cellular response to the disease. As such, these genes are potential diagnostic markers and may also represent drug targets.

Drug/Lead Discovery

Microarrays can also be used once the target has been identified. It is possible to use microarrays to screen potential therapeutic compounds, for example, to determine which candidates reverse the pattern of gene expression that is indicative of disease. Microarrays have been even more effective in looking at toxicity of lead compounds. One of the leading contributors to failure of a pharmaceutical compound is toxic or off target events. Microarrays have proven useful in screening for the up-regulation in toxicity related genes. In addition, it is possible to determine if the compound creates other effects that while not toxic *per se* could cause undesirable side effects from nonspecific interactions. Often toxicity models are tested in model organisms such as rats or dogs. Several toxicity specific arrays have been developed that allow for profiling of genes in these model systems rather than human cells.

Diagnostics and Prognostics

One of the more promising areas for microarrays to have direct impact as a medical device is in the area of diagnostics and prognostics. As mentioned under target discovery, basic research has often strived to look for a panel of genes that can be used as a molecular fingerprint of a disease. There are numerous publications in which researchers have attempted to use molecular profiles to correlate to patient outcome, disease state, tumor type, or any of several other factors. DNA

microarrays are particularly well suited to this type of analysis. Many complex diseases are multifactorial; rather than a single prognostic or diagnostic marker being present, it may be necessary to look at several genes at one time. Microarrays allow for identification of a panel of genes, which when looked at together may provide diagnostic or prognostic power. Although it has not become common practice yet, there are examples of microarrays being used to prescreen patients on the basis of a molecular profile (14).

Other attempts are being made at using microarrays to study infectious disease. Often times a patient may present with a set of symptoms that could be indicative of several different infectious agents. It is possible to prepare a microarray that would identify the agent as well as to subtype the bacterium or virus on the basis of pathogenicity. This particular application may prove very useful in identifying not only the infectious agent, but also the best course of treatment.

Pharmacogenomics and Theranostics

A concept that is gaining in popularity is pharmacogenomics or theranostics (15). Both of these terms refer to the idea of tailoring a patient's treatment or therapy on the basis of their genetic makeup. Many pharmaceuticals on the market have not known any potentially serious side effects in a subset of patients. In addition, there are typically at least some patients that are nonresponders to a particular treatment. These effects are often times the result of the patient's genetic make-up. Most of the work in this area has focused on genotyping: looking at certain variable regions of DNA and determining which variants are present in people who have negative reactions or in people who respond well to a treatment. It is hoped that in the near future it will be possible to screen a patient and determine which of a panel of drugs will be most beneficial. Perhaps even more important, it will be possible to prevent serious negative outcomes by avoiding treatment of a patient that will have a poor reaction to a drug. Theranostics also involves monitoring a patient through a course of treatment. It is possible that a patient can be screened during treatment to ensure that the therapy is working as expected. If a change occurs, the physician would be able to alter the therapy to ensure that the disease is treated in the most effective way possible.

SUMMARY

Microarrays provide a means to screen hundreds to thousands of biological analytes in parallel. These analytes can be DNA, RNA, or protein. DNA microarrays allow for rapid profiling of gene expression. While there are a few competing platforms that can be utilised, the basic principles are the same: RNA from a biological sample is extracted, labeled and applied to an array of DNA probes. Signals generated from the array indicate which genes are active and which are not. The ability to screen multiple tissues or patients make microarrays particularly well suited to uncovering the complex gene networks involved in disease. While typically used in basic research applications for

target or marker discovery, the future will most likely see microarrays used in diagnostic applications and for tailoring medical treatment.

INTRODUCTION

Infectious diseases accounted for 25–33% of the estimated 54 million deaths worldwide in 1988 (1), of which more than half are attributed to tuberculosis, malaria, chronic hepatitis B, diarrheal diseases, and human immunodeficiency virus/Acquired Immune Deficiency Syndrome HIV/AIDS. The incidence of more than 30 diseases identified since the mid-1970s continues to grow, which include HIV/AIDS, liver disease due to hepatitis C virus, cholera, tick-transmitted Lyme disease, foodborne illness caused by *E. coli* O157:H7 and *Cyclospora*, waterborne disease due to *Cryptosporidium*, and the hantavirus pulmonary syndrome. Additionally, the first known cases of human influenza caused by the avian influenza virus, H5N1, were identified in Hong Kong in 1997 (2).

Although death due to infectious diseases in the United States remains low relative to that of noninfectious diseases, their occurrence is increasing. In 2000, the Federation of American Scientists reported that infectious-disease-related death rates nearly doubled from 1980 to 170,000 annually (1). Many of these diseases, most recently the West Nile virus, were introduced from outside the U.S. borders by international travelers, immigrants, returning U.S. military personnel, or imported animals and foodstuffs. Still, the most dangerous infectious microbes reside within U.S. borders. Four million Americans are chronic carriers of the hepatitis C virus, a significant cause of liver cancer and cirrhosis. It is predicted that the death rate due to hepatitis C virus infection may surpass that of HIV/AIDS in the next five years. Influenza viruses are responsible for approximately 30,000 deaths annually. In addition, hospital-acquired infections are surging due to highly virulent and resistant pathogens such as *Staphylococcus aureus*.

The burden of identifying and treating infected individuals and controlling disease outbreaks generally lies with physicians, hospitals, and first responders. Table 1 contains important characteristics for several of the more common pathogenic microorganisms. As evidenced by this noninclusive table, a wide variety of microorganisms exists from which the specific diseasecausing microbe must be identified. In addition, the number of cells or particles that can provide an infectious dose is often extremely low. For example, the infectious dose of *E. coli* O157:H7 is as low as 10 cells (3), which poses a significant challenge to health-care professionals and first responders who must quickly identify the infectious agent. Antimicrobial treatments that attempt to neutralize all possible infectious pathogens are often not possible or safe. Depending on the nature and severity of the infection, a delay of only a few hours in providing the proper therapy may lead to death.

Medical Microbiology

Medical microbiology is the discipline of science devoted to identifying microbial agents that are responsible for infectious disease and elucidating the mechanism of interaction between the microorganism and human host. Historically, microbiologists have used plating, microscopy, cell culture, and susceptibility tests to identify and study microorganisms. In the hospital and clinical diagnostic laboratory, these, methods are still widely used and will be briefly discussed in this article. The general procedure for isolation and identification of infectious and parasitic microbes is (1) specimen collection and streaking onto culture plates for production of isolated bacteria colonies, (2) staining and microscopic analysis, (3) cell culture in various media, and (4) antibiotic susceptibility testing.

Plating. Plating entails the streaking of a specimen onto a solid nutrient media-filled Petri dish and incubation at 35–37 °C. Under these conditions, a single bacterium divides and eventually produces a colony that is visible to the eye (Fig. 1). A visible colony generally contains more than 10^7 organisms. The colony morphology, color, time required for growth, appropriate media, and other growth conditions are used to characterize the microbe. The incubation time required for growth of a colony from a single cell is dependent on the growth rate of the microorganism. Fast-growing organisms such as *E. coli*, with a doubling time of 30 minutes, would require approximately 13 hours to produce a colony of 10^7 organisms. More typically, microorganisms require several days to a week to generate visible colonies. The plated specimen is often a complex solution such as blood, urine, feces, or sputum containing diverse native flora in addition to the infectious microbe. Plating serves as a method to isolate the infectious microbe as each

Figure 1. Colonies of *E. coli* grown on LB +ampicillin and X-gal +IPTG agar media in a Petri dish.

Table 1. Characteristics of common pathogenic organisms

Organism	Site(s)	Disease(s)	Incubation period	Mode of transmission	Infectious Dose
Bacteria, Gram positive					
<i>Corynebacterium diphtheriae</i>	upper respiratory tract, skin	diphtheria	2–7 days	direct contact, droplet spread	unknown
<i>Streptococcus pneumoniae</i>	lower respiratory tract	pneumonia, meningitis	1–3 days	direct contact, droplet spread	unknown
<i>Listeria monocytogenes</i>	monocytes, leukocytes, blood, intestine, skin	listeriosis, meningoencephalitis	variable; 3–70 days	ingestion, direct contact, neonatal contact (birth), transplacental	unknown, <1000 cells
<i>Bacillus anthracis</i>	lower respiratory tract, skin lesions, intestine	anthrax	few hours –7 days	direct contact, airborne, ingestion	8,000–50,000 spores
<i>Staphylococcus aureus</i>	skin, osteomyelitis, blood, heart	boils, furuncles, abscesses, impetigo, osteomyelitis, sepsis, toxic shock syndrome	variable; 4–10 days	direct contact, ingestion, autoinfection, neonatal contact (birth)	10 ² – 10 ⁶ cells
<i>Streptococcus pyogenes</i>	throat, skin, blood, middle ear	pharyngitis, septicemia, erysipelas, rheumatic fever, scarlet fever, otitis media, foodborne illness	1–3 days	direct contact, droplet spread, injection	<1000 cells
Bacteria, Gram negative					
<i>Bordetella pertussis</i>	oropharynx	whooping cough	6–20 days	direct contact, droplet spread, airborne	unknown
<i>Escherichia coli</i> (O157:H7)	large intestine	hemorrhagic colitis	2–8 days	ingestion	~10 cells
<i>Legionella</i> spp.	lower respiratory tract	Legionellosis, Pontiac fever	2–10 days	airborne (non-communicable)	unknown
<i>Neisseria gonorrhoeae</i>	genitourinary tract, eye	gonorrhoea, pelvic inflammatory disease, septicemia, pharyngitis	2–7 days	direct contact (usually sexual), neonatal contact (birth)	unknown
<i>Neisseria meningitidis</i>	meninges	meningitis	2–10 days	direct contact, droplet spread	unknown
<i>Salmonella</i> spp.	small intestine	gastroenteritis	6–72 hours	ingestion	10–100,000 cells
<i>Salmonella typhi</i>	small intestine	typhoid fever	1–3 weeks	ingestion	1,000–100,000 cells
<i>Shigella</i> spp.	intestine	shigellosis (enteritis); Bacillary dysentery	1–7 days	ingestion	10–200 cells
<i>Yersinia</i> spp.	intestine	enterocolitis, acute mesenteric lymphadenitis	3–7 days	ingestion	10 ⁶ cells
<i>Vibrio</i> spp.	intestine	cholera, enteritis	4–96 hours	ingestion	~10 ⁶ cells
Anaerobes, Gram positive					
<i>Actinomyces</i> spp.	jaw, thorax, abdomen	chronic abscesses, draining sinuses	variable; days or months	direct contact (mouth), airborne, fomites	unknown
<i>Clostridium botulinum</i>	nerves, muscle, skin, intestine (infants)	botulism, acute bilateral cranial nerve impairment	12–36 hours	direct contact, ingestion (non-communicable)	unknown
<i>Clostridium difficile</i>	intestine	pseudomembranous colitis	6–24 hours	environmental	unknown
<i>Clostridium perfringens</i>	skin lesion, large intestine	gas gangrene, food poisoning	1–4 days	ingestion	10 ⁵ –10 ⁸ cells
<i>Clostridium tetani</i>	nerves, muscle	tetanus	3–21 days	direct contact (non-communicable)	potent toxin

Table 1. (Continued)

Organism	Site(s)	Disease(s)	Incubation period	Mode of transmission	Infectious Dose
Anaerobes, Gram negative <i>Bacterioides</i> spp.	mouth, respiratory tract, large intestine	peritonitis, endometritis, abscesses, septicemia	unknown	endogenous	unknown
Bacteria, acid-fast <i>Mycobacterium tuberculosis</i>	lower respiratory tract, laryngeal, meningeal	Tuberculosis	4–12 weeks	direct contact, droplet spread, airborne	10 cells
<i>Mycobacterium avium</i> complex	lower respiratory tract, lymph nodes	pulmonary, lymphadenitis	unknown	ingestion, skin lesions (non-communicable)	10 ⁴ –10 ⁷ cells
Yeasts <i>Candida albicans</i>	mucous membranes, skin	oral thrush, intertrigo, vulvovaginitis, paronychia	variable; 2–5 days in infants	direct contact (sexual), neonatal contact (birth)	unknown
<i>Cryptococcus neoformans</i>	meninges, lower respiratory tract	meningitis, pneumonia	unknown	airborne	unknown
Molds <i>Aspergillus</i> spp.	lower respiratory tract	aspergillosis	variable; days to weeks	airborne (non-communicable)	unknown
<i>Blastomyces dermatitidis</i>	lower respiratory tract, skin	blastomycosis	few weeks to months	airborne (non-communicable)	unknown
<i>Coccidioides immitis</i>	lower respiratory tract, skin	coccidioidomycosis	1–4 weeks	airborne (non-communicable)	unknown
<i>Histoplasma capsulatum</i>	lower respiratory tract, skin	histoplasmosis	3–17 days	airborne (non-communicable)	10 spores
Viruses Acquired immunodeficiency syndrome	progressive damage to immune and other organ systems	HIV/AIDS	6 months – 7+ years	direct contact (sexual, contact with blood or bodily fluids) ingestion	unknown
Hepatitis A	liver	hepatitis, type A	10–50 days	ingestion	10–10 ³ virus particles
Hepatitis B	liver	hepatitis, type B	24–180 days	direct and indirect contact (bodily fluids), fomites	unknown
Hepatitis C	liver	hepatitis, type C	6–10 weeks	direct contact (contaminated blood)	10 ² –10 ³ particles/mL blood
Herpes simplex I	skin	herpes (vesicular lesions)	7–10 days	direct contact (saliva)	unknown
Herpes simplex II	skin	herpes (genital)	2–12 days	direct contact (usually sexual)	unknown
Influenza	upper respiratory tract	flu	1–4 days	direct contact, droplet spread, airborne	2–800 virus particles
Measles	skin	rubeola	8–13 days	direct contact, droplet spread	~10 virus particles
Rubella	skin	German measles	12–23 days	direct contact, droplet spread	10–60 virus particles
Varicella-Zoster	skin	chicken pox, shingles	13–17 days	direct contact, droplet spread, airborne	unknown

colony originates from a single cell and is therefore pure of any other cell types. A colony can subsequently be used as a pure sample for microscopy, cell culture, and other analytical tests. Additionally, as only viable cells divide, plating can differentiate between dead microbes and those that are viable and may be the source of infection.

Staining. Microscopic observation of microorganisms is generally preceded by staining a specimen on a microscope slide. The microbe response to various stains (gram-positive/negative, acid-fast, etc.), size, grouping (single, double, chains), and morphology (bacillus, coccus, spirillum, pleomorphic) provide characteristic information helpful in identifying the microorganism. However, several pathogenic species appear similar, or are indistinguishable, under the microscope. For effective observation under a microscope, at least 10^5 cells per milliliter of sample should be present. A colony specimen usually meets this requirement, and preconcentration is generally necessary for viewing a nonplated specimen. Still, very small cells can be difficult to observe and may be overlooked. Finally, microscopic observation usually cannot distinguish between dead and live cells.

Cell Culture. Cell culture is used to ascertain the biochemical properties of a microorganism. A single colony is inoculated into a liquid media broth and incubated. Incubation is usually performed near 37°C with agitation via shaking or gas sparging to facilitate gas transport into the liquid media for uptake by the microbes. Signs of microbial growth in liquid media include turbidity and gas formation. Turbidity can be used as a simple and nondestructive method to measure cell growth. An optical density measurement provides the degree of light scattering at a particular wavelength through a given path length of liquid media. Increasing cell density due to growth usually increases the degree of light scattered. The measured optical density can, therefore, be directly related to the total cell mass. A calibration curve for each bacterial species is required as various sizes and shapes of different microbes scatter light to varying extents.

Microbial growth in several different media is used to determine a specific microbe's biochemical and physiological characteristics. Definitive identification can require 20 or more media tests. Such tests often use selective media. A media can be made selective by addition of chemicals that inhibit microbe and native flora growth while allowing growth of a specific organism. For example, Thayer–Martin medium selectively isolates pathogenic *Neisseria gonorrhoea* and *Neisseria meningitides* (4). The medium contains vancomycin to inhibit growth of gram-positive bacteria, anisomycin to inhibit fungi growth, colistin to inhibit most gram-negative bacilli growth, and trimethoprim-sulfamethoxazole to inhibit *Proteus* growth. The *Neisseria* species are resistant to these inhibitors at the concentrations present in the medium and grow freely.

Antibiotic Susceptibility Testing. Upon isolation and identification of the infectious microbe, antibiotic susceptibility testing can be performed to identify antimicrobial agents that inhibit growth. Additionally, the minimal

inhibitory concentration (MIC) is determined by exposing bacteria in media broth to various concentrations of an antimicrobial agent. The lowest antibiotic concentration that inhibits growth is the MIC. A concentration of the antibiotic in the blood at or above the MIC should successfully treat an infection.

Development

Plating, microscopy, cell culture, and susceptibility testing techniques for identifying and treating infectious microorganisms have proven effective against a plethora of pathogens, hence its continued use today. However, these clinical microbiology methods have changed very little over the past century, often require days to obtain confirmed results, and cannot be used successfully to characterize several significant infectious agents including the hepatitis virus. However, with the recent and significant advances in molecular biotechnology, two additional microbe identification methods have found wide use, immunoassay and polymerase chain reaction.

Developed in 1959, the utility of the immunoassay was not fully realized by the medical diagnostic community until the late 1970s and early 1980s. The immunoassay takes advantage of an immune system reaction, the highly specific and strong binding of antibody to antigen. Antibodies are developed that specifically bind a given microorganism, chemical byproducts or proteins produced by a given microorganism, or antibodies produced by the host in response to infection caused by a given microorganism. The developed antibodies are tagged with a reporter molecule. Reporters can be radioisotopes, chemiluminescent or fluorescent molecules, or enzymes (i.e., alkaline phosphatase, horseradish peroxidase) that can produce a radiographic, colorimetric, or fluorescent signal. In the presence of the antigen, the antibody will bind and will remain bound through washes that remove unbound antibody. Detection of the reporter after washes indicates that the antigen was present, as bound antibody was not removed during washing. Although rapid, highly specific, and sensitive, immunoassays cannot differentiate between viable and dead cells and are limited to tests for which antibodies can be developed. They also can be affected by contaminants in the test specimen and do not provide quantitative information regarding the number of pathogenic agents present.

Serological assays are the most commonly used immunoassay in the medical laboratory and by the Centers for Disease Control and Prevention (CDC). The mechanism of Serodiagnosis entails binding of lab-developed antibodies to antibodies produced in the host in response to a specific infection. This indirect method of detecting infectious agents allows identification of microbes that are currently difficult or impossible to isolate and culture. For example, because HIV-1 virus requires advanced containment facilities and is difficult to isolate and culture, it is serologically diagnosed via detection of antibodies produced by the host against the virus. Additionally, a method to effectively isolate and culture hepatitis virus has not yet been devised. Therefore, diagnosis of hepatitis virus infection is done serologically. A lag phase of several weeks often exists

between onset of infection and production of antibodies by the host against the microbial agent and, thus, possibly leads to false negatives. False positives are also a concern as antibodies produced by the host during a previous infection may be present and detected.

Immunoassays were the primary diagnostic method used for microbial detection by the CDC until the development of polymerase chain reaction (PCR) (5). PCR is a technique that specifically amplifies DNA sequences (for more information, see page 8). This technology has transformed molecular biology and genetics and has changed diagnostic approaches to the identification, detection, and characterization of infectious agents. With PCR, extremely small quantities of DNA from a microorganism can be amplified and detected. Detection of amplified DNA can occur through gel electrophoresis or via genetic probes. Based upon the highly specific binding between complementary nucleobases of DNA and RNA, genetic probes are nucleic acid sequences that bind to DNA or RNA unique to a given microorganism. Genetic probes are marked with radioisotopes, chemiluminescent or fluorescent molecules, or enzymes and will produce a quantitative signal only when the complimentary microorganism DNA or RNA is present in the sample (for more information, see page 9). Ou et al. (6) used PCR to amplify and detect HIV sequences from seropositive individuals. Subsequently, PCR amplification and sequence analysis of HIV amplicons (amplified DNA sequences) became the first use of comparative nucleic acid sequence information in a disease outbreak setting (7). Although PCR is very sensitive and sequence analysis provides specific identification capability, these technologies are expensive, time-consuming, labor-intensive, and require expertise in molecular biology. Consequently, use of PCR and genetic probes for identification of microbes is common in research laboratories and academic institutions, but, to date, is not widely used in hospital or medical diagnostic laboratories.

To address rising national and worldwide public health needs, it is desirable that a sensitive, specific, fast, and simple-to-operate device be employed to detect infectious agents. Microbial detection systems that attempt to meet this need have been commercially available since the late 1970s and have progressed significantly with the molecular biotechnology revolution. Still, microbial detection systems face three major challenges: time, sensitivity, and specificity of analysis. Microbial testing and detection must be rapid to allow adequate time for treating the infection and be highly sensitive as a single pathogenic organism may be infectious. Additionally, as a low number of pathogenic microbes may be present in complex biological samples, such as blood or urine, high specificity remains an essential requirement. To tackle these problems, alternative nucleic acid-based approaches have been integrated into user-friendly microbial detection systems that are commercially available for diagnostic purposes.

Contemporary microbial detection systems or biosensors typically consist of a selective biorecognition molecule connected to a transducer that converts a biochemical interaction into a measurable signal. Recognition molecules include nucleic acids, antibodies, and peptides. Commonly used transducers include electrochemical, optical,

and piezoelectric. The following sections will discuss numerous commercially available microbial detection systems used in clinical and field settings, including (1) nucleic acid-based, optical technologies and systems; (2) fiber-optic, waveguide-based fluoroimmunoassay systems; (3) a chip- and nanoparticle-based bio-barcode optical technology; (4) an electronic microchip-based technology; and (5) an electronic nose microbial detector.

NUCLEIC ACID-BASED OPTICAL TECHNOLOGIES

Line Immunoprobe Assay (LIPA)

The line immunoprobe assay (LIPA) is a nucleic acid recombinant immunoblotting assay (RIBA) (i.e., oligonucleotides that differentiate different genetic variants are transferred onto a nitrocellulose membrane in a straight line) (8,9). PCR is performed from the clinical sample using primers that selectively amplify a DNA region containing nucleotide differences. The amplicons are hybridized with the immobilized oligonucleotides on the membrane, and an enzyme-based colorimetric method is used to detect binding and positive reactivity. The nucleotide differences contained within the amplified sample DNA provide a unique signature that differentiates target genotypes or mutant microorganisms. These assays were among the first commercially available assays using nucleic acid hybridization for diagnostic purposes.

COBAS AMPLICOR Analyzer

A second commercially available system using PCR technology is the COBAS AMPLICOR Analyzer (Roche Diagnostics; Rotkreuz, Switzerland). This system automates amplification and detection of target DNA from infectious agents by combining five instruments into one: a thermal cycler, automatic pipettor, incubator, washer, and reader. Amplified biotinylated products are captured on oligonucleotide-coated magnetic microparticles and detected colorimetrically with use of an avidin-horseradish peroxidase (HRP) conjugate. The system can detect a broad range of agents including *Bacillus anthracis*, *Chlamydia trachomatis*, *Neisseria gonorrhoea*, *Mycobacterium tuberculosis*, cytomegalovirus, hepatitis B and hepatitis C viruses, and HIV in clinical specimens including serum, urine, and sputum. The manufacturer reports that more than 4000 COBAS AMPLICOR Analyzers are currently used in clinical settings worldwide (10).

Real-Time PCR (RT-PCR)

A number of commercially available systems for the diagnosis of infectious diseases make use of a third nucleic acid-based approach (i.e., RT-PCR). As the name implies, RT-PCR, pioneered by Applied Biosystems (Foster City, CA) in the mid-1990s (11), amplifies and measures agent-specific DNA as the reaction proceeds in real-time. It is used to quantify the amount of agent-specific input DNA or cDNA by correlating the amount of DNA with the time it takes to detect a fluorescent signal. This technology uses fluorescent reporter probes (i.e., molecular beacons) that are

detected and quantitated at each cycle of the PCR. Molecular beacons are single-stranded, dual-labeled fluorogenic DNA or RNA probes that form a stem loop structure. The loop hybridizes to the target nucleic acid, whereas the stem is end-labeled with a fluorophore at the 5'-end adjacent to a quencher at the 3'-end. Fluorescence resonance energy transfer (FRET) is the process by which energy from an excited fluorophore (donor) is transferred to the adjacent fluorophore (acceptor) at close proximity, resulting in the quenching of fluorescence. Hybridization of the target sequence to the loop separates fluorophore and quencher, and the fluorescence is measured.

The GeneXpert System (Cepheid; Sunnyvale, CA) fully automates and integrates sample preparation with the RT-PCR detection processes. It uses microfluidics technology integrated into disposable assay cartridges. The cartridges contain all the specific reagents required to detect disease organisms such as *Bacillus anthracis*, *Chlamydia trachomatis*, or foodborne pathogens. The system provides quantitative results from unprocessed clinical samples in 30 minutes or less and is capable of self-cleaning and decontamination before its next use. The GeneXpert module forms the core of the Biohazard Detection System deployed nationwide by the United States Postal Service for anthrax testing in mail-sorting facilities (12). It is also used in hospital laboratories, physician offices, and public health clinics.

Idaho Technology (Salt Lake City, UT) manufactures an automated, field-ready RT-PCR instrument, the R.A.P.I.D. (ruggedized advanced pathogen identification device) system, which is based on the Light Cycler Instrument from Roche Diagnostics (Alameda, CA). The R.A.P.I.D. is developed for military field hospitals and first responders in harsh field environments. Amplification of DNA in real-time can be performed on environmental and blood samples. Idaho Technology claims a 15 minute set-up time and a 20 minute PCR run for a total of 35 minutes using the R.A.P.I.D. Pathogen Test Kit. This instrument is reported to be very sensitive (i.e., *Pseudomonas aeruginosa* was detected in blood culture samples at 10 cfu (colony-forming units)/ml (13). (A colony-forming unit is a single viable cell that forms a colony of identical cells when plated.) This technology is well-established and has been in use worldwide since 1998.

The R.A.P.I.D. technology was recently put to the test at the Prince Sultan Air Base in Saudi Arabia (14). Medical personnel observed a clustering of diarrhea cases and thought them to be due to influenza. However, testing of patient samples with the R.A.P.I.D. identified the cause to be foodborne *Salmonella* within hours of sample submission. Due to the prompt response by medical and services personnel, the outbreak was limited to less than 3% of the base population.

Nucleic Acid Sequence-Based Amplification (NASBA)

A fourth approach for nucleic acid-based detection of infectious organisms is nucleic acid sequence-based amplification (NASBA), a bioMérieux, Inc. (Marcy-l'Etoile, France) proprietary isothermal amplification technology. This method is based on specific amplification of RNA by the

Figure 2. NucliSens Reader ECL detection scheme (16).

simultaneous activity of three RNA-specific enzymes, AMV-reverse transcriptase, T7 RNA polymerase, and RNase H, generating single-stranded RNA as the endproduct (15). NASBA is an isothermal amplification procedure, carried out at 41°C.

Two commercially available systems, NucliSens Reader and NucliSens EasyQ Analyzer (bioMérieux, Inc.), make use of the NASBA technology. Although both systems use NASBA for selective amplification of RNA, as well as a bioMérieux proprietary Boom silica-based nucleic acid extraction method, the NucliSens Reader relies on an electrochemiluminescence (ECL) detection technology, and the NucliSens EasyQ uses fluorescent detection by incorporating specific molecular beacons to which amplicons hybridize. With this method, amplification and detection occur simultaneously in a single tube.

The ECL-based NucliSens Reader employs a sandwich hybridization method for the detection of amplified target RNA (Fig. 2) (16). Two target-specific DNA probes are used: a capture probe bound to magnetic beads and a detection probe labeled with tris (2,2'-bipyridine) ruthenium (Ru). Each of these probes bind to a different region of the target RNA. After the hybridized sample is drawn into the ECL flow cell and the beads are magnetically immobilized on the electrode, a voltage is applied, and the resulting emitted light is detected by a photomultiplier tube (PMT). According to the manufacturer, measurement of 50 reactions takes approximately 50 minutes.

Real-time NASBA and fluorescent detection of target-bound molecular beacons are accomplished by the NucliSens Basic Kit and EasyQ Analyzer (Fig. 3) (17). This technique is most often used to detect RNA viruses. Using a multiplexed NASBA technique to detect four human immunodeficiency virus type 1 (HIV-1) subtypes, DeBaar et al. (18) reported an 89% correct subtype identification relative to sequence analysis and a sensitivity of 92%. The limit of detection was approximately 10³ copies of HIV-1 RNA per reaction. Lanciotti and Kerst (19) conducted a study comparing TaqMan RT-PCR (Applied Biosystems) and standard reverse-transcription PCR (Roche Molecular Biochemicals) assays with NucliSens NASBA assays

Real-time Detection in NASBA

Figure 3. NucliSens EasyQ detection scheme (17).

for detecting West Nile (WN) virus and St. Louis encephalitis virus. The ECL-based and molecular beacon-based NASBA assays demonstrated equal or greater sensitivities and specificities than reverse-transcription PCR in human cerebral spinal fluid. The NASBA-ECL assay for WN virus was 10-fold more sensitive than either the Taq-Man or NASBA-molecular beacon assay, detecting 0.01 pfu of WN virus. Moreover, the NASBA molecular beacon-based assay performed significantly faster than either PCR procedures (i.e., a positive signal was detected within 14–45 minutes).

Strand Displacement Amplification (SDA)

A fifth approach for nucleic acid-based detection of infectious organisms is strand displacement amplification (SDA). SDA, first reported by Walker et al. in 1992 (20), is an isothermal process that amplifies DNA or RNA using a restriction enzyme and a DNA polymerase plus several primers, without requiring temperature cycling. Available since 1999, the BDProbeTecET System (Becton, Dickinson & Co.; Franklin Lakes, NJ) couples the proprietary technology, SDA, and real-time fluorescent detection in a rapid one-hour format. This high throughput, chip-based, closed system was developed for detection of *Chlamydia trachomatis* and *Neisseria gonorrhoea* in urine samples, endocervical swabs, and male urethral swabs in a one-hour assay time. The complete system includes a sample preparation module, a priming and warming heater unit, and an amplification and fluorescence detection unit. The optical system consists of a fiber-optic bundle with eight branches, and the fluorescent detection reader monitors real-time fluorescence by FRET. Emitted light passes through a custom optical band-pass filter, is detected by a PMT, and is analyzed by software.

Little et al. (1999) (21) reported a sensitivity of 10–15 *N. gonorrhoea* cells or *C. trachomatis* elementary bodies. Akduman et al. (22) reported that out of 3544 urine samples tested, 152 were positive using the BDPro-

beTecET System, and 130 were positive by standard culture techniques resulting in a sensitivity of 99.2% and a specificity of 99.3%.

FIBER-OPTIC FLUOROIMMUNOASSAY SYSTEMS

Analyte 2000 and RAPTOR

The Analyte 2000 and its sister field model, RAPTOR (Research International; Monroe, WA), detection systems use a fiber-optic, waveguide-based sandwich fluoroimmunoassay for the near real-time detection of pathogens in a variety of raw fluid samples (23). Optical fibers are long, thin strands of either glass or plastic that can transmit light over long distances. In the RAPTOR, a monolayer of capture antibodies are immobilized on the surface of a cylindrical waveguide (Fig. 4)(23). The waveguide is incubated with a clinical sample for three to five minutes, washed, and re-incubated with a fluorophore-labeled antibody to form an antibody/antigen/labeled-antibody “sandwich.” Excitation light, injected into the waveguide, creates an evanescent wave electric field in the fluid and generates an optical emission from the antibody-antigen complexes. The fluorescent signals are then monitored by a photodetector.

Using the Analyte 2000, the detection limits for *Bacillus anthracis* (vegetative cells) was reported as 30 cfu/ml in water, and for the avirulent strain of *B. anthracis* (i.e., Sterne strain), 100 cfu/ml in whole blood. For spores, the detection limit was 5×10^4 /ml (23). The infectious dose of *B. anthracis* in a healthy individual requires inhalation of about ~8,000–50,000 spores (24). This number is reduced in more vulnerable individuals, such as the elderly or those with respiratory problems. Vaccinia virus (a surrogate of the Smallpox virus) from throat swabs was detected at 2.1×10^4 pfu (plaque-forming units, the viral equivalent of bacterial colonies)/ml (25). The infectious dose of smallpox is thought to be low (i.e., 10–100 organisms) (26).

Figure 4. Optical and biomolecular processes of RAPTOR technology (23).

NANOPARTICLE-BASED BIO-BARCODE TECHNOLOGY

Verigene System

The Verigene System (Nanosphere; Northbrook, IL) is an automated device for the chip-based detection of proteins and nucleic acids using an innovative gold nanoparticle-based bio-barcode technology. For proteins, the assay uses two types of probes (Fig. 5 (27)): (1) magnetic microparticles (MMPs) functionalized with monoclonal antibodies (mAbs) specific for a target antigen and (2) gold nanoparticles (NP) functionalized with polyclonal antibodies specific for the same target and DNA oligonucleotides (the “bio-barcodes”) with a sequence that is a unique identification tag for the target. The Au nanoparticles and the MMPs sandwich the target, generating a complex with a large ratio of barcode DNA to protein target. A magnetic field is applied, allowing the separation of all the MMP/target/NP complexes from the reaction mixture. After a wash to

dehybridize the barcode DNA from the nanoparticles, another magnetic field removes the NPs, leaving only the barcode DNA. Detection and identification of the barcodes occurs next through a PCR-less process of amplification. Chip-immobilized capture DNA, complementary with half of the target barcode DNA sequence, is used to bind the barcode DNA. Then, gold nanoparticles, functionalized with oligonucleotides that are complementary to the other half of the barcode DNA, are hybridized to the captured barcode strands. The signal is amplified by the catalytic electrodeposition of Ag onto the Au nanoparticles, and the results are recorded with the Verigene ID system, which measures scattered light intensity from each barcode/Au/Ag complex.

Like protein detection, DNA detection via the nanoparticle bio-barcode approach uses two types of probes (Fig. 6)(28): (1) magnetic microparticles functionalized with oligonucleotides that are complementary to one-half

Figure 5. Prostate-specific antigen (PSA) detection and barcode DNA amplification and identification (27).

Figure 6. The DNA-bio-barcode assay. (a) Nanoparticle and magnetic microparticle probe preparation. (b) Nanoparticle-based PCR-less DNA amplification scheme (28).

of a target sequence and (2) gold nanoparticles functionalized with two types of oligonucleotides, one that is complementary to the other half of the target sequence and one that is complementary to a barcode sequence that is a unique identification tag for the target sequence. The assay proceeds in the same manner as with protein targets, with the analysis also accomplished by the scanometric method with a Verigene ID system.

The nanoparticle-based bio-barcode approach is reported to provide a sensitivity of 500 zeptomolar, approximately 10 target DNA strands in a 30 μl sample (27). Prostate-specific antigen was detected at 30 attomolar levels with this method, and PCR on the DNA barcodes boosted sensitivity to 3 attomolar (28). The entire assay can be carried out in 3–4 h.

MICROCHIP TECHNOLOGY

NanoChip System

The NanoChip System (Nanogen; San Diego, CA) is an electronic microarray device based on the electrophoretic transport of proteins and nucleic acids on a microchip to specific sites where traditional immunoassays or nucleic acid hybridization reactions occur (Fig. 7) (29). The electronic microchip is a planar array of microelectrodes that electrophoretically transport-charged biomolecules to any individually-electrically-addressed microsite on the surface of the device. Each microsite has an agarose-streptavidin permeation layer coated on top of a platinum microelectrode to bind biotinylated capture molecules. The microchips are referred to as “active electronic microchips” because electric fields are generated for the purpose of transporting biomolecules to and from specific

Figure 7. Active electronic microchip technology. (a) Basic chip layout; (b) Cross-section of microchip for electrophoresis of proteins (29).

microsites in a process the manufacturer terms “electronic addressing” (29). As the electric field is generated only in the immediate vicinity of the electrodes, not affecting the solution in other parts of the device, each microsite is an independent assay site allowing for the detection of multiple analytes. Also, the generated electric fields can be used to selectively dehybridize nonspecifically bound analytes from assay sites, which greatly improves the selectivity of the assay. When the biotinylated capture probes are attached to the array, fluorescently labeled analytes are introduced, and further electrical adjustments are made to direct the analytes to concentrate at the microsites for rapid hybridization or antibody-antigen interactions. The fluorescent signal is monitored in a laserinduced fluorescence scanner, and the analytes are identified based on the microlocation of the fluorescence.

Nanogen researchers performed a diagnostic immunoassay for two fluorescently labeled toxins simultaneously, staphylococcal enterotoxin B (SEB) and cholera toxin B. They reported a sensitivity of better than 20 nM concentrations of toxins (29). High specificity was also demonstrated by low nonspecific binding and cross-binding. This assay took 6 minutes to perform, 1 minute for electronic addressing to bind analytes and 5 minutes for washing to reduce nonspecific binding.

More recently, Nanogen researchers reported on an integrated “stacked” microlaboratory for performing automated electric field-driven immunoassays and DNA hybridization assays (30). This device is composed of a CMOS-based electronic microarray chip, a dielectrophoresis microchip, and several modules for DNA sample preparation, strand displacement amplification, and hybridization. *E. coli* bacteria and Alexa-labeled staphylococcal enterotoxin B were detected in the device with specific-to-nonspecific signal ratios of 4.2:1 and 3.0:1, respectively. Identification of the Shiga-like toxin gene from *E. coli* was accomplished in a 2.5 h comprehensive protocol including the dielectrophoretic concentration of intact bacteria, DNA amplification, electronic DNA hybridization to fluorescently-labeled probes, and detection with a fluorescent microscope. This experiment used bacteria cell suspensions of 10^9 cells/ml with a specific-to-nonspecific signal ratio of 22.5:1, showing outstanding specificity.

ELECTRONIC NOSE

Osmetech Microbial Analyzer

An electronic nose is a device that consists of an array of gas sensors with different selectivity patterns, a signal collecting unit, and data analysis by pattern recognition software. When microorganisms grow and metabolize, they emit volatile organic compounds and gases that can be monitored by a biosensor array. The Osmetech Microbial Analyzer (OMA; Osmetech; London, UK) is an automated headspace analyzer using arrays of organic conducting polymers as sensors. The device samples the headspace above the surface of the specimen and detects volatile compounds with an array of up to 48 conducting polymer sensors. Each polymer has unique adsorptive properties, and, once adsorbed, the volatile components modulate the conduction mechanism of the polymer resulting in reversible changes in resistance (Fig. 8) (31). The signal is measured as a percentage change of the original resistance of the polymer. Multivariate data algorithms are used to compare the responses and establish a diagnosis.

When 534 clinical urine samples were analyzed by the OMA, 22.5% had significant bacteriuria (i.e., $>10^5$ cfu/ml), resulting in a sensitivity of 84% and a specificity of 88% relative to standard culture methods (32). Although less than optimal, this device shows promise for automated, rapid screening. The company’s second FDA approval for detection of bacterial vaginosis was secured in January 2003. Clinical trials with more refined versions of the instrument are in progress. Although electronic nose technology is still in its infancy, it clearly has the potential for providing rapid, sensitive, and simultaneous detection of different strains of bacteria.

FUTURE TRENDS IN MICROBIAL DETECTION SYSTEMS

In the development of the microbial detection systems mentioned, researchers have begun to focus on building integrated devices that combine a pre or post-processing step such as PCR-based amplification, with post-derivatization (fluorescent labeling) and detection. Microarray technologies are being developed to overcome limitations of sample volume and high throughput analysis. In the

Figure 8. Osmetech Microbial Analyzer detection technology (31).

near future, biomedical science can realize the integration of all laboratory equipment used in molecular biology on a chip-based platform arrayed to detect large numbers of pathogens in a high throughput, portable device. Biological Micro-Electro-Mechanical systems (BioMEMS), also referred to as lab-on-a-chip and micro total analytical systems (μ -TAS), is an area rapidly advancing due to the integration of micro and nanotechnology with biotechnology. Current reviews for this technology are abundant in the literature (33,34). Microfluidic-based devices have been on the market since 1999, but much work is still underway to build modular-type systems with complete integration of sample collection, concentration, pre and post-processing steps, separation, selective capture, viability detection, lysing, and protein and DNA analysis. Development of such systems in a high throughput fashion capable of detecting and discriminating between hundreds of pathogenic agents would impact not only medical diagnostics but homeland security and public health, including home monitoring, medicine, and veterinary diagnostics. As the field moves toward lab-on-a-chip systems, cost, limited sample throughput, ease-of-use, and limited waste production (reagentless systems) will be considered in design strategies. The second progression toward advanced microbial detection systems will be the incorporation of nanotechnology. Current nanotechnologies such as quantum dots, nanoparticles, and synthetic nanopores are already being incorporated into current chip-based diagnostic systems. CellTracks technology (Immunicon Corporation, Huntingdon Valley, PA) has developed magnetic nanoparticles called ferrofluids, which consist of a magnetic core encompassed by a polymer coating tagged with antibodies for whole cell and pathogen detection. Up-Converting Phosphor Technology (UPT), by OraSure Technologies, Inc., makes use of proprietary ceramic nanoparticles for DNA detection. These particles have been shown to be a 1000 times more sensitive than fluorescent technologies. Finally, a trend exists to build detection systems from the bottom up rather than the top down. Small building blocks such as protein motors are being designed to move cargo including peptides and antibody fragments as a method of patterning arrays. "Switchable" materials such as poly-n-isopropylacrylamide (PNIPAM) are used to pattern antibodies, capture proteins, and move fluids, replacing mechanical components of BioMEMS systems. PNIPAM has a thermally activated lower critical solubility temperature (LCST) of 32 °C. At temperatures below the LCST, the polymer swells in water to create a hydrophilic surface that resists protein adsorption. Above the LCST, the polymer collapses to form a hydrophobic surface that promotes protein adsorption. Whether the bottom up approach based solely on nanomaterials will hold in the long run remains to be seen. However, it is clear that nanotechnology that complements and extends current MEMS detection methods will revolutionize the field of medical diagnostics. Early examples of lab-on-a-chip technologies integrating nanotechnologies already exists, which address the current limitations of detection systems. The approach is toward development of portable microsystems that are reagentless; handle small sample size; eliminate the need of labels and probes; are specific, sensi-

tive, and high throughput; perform multiple functions from sample concentration to final detection; and are easy to use.

Briefly, some of these technologies include cantilever arrays, which operate by a slight bending of the cantilever beam at the nanoscale level upon analyte binding. Proti-veris, Inc. (Rockville, MD) is developing microcantilever arrays for combined detection of DNA and protein. Capture molecules are attached to the beams and, as samples moves across the device, binding of a target molecule results in nm bending of the beam. These devices can be integrated into microfluidic systems, require no labels or reagents, and are very sensitive and specific. Nanowires, nanoneedles, and nanoelectrode arrays are additional technologies that can detect multiple analytes simultaneously. Electronic signals can be averaged over thousands of electrodes eliminating the need for PCR amplification, and no reagents are required. These devices are coated with selective molecular recognition molecules and change in conductance occurs during a binding/recognition event. Aside from integration into lab-on-a-chip systems, these technologies have applications in *in vivo* medical diagnostics.

Over the next few years, nanotechnologies will continue to evolve and become integrated into chip-based microsystems for detection, diagnostics, and drug delivery. Later, in perhaps 20–30 years, the introduction of nanomachines for *in vivo* diagnostics and treatment may well emerge, changing the current way of conducting medical and health-care practice.

MICROBIOREACTORS

XIAOYUE ZHU
TOMMASO BERSANO-BEGEY
YOKO KAMOTANI
SHUICHI TAKAYAMA
University of Michigan
Ann Arbor, Michigan

INTRODUCTION

This article defines microbio-reactors as micrometer scale reaction vessels in which biological reactions are performed. Whereas large-scale bioreactors mainly focus on efficiently producing desired end products, microbio-reactors have additional targeted applications such as studying cellular processes under simulated physiological microenvironments, and functioning as portable cellular biosensors or implantable devices inside the body to restore tissue functions. Increasing needs in developing personalized cell-based therapies and medicines together with rapid advances in micro- and nanotechnologies ensure that the field of microbio-reactors will continue to flourish. Although most microbio-reactors are still in their infancy, relatively simple compared to their macroscopic counterparts, and often not fully integrated or packaged into compact self-contained platforms, they already have started to have an

Figure 1. What are bioreactors and microbioreactors? Part (a) shows a generalized bioreactor application, feeding cells to produce complex biomolecules for pharmaceutical applications. Part (b) shows the main components of both bioreactors and microbioreactors: a reaction chamber containing main reagents and cells, sensors (for temperature, flow rate, pH, oxygen, glucose, etc.), actuators (pumps, valves, heaters, mixers, filters), and controllers to regulate actuators based on sensor readings.

impact in pharmaceutical, medical, clinical, and biological fields (Fig. 1).

Microbioreactors enable low cost high throughput investigation of bioreactions in ways not possible with macroscopic bioreactors. For example, the development of a biopharmaceutical requires extensive optimization processes prior to scale-up for industrial manufacture: The bacterial strain or mammalian cell that produces the highest yield of a particular product is constructed or identified; cultural parameters (e.g., temperature, pH, oxygen concentration, and media composition) are systematically evaluated to maximize cell growth and product formation; the design of the reactors themselves are adjusted iteratively as the development process gradually scale-up from benchtop to production scale. With microfabrication techniques, hundreds and thousands of small reaction chambers can be produced simultaneously and operated in parallel allowing vast combinations of parameters to be screened concurrently in short periods of times (Fig. 2a). The consumption of reagents and resources are reduced dramatically because for a given reaction chamber geometry, every 10-fold reduction in linear dimension would lead to a 1000 time reduction in its volume.

To enhance the quality of information obtained from cellular studies, rather than simply increasing throughput, some microbioreactors are designed to simulate physiological cellular microenvironments. Using microbioreactors for studying cellular physiology makes intuitive sense when one considers that much of the bioreactions within living organisms occur at the microscale. For example, capillary blood vessels, lung small airways, livers sinusoids, kidney nephrons, and reproductive tracts are all networks of small sacs, ducts, and tubes. Cells in these and other similar systems are constantly perfused with nutrients and oxygen and exposed to shear stresses and gradients of chemicals (1–3). Conventional *in vitro* cell culture studies, such as culture dishes or 96 well plates, often fail to present many of these dynamic physiological parameters. Microbioreactors, however, can be designed to simulate many such physical and chemical conditions that cells experience inside the body. In the body, different

tissues and cell types also interact and communicate with each other. Microbioreactors can be designed to network multiple reaction chambers together to capture the complexity of living organisms and used as animal and human surrogates in pharmacokinetic and toxicology studies. Microbioreactors can also work as cell-based biosensors, where effects on cell behaviors serve as readouts for selective and sensitive detection (Fig. 2c).

Some microbioreactors aim to continuously produce and deliver small quantities of biopharmaceuticals (e.g., insulin for regulation of blood sugar) inside the body (Fig. 2e). Implantable devices that continuously produce drugs based on physiological demands would eliminate the need for repeated injections and blood tests, and allow for delivery of stable, safe, and effective doses that resemble physiological concentration profiles. Such devices contain cells that use nutrients from the body to produce and secrete drugs (4).

Besides cell-based microbioreactors, enzymatic microbioreactors are also useful for detection and analysis. Enzyme-linked immunosorbent assays (ELISA), for example, are useful in high sensitivity detection and analysis of a wide variety of proteins and chemicals related to pollution, disease, and basic biology. Microscale systems often require shorter incubation time due to the short distances that analytes and reagents have to diffuse. Microbioreactors are also more portable and thus suitable for field and point-of-care use.

The development, integration, and packaging of microbioreactors present many challenges, as well as unique opportunities. Because of scaling issues and fabrication limitations, functional microscopic devices often require totally new designs instead of simply “shrinking” their macroscopic counterparts. Thus microscale pumps, valves, and mixers not only look different from their macroscopic counterparts, but may also operate with different mechanisms. Microscale sensors, another crucial component of microbioreactors, is an active area of research that has yielded a variety of useful systems based on optical, electrochemical, ultrasonic, and mechanical detection schemes. Although many microscale components have been developed to date, functional microbioreactors that integrate multiple pumping, valving, mixing, sensing, and control features are still relatively uncommon. Microbioreactors generally have fewer components integrated into their systems compared to their larger counterparts.

The organization of the remainder of this article is as follows. First, the principles that govern microscale reactions and microbioreactor operation are discussed. Second, elements of microbioreactor components are described, along with a brief description of the microfabrication processes that can be used to create them. Finally, highlights of state-of-the-art microbioreactors are given with focuses on production optimization, clinical treatment, toxicology testing, development of implantable systems, and basic cell biology studies. Because of space limitations, this article is representative rather than comprehensive. We also focus mainly on cell-based bioreactors rather than enzyme-based ones. Interested readers are referred to reviews on immobilized microfluidic enzymatic reactors (5). We also exclude important bioreactor categories that are not directly

Figure 2. Advantages and new applications of microbio reactors over large scale bioreactors: (a) microscale parallel cell culture and testing in a microchip configuration can be used to test and compare hundreds of conditions and parameters simultaneously, to optimize a reaction or screen potential treatments. (b) Microdevices containing interconnected chambers and microcultured cells from different tissues can be used to test drug effects on entire organisms, taking into account systemic impact of organs such as liver on drug metabolism, possibly replacing some stages of animal and human testing. (c) Microbio reactors can be used as detectors for bioactive compounds (e.g., toxins, endocrine disruptors, drugs) or biodisruptive conditions (e.g., radiation) with the advantage that all the steps of a test can be integrated in a single device that requires only trace amounts of samples and reagents. Cell-based sensors may be able to detect unknown reagents that affect living organisms. (d) Microfabrication can also provide microbio reactors with more physiologically accurate microenvironments, thus making *in vitro* testing more reliable and closer to *in vivo* conditions: for example, in actual tissues, each cell is held in its three-dimensional (3D) shape by tension through connected cytoplasmic fibers (the cytoskeletons), and cells have many surface interactions with other surface microfeatures and other cells. In contrast, in conventional cell culture that cannot microfabricate these features, cells configuration, and environment conditions, such as the amount of surface contacts, are drastically different. (e) Implantable devices containing cells such as insulin-producing pancreatic islets can be used as an improved treatment that continuously produce insulin based on the body's minute-by-minute needs, eliminating the need for periodical blood tests and consequent injections of insulin mass-produced in conventional bioreactors.

related to medicine, such as those used for food testing, plant cell culture, and wastewater treatment.

MICROBIOREACTOR DESIGN PRINCIPLES

Basic principles of bioreactor operations, such as thermodynamics, kinetics, mass transfer, sterilization, and struc-

tural considerations, are similar for both macro- and microbio reactors. The implementation of these principles into actual practice, however, can differ greatly.

Scaling Effects

At first glance, development of microbio reactors may seem to be a matter of simply shrinking macroscopic components

Figure 3. Microscale physics useful for microbio reactors. (a) As dimensions of devices scale down to microscopic scales, surfaces and volumes scale at different rate, so that smaller devices have a much greater surface/volume ratio. This change affects many physical phenomena such as capillary force (c) and produces effects such as laminar flow (d), which allows two liquids to flow side by side with minimal turbulent mixing. These microscale phenomena can be useful for microbio reactor operation. For example, capillary force can be used to pump liquid through microchannels, and laminar flows can be used to selectively deliver different reagents to different parts of single cells. (b) Microfabrication can further increase the surface/volume ratio, in a biomimetic manner, by creating microporous structures. This is useful since many biological reactions occur on surfaces.

into smaller ones. Directly downsizing systems and components, however, compromise their functions. Operations at microscales are often altered in unexpected ways compared to those at macroscales because the relative importance of physical effects that determine the functions of the microbio reactor components is size dependent. For example, if the linear dimensions of an object are reduced equally by a factor of 100, the surface area decreases by a factor of 10,000, and the volume decreases by a factor of 1,000,000 (Fig. 3a). The resulting increase in surface/volume ratio leads to prominence of surface effects such as surface tension and viscous drag over gravity and momentum. Thus, at the microscale, laminar flow, diffusive mixing, and capillary forces dominate over turbulence, convective mixing, and gravitational forces (Fig. 3c, d) (6). Scaling laws affect almost every aspect of microbio reactor operation. For example, it is more difficult to perform turbulent mixing at the microscale compared to at the macroscale (7–9), but more convenient to use electroosmosis flow to transport fluid samples through microchannels (10). More details of how scaling laws affect the design and operation of the microbio reactor components are noted in each section below.

Microbio reactor Operation Principles

The main challenge in bio reactor operation lies in its dynamic nature. Optimal reaction conditions must be maintained even as multiple parameters, such as concentration of molecules, activity of enzymes, quantity and quality of cells, and heat production are changing. Understanding the reaction mechanisms is helpful for

optimizing reactor designs. It is also desirable to constantly monitor and control reaction environments in real time.

Mass And Heat Balance. In bio reactor processes, it is common to assume steady state, that is, a balance of input, output flow of materials, and thermal homeostasis. As substrate input is converted into product, mass balances need to be closely monitored and controlled. In many enzymatic processes, for example, the reactions are reversible or are inhibited by products. In such cases, it is beneficial to favor the forward enzymatic reaction by keeping the upstream reagent concentrations high and constantly removing downstream products. This type of balance can be achieved to different extents by fed-batch systems or continuous flow systems that constantly replenish and remove reactor contents. Even in so-called batch reactors, where there is no flow of liquid in and out of the reaction chamber, it is often crucial to aerate and maintain sufficient levels of oxygen at all times.

As dimensions are diminished, the conductive resistance at the channel wall/fluid interface decreases, and temperature gradient increases, leading to a greater efficiency of thermal conductivity (11). Because heat flux scales with surface area while heat capacity scales with volume, thermal time constants and heat flux scale linearly with decreasing dimensions. The small thermal mass and associated fast thermal response allows for quick temperature control. On the other hand, since the microsystems can be heated and cooled quickly, it is difficult to maintain a constant temperature; external temperatures must be set at the desired temperature, or constant heating and cooling

of the microbio reactor will be required to avoid fluctuations.

A phenomenon that may not impact macroscopic bioreactors considerably, but has a significant effect on microbio reactors, is evaporation. Unless carefully monitored, evaporation will greatly affect reactant concentrations and osmolarity because of the small volume that a microbio reactor can hold.

A variety of mathematical models have been developed to analyze and control bioreactor thermodynamics and stoichiometry. Interested readers are referred to existing texts on the topic (12). For example, Roels (13,14) developed correlations to estimate some of the important thermodynamic parameters to predict yields, substrate and oxygen requirements, and heat dissipation for cellular reactions.

Reaction Kinetics. Bioreaction kinetics depends critically on temperature, pH, dissolved oxygen concentrations, and presence of inhibitors or enhancers. Oxygen fluctuation affects the metabolic and signaling pathways of cells. For bacterial bioreactors, the main concern is often to achieve a high enough oxygen transfer rate to match the oxygen uptake rate and maintain sufficiently high dissolved oxygen concentrations. For mammalian cell cultures, it is necessary to maintain an appropriate dissolved oxygen concentration. In expansion of stem cells, for example, lower oxygen concentrations that mimic physiological values gives higher yields and purity of cells (15,16). Microbio reactors present unique challenges and opportunities in terms of oxygen transfer. Microbial and eukaryotic cell cultures require constant replenishment of dissolved oxygen into the medium because of the low solubility of oxygen in aqueous solutions (8 mg/L⁻¹ at 35 °C in distilled water) (17). For larger bioreactors, bubbling oxygen or passing ambient gas through the cell culture suspension are commonly used (18). Microscale gas formation is more challenging, but has been demonstrated elegantly using electrolysis by Maharbiz et al. (19) (see Components section for details). For microbio reactors with submilliliter volumes, bubbles are generally avoided because they can clog channels and are difficult to dislodge from microchannel walls. For such systems, it is common to use a gas-permeable membrane to oxygenate the culture medium (20,21). The large surface/volume ratio of microdevices provides an advantage for such membrane-based oxygen transfer processes. Poly(dimethylsiloxane) (PDMS), a biocompatible polymer material commonly used for microdevice fabrication, is particularly advantageous in this regard due to its high permeability to oxygen.

Enzyme performance and cell growth and function are particularly sensitive to pH changes. When the reaction is not within the optimal pH range, the reaction rate declines dramatically (12). Substrates, products, or contaminants can reversibly or irreversibly affect enzyme activity. Surface interactions can also alter the kinetics of enzyme reactions, stability of enzymes (22), as well as growth and function of cells (23). Precisely dispensing nano- or picoliters of acids and bases into the tiny reaction chamber to adjust pH is technically challenging. Furthermore, because it is difficult to perform convective mixing in

microbio reactors, there may be local variations in the pH and in the reaction kinetics.

Mechanical Considerations. When microbio reactors are coupled with microfluidic systems, cells are subjected to shear stresses. For a given maximum flow velocity, smaller channels will give rise to larger shear stresses (1). Although excess forces can damage cells, moderate shear stresses on genetically engineered cells have actually enhanced the production yield of recombinant proteins (24). Cells in the body are also often exposed to stretching and/or compression. These forces are critical factors that regulate function of cells in muscles, hearts, blood vessels, lungs, and other tissues (25,26). For example, shear stress regulates morphology, gene expression and function of endothelial cells, the monolayers of cells lining the inside of blood vessels (27–30). Shear stress is physiologically important for maintaining vascular homeostasis (31), regenerate bone and healing fractures (32), differentiate embryonic stem cells into cardiovascular fate, leukocytes rolling and tethering to endothelial cells (33). Nuclear factor- $\kappa\beta$ (NF- $\kappa\beta$), for example, has been identified as a shear stress-responsive transcription factor that enhances the transcription of many genes including cytokines, growth factors, adhesion molecules, and immunoreceptors in response to shear stress (34).

Some of the biochemical and structural responses of cells to stretch include enhanced expression of endothelin (35), nitric oxide (36), and integrin (37) in vascular endothelial cells, and increased extracellular matrix production in cardiac fibroblasts (38) and in smooth muscle cells (39). Mechanical loading influence cellular functions *in vitro*, including proliferation (40,41), differentiation (42), hypertrophy (40,43), alignment (41,44), G protein activation, second messenger activity (45), and gene expression (43,46).

Cells in the body are constantly subjected to physical forces, such as cyclic mechanical deformation involving tension, compression, shear stress, or all three. Cell proliferation, differentiation, migration, signal transduction, and gene expression are all affected by such mechanical forces (47). Although it is largely unknown how mechanical stimuli are converted into intracellular signals of gene expression (48), there are many efforts to recreate physiological mechanical signals *in vitro*, either in the form of shear stresses from fluid flow, hydrodynamic pressures, or mechanical stresses applied to cells through the substrates. An ideal microbio reactor would provide optimal biomechanical and biodynamic stimuli for cell and tissue growth.

Material Considerations. The material used to fabricate the reaction chambers is crucial because they directly contact cells, enzymes, and products of bioreactors. Sometimes, it is also necessary to mimic physiological cellular environments (Fig. 2d) by altering the properties of the chamber surface to resemble that of the extracellular matrix (ECM). Proteins or enzymes can be immobilized onto surfaces to manipulate cell growth. Topographical features can also be incorporated to further mimic the ECM environment.

Surface Chemistry. As the size of devices decreases, their surface/volume ratio increases, making surface properties increasingly important in defining the performances of smaller bioreactors because cell function is intimately linked to the properties of the surfaces to which cells attach. Depending on the application, it is necessary to promote specific adsorption of proteins that mediate cell attachment and growth onto surfaces, or to prevent adsorption of proteins and cells. Because cellular receptors that bind to surfaces are nanoscale in size, it is also important to be able to pattern adhesive surfaces with resolutions from microns to nanometers (2,49–51). Surface properties are also important for enzyme-based microbioreactors because surface properties alter enzyme activity and stability. Enzymes are commonly immobilized through physical adsorption or covalent binding onto high surface area materials, such as carbon, silica, and polymers. Use of immobilized enzymes is often favored over free enzymes because of reduction in enzyme costs, ease of recovery, stability, and ability to be incorporated into microsystems. Ratner's recent review covers important topics including surface modification of materials to prevent nonspecific protein adsorption, immobilizing functional groups on surface, and development of synthetic materials (52).

A useful model surface for studying biomaterials interactions is a self-assembled monolayer (SAM). Often formed on gold using alkane thiols, SAMs are highly ordered arrays of linear molecules that have one end attached to the surface of gold or other bulk materials and the other end exposed to the environment. A useful feature of SAMs is that their surface properties are determined predominantly by the very terminal functional group. By altering the nature of these terminal groups, SAMs can prevent protein and cell attachment or promote binding of specific ones (53). Other types of systems that are useful for controlling protein adsorption include covalent bonding, via silanes, to silica or metal. Micropatterns of biopolymers can also be generated using photolithography, which uses patterns of light to induce region-selective chemical reactions on a surface. A more recent technique is microcontact printing, which involves transfer of small molecules or proteins onto solid substrates from an elastomeric stamp (53). Microfluidic networks have also been used for protein patterning: elastomers with embedded channel features are used to direct small volumes of protein solutions into networks of channels to create protein patterns corresponding to the path of fluid flow (54–56). Surface patterned microfluidic channels can then be used directly as microbioreactors in which micropatterned cell culture can be performed.

Topography Control. Living organisms are not flat. The endothelial lining of blood vessels, for example, exhibit an irregular wave-like topography to prevent build-up of fatty deposits (57). Endothelial monolayers have been modeled as a wavy surface by computational methods to estimate the influence of the waviness on local flow forces (58). Muscle fibers form microscale ridges and grooves onto which myoblasts can attach and proliferate (59). Microfabricated topographical features, regardless of whether they mimic physiological microtopographies or not, can be

used in microbioreactors to modulate adhesion, align or orient cells, and even affect cell growth and differentiation. Examples of topographical features that have been studied include single cliffs, grooves/ridges, spikes, hills, tunnels and tubes, fibers, cylinders, mesh, waves, and random roughness. Materials used for topographical controls include gold, silicon, carbon, inorganic compounds, such as silica, lithium niobate, silicon nitride, and polymers, such as polymethylmethacrylate, silicones, cellulose acetate, collagen, fibrin, and PDMS (51). Microtopography can also affect surface wetting and fluidic flow patterns. Even for a simple groove structure, variations of the aspect ratio and contact angle of the underlying substrate materials can dramatically alter the morphology of liquid droplets contacting the surface (60).

Sterilization. Similar to larger scale bioreactors, microbioreactors and their solutions and gases can be sterilized using heat, chemicals, radiation, or through the filtration of agents. The small reaction volumes of microbioreactors provide an advantage in terms of sterilization, because for a given concentration, the total number of cells, spores, or other contaminants depends on the volume. Then, assuming that the "death rate" of the contaminant is independent of reactor size or contaminant numbers, the sterilization time needed to extinct the contaminants will decrease with decreasing reactor size. In this respect, microbioreactors are more time efficient in batch sterilization than macroscopic ones. Ultraviolet (UV) sterilization is particularly convenient for transparent microbioreactors, such as those fabricated in PDMS. When pH sensors or dissolved oxygen sensors are packaged into the microbioreactor, autoclave and UV radiation may not be feasible, and alternative methods may need to be used. Flowing 70% ethanol through the chambers/channels and subsequently drying is also sufficient for many microbioreactor applications.

Other Considerations. Phototrophic microorganisms consume light energy to survive; they can grow in simple and inexpensive nutrient media. The light requirements of phototrophic microorganisms, however, impose other significant constraints on photobioreactor designs (61). These constraints are due to an exponential attenuation of the light flow passing through an optically absorbing medium. Microbioreactors, given their large surface/volume ratios, are promising for photobioreactor applications. Cultivation of phototrophic microorganisms in optimized photobioreactors would increase the product yield several folds by maintaining the culture under appropriate conditions.

Ultrasound irradiation can change both the structure and function of biologic molecules such as proteins and deoxyribonucleic acid (DNA) (62). At mild intensity, ultrasound irradiation can increase the activity of free enzymes (63). For example, significant enhancement of reaction rate can be achieved when exposing subtilisin power to ultrasound irradiation (64). Low energy ultrasound wave irradiation can also optimize the efficiency in ethanol production by yeast from mixed office waste paper in bioreactors (65). A variety of microscale ultrasound systems have been reported. Advanced microbioreactor

systems with ultrasound components may be developed to make bioreactors more efficient.

MICROBIOREACTOR COMPONENTS

Components For Heat Transfer

External heating elements can be incorporated into micro-bioreactors to control temperatures. External controls of temperature include the use of standard cell culture incubators that can accommodate the whole micro-bioreactor (66), heating tapes, and water-to-water heat exchangers (67). Internal, embedded heaters can be comprised of materials such as thin platinum films (68) or optically transparent indium–tin oxide (ITO) (69). Temperature measurements can also be made on chip using metallic, semiconducting, or optical materials.

An important application where heaters are crucial and micro-bioreactors have an advantage is the polymerase chain reaction (PCR), a temperature-controlled and enzyme-mediated DNA amplification technology (70). Polymerase chain reaction requires multiple cycles of high, low, and medium temperatures to separate DNA strands, anneal the primer to the template DNA, and make complementary copies of the template DNA. Since microsystems usually have high heat conductivity and low heat capacity, the time for raising and lowering the temperature is shortened and time will be saved when cyclic temperature fluctuations during the PCR reaction is necessary. Northrup et al. (71) integrated microfabricated polysilicon heaters into a micromachined silicon reaction chamber. Schneegass et al. (68) used a thermocycler chip with integrated thin platinum film heaters and sensors for temperature. Kopp et al. (72) used external copper blocks and heating cartridges with the surface temperature monitored by a platinum thin-film resistor. Burns and co-workers (73) developed a very simple and elegant PCR device that utilizes Rayleigh–Benard convection—a steady, buoyancy-driven circulatory flow that occurs between two surfaces, one on top and one on the bottom, maintained at two fixed temperatures—to perform temperature cycling.

Components For Aeration

Electrolytic gas generation provides a compact, scalable approach for gas delivery to micro-bioreactors (19). In brief, a pair of interdigitated Ti/Pt electrodes hydrolyzes electrolyte to generate oxygen gases at the narrow end of a gradually widened hydrophilic microchannel. The oxygen bubbles move along the conical microchannels and transfer into culture medium because of the positive pressure built up during gas generation and the different surface tension forces at the front and back of the bubbles formed in the gradually widening channel. The rate of oxygen generation can be precisely controlled by pulse width modulation of the electrode potential.

The smaller the bioreactor, the more crucial it is to avoid bubble formation to prevent blockage of microchannels. For such systems, it is advantageous to use gas permeable membranes that allow diffusion of gases through it without introduction of bubbles. Because the surface/volume ratio

is large in microsystems, oxygen transfer through gas-permeable membranes is often sufficient to ensure adequate oxygenation for biomass production. A straightforward method to fabricate gas-permeable membranes is to spincoat PDMS prepolymer onto silanized silicon wafers, cure and harden to generate a thin membrane, then peel it off (20,21).

Components For Fluid Control

Valves. Valves can be categorized into active and passive valves. A passive valve is a flow-dependent obstruction that functions without any external actuation. Passive valves are mostly unidirectional. In an active valve, fluid flow is directed by active actuation (74). The advantage that active valves have over passive valves is the degree of control one has over the timing, rate, and direction of fluid flow. This type of control is necessary to make real-time adjustments and for feedback control of micro-bioreactors. Although a large variety of valves have been reported, it is still a challenge to integrate multiple valves into a functional bioreactor system. Difficulties arise because many valves are incompatible with other components to be integrated, or because the valves require large external systems for actuation.

Passive valves have been used for restricting flow to one direction, removing air from liquid, or making flows stop at select channel regions. Although the level of control is lower compared to active valves, passive valves have the advantages of having few or no moving parts, less complexity, easy fabrication, and less chance to break due to fatigue (75). Recent approaches for passive control valves involve the use of hydrophobic materials, surface patterning, and changing channel fluid resistance (by changing channel geometry) (11). Passively moving micro-piston valves have also been fabricated *in situ* inside microchannels using laser polymerization of a nonstick polymer (76).

Most conventional active microvalves couple a flexible diaphragm (77,78) to, thermopneumatic (79), piezoelectric (80), electrostatic, electromagnetic (81), bimetallic, or other types of actuators. The scaling of these actuation forces to the microscale, however, is often unfavorable and requires macroscale external actuators for operation. An interesting alternative to active valves is the use of autonomously regulated valves made of hydrogels that swell in response to pH or other specific chemical or thermal environment (11,82). The volume changes of the hydrogel can valve or obstruct fluid flow directly, or indirectly, through deformation of a thin PDMS membrane. The PDMS, when deformed, partially occludes an orifice to regulate the feedback stream of compensating buffer solution (17). By altering their chemistry, hydrogels can also valve in response to the changes of temperature, light, electric fields, carbohydrates, or antigens. Ehrick et al. (83) incorporated genetically engineered proteins within hydrogels that swell in response to various ligands as potential valves for microfluidic channels. Other types of valves include the use of commercially available Braille displays (84) or a pneumatic valve system to deform flexible microchannels (85).

Pumps. A micropump should ideally be able to pump a wide range of fluids and gases, be self-priming, and be programmable. Ideal micropumps are still lacking; thus, many microfluidic applications use macroscopic pumps, such as syringe pumps. Micropumps can be classified into two main types: mechanical pumps and nonmechanical pumps (71). Mechanical pumps use electromagnetic, piezoelectric, pneumatic, shape memory, electrostatic, thermopneumatic, or thermomechanic components to deliver fluid. Mechanical pumps provide higher control over average flow rates, but the flow is often pulsed and the fabrication relatively complex (53,85). Many types of nonmechanical micropumps have also been successfully developed. The flow from nonmechanical pumps is usually pulse-free with a wide range of flow rates at low pressures and the fabrication is often less complex compared to mechanical pumps. An electrokinetic pump that utilizes an electric field for pumping conductive fluids by electrophoresis or electroosmotic flow (EOF) is the most common method to control flow in microfluidic systems (71). Electrokinetic pumps have the advantages of direct control, fast response, and simplicity. However, the substrate material, joule heating effect, and microchannel charge have to be considered. Other types of nonmechanical pumps include electrohydrodynamic pumps that use electrostatic forces acting on dielectric fluids, phase-transfer pumps that use pressure gradient between gas and liquid phases, electrowetting fluid actuation systems that use interfacial forces, electrochemical pumps that use the pressure of gas bubbles generated by electrolysis of water (71), magnetohydrodynamic pumps (86), capillary force, gravity-driven pumps (87), pneumatic pumps (85), and pumps that use action of piezoelectric pin arrays in refreshable Braille displays (84).

Multiple Laminar Streams. For most flows in small channels, viscous forces dominate; thus flow is laminar and lacks turbulence. When two or more streams pass through microchannels, they flow in parallel as if they are separated by physical boundaries. Laminar flow is a challenge for mixing, but a useful phenomenon for microscale fluid patterning (Fig. 3d) (55,88). By taking advantage of diffusive mixing (but not turbulent mixing) and laminar flows, spatiotemporally defined gradients can be generated and have been used to study chemotaxis (89,90). Multiple laminar flows have also been used for developing microfluidic assay systems [i.e., T-sensor (91)], and studying subcellular processes when the interfaces of the laminar streams are positioned over a single cell (92).

Mixers. Mixing is challenging in microfluidic systems because laminar flows preclude turbulent mixing (Fig. 3d). Microscale mixers, therefore, generally use elongational flows or laminar shears to increase interfacial areas between different fluids and mixing by diffusion. Distributive mixing physically splits the fluid streams into smaller segments and redistributes them to reduce the striation thickness. Passive and active mixers have been developed for microfluidic systems, including laminating mixers (93), rotary mixers (94), mixing based on out of phase forward and backward pumping of different liquids (84), plume

mixers (nozzle arrays), chaotic advection mixers (9,95), movement of liquid plugs (96), and an electroosmotically driven micromixer that uses multiple intersecting channels to enhance lateral transport (97). Thorough reviews on micromixers have been given by Hessel et al. (98) and Nguyen and Wu (99).

Components For Mechanical Stimulation

Shear. Methods commonly used to impart shear stress on cells include cone viscometers, parallel plates, and capillary tube flow chambers (100,101). Gradients of shear stress can also be generated in a curved D-shape microchannel (102). Flow-induced cytoskeleton rearrangements were shown to depend on the geometry of the channel (D-shape channel versus flat surfaces, representing experience in microcirculation and large veins, respectively) and the presence of inflammatory drugs (103).

Stretch. When subjecting cultured cells to mechanical stretch, proper design and application of a strain device are required to provide a well-defined and reproducible strain field to study mechanotransduction. Information from such *in vitro* models, which facilitate systematic variations in mechanical conditions and allow rapid analyses, would yield tremendous insights into mechanical parameters that may be important *in vivo* (104). Biaxial cell strain devices have been used to strain lung cells (105,106) by repeated mechanical deformations of a membrane on which cells are attached. Strain could also be applied using a magnetic force (107), or via uniaxial cyclical stretch (108).

Components For Separation And Purification

Lysing. Cell contents are separated from their surrounding environment by a cell membrane. The membrane and an underlying cytoskeletal network provide mechanical strength to the cell and preserve its integrity. The first step in many analyses or isolation of cell contents is to disrupt the cell membrane. There are a variety of mechanical (homogenization, milling, ultrasonic disruption, and blenders) and nonmechanical (detergent, organic solvent, osmotic shock, enzymatic permeabilization, electrical discharge, heating, and pressure cycling) methods for disrupting cell membranes on the macroscopic scale. Demonstration of cell lysis on the microscopic scale inside microfluidic devices, however, has mostly been with nonmechanical methods that use detergents (96,109), electrical discharges, or lasers (110). Miniaturized cell electrolysis devices can work with small amounts of cells and reduce the amount of purification compared to other protocols (111,112). For example, Waters et al. (113) developed a microchip that is capable of performing *Escherichia coli* lysis, PCR amplification, and electrophoretic analysis on a single device.

Separation. Cell separation techniques are fundamental to clinical diagnosis, therapy, and biotechnological production (114). For example, it is crucial to have purified cells before proliferation and production of cellular products. Current approaches include optical tweezers (115), centrifugation (116,117), filtration

(109,116,118), fluorescence-based cell sorting (FACS) (119,120) or magnetically activated cell sorting (MACS) (121), electric field-based manipulations and separations (114,122–124), and cell-motility based sorting (125,126). Microtechnology opens new opportunities in cell and biomolecule sorting that take advantage of laminar flow behaviors (125), electrical field properties (127), or other microscale phenomena. It also provides the opportunity to combine multiple modes of separation into an integrated system. Researchers have used physiological fluid mechanical phenomenon observed in blood microcirculation (plasma skimming and leukocyte margination) to filter leukocytes from whole blood (128). Petersson et al. (129) combined acoustic wave forces and laminar flow to continuously sort erythrocytes from lipid particles in the whole blood. Because these two components were different in density and responsiveness to pressure, erythrocytes were enriched at the pressure node (along the center of the channel) and lipid particles were gathered at the pressure antinodes (along the side walls). Finally, the erythrocytes and lipid microemboli separated into different branches at the end of the main channel. Because of the variety of different properties by which cells of interest need to be sorted, it is important to develop multiple modes of cell sorting. Reviews about microfluidic cell analysis and sorting devices can be found elsewhere (130,131).

Filtration. Microfabrication techniques have been developed to integrate filters and membranes inside microreactors. Zhao et al. (132) and Hisamoto et al. (133) successfully produced semipermeable nylon membranes inside microfluidic channels, by taking advantage of laminar flow so that a polymerization reaction would occur at the liquid interface of the two flows and produce a thin membrane in predetermined areas of a microfluidic device.

Components For Monitoring And Control

A key requirement for microreactors is the ability to measure parameters, such as temperature, dissolved oxygen, pH, and flow rate. For systems involving cells, mass balances are even more complex than with enzyme bioreactors because of the larger number of products and byproducts produced and the complex responses of cells to the changes in material concentrations. In small volumes, it is difficult or impossible to use standard, macroscopic, industrial probes. Miniaturized sensors must be developed (17). Sensors that do not consume the analytes are also preferred to avoid depletion and also because sample extraction is hard to achieve in closed and compact microsystems without disrupting the devices.

Optical, electrochemical, and thin-film solid-state conductivity are the three main categories of microsensing schemes. Many of the most useful microdetection schemes are based on optical measurements such as fluorescence intensity (134), fluorescence lifetime, chemiluminescence (135), and bioluminescence (136). Optical sensing is convenient because molecular or nanoscale “sensors” are simple to introduce inside microchannels and readout can be detected from a distance without direct external contacts. In addition, many optical probes can sense without con-

suming oxygen or perturbing pH. Nonperturbing sensors are important for maintaining a constant microenvironment because the quantities of chemicals are small in microreactors. Bioluminescence and chemiluminescence are sensitive with the detection limits down to 10^{-18} – 10^{-21} mol, which offers great advantage over other spectroscopic-based detection mechanisms. Laser-induced fluorescence detections in microsystems have been reviewed by Johnson and Landers (137). Other optical detection methods for microfluidic systems have been reviewed by Mogensen et al. (138).

Sol-gel-based probes encapsulated by biologically localized embedding (PEBBLEs) allow real-time measurement of molecular oxygen, pH, and ions inside and around living cells (139). Kostov et al. (17) used an optical sensing system integrated with semiconductor light sources and detectors to perform continuous measurements of pH, optical density, and dissolved oxygen in miniature bioreactors. A drawback of optical sensing is the need for light sources, lenses for focusing, and detectors, which are more challenging to miniaturize compared to the sensor probes themselves. A useful solution is to use optical fiber-based systems, which allows decoupling of the probes from the light sources and detectors, and enables detection at sites inaccessible by conventional spectroscopic sensors (140). Compared with silicon micromachining techniques, the fabrication and integration of polymeric optical elements (waveguides, lenses and fiber-to-waveguide couplers) with microfluidic channels are fast and simple (141). An oxygen-sensitive fluorescent dye has been developed to monitor dissolved oxygen levels in a system. This provides advantages over electrochemically based sensors [for a review, see Ref. 142] due to their size, ease of fabrication, and sensitivity (141).

Electronic microsensor is another category that contains a large number of useful biochemical detectors (143). Electronic microsensors usually require direct hard wiring of sensors to a readout system but can be easier to multiplex and are often smaller overall compared to optical systems. For example, Walther et al. (144) integrated a pH-ISFET (ion-sensitive field-effect transistor), a temperature-sensitive diode, and a thin-film platinum redox electrode on a single chip. The chip is mounted on a carrier and inserted into the chamber to monitor various biological parameters such as pH and redox potential. Brown and coworkers developed polymer membrane-based solid-state sensors to measure pH, and ions (145).

Microfabricated ultrasensitive nanocalorimeters can measure heat generation to monitor cell metabolic activity in response to agonist and antagonist using as few as 10 cells and without prior knowledge of the mode of action of these drugs. This measurement is noninvasive and quantitative and is envisioned to be useful for pharmaceutical companies to find drug candidate (146).

Li et al. (147) developed a microfabricated acoustic wave sensor to measure the stiffness of a single cell. This sensor is promising for drug screening and toxicology studies. For example, the acoustic wave sensor is envisioned to measure the rigidity of a heart cell to distinguish the effect of positive and negative inotropic drugs. Positive inotropic drugs are useful for treating congestive heart failure and

negative ionotropic drugs for hypertension. The acoustic wave sensor is also interesting for single cell muscle physiology.

Cells themselves can be used to sense and amplify biological signals. Several groups have developed histamine sensors by integrating cells on microfluidic devices (148,149). This chip-based detector caters to the need for a simple, rapid, and safe method for allergy identification. Cells can be engineered to have a variety of biological recognition events coupled to reporter genes to specifically sense analytes of interest (150).

Some new exciting prospects for future biosensors are in the area of nanotechnology. For example, quantum dots (151) and nanoscale PEBBLES (139) are extending the limits of sensitivity, stability, biocompatibility, and flexibility in optical sensing. Quantum dots are small semiconductor nanocrystals (on the order of nanometers to a few micrometers). Fluorescent quantum dots are able to detect biological species by fluorescing only when coming in contact with viable cells, making them useful probes for many types of labeling studies. These quantum dots are photobleached very slowly and can be manufactured to emit a wide range of wavelengths. They can be used in cell biology for the labeling of cellular structures, tracking the fate of individual cells, or as contrast agents (152). Nanowire-based sensors with their small size and higher sensitivity would also be ideal for integration into microbioreactors (153). Many microsensors have been developed and are ready for integration into microbioreactors.

Fabrication

A variety of methods and types of substrates are available for microfabrication. The most traditional and widely used method of microfabrication is photolithography. Originally developed for the microelectronics industry, photolithography is precise, highly reproducible, and capable of mass production. Photolithography uses patterns of UV light coming through a photomask to area-selectively induce chemical reactions in a polymeric, light-sensitive photoresist coated onto a semiconductor substrate. During development, the light exposed regions of the photoresist are selectively removed or selectively left behind generating micropatterned photoresist structure. The exposed areas of the substrate are then chemically etched to provide features of various depths and shapes.

Due to the high equipment costs involved in photolithography and because silicon and glass substrates used in electronic and mechanical devices are not necessarily the best materials for biological applications, alternative types of microfabrication have been developed. A cost-effective and experimentally straightforward method called soft lithography has been particularly useful for biological applications (2,53). Soft lithography uses elastomeric materials, such as PDMS to create microstructures, and to pattern and manipulate surfaces. The process involves casting PDMS against a photolithographically defined master mold to yield a polymeric replica. The PDMS replica is then sealed against another material to form channels and reservoirs. Alternatively, the replica can be used in a

technique called microcontact printing, where the PDMS mold is used as a stamp to transfer protein or molecular ink to a substrate. The PDMS has several properties, which make it useful for biological applications: (1) biocompatibility allows cell culture on and inside PDMS structures, (2) optical transparency allows optical inspection and sensing, (3) gas permeability allows long-term growth of cells without depletion of oxygen, (4) flexibility allows cell cultured on PDMS to be mechanically stretched (2,50,53).

Other polymer based microfabrication techniques include hot embossing, injection molding, and laser ablation. A hot embossing technique called nano-imprint lithography developed by Chou et al. (154) has the ability to fabricate sub-10 nm nanometer features. This process creates nanostructures in a resist by deforming the resist shape with embossing (155). Moriguchi et al. (156) developed a unique photothermal microfabrication technique, where agar microchamber arrays with living cells inside them can be remolded *in situ* during cell cultivation.

Integration

The development of a microbioreactor requires assembling multiple functional units (for electronic, mechanical, biological, and chemical processing) into a compact device. Integration and packaging poses a whole new challenge on top of the challenges to develop individual components. With macroscopic bioreactors, it is relatively straightforward to connect different components together with little or no worries of space organization. As one scales down, the placement of components must be performed strategically as the room around the reactor chamber decreases dramatically (because volume scales as length cubed, a 10 time reduction in linear dimensions, e.g., will lead to a 1000 time reduction in the available space). There are also technical challenges to fabricate microscale fittings and connectors, or to join two components via connectors even if they could be fabricated. A variety of processes used to build integrated circuits and microelectromechanical systems have played a major role in fabricating integrated microfluidic systems and microbioreactors. These technologies, known collectively as micromachining, selectively etch away or deposit structural layers on silicon wafers.

Recent efforts to reduce costs, enhance material biocompatibility, and needs for diverse chemical and mechanical properties have also led to the use of a wide variety of polymeric materials in microfabricated devices. Integration, unless planned carefully, can lead to material incompatibilities in fabrication or operation. Notable accomplishments of integrated microfluidic systems include DNA analysis chips (78,157), pneumatically driven microfluidic cell sorters and protein recrystallization chips (77,119,158,159), portable cell-based biosensor systems (160), microfermentors with integrated sensors (17,20,21), and a computerized microfluidic cell culture system actuated using the pins of a refreshable Braille display (84). Integrating fluid control components for cell-culture microbioreactors is rapidly progressing, but still underdeveloped. Interested readers are referred to recent review articles on integrated microfluidic devices (161).

SPECIFIC EXAMPLES OF MICROBIOREACTORS

This section presents select examples of microbio-reactors. The examples are not exhaustive, but are meant to show representative examples in each of the following four categories: (1) microbio-reactors that are used to optimize bio-production, (2) microbio-reactors that provide cells with physiological microenvironments to more accurately predict physiological drug kinetics and toxicity, (3) microbio-reactors that are used to develop cell-based therapies, and (4) microbio-reactors for mechanistic studies. Because the field is still young, the devices are relatively simple and many are still prototypes rather than refined products ready for real world applications. The rapid advances, however, promise an increasing role of microbio-reactors in the clinic, laboratory, and at home or other points of need.

Microbio-reactors For Optimizing Production Conditions

With the development of microtechnologies, more and more bioprocess optimization is performed in small volume bioreactors with integrated detection systems. For example, Rao and co-workers (17) have demonstrated parallel fermentations of *E. coli* in a milliliter-size microbio-reactor. A smaller, microliter-size fermentor has been developed recently by the Jensen's group (20). The performances of these microbio-reactors are comparable to traditional liter-size fermentors: Measurements of pH, dissolved oxygen (DO) and optical density (OD) of biomass in these microbio-reactors have similar profiles as those in benchtop fermentors. Similarities in cellular metabolism and growth show the potential of using microbio-reactors for bioprocess optimization. Arrays of microfermentors with integrated sensors and actuators are envisioned to drastically reduce the cost and time for developing new bioprocesses.

Microbio-reactors For Toxicological And Drug Testing

Drugs need to be tested for toxicity and efficacy before administration to humans. Accurate prediction, however, is a challenge because most current drug tests are performed only on human cells or animals. Animal tests are expensive and time consuming, and efficacy of a drug obtained from an animal surrogate study can still be difficult to extrapolate to humans (162). Even when one uses human cells for analysis, the result may be totally different from what occurs physiologically because cells cultured in flasks or dishes experience a totally different microenvironment. Therefore, a microscale human surrogate with microcirculatory systems, three-dimensional (3D) tissue organizations, and appropriate cell-cell and tissue-tissue interactions would be beneficial in predicting human responses to drug treatment more precisely. Below are two notable examples of such efforts.

Bioartificial Livers. There are two major applications for which artificial livers are developed: one is to replace organ functions in patients with liver failure, and the other is to perform toxicology testing of drug candidates. Organ repla-

cement functions require large bioartificial livers (BALs), whereas the toxicology studies would benefit from micro-scale BALs capable of conducting high throughput analyses. Microscale BALs are promising as convenient and low cost *in vitro* models for screening drug toxicities particularly in light of the fact that approximately one-half of all drug toxicities involve the liver.

Liver failure is the seventh leading cause of death by disease in the United States. About 26,000 people died each year because of liver failure. Transplantation is limited by the supply of donor organs and the cost of the surgery (163). Extracorporeal BAL devices have been proposed as substitutes for transplantation. Macroscopic BALs have been tested in clinical trials (164). In an attempt to maximize the efficacy of the BALs, and to develop *in vitro* liver systems for biological and toxicological studies, several groups have microfabricated liver cell culture systems (165).

Microbio-reactors for liver cell cultures have several configurations, ranging from flat-plate (163) or matrix-sandwiched monolayer designs (166) to 3D perfusion cultures (165). A flat-plate microbio-reactor with an oxygen permeable membrane was shown to support viability and synthetic functions of hepatocytes cocultured with 3T3-J2 fibroblasts (163). This microchannel bioreactor was also functional when connected extracorporeally to a rat (162). The results indicate that this device can potentially be used as a liver support device and for the eventual scale-up to clinical devices. Compared with other configurations, monolayer designs excel in mass transfer, easy fabrication, and easy optical analysis of cells (165), although cells might be damaged by exposure to shear stress (167). Griffith and co-workers (165) developed an array of microbio-reactors (with each channel $300 \times 300 \times 230 \mu\text{m}$, $L \times W \times H$ in dimension) that support 3D culture of liver cells by perfusion. Liver cells cultured in this device showed viable tissue structures and tight junctions, glycogen storage, and bile canaliculi. Membrane-based 3D perfusion hepatocyte culture systems have also been developed (66).

Micro CCA. It is important to integrate cells from different tissues together to simulate physiological drug metabolism. Shuler and co-workers developed Cell Culture Analogs (CCAs) that combine mathematical pharmacokinetics models with cell culture-based experimental studies to mimic human responses. The CCAs have compartmentalized cell cultures representing different tissues. Interconnections between these compartments allow circulation of media and metabolites. Since the CCAs mimic the time-dependent exposure and the metabolic interaction between multiple types of tissues and cells, predictions from the CCAs may be more accurate compared to existing *in vitro* models. Shuler and co-workers proved the concept of CCA with a macroscopic three-compartment (liver, lung, and other tissues) system and showed the feasibility and potential usefulness of such devices in testing naphthalene toxicity (168,169). MicroCCAs with three (liver, lung, and other tissues) and four (liver, lung, fat, and other tissues) compartments have also been reported (170,171).

Microbioreactors For Therapeutical Applications

Microfluidic Systems As Assisted Reproductive Technologies. Microdevices provide unique platforms for artificial reproduction and may ultimately increase the efficiency, safety, and cost-effectiveness of *in vitro* fertilization procedures. Currently, many embryo experiments are performed in macroscopic culture dishes, where human or animal oocytes (eggs) and embryos are manipulated manually. Use of pipettes for cellular manipulations is labor intensive and low in accuracy, reproducibility, and efficiency. In addition, the practice of transferring embryos from one type of media into another is abrupt and may shock the embryo due to the sudden change of environment (172–174); inside the female tract, the supply of nutrients, growth factors, and hormones changes gradually as the embryo development progresses. An alternative to manual pipetting is the use of microfluidic channels. Microfluidics is ideal for use in artificial reproduction, because it is a procedure that occurs physiologically inside small tubes and ducts, the size and numbers of cells (oocytes, sperms) required match well with dimensions of microsystems.

Beebe et al. (175) demonstrated manipulations of embryos and oocytes within microfluidic channels. The microfluidic systems can transport single mouse embryos through a channel network (176), remove the zona pellucida by chemical treatment (177), remove cumulus cells from oocytes via mechanical suction (178), and culture embryos in static or dynamic fluid environments (179). In some cases, embryos cultured in microfluidic channels develop faster compared to embryo grown in culture dishes and with growth kinetics that are closer to what is observed *in vivo*.

Cho et al. (125) developed a Microscale Integrated Sperm Sorter (MISS) that isolates motile sperms based on the ability of the motile sperms, but not the nonmotile ones, to cross-laminar flow streamlines. The device allows small volume samples that are difficult to handle with conventional sperm-sorting techniques to be sorted efficiently using a mild biomimetic sorting mechanism. The MISS integrates power source, sample injection ports, and sorting channel into one disposable polymer device making the device potentially useful not only clinically, but also as an at-home male infertility test (180).

Implantable Microcapsules. Microbioreactors that produce and release natural or recombinant bioagents are useful for delivering therapeutic agents *in vivo* to enhance metabolic function (181) or treat neurological disorders (182) and cancers (183,184). Mammalian cells, plant cells, microorganisms, enzymes, and biochemical compounds have been encapsulated in a variety of semipermeable containers mainly made of synthetic and natural hydrogels (e.g., poly(vinyl alcohol), poly(hydroxyl ethyl methacrylate), calcium alginate κ -carrageenan, chitosan, collagen, and gelatin). Here we focus on the application of microencapsulated mammalian cells. The outer membranes of the microspheres encapsulating the cells serve as selective barriers that allow exchange of nutrients, wastes, and therapeutic agents but block the passage of encapsulated cells as well as macromolecular components of the immune

system. This approach has been effective in delivering genetically engineered cells that secrete growth hormone to partially correct growth retardation (185), recombinant human bone morphogenetic protein-2 (rhBMP-2) to induce bone formation and regeneration (186), interleukin-2 to delay tumor progression and prolong survival (187), coagulation factor IX for treatment of hemophilia B (188), dopamine to treat Parkinson's disease (182), insulin to maintain blood glucose level (189), and analgesic substances to relief pain (190). Most of these works are aided by using murine and canine models. Some of the most advanced systems are in early clinical trials. Biocompatibility (191,192) mechanical stability of the capsule material (193–195), efficacy (196), safety (197), and cost are still under evaluation and optimization. Reviews of therapeutic uses of microencapsulated genetically engineered cells can be found elsewhere (198).

Microbioreactors For Understanding Biological Responses

Use Of Multiple Laminar Streams To Study Subcellular Biology And Chemotaxis. Physiological cell environments are heterogeneous with local production and consumption of key growth factors, nutrients, and signaling molecules. Microfluidic systems are useful for mimicking such micro-patterns of chemicals around cells. A particularly simple and useful method is to take advantage of small channel dimensions to generate multiple laminar streams that flow in parallel and adjacent to each other inside the same microchannel with minimum mixing (Fig. 3d). Such techniques can be even used to treat different parts of single living cells with different small molecular drugs, proteins, and small particles such as low density lipoprotein (LDL) (88).

Cancer and normal cells receive similar local stimuli inside the body, but behave totally differently. A critical question is why these differences arise. Taking advantage of multiple laminar flows to perform subcellular epidermal growth factor (EGF) stimulation, Sawano et al. (92) revealed differences in signal propagation between carcinoma and normal cells in response to local EGF stimulation.

Many cells direct their motion in response to chemical gradients. This phenomenon, called chemotaxis, protects microorganisms by allowing them to move toward more favorable conditions. In mammals, chemotaxis is important for guiding cell migration during development, embryogenesis, cancer metastasis, and inflammation. A challenge for analyzing chemotaxis is the lack of methods to generate well-defined chemical gradients that are stable and do not change with time. This difficulty arises due to the diffusivity of molecules and resulting changes of concentration profiles over time. Jeon et al. (90) demonstrated the use of microfluidic systems with branched networks of channels to generate stable gradients of interleukin-8 (IL-8) with linear, parabolic, and periodic concentration profiles. The position and shape of the concentration gradients were controlled by adjusting the flow rates and the positions to which reagent of interest were added into the channel network (89,199). The well-defined gradients allowed straightforward quantification of chemotaxis

coefficients as well as to observe complex migration behaviors of leukocytes in response to different concentration gradient profiles.

Studies Of Vascular Diseases In Microfluidic Channels.

The mechanical forces that accompany blood flow and pressure fluctuation influence vascular cellular biology and pathology in many ways. As the blood flow along a vessel, the viscous drag forces constantly expose endothelial cells (ECs) to shear stress. The pulsatility of the blood flow also induces a periodic change of circumferential strain on ECs and their underlying smooth muscle cells (SMCs). These mechanical forces have been found to cause important biological changes in endothelial cell morphology and function, such as alignment and elongation (30,200), low density lipoprotein uptake (201), tissue plasminogen activator synthesis and secretion (202), and proliferation (67). There has also been studies about the combined effect of shear stress and cyclic strain on ECs (203–205) and SMCs (206–208). While much has been revealed about the alterations in EC function induced by mechanical stresses, relatively little is known about the mechanism mechanical signaling.

Capillary-size microfluidic channels were used to model malaria, a potentially vital disease caused by loss of deformability of red blood cells due to *P. falciparum* parasites infection. Erythrocytes exhibited increased rigidity and decreased deformability with the progression of the disease, as demonstrated by their increased difficulties to transverse through 2 to 8 μm wide PDMS channels. This type of microfluidic system may potentially be useful to screen antimalaria drugs (209).

CONCLUSION AND FUTURE PROSPECTS

The convergence of bioreactors with advances in microtechnology is starting an exciting revolution in medicine. With microfabrication technologies, many copies of a device can be generated and operated with quick procedures and reduced cost. The ability to perform parallel assays allows high throughput optimization of bioprocess conditions, opening the way for cost-efficient biopharmaceuticals production.

Humans and other living organisms are inherently microscopic in their essence, being comprised of networks of microscopic reactors (i.e., the cells), and interconnected by microfluidic vasculatures. Efforts to miniaturize bioreactors would lead to not only the development of smaller pharmaceutical production and screening systems, but also the construction of more physiological *in vitro* cell culture systems where the ultimate goal is to develop microbioreactors as animal or human surrogates. Even for culture of single cell types, the ability of microfluidic systems to simulate physiological microenvironments is useful for revealing disease mechanisms, drug testing, use as biosensors, and single-cell-based clinical procedures such as *in vitro* fertilization. More complex microbioreactor systems with multiple cell types are being developed for toxicology studies. So-called animals-on-a-chip or minihumans provides exciting prospects for efficient drug discovery and personalized medicine.

Current state-of-the-art microbioreactors are still relatively simple with few components and limited sensing and control. Many are highly specialized and nonroutine in their use. The overall footprints of the systems are also often still macroscopic. Current advances in micro- and nanotechnologies as well as in medicine, however, promise rapid improvements in performance, accessibility, and sophistication of microbioreactors. Current trends point to a future where the gap between manmade devices and living organisms will narrow and applications of microbioreactors to medicine will grow.

MICRODIALYSIS SAMPLING: NON-SPECIALIST VIEW

Microdialysis sampling devices are minimally invasive miniature dialyzers that can be implanted into a distinct tissue region to obtain a chemical snapshot over an integrated time period. In combination with appropriate chemical detection methods for the targeted substances, a microdialysis sampling device may be considered to be a universal biosensor. Obtaining chemical information from different tissues can often lead to either a greater understanding of the underlying chemistry involved with the physiological function of the organ or the origin of a particular disease process. A simplified view of the microdialysis sampling device is shown in Fig. 1. The central part of the microdialysis sampling device is a single semipermeable hollow fiber membrane with dimensions that range between 200 and 500 μm for its external diameter and 1 and 30 mm in length. A perfusion solution is passed through the device at microliter per minute flow rates. Compounds diffuse from the tissue space into the dialysis probe and are carried to an outlet to undergo chemical analysis. Originally microdialysis sampling was developed to obtain real-time chemical information from rodent brain and was termed intracranial dialysis. Microdialysis sampling has now been applied for chemical collection from nearly every single organ. In addition to neurotransmitter collection, the device has been used for endocrinology, immunology, metabolism, and pharmacokinetic applications as shown in Table 1. The biomedical literature cites

Figure 1. Microdialysis sampling process. A perfusion fluid that closely matches the ionic strength and composition of the fluid external to the microdialysis membrane is passed through at flow rates between 0.5 and 2.0 $\mu\text{L}\cdot\text{min}^{-1}$. Analytes, A, that are not protein bound, AP, diffuse through the extracellular fluid space (wavy lines) and can pass through the pores of the semipermeable membrane are collected into the device. The analyte outlet concentration $[A]_{\text{outlet}}$ can then be quantified using a suitable detection method.

Table 1. Typical Microdialysis Sampling Uses

Collection of endogenous analytes from brain including neurotransmitters (dopamine, norepinephrine, serotonin, glutamate, GABA ^a , glucose, peptides and proteins (cytokines).
Collection of endogenous small hydrophilic analytes from other tissues (e.g., glucose for diabetics).
Collection of peptides and proteins from peripheral tissues, for example, glutathione, neuropeptides, and different cytokines and growth factors (e.g., VEGF).
Collection of xenobiotic analytes for pharmacokinetic or pharmacodynamic studies from numerous tissue sites (brain, dermis, muscle, and tumors) in both animals and humans.
Localized delivery of analytes followed by concomitant recovery of endogenous analytes or metabolized products (e.g., spin traps, metabolites).

^aGABA = γ -aminobutyric acid

thousands of research articles that have used microdialysis sampling devices to study many different basic and clinical research problems with perhaps 90% or greater of these applications focused in neuroscience. As more life scientists realize that microdialysis sampling devices exist, this device will be used more often to solve many additional clinical problems outside of the neurosciences.

INTRODUCTION

Mammalian organs are highly complex systems that achieve their functions through a multifaceted chemical communication network. For laboratory studies focused on understanding these chemical networks, the organ is often broken down into its component parts (cells, subcellular components, extracellular matrix components, etc.) to create more controlled conditions. These types of studies have allowed for a great understanding of the individual component parts, but do not address how the chemical communication may occur within the intact organ. Common diagnostic collection methods, such as blood or urine sampling, are too far removed from organs to be able to provide desired information about localized organ biochemistry. Gaining chemical information from an organ system prior to the creation of microdialysis sampling devices required either organ dissection or noninvasive analysis methods. Removing organs to access chemical content is fraught with many concerns including the preparation of the sample that involves in most cases sacrifice of the animal (or a biopsy for humans) as well as concerns about chemical stability and loss during the sample preparation process. For nearly all organs, the changes in localized tissue chemistry caused during sacrifice may severely alter some chemical communication systems. Finally, organ dissection does not allow for temporal studies of targeted analytes.

An increasing number of medical devices and instruments are becoming available to noninvasively measure *in vivo* chemical composition at spatially defined sites. Noninvasive measurements typically use spectroscopic instruments that are highly analyte specific. In particular, the most well-known medical devices for achieving these tasks

are positron emission tomography (PET) and magnetic resonance imaging (MRI). Positron emission tomography scanning requires production of special isotopes (¹¹C, ¹³N, ¹⁵O, ¹⁸F) with limited half-lives. Similarly, MRI uses ¹H to create an image and is a useful imaging technique because the concentration of hydrogen nuclei in water and fat is roughly 100 M (mol/L⁻¹). Magnetic resonance spectroscopy (MRS) can be used to noninvasively detect other isotopes (¹H, ¹³C, ¹⁵N, ¹⁹F, ³¹P), but requires very high concentrations of these nuclei for detection. Fluorescence imaging has also been used for noninvasive measurements in conjunction with near-infrared (IR) tags or with enzyme substrates that become fluorescent when cleaved (1–3). While these spectroscopic techniques hold significant promise for some areas of clinical medicine (cardiovascular and oncology), they are quite limited with respect to the range of analytes that can be detected and thus potential applications. While not noninvasive, minimally invasive microdialysis sampling devices coupled with appropriate dialysate analytical detection methods allow for measurements of localized tissue chemistry with significantly greater analyte flexibility and spatial resolution.

Microdialysis sampling originated as an alternative to push–pull perfusion devices for use in mammalian brain. Push–pull perfusion devices were used to collect fluid relevant to synaptic transmission (4). During a push–pull perfusion, a solution that closely matches the ionic chemical composition of the extracellular fluid (ECF) is loaded into a syringe and this is gently infused into the implantation site. This perfusion fluid mixes with the existing ECF and then is pulled back into the device. The analysis of push–pull samples became a useful tool for tracking neurotransmitter activities coupled with allowing for a remarkable understanding of the underlying chemical events associated with a wide variety of behavioral and physiological stimuli. Insertion of push–pull cannula could potentially cause tissue damage or lesions, which raised many concerns among researchers since this type of damage could limit the usefulness of the neurochemical data collected. In other words, researchers were often concerned that sampling was really taking place in a “lake” of fluid that may not contain the representative chemical components of the extracellular fluid space.

The push–pull sampling method was principally applied to neurochemical sampling. For other tissues, other extracellular fluid sampling methods have been described. These other methods include open-flow microperfusion and wick methods. Both of these methods have been used in muscle, as well as dermal sampling. Additionally, blister methods are common for obtaining interstitial fluid from the skin. Open-flow microperfusion is similar to push–pull perfusion. A cannula device contains an inner tube and an outer tube with open pores (typically ~500 μ m) is placed over this inner tube. A peristaltic pump then simultaneously delivers and withdraws fluid through the device (5). Open-flow microperfusion has primarily been used for sampling the extracellular fluid in muscle and skin. Alternatives to perfusion methods are wick methods, which use nylon wicks to sample the extracellular fluid space in animals and humans (6–8). To obtain multiple samples over a specified time period would require insertion and

removal of individual wick devices. This repeated insertion and removal might cause additional trauma to the sampling site.

To overcome the tissue damage concerns associated with push-pull perfusion for neuroscience applications, the use of semipermeable dialysis membranes at the tips of the push-pull cannula were used (9,10). These original dialysis bags eventually led to flow-through microdialysis probes introduced by Pycocock and Ungerstedt in 1974 (11). The advantage of microdialysis sampling over the push-pull cannula is that fluid is not pushed into sensitive brain tissue. Unlike a push-pull perfusion, microdialysis sampling is a continuous process that provides a sample that excludes many of the components from the ECF. This exclusion process serves to provide a relatively clean sample for chemical analysis. Today, this technique has been widely used by life scientists to attain site-specific access to numerous tissue sites to study and solve many problems, which include, but are not limited to the following applications: (1) To elucidate the role of different neurotransmitters and neuropeptides in specifically defined brain regions; (2) To collect glucose continuously over many days to give a better chemical picture to diabetes specialists to determine the efficacy of an insulin regimen for individual patients; (3) To collect energy metabolites (glucose, lactate, pyruvate) as well as administered drugs (morphine) to understand diseased energy metabolism and blood-brain barrier transport from head trauma patients; (4) To determine if an efficacious drug concentration is reaching a specific infection site or diseased tissue sites for antineoplastic therapy or antimicrobial therapy; (5) To determine pharmacokinetic parameters in single animals; (6) To determine metabolite formation and accumulation in various tissues after a drug dose in a single animal over time; (7) To determine the extent of drug blood-brain barrier permeation of new drugs in animal models; (8) To collect various endogenous peptides and proteins (e.g., cytokines and growth factors) from different peripheral sites in animals and humans (12).

To newcomers to this device, the principles of microdialysis sampling operation at first seem deceptively simple. At the most basic level, the microdialysis sampling device may be considered to behave as an artificially implanted blood vessel that allows free analyte diffusion into the inner fiber lumen. However, as will be discussed in this article, numerous considerations that involve both an understanding of the localized biology and physiology, as well as the underlying mass transport processes are essential to microdialysis sampling data interpretation.

MICRODIALYSIS SAMPLING PRINCIPLES OF OPERATION

In principle, as long as the microdialysis probe can be implanted, it can be used for sampling localized tissue biochemistry. Microdialysis sampling requires only a few pieces of equipment. This equipment is not cost-prohibitive, which is the reason that many different researchers can perform microdialysis sampling experiments in their own laboratories. For most experiments, the necessary equipment includes a perfusion pump to deliver the perfu-

sion fluid and a microdialysis probe. In addition to the pump and probe, for animal studies, a device to hold either an anesthetized animal (e.g., stereotaxic unit for neuroscience procedures) or a bowl with appropriate swivels to prevent tangled tubing for freely moving animals may be necessary.

Microdialysis Sampling Instrumentation Components

The basic components needed to perform microdialysis sampling experiments in an awake-freely moving animals has been described (13). The components required for this type of experiment includes the microperfusion pump, an inlet and outlet fluid swivel that prevents the fluid lines from becoming tangled, and a bowl system to allow the animal to freely move. Additional components can include refrigerated fraction collectors to allow collection and storage of sensitive samples. Microperfusion pumps used to deliver the perfusion fluid through the microdialysis probe are capable of delivering volumetric flow rates between 0.1 and 20 $\mu\text{L}\cdot\text{min}^{-1}$. Flow rates between 0.5 and 2.0 $\mu\text{L}\cdot\text{min}^{-1}$ are commonly used during most microdialysis sampling experiments.

Microdialysis sampling perfusion fluids are chosen to closely match the ionic strength and composition of the external tissue extracellular fluid surrounding the microdialysis probe. Perfusion fluids passed through microdialysis sampling probes are a form Ringer's solution for which there are numerous published chemical compositions (14,15). Typical Ringer's solutions contain ~ 150 mM NaCl, 4 mM KCl, and 2.4 mM CaCl_2 and can also be supplemented with glucose and other ionic salts (MgCl_2). These solutions are used both to maintain fluid balance, as well as ion balance across the dialysis membrane. Maintaining fluid balance across the dialysis membrane is important so that large osmotic pressures are not created. Significant osmotic pressure differences will cause fluid to be gained or lost during microdialysis sampling (16). Fluid loss is often undesirable for analytical as well as biological reasons. From an analytical perspective, oftentimes the analysis requires a set volume. For example, a liquid chromatographic analysis may require 10 μL of sample and a standard enzyme-linked immunosorbent assay (ELISA) may require 100 μL of sample. From a biological perspective, fluid loss can be undesirable in some tissues that are particularly sensitive, such as the brain. Furthermore, brain tissue is also highly sensitive to ionic concentration alterations since such changes can alter neurotransmitter release (17). By maintaining an osmotic balance, the fundamental mass transport mechanism for moving an analyte from the extracellular fluid space (ECF) to the dialysate lumen is principally diffusion.

Probe Geometry

Microdialysis sampling is typically considered to be synonymous with the term intracranial dialysis sampling because of its neuroscience origins. The first intracranial dialysis device was a linear design that traversed longitudinally through different brain regions. A variety of different probe designs have been described in many different review articles (18–20). Microdialysis probe design

has evolved to allow use of the device for biomedical applications beyond neuroscience. Linear geometry microdialysis sampling devices for neuroscience were not as useful as the push-pull cannula that could be inserted into known brain regions (e.g., striatum, hippocampus, *substantia nigra*) based on known stereotaxic coordinates that in some cases are < 1 mm wide in rat brain. To overcome this challenge for neurochemistry studies, more rigid cannula designs were created that can be inserted into specific brain regions and are now commercially available from a variety of sources (21).

As microdialysis sampling devices became a standard tool used by neuroscientists, researchers in other fields began to realize its great *in vivo* analysis potential. Principally, the use of the probes for collection of endogenous or xenobiotic components in blood and peripheral tissues became of interest (22). In these tissues, a rigid stainless steel cannula causes tissue damage and may make awake and freely moving experiments with animals quite difficult. Cannula designs using Teflon or fused silica are commonly used for to make flexible probes for either sampling in soft peripheral tissues (e.g., skin or liver) or for blood sampling. Linear probe designs have also been reintroduced after originally being applied to brain studies and are now used for insertion into soft peripheral tissues. An additional advantage of these flexible designs is they also allow for studies in awake and freely moving animals in peripheral tissues. Recent research interests in transgenic mice have forced the creation of smaller microdialysis sampling devices (23).

Probe Materials

Semipermeable hollow fiber membranes used for microdialysis sampling are the same as those used for kidney dialysis. Different polymeric semipermeable membranes have been used in microdialysis sampling probes and are listed in Table 2. Typical materials include cellulose-based membranes (cuprophane or cellulose acetate), polycarbonate/polyether blends, polyacrylonitrile, and polyethersulfone. These membranes span a wide range of molecular weight cutoffs (MWCO) from 5000 to 100,000 Da. Choice of the membrane to be used during microdialysis sampling requires both analyte molecular weight information, as well as where the probe will be implanted as some tissue

regions (particularly in the brain) are too narrow for > 500 μm external diameter membranes.

Semipermeable hollow fiber dialysis membranes can be obtained with a known molecular weight cut off (MWCO). The MWCO can be experimentally determined for a hollow fiber using several different experimental methods. The primary method used to determine MWCO for hollow fiber membranes is to continuously pass through the fiber lumen over a long period of time (24 h or greater) a solution containing known molecular weight markers. Known solutes that are rejected by the membrane are then used to calculate membrane MWCO. In practice, the MWCO is really not an absolute number, but rather the median of a range. This molecular weight rejection range is highly dependent on the semipermeable membrane materials pore distribution and can exhibit either a narrow or broad MWCO range (24).

Originally, the purpose of microdialysis sampling was to use the dialysis membrane as a means to provide a sample for chemical analysis that did not require further sample preparation steps such as protein removal. Intracranial dialysis applications typically target hydrophilic analytes with molecular weights < 500 Da. For these applications, dialysis membranes with low MWCO of \sim 5000–6000 Da were commonly used to reject larger analytes and proteins so to allow liquid chromatographic analysis without further sample purification.

Recently, there has been a greater interest of applying microdialysis sampling to collect peptides and proteins. There have only been a few reports describing the use of different types of dialysis membranes towards the collection of large molecules, such as peptides and proteins (25). This is unfortunate as the types of commercially available membranes that are capable of providing the performance characteristics necessary for protein collection are relatively few. Kendrick extensively compared the recovery performance of different amino acids and peptides among different types of dialysis membranes (26). Torto *et al.* compared the dialysis collection efficiency for a series of saccharides [glucose (DP1), maltose (DP2), though maltoheptaose (D7)] among many different types of dialysis membranes (polyamide, polyethersulfone, and polysulfone) as well as different MWCO between 6 and 100 kDa (27). In some cases, membranes with similar MWCO and different chemistry exhibited similar recovery values. Whereas, some of the polysulfone membranes with 100 kDa MWCO exhibited quite low recovery for these low molecular weight analytes when compared to membranes with similar chemistry, but lower MWCO.

A set of model proteins including insulin (5.7 kDa), cytochrome *c* (12.4 kDa), ribonuclease A (13.7 kDa), lysozyme (14.4 kDa), and human serum albumin (67 kDa) were tested with different polymeric membranes and molecular weight cutoffs ranging between 20 and 150 kDa (28). All the membranes had similar external diameters (500 μm). Among the different membranes, only the polyethersulfone (100 kDa MWCO) commercially available from CMA Microdialysis, Inc and a Fresenius polysulfone membrane (150 kDa MWCO) exhibited similar recovery characteristics for the above-mentioned set of model proteins.

Table 2. Commercially Available Microdialysis Membrane Dimensions^a

	PC	PES	PAN	CUP
Outer radius, μm	250	250	170	120
Inner radius, μm	200	205	120	95
Wall thickness, μm	50	45	50	25
Molecular weight cutoff	20,000	100,000	29,000	6,000
Outer surface area, mm^2	6.28	6.28	4.27	3.01

^aThe data provided here is that given by the manufacturers of the microdialysis probes. It is not known if the radii are for dry or wet membranes. The abbreviations are as follows: PC = polyether/polycarbonate, PES = polyethersulfone, PAN = polyacrylonitrile (or AN-69), CUP = cuprophane. CMA Microdialysis, Inc sells PC, PES, and CUP membranes. Bioanalytical Systems, Inc sells PAN membrane probes.

Membrane MWCO cannot be used as a means to specifically predict how well an analyte will be recovered during a microdialysis sampling procedures. New microdialysis sampling practitioners sometimes mistakenly believe that analytes near the membrane MWCO will be recovered. Although a membrane with 100 kDa MWCO allows some transport of molecules of this molecular weight, the recovery of an analyte of this size will be significantly $< 1\%$ (if at all) of the external sample concentration during microdialysis sampling. Dialysate analyte concentrations rarely reach equilibrium with the external sample concentrations except under unique conditions (very low flow rates and long membranes). For dialysate concentrations to reach those of the tissue medium surrounding the probe and thus approach equilibrium with the surrounding tissue concentrations, low perfusion fluid flow rates or long membranes are required in order to achieve residence times sufficient to obtain equilibration. During microdialysis sampling, the perfusion fluid only passes once through the inner membrane lumen with residence times on the order of seconds. Since this is in contrast to the methods used to obtain membrane MWCO, it is not surprising that sampled analyte molecular weight range is reduced due to the perfusion fluid making only one pass through the device. In general, the analyte molecular weight that easily passes through the membrane with 10% or greater recovery is roughly one tenth of the MWCO as shown in Fig. 2 (29). However, this is not an absolute value and different analytes have been reported to be difficult to dialyze across particular membranes. With rare exception (30), hydrophobic analytes typically are poorly dialyzed during microdialysis sampling (31,32). Furthermore, AN-69 membranes (polyacrylonitrile), which are sometimes used for kidney dialysis and have been used for in-house microdialysis probes, carry a negative charge that may cause rejection of certain negatively charged analytes (33,34).

Microdialysis sampling requires an inlet and outlet tube to be attached to the membrane. The length and inner diameter of the outlet tube attached to the membrane

affects membrane backpressure. For some hollow fiber membranes, convective fluid loss (ultrafiltration) across

$$J_v = P(\Delta p - \Delta\pi)/l \quad (1)$$

these hollow fiber semipermeable membranes is possible and the extent of this ultrafiltration is related to the volumetric flux (J_v) shown in Eq. 1, where P is the permeability coefficient for the membrane, l is the length across the membrane (e.g., the membrane thickness), and Δp and $\Delta\pi$ the hydrostatic and osmotic pressure differences (35). Different membranes have different permeability coefficients. The physical manifestation of this fluid loss is that the probe appears as if it is sweating during the dialysis procedure and is often observed with larger MWCO membranes.

Peptides and proteins diffuse very slowly across the small pores of membranes with MWCO between 5000 and 30,000 Da. To improve the relative recovery of these analytes, larger 100 kDa dialysis membranes have become commercially available. The disadvantage of these larger MWCO membranes is that they often exhibit ultrafiltration due to their larger pore sizes. Ultrafiltration fluid losses across 100 kDa or larger MWCO dialysis membranes should be determined prior to *in vivo* experiments. In particular, the ultrafiltration is exacerbated by the use of long outlet tubing with narrow diameter (a common need with awake and freely moving animal experiments). Osmotic balancing agents, such as dextrans or albumin, are commonly added to microdialysis perfusion fluids passed through 100 kDa or larger MWCO membranes to prevent excessive ultrafiltration as well as to prevent non-specific adsorption on the device materials (36,37). While these agents are passed through the membrane, their potential loss to the surrounding tissue space has not been reported.

Recovery, Delivery, and Localized Infusion

Sensor devices are highly specific analytical detectors and can only be used to detect analytes that physically contact

Figure 2. Semilog graph of relative recovery versus molecular weight for PC, PAN, and CUP membranes using different perfusion fluid flow rates. Flow rates are $0.5 \mu\text{L}\cdot\text{min}^{-1}$ (■), $1.0 \mu\text{L}\cdot\text{min}^{-1}$ (○), $2.0 \mu\text{L}\cdot\text{min}^{-1}$ (▲) and $5.0 \mu\text{L}\cdot\text{min}^{-1}$ (▲). Adapted from Ref. 29).

Figure 3. Localized infusion. A substrate or drug is locally infused through the microdialysis sampling probe. It diffuses into the ECF and then either reacts to form a product or causes a biochemical event to increase the concentrations of other molecules.

the sensor. Microdialysis sampling provides extensive flexibility with respect to ways in which it can be applied. Typical microdialysis sampling applications use what is termed the recovery mode where the device is placed into a sample matrix and analytes diffuse into the inner-fiber lumen of the probe (Fig. 1). Alternatively, the device can be used as a delivery device where a compound is infused through the probe causing either some alteration in a biochemical event (enzymatic reaction, enzymatic inhibition, or receptor binding) followed by collection of an endogenous analyte or enzymatic product. The probe can also be used to pass a substrate for a chemical or biochemical reaction and the products of that reaction can then be locally sampled as shown in Fig. 3. Unlike a specific sensor, microdialysis sampling devices allow for many physiological and biochemical processes to be studied within living tissue. Different examples of this approach for a variety of different tissues are shown in Table 3.

DEVICE CALIBRATION

Theoretical Foundations

Typical microdialysis sampling operating conditions (flow rates between 0.5 and 2.0 $\mu\text{L}\cdot\text{min}^{-1}$) will yield a represen-

tative fraction of the analyte concentration in the surrounding ECF. Since most microdialysis conditions are such that equilibrium between the dialysate and the sample is not obtained, a calibration has to be used to relate dialysis concentrations to external sample concentrations. Extraction efficiency (E_d) is used to relate the dialysis concentration to the sample concentration. The steady-state E_d equation is

$$E_d = \frac{C_{\text{outlet}} - C_{\text{inlet}}}{C_{\text{tissue}, \infty} - C_{\text{inlet}}} = 1 - \exp\left(\frac{-1}{Q_d(R_d + R_m + R_e + R_t)}\right) \quad (2)$$

shown below in Eq. 2, where C_{outlet} is the analyte concentration exiting the microdialysis probe, C_{inlet} is the analyte concentration entering the microdialysis probe, $C_{\text{tissue}, \infty}$ is the analyte tissue concentration far away from the probe, Q_d is the perfusion fluid flow rate and R_d , R_m , R_e , and R_t are a series of mass transport resistances for the dialysate, membrane, external sample, and a trauma layer that exists at the interface of the probe membrane and the tissue as defined in Scheme 1 (48,49).

The resistance terms are additive and understanding how these resistance terms affect E_d is vitally important with respect to experimental design. Throughout the microdialysis sampling process, collected analytes must diffuse through at least three regions (tissue, membrane and dialysate) in order to exit the microdialysis probe. Each mass transport resistance term defined in Scheme 1 has a diffusive component, which indicates that analytes with smaller diffusion coefficients will exhibit much lower E_d . The combined resistance contributions from R_d and R_m can be experimentally determined *in vitro* by collecting dialysates at different flow rates. A plot of the natural log of $(1-E_d)$ versus $1/Q_d$ should yield a straight line, which can be regressed to determine the additive values for R_d and R_m . In addition to this information, an *in vitro* E_d experiment performed at 37 °C with stirring to cause the sample resistance, R_e , to approach a zero value, will yield the highest possible *in vivo* E_d .

The variables shown in Eq. 2 illustrate that a combination of perfusion fluid flow rate (Q_d), as well as mass transport resistances for the dialysate, membrane, and tissue medium external to the microdialysis probe affect E_d . Decreasing Q_d allows for a greater fluid residence time within the dialysis membrane thus allowing analyte concentration to increase along the membrane axis.

Table 3. Some Examples of Localized Infusion Using Microdialysis Sampling

Type (substrate or inhibitor)	Infused Compound	Measured Analyte or Application	Tissue	References
Inhibitor	Cocaine	Dopamine	Brain	38
Substrate	Substance P and other neuropeptides	Proteolytic Products	Brain	39,40
Substrate	Salicylic acid or 4-hydroxybenzoic acid	2,3-DHBA, 2,5-DHBA, 3,4-DHBA	<i>In Vitro</i> , Brain	41–43
Substrate	Phenol or acetaminophen	Metabolites	Liver	44,45
Substrate and inhibitor	Angiotensin, phosphoramidon, captopril	Metabolites and enzymatic inhibition	Renal Cortex	46
Substrate	Suc-(Ala) ₃ -pNA	Elastase (protease) activity	<i>In Vitro</i>	47

$$R_d = \frac{13(r_i - r_\alpha)}{70\pi L r_i D_d}; R_m = \frac{\ln(r_o / r_i)}{2\pi L D_m \phi_m}; R_c = \frac{\Gamma[K_o(r_o / \Gamma) / K_i(r_o / \Gamma)]}{2\pi r_o L D_s \phi_s}$$

$$\Gamma = \sqrt{\frac{D_s}{(k_{ep}(r) + k_m(r) + k_c(r))}}$$

Scheme 1. The multiple mass transport equations used to describe microdialysis sampling. D is the diffusion coefficient through the dialysate, D_d , membrane, D_m , and sample, D_s . The parameter L is the membrane length; Γ (cm) is a composite function; $k_{ep}(r)$, $k_m(r)$, and $k_c(r)$ are kinetic rate constants as a function of radial position (r) from the microdialysis probe. Additional term definitions can be found in Ref. 48.

Fig. 4 shows a typical E_d curve simulated using the above equations (only R_d and R_m assuming a well-stirred system) for analytes with different aqueous diffusion coefficients. Fig. 4 clearly shows how microdialysis sampling membranes even for a hypothetical case perform in a manner that is consistent with diffusion being the major contributor affecting recovery. This scenario for the diffusivity is especially true for protein collection as many proteins of interest such as the cytokines have molecular weight values that can begin to approach the molecular weight cutoff limit for the dialysis membrane. In these cases, the protein diameter can begin to approach the values for the pore diameters resulting in restricted diffusion through the membrane, higher membrane mass transport resistances and thus reduced analyte recovery.

The parameter E_d is highly dependent on several physiochemical parameters (analyte diffusion coefficient, perfusion fluid flow rate, membrane pore size, and membrane surface area), kinetic uptake into cells (50) and the microvasculature (51), as well as the overall ECF volume fraction. The mass transport, resistances shown in Scheme 1 include analyte diffusivity terms for all three regions of mass transport, as well as kinetic terms for

the tissue space, as shown in the above equations. Tissue diffusive and kinetic properties of the sample surrounding an implanted microdialysis probe will dictate the how reduced the *in vivo* E_d will be from the maximum possible *in vitro* E_d value at any particular flow rate. For hydrophilic analytes, it is generally assumed they diffuse only in the ECF that surrounds the tissue cellular components. This ECF space comprises approximately 20% of the overall tissue volume (52). Typically hydrophilic analytes have to diffuse around the cells en route to the microdialysis probe, the overall effective diffusive path length is increased due to the tortuous path traversed by the analyte. This tortuosity alters the tissue diffusion coefficient which can be approximated using $D_{ecf} = D_{aq}/\lambda^2$, where λ has a value of ~ 1.5 . In addition to the alteration in diffusive characteristics, tissues are vascularized and have active cellular components. Depending on the analyte, the active components will affect the overall microdialysis E_d .

In addition to these parameters influencing microdialysis E_d , analyte properties affect the shape and the time to reach steady state for the concentration profile to the microdialysis probe. Analytes that diffuse rapidly and have a rapid supply to the tissue have narrow concentration profiles to the dialysis probe. Conversely, analytes that slowly diffuse and are not readily supplied to the tissue space will have concentration profiles to the dialysis probe that are not as steep. During microdialysis material is removed from the sampling site and the extent to which matter is removed is a function diffusive and kinetic parameters applied to that particular analyte, for example, how rapidly it the analyte replenished to the ECF from either capillaries (drugs) or cellular release processes. This has been a concern by others particularly as it relates to the understanding of dopamine transmission in the brain (53). However, dopamine is a special case and has rapid release and uptake kinetics in the ECF. For analytes that are poorly transported across the capillary space in the brain along with analytes that do not undergo significant uptake (e.g., drugs), their relative recoveries are generally lower than those with higher uptake/kinetic rates. It may appear to be counterintuitive to think that analytes with very rapid kinetic removal from the space surrounding the microdialysis probe have increased relative recovery. However, the higher removal rates cause the concentration profile to the dialysis probe to have a much greater gradient to the device as compared to a poorly removed analyte which would have a much shallower concentration profile to the device. For analytes with similar ability to diffuse through the membrane, that is, their membrane diffusion coefficients are nearly equal, the flux should be greater for the sharper concentration gradient thus causing greater relative recovery.

The theoretical foundations for microdialysis sampling during steady state operations derived by Bungay et al. have been widely used to corroborate many different *in vivo* experimental observations. In a series of papers focused on neurotransmitters, Justice's group has studied how uptake inhibition decreases microdialysis E_d 38,54,55. Stenken et al. 56 showed that since kinetic removal of targeted analyte may in some cases be additive, the inhibition of a particular cytochrome P450 isoform for phenacetin and

Figure 4. Simulated E_d using Bungay et al. (48) model with the following aqueous diffusion (D_{aq}) coefficients and with a membrane diffusion value of $0.2D_{aq}$ with length of 10 mm and R_i (200 μm) and R_o (250 μm).

antipyrine metabolism did not significantly alter E_d . This suggested that multiple kinetic components (capillary permeability plus metabolism) are important for analyte removal from liver tissue. Elmquist has shown that transporter inhibition in brain causes alterations in E_d for different drugs (57).

Calibration Methods

If the different variables shown in Eq. 2 and Scheme 1 are known prior to experimentation, then it is possible to predict the *in vivo* E_d . However, the difficulty with *in vivo* experiments is that obtaining values for variables is highly challenging. Furthermore, it is difficult to obtain an absolute value for C_{tissue} and an *in vivo* calibration requires that C_{tissue} (Eq. 2) be known. Even today, many experiments employing microdialysis sampling are semiquantitative and dialysate concentrations obtained are approximations of C_{tissue} at best. Since quite often ratios of dialysate analyte concentrations are obtained before and after some input (e.g., pharmacological or physical) with no attempt to measure the C_{tissue} during the experiment. To date, the *in vivo* calibration of implanted devices, including microdialysis probes, is an active area of research in the analytical chemistry and bioengineering communities and many authors have reviewed this subject (58,59). The principal difficulty with respect to obtaining a reliable device calibration is the inability to fully reproduce *in vitro* all the salient physiological features of tissue including permeation across capillaries and uptake processes (60,61).

Initial microdialysis sampling calibration focused on using an *in vitro* E_d calculation to estimate tissue analyte concentration. This approach gives a rough estimate of E_d and may provide an incorrect calibration factor. Furthermore, *in vitro* methods used for E_d measurement are affected by temperature (microdialysis sampling again is inherently a diffusion separation method), as well as sample stirring. A well-stirred buffer medium provides a mass transport external medium mass transport resistance (R_e) that approaches a value of zero. It is important to note that a quiescent medium does provide diffusional mass transport resistance and thus relative recoveries performed *in vitro* under stirred conditions will be different than those performed using quiescent conditions (48). How close a quiescently determined *in vitro* E_d is to the *in vivo* E_d would be wholly dependent upon the tissue kinetic properties for the targeted analyte. In other words, an analyte, such as dopamine, may exhibit higher *in vivo* E_d than *in vitro* quiescent E_d due to its extensive uptake kinetics causing a steeper concentration gradient to the dialysis probe as compared to the *in vitro* quiescent E_d measurement. Differences in the ability of the analyte to diffuse through the tissue space due to increased tortuosity and decreased volume fraction led to empirical methods that could be used to amend *in vitro* relative recovery calibration determinations (62). These methods focused on differences in tissue diffusion properties, but did not include the role of kinetic affects on microdialysis E_d causing significant errors for estimating *in vivo* values for C_{tissue} .

Jacobson et al. (63) were the first to try to create a more analyte-specific calibration procedure for microdialysis

sampling. In their work, varying the perfusion fluid flow rates through the dialysis probe derived an analyte-specific membrane mass transport coefficient, K , shown below in Eq. 3, where A is the membrane surface area and Q_d is the dialysate volumetric flow rate. Eq. 3

$$\frac{C_{\text{outlet}}}{C_{\text{tissue}}} = 1 - \exp(-KA/Q_d) \quad (3)$$

is similar to Eq. 2, showing how the model of Bungay et al. incorporated previously known experimental results. In this case, the product ($-KA$) is related to the sum of the fraction of the mass transport resistance terms. Experimental results from this work immediately showed that understanding the underlying *in vivo* mechanisms affecting microdialysis E_d was more complicated than initially expected. These researchers found that different amino acids exhibited different *in vivo* mass transport coefficients. This was unexpected since the amino acids would be expected to have very similar diffusion coefficients due to their similar molecular weight. This data began to lead to the understanding that analyte properties (diffusion and kinetics) in the tissue play a major role with respect to microdialysis sampling calibration. An extension of calibration approach of Jacobson et al. is to pass the perfusion fluid through the dialysis probe so slowly that zero flow is approached and nearly 100% relative recovery as shown in Fig. 5. In this case, the goal is to calculate C_{sample} by attempting to reach an equilibrium state across the microdialysis membrane (64).

The most widely used calibration method for microdialysis sampling is based on knowing that diffusive flux should not occur across the dialysis membrane when the analyte concentration inside the perfusion fluid matches the concentration external to the microdialysis probe. This method was originally demonstrated by Lönnroth and has been called by a variety of names including Lönnroth plot,

Figure 5. Mathematically modeled E_d for an approach to zero flow.

Figure 6. Lonnroth plot using hypothetical data.

method of no net flux (NNF) and method of zero net flux (ZNF). The ZNF method requires the tissue analyte concentration be at a steady state and has been used to determine basal concentrations for many analytes. The probe is perfused with different analyte concentrations that are either above or below the targeted analyte concentration. With these different perfusion studies, the loss or gain of analyte across the microdialysis probe can be determined and then plotted versus the inlet concentration as shown in Fig. 6. The analyte concentration is determined by the x -axis intercept and the relative recovery is the absolute value of the calibration line slope. A major drawback with this approach is the extensive amount of research time that has to be invested during the different perfusion studies. In particular, this is quite difficult to achieve with exogenous analytes (drugs) that would require a continuous infusion to achieve steady-state concentrations.

Quite often what is desired from a microdialysis sampling procedure is the analyte concentration during some sort of pharmacological challenge to an animal. This much needed analyte temporal information is not possible to collect with the requirement of steady state for the ZNF method. To overcome this problem and to gain information regarding the probe calibration from sample to sample, internal standards have been used during microdialysis sampling. Typically, internal standards have been chemicals with similar physicochemical properties as the targeted analyte. Some early work in internal standards proposed using one standard, such as antipyrine or ^3H -water to allow assessment of sample-to-sample differences should they arise throughout the duration of the microdialysis sampling events (65). Antipyrine would be a suitable reference for probe-to-probe variability because of its highly hydrophilic nature and ease of chemical detection. Urea has also been used as a microdialysis calibration reference for different metabolism studies (66–68). It is again important to note that the extraction efficiency of any particular analyte is a combined function of the different mass transport regions: dialysate, membrane, and most importantly tissue. Most likely during an *in vivo* micro-

dialysis sampling experiment, the variability from sample to sample will occur due to alterations in tissue physiology, such as blood flow, metabolism, and uptake, which would serve to alter the tissue resistance and thus E_d . For this reason, it is generally preferred to have internal standards with similar tissue diffusion and kinetic properties as the analyte. Finding an appropriate internal standard is not a trivial task since analytes with similar structure and diffusive properties may also compete for enzymatic sites and may inhibit metabolic pathways that are important to removal and thus E_d values. However, this possibility must be considered in context of the tissue being sampled, as well as other additive kinetic properties (e.g., uptake into cells or capillaries) that may have a much greater impact on the E_d . For example, in the brain, the kinetic process that has been shown for several neurotransmitters to be most weighted towards affecting E_d are the neuronal uptake processes rather than metabolism processes. Additionally, in the liver, it appears that capillary blood flow and permeability are the primary contributors toward the E_d value obtained. Internal standards for peptides and proteins may be much harder to devise as receptor binding or for the cytokines, binding to the proteoglycan components of the ECF space may affect E_d and thus using molecular weight markers, such as inulin (69,70) or higher molecular weight fluorescein-labeled dextrans (e.g., FITC-Dextran 3000, FITC-Dextran 10,000) may only serve to report back diffusional mass transport differences during the duration of microdialysis sampling.

Effect of Probe Insertion Trauma

Insertion of microdialysis probes causes tissue damage (71,72). Although this has been known for quite some time, it has generally been overlooked by many microdialysis sampling users. The extent to which this insertion trauma affects the integrity of the microdialysis sampling concentrations and its true overall importance has been debated in the literature. The biomaterials literature is full of descriptions of the cellular events that occur after a foreign body implantation (73). It is known that edema occurs at the site of probe implantation (74) along with the recruitment of polymorphonuclear leukocytes (75,76) and matrix metalloproteinases (extracellular matrix remodeling enzymes) (77). Moderately reduced analyte flux to microdialysis probe chronically implanted has been reported for glucose (78).

The validity of the ZNF calibration methods for *in vivo* calibration, as well as determination of C_{tissue} for some analytes, has recently been a concern for neuroscientists interested in dopamine. Many careful studies performed by Michael's group illustrated that dopamine concentration measurements obtained with microelectrodes and microdialysis sampling devices were quite different (79,80). In particular, microdialysis sampling devices often exhibited much lower basal concentrations of dopamine than microelectrodes. Additional concerns have been raised for drug blood-brain barrier studies (81,82). Between these two examples, dopamine collection via microdialysis sampling appears to be the most severely affected because of its release and uptake sites being compromised due to the

insertion trauma (49,83,84). In essence, the creation of a trauma layer creates four separate mass transport regions during microdialysis sampling: the dialysate, membrane, trauma layer, and normal tissue that need to be accounted for during data interpretation.

ANALYSIS OF MICRODIALYSIS SAMPLES

Microdialysis sampling is essentially married to appropriate detection methods for the collected dialysates. In addition to providing a means to sample from an *in vivo* site, microdialysis sampling also provides a relatively protein free or clean sample for chemical analysis. The only selectivity imparted into a microdialysis membrane is its molecular weight cutoff. For this reason, as long as a targeted analyte can diffuse through the membrane, the microdialysis sampling probe can be used as an *in vivo* chemical collection device. Thus, assuming the targeted analyte can pass through the dialysis membrane pores coupled with the appropriate analytical methods, a microdialysis sampling device could be considered to be essentially an all-purpose *in vivo* sensor (85). There is an extensive literature that has reviewed the associated analytical chemistry for making measurements in microdialysis samples (86). Additional reviews include: Adell et al. (87), Chaurasia (88), Church and Justice (89), Davies and Lunte (90), Horn (91), Kennedy (92), Kennedy et al. (93), Lunte et al. (94), Lunte and Lunte (95), O'Brien (96), Parkin et al. (97), and Parrot et al. (98).

Sample Volume Limitations

The major bottleneck 25 years ago for microdialysis sampling gaining more wide-spread and universal acceptance had to do with the analytical detection method sample volume limitations. During the early stages of microdialysis sampling, the primary analytical detection methods used for analyte quantification were liquid chromatography (LC) coupled with various types of detectors [ultraviolet-visible (UV-Vis), fluorescence, and electrochemical]. In addition to LC methods, radioimmunoassay (RIA) was occasionally used for peptides and proteins. Twenty-five years ago, it was not uncommon to require 25–50 μL of sample for LC analyses. Today, 50–100 μL of sample is still needed for standard immunoassays. The trade off that had to occur became one of either obtaining higher concentration recovery across the membrane by using low perfusion flow rates (1 $\mu\text{L}\cdot\text{min}^{-1}$ or less) or gaining sufficient temporal resolution by going to faster flow rates to achieve sufficient sample volumes for chemical analysis.

With the exception of glucose and lactate, many of the endogenous as well as xenobiotic analytes sampled using microdialysis had either micromolar (μM ; 10^{-6} M) to nanomolar (nM 10^{-9} M) concentrations. These low concentrations often pushed the limitations of common analytical equipment since for most analytes an approximate detection limit with most UV-Vis detectors is roughly in the low μM range and for fluorescence and electrochemical detectors their detection limits are approximately in the nM range. The need to be able to perform analytical measurements from such low volume dialysates drove analytical

method development in multiple directions towards systems that could accommodate the low volumes without sacrificing method sensitivity, as well as development of high throughput methods that allowed for increased temporal resolution. Presently, there are many commercially available technologies that allow for samples that are $<1\ \mu\text{L}$ (e.g., capillary electrophoresis) or have duty cycles that are $<1\ \text{min}$.

Separations-Based Methods for Microdialysis Sample Quantitation

Using separation methods, such as LC or capillary electrophoresis, for the quantitation of microdialysis samples is highly advantageous since these methods can be quickly adapted to many different analytes. Before the extensive use of microdialysis sampling for studies of neurochemical transmission, the use of *in vivo* voltammetry for analysis of neurotransmitters was just beginning to be described as a method for catecholamine (dopamine and norepinephrine) (99,100). The difficulty with using these methods was that electrode potentials needed to oxidize the catecholamines, as well as their metabolites (3, 4-dihydroxyphenylacetic acid, DOPAC) were similar. Furthermore, it was soon discovered that during vesicular release of dopamine, very high concentrations of ascorbic acid were released (101). For this reason, *in vivo* voltammetry of these important neurochemicals became more challenging since all of these chemicals can be oxidized at or below the same potential. The advantage of separations methods with appropriate detectors is that components including targeted analytes, as well as endogenous and exogenous interferences (see Fig. 7) can be appropriately separated and quantified. Thus, an additional advantage of using chromatographic methods is that chromatographic methods provide intrinsic multiplexing capabilities for the chemical analysis of microdialysis samples if different analytes are expected in the same samples.

Liquid Chromatography. Liquid chromatographic methods have been used for analyzing a broad class of analytes from microdialysis samples including catecholamines, amino acids, pharmaceuticals, and their metabolites. Several articles are available that describe the necessary requirements for microdialysis sample analysis using LC (102,103). Liquid chromatographic separations methods are well suited to microdialysis samples because of the high salt content contained in the perfusion fluids. Salts are generally not retained by the LC stationary phase and are therefore eluted in the chromatographic void volume. The resolving power of LC stationary phases allows for multiple analytes to be quantified during a single chromatographic run. Different detectors have been applied to LC separations for quantitation of dialysis samples.

Capillary Electrophoresis. Capillary electrophoresis (CE) is a separation method that involves passing an electric field across a micron-sized (~ 25 to $75\ \mu\text{m}$ internal diameter) capillary so as to allow separation of analytes based on their additive electrophoretic and electroosmotic mobilities. Neutral components in capillary electrophoresis

Figure 7. Example of different analytes that can be oxidized at approximately the same potential using a carbon electrode under physiological conditions. The formal potential for dopamine, norepinephrine, and DOPAC are ~ 0.7 V versus Ag/AgCl. For acetaminophen, the formal potential is $\sim +0.8$ V versus Ag/AgCl. For ascorbic acid, the oxidation formal potential is $\sim +0.15$ V versus Ag/AgCl.

will elute based on their electroosmotic mobility. Compared to LC analysis, CE provides greater separation efficiency and the possibility of faster separations. An additional advantage of CE is that an enormous research effort has been placed into microfabrication of CE devices onto microchips. This suggests the possibility for point-of-care technologies to be integrated with microdialysis sampling.

Like LC, CE has been used for a wide range of microdialysis sampling analyses including catecholamine neurotransmitters, amino acid neurotransmitters, and pharmaceutical compounds. Capillary electrophoresis has one main disadvantage and that has to do with the poor UV detection limits due to the path length being significantly reduced. However, sensitive detection can be achieved using electrochemical or laser-induced fluorescence detection approaches.

Although there are several disadvantages with CE detection, that is, no standard equipment, requirement of expertise, there is one advantage to this detection method for microdialysis samples. By using pH-stacking methods, significant on-column preconcentration (100 or greater) can be achieved (104). The mismatch of pH serves to greatly concentrate the sample zone on the head of the capillary column. This allows for online preconcentration to occur during the CE experiment. For collection and detection of peptides or proteins this preconcentration can serve to be highly useful. An additional advantage of CE is that extremely fast separations on the order of seconds can be achieved making this technology similar to that of a separations-based biosensor (105).

Fast Separations. Microdialysis sampling can be a slow temporal process due to the need to collect sufficient sample with sufficient relative recovery. To make microdialysis sampling more sensor like in terms of its response time, a number of groups have worked on achieving high speed separations, as well as direct coupling dialysate outflow the detection method. This is particularly important for studies of neurotransmitter dynamics. While electrochemical approaches for studies of catecholamine neurotransmis-

sion provide millisecond time resolution, microdialysis sampling is hindered by the turn-around time for the analytical method. High speed detection capability of cycle times of <1 min have been reported by many different groups using both liquid chromatographic, as well as capillary electrophoresis separations including 1 s time resolution with neurotransmitters (106) and <1 min resolution with pharmacokinetic analyses (107).

Examples of Different Types of Detection

Electrochemical Detection. Liquid chromatography coupled with electrochemical detection (LC-EC) is both a highly sensitive and selective method for analysis of compounds that can undergo an electrochemical reaction (oxidation or reduction). In this sense, LC-EC is highly suited to the chemical analysis of important biogenic amines (dopamine, norepinephrine, etc) obtained from microdialysis probes implanted into the brain (108). For these measurements, the electrochemical detector has a glassy carbon electrode that allows for oxidation of the amines at potentials of roughly 700 mV versus a Ag/AgCl reference electrode. The LC-EC excels in this analysis task because these analytes can be oxidized and furthermore their basal concentrations are in the low to mid-nanomolar range. The advantage of the separation is evident when considering that catecholamine metabolites (DOPAC, HVA) have basal concentrations that are ~ 100 – 1000 times greater than the clinically relevant catecholamines (dopamine, norepinephrine, serotonin).

In addition to catecholamine detection of microdialysis samples, LC-EC analysis has been applied to low concentration analytes obtained under varying conditions of oxidative stress. In these cases, typically either salicylic acid or 4-hydroxybenzoic acid is directly infused through the microdialysis probe to locally deliver a trapping agent as shown in Fig. 3 (109). These benzoic acids react with hydroxyl radical to form catechols which can then be separated and detected by LC-EC (110). The LC-EC has also been used to quantify the DNA oxidative damage biomarker, 8-dOH-dGuanosine (111,112).

Electrochemical detection can be made to be more selective by altering the electrode surface. Gold electrodes coated with Hg to create an amalgam are highly selective toward thiols such as cysteine and glutathione with low potentials needed for oxidation ~ 150 mV versus Ag/AgCl (113). Lunte and O'Shea used this approach for glutathione detection using CE (114).

In addition to electrode modification, packed enzyme beds containing specific oxidase can be used prior to electrochemical detection. This is commonly applied to detection of the neurotransmitters choline and acetylcholine. Acetylcholine and choline can be separated chromatographically and then an enzymatic bed containing acetylcholine oxidase and choline oxidase is placed at the end of the column. These specific enzymatic reactions produce hydrogen peroxide which is then detected downstream at a platinum electrode (115). Note that more recent developments have attempted to immobilize the enzymes specifically to the electrode (116).

Examples of Fluorescence for Dialysates. Fluorescence detection is often employed when a known derivatization method can be applied to dialysate samples to improve method detection limits or to create a molecule that has a better handle for detection. For microdialysis samples, fluorescence derivatization is commonly applied to important amino acid neurotransmitters such as glutamate and GABA (117–119) and occasionally to biogenic amines (e.g., dopamine and norepinephrine) (120).

Examples of Mass Spectrometry for Dialysates. Mass spectrometry (MS) is a unique LC detector in that as long as the analyte has the ability to form an ion, MS can be used for analysis. However, mass spectrometric detection can be difficult with microdialysis samples because of the high salt content. This method has been particularly useful with neuropeptides because of their low concentrations. A problem with mass spectrometric detection is that salts from the dialysis perfusion fluid can cause analyte ionization suppression that leads to dramatically decreased detection capability for the method (121). Salts from dialysates are often removed via a column-switching technique that pre-concentrates the analyte onto a C18 phase followed by desorption and detection (122). However, the use of nanoelectrospray devices can also reduce some of the problems associated with salt adducts (123–125). A particularly powerful method of LC-MS has been the ability to perform ionization in stages, which allows for structural elucidation of unknowns. The Kennedy group has been particularly successful with this approach for sequencing neuropeptides obtained from microdialysis samples (39,126).

Sensor Attachment to Microdialysis Probes

The microdialysis sampling process results in a relatively analytically clean (little to no protein) sample. Separations methods provide extensive analysis flexibility because they can be quickly optimized to the targeted analytes. However, there are *in vivo* monitoring situations where only one or a few analytes are targeted and highly specific analysis methods are available. A particular case in point

is the continuous detection of glucose or lactate from diabetic humans (127). The primary advantage of coupling a sensing device to the end of the microdialysis sampling device is the sample matrix is simply saline passing across the analytical sensor. This prevents many of the difficulties associated with biofouling of implanted sensors (128). However, a critical problem for glucose sensing using this approach is that it can only provide information regarding the glucose concentration fluctuations throughout the day, but cannot really serve as an alarm system because of the lag times that are ~ 20 – 30 min as compared to normal glucose sensors of a few minutes (129). Despite this concern, there is great value in using specialized sensors to a microdialysis device because of the clean sample delivered to the sensing device.

The use of biosensors attached to the end of microdialysis probes has become highly useful for clinical neuroscience where measuring glucose and lactate and in some cases other neurotransmitters are needed to understand homeostatic mechanisms (130,131). Most biosensors attached to dialysis probes have been for glucose, lactate, or glutamate detection (132–134). Cook has published an interesting approach combining immunoassay with electrochemical detection for specific measurements of cortisol (135).

Immunoassay for Peptide and Protein Detection

Peptide and protein analysis of microdialysis samples is challenging since the concentrations of these targeted analytes are often in the $\text{ng}\cdot\text{mL}^{-1}$ to $\text{pg}\cdot\text{mL}^{-1}$ levels. This requires either highly sensitive fluorescence derivatization techniques for use with capillary electrophoresis (136) or sensitive immunoassays. Conventional immunoassays require 50–100 μL of sample. To obtain these volumes requires the use of high flow rates ($2\ \mu\text{L}\cdot\text{min}^{-1}$ or greater) or very long collection times. In most cases, because highly sensitive radioimmunoassays (RIA) are used, higher flow rates are used to achieve moderate temporal resolution.

It is becoming increasingly evident that cellular communication in biological systems is highly complex and networked. Despite the tremendous growth in microdialysis sampling to monitor cellular biochemistry and an increased interest in peptide and protein detection in dialysates, there has been relatively little research towards new analytical methods that can detect peptides and proteins in low volume dialysate samples. A few approaches have been published that require 80–100 μL of sample for detection of several different proteins (137,128). Multiplexed assays (up to 25 analytes or more) that can be performed on a single sample have been recently created for immunology studies of the important inflammatory mediator class of cytokine proteins.

Highly sensitive multiplexed immunoassay platforms based on particle-based flow cytometry has become commercially available that allows cytokine measurements in 50- μL sample volumes (139,140). The limit of detection for these assays fall into the low pg/mL range comparable and have been compared and validated against standard ELISA methods (141). The use of these particle-based

immunoassays is highly advantageous to the sample-limited microdialysis process and the sample volume needed has been decreased to $< 25 \mu\text{L}$ by our group for cytokine detection. The advantage of these bead-based immunoassays for microdialysis samples is that several analytes can be analyzed in a single low volume sample. To illustrate the significant advantage that the bead-based immunoassay provides, if six separate cytokines were to be quantified in microdialysis samples using standard ELISA techniques more than $600 \mu\text{L}$ of sample would be needed. Using a flow rate of $1 \mu\text{L}\cdot\text{min}^{-1}$, this would require 10 h of microdialysis sampling.

Mass versus Concentration Recovery

Microdialysis sampling E_d is a concentration recovery term and E_d increases as fluid flows decrease through the dialysis fiber creating longer residence times. Conversely, overall mass recovery typically increases as the flow rate increases as shown in Fig. 8. For some analytical applications, this increase in mass recovery may prove to be highly beneficial since it opens up possibilities for analytical pre-concentration methods for the increased dialysate volumes.

MICRODIALYSIS SAMPLING APPLICATIONS

Microdialysis sampling applications have now been widely used in many different mammalian species including humans. The applications in humans have included studies in cancer, dermatology, immunology, pharmacokinetics and neuroscience. Many of these applications have been extensively reviewed by others and therefore will not be extensively discussed here. It is again important to note that microdialysis sampling has to date been principally applied to applications in neuroscience for the past

three decades. However, over the past decade, more microdialysis sampling applications in other areas are now being described.

Neuroscience Applications

Microdialysis sampling has been in the neuroscientist toolbox for > 25 years. This device has been principally applied to neurotransmitter collection. Early on, the primary focus was in rat and more recently with probe redesigns and the biomedical value of knockouts, additional studies have been performed in mice (23,142). Current research interests focus on bridging the gap between animal models and human studies.

Reviewing all the microdialysis literature for neuroscience applications is a daunting task since the microdialysis sampling technique is now in wide use. Some of the applications have already been mentioned in the Analysis section of this article. However, several reviews and a book (see Bibliography section) are available as background. These reviews have covered general aspects of neurochemical collection with microdialysis sampling (143–146), microchemical analysis (147,148), and controversial aspects of neurotransmitter collection (84,149–151)

Neuropeptides. With successful sampling of hydrophilic neurotransmitters with microdialysis sampling, the next logical analyte class to target was neuropeptides. Like neurotransmitters, the quantitation of neuropeptides is challenging with microdialysis sampling due to their low concentrations. Furthermore, their lower diffusion coefficients cause their E_d values to be low. Temporal resolution can also be an issue since quite often immunoassays that require $50\text{--}100 \mu\text{L}$ are often used for detection. Despite these limitations, many neuropeptides have been sampled using microdialysis sampling and have been reviewed > 15 years ago (152,153). With the increased use of mass spectrometry for neuropeptide detection of dialysates (154,155) coupled with additional bead-based immunoassays, the application space for microdialysis sampling of neuropeptides should increase tremendously.

Pharmacokinetics

Microdialysis sampling has been applied for pharmacokinetic studies in animals and humans. The great advantage here is that microdialysis sampling tremendously decreases the overall number of animals used for a pharmacokinetic study. Typical pharmacokinetic studies in rodents require the animal to be sacrificed at each time point used for the analysis. Microdialysis sampling allows for collection throughout the time course of the experiment because it can be easily inserted into the jugular vein. Again, because of the highly flexible nature of liquid chromatographic analysis for drug studies, the microdialysis sampling technique can be rapidly applied to new drugs and their metabolites.

Microdialysis sampling applications in pharmacokinetics have been extensively reviewed. In addition to general reviews of the subject (156–158), there have been reviews focused on data analysis (159,160) and calibration (161,162). One of the more important points to consider

Figure 8. Modeled microdialysis sampling mass recovery for different analytes with different diffusion coefficients.

when working with pharmacokinetic data obtained using microdialysis sampling is that a microdialysis sample represents a concentration average over the collection time period. This is in contrast to blood sampling that represents the analyte concentration directly at the sample time.

Clinical Applications

Clinical applications of microdialysis sampling have grown tremendously over the past decade and will continue to grow (163). At the present time, microdialysis sampling methods in human subjects have focused on studies in peripheral tissues for glucose collection (164–167) or drug distribution (168–170). Additional applications have been to determine gut barrier dysfunction (171). Microdialysis sampling applications in tumors has spanned both pharmacokinetic investigations (172–174), as well as collection of growth factors and cytokines (175). Microdialysis sampling has also been applied to human brain studies that have focused on understanding the underlying altered biochemistry that occurs when head trauma to drug distribution (176–180). Microdialysis sampling has been used as a means to monitor pharmacokinetics in the human dermis and has been compared to blister suction techniques (181). While both sampling methods produced similar data, it was found that microdialysis sampling was much easier to handle for both the patient and clinician.

Monitoring different growth factors and cytokines is becoming more important in clinical medicine since these proteins are known to affect cell-to-cell signaling and communication and are therefore becoming important biomarkers to measure. In particular, a group of proteins that are of great *in vivo* interest are the cytokines. Cytokines are potent, transient, and highly localized soluble messenger proteins (~6–80 kDa) produced by T-cells and macrophages that control nearly every aspect of the immune system (182). Cytokines exhibit complex interactions and therefore it is often more important to determine the concentration and cytokine profile after an immune challenge rather than the concentration of one single cytokine.

Microdialysis sampling is an ideal technique to achieve real time *in situ* monitoring of these important protein mediators and also has been recently described for proteomics applications (183). The application of microdialysis to this area is now emerging as potential approach for clinical

in vivo studies in both healthy and diseased subjects to recover targeted cytokine molecules from the exact action sites and has recently been reviewed by Clough (25). Commercially available microdialysis probes with a 100 kDa MWCO membrane have been used for *in vivo* microdialysis of some cytokines (184,185). It is important to note that microdialysis sampling provides localized sampling and thus insight into localized concentrations of cytokines that cannot be achieved via sampling from blood plasma. This has been recently demonstrated with the cytokine IL-6 where its interstitial fluid concentration was 100-fold higher than that found in the plasma (186).

Cytokines have low E_d through 100 kDa membranes. To improve cytokine E_d larger MWCO membranes (3000 kDa) typically used for plasmaphoresis have been used (187). Others are beginning to use the 3000 kDa MWCO membrane for collection of IL-6 and TGF- β_1 (186,188–190). The range of *in vitro* recoveries for different cytokine proteins is shown in Table 4.

EVALUATION AND FUTURE USE

Microdialysis sampling has become a mature technology for neurotransmitter collection and pharmacokinetic determinations in animals. Clinical microdialysis sampling applications provide the greatest opportunity for growth. Despite the extensive biomedical use of conventional microdialysis sampling, there are still aspects of the device that could be tremendously improved.

As currently practiced, microdialysis sampling in animals can be cumbersome due to the tubing lines required. Work in Lunte's group has focused on making micropumps using osmotic pumps as means to create line-free dialysis device (191,192). Reducing the microdialysis size by creating it on a microchip also has some advantages given that a decreased volume flow chamber may allow rapid equilibration across the device allowing E_d to approach nearly 100% (193–195).

A common problem with microdialysis sampling is the difficulty incurred when sampling hydrophobic analytes. This is an area with great promise with respect to either new device development or improvements to existing microdialysis sampling technology. Albumin is commonly included in the perfusion fluid to block

Table 4. Cytokine In Vitro Relative Recovery and Relevant Physicochemical Properties^a

Cytokine	$E_d\%$ 0.5 $\mu\text{L}\cdot\text{min}^{-1}$	$E_d\%$ 1.0 $\mu\text{L}\cdot\text{min}^{-1}$	MW, kDa	Conformation	Active Protein, kDa

^aCytokine standards were either 1250 or 2500 $\text{pg}\cdot\text{mL}^{-1}$. All solutions were quiescent at room temperature. A CMA/20 10-mm 100-kDa PES membrane was used for these studies performed in our laboratory. The numbers in parentheses after the RR values are the number of trials (n). All data are reported as mean \pm SD. N.D. is not detected.

Figure 9. Schematic of microdialysis enhanced transport. The analyte (S) or substrate for an affinity agent (A) binds with the affinity agent in the perfusion fluid. Affinity agents include antibodies, cyclodextrins or other supramolecular agents. The symbols in the equation are as follows: C_o = Concentration at $x = 0$, C_L = Concentration at $x = L$ (membrane length), D_{mem} = membrane diffusion coefficient, k = first-order rate constant for the reaction between the analyte, S, and the affinity agent, A, Q = perfusion fluid flow rate and R_i, R_o = inner and outer radii.

nonspecific adsorption sites within the microdialysis polymeric materials (196,197), and is still widely practiced (198). Unfortunately, this adds protein back into the dialysis perfusion that for small analytes causes difficulties with CE and LC analyses. A second approach involves using lipids, such as Intralipid, a material used to suspend hydrophobic drugs, to coat the nonspecific adsorption sites on the dialysis membrane or tubing (196,199). It is not known how compatible this approach is for CE or LC analysis.

Cyclodextrins have been used as perfusion-fluid additives for improving the microdialysis recovery for different analytes (200,201). A general scheme for the enhancement process is shown in Fig. 9. Cyclodextrins are well-known cyclic oligosaccharides that have the capability to form inclusion complexes with various organic molecules by the capture of the guest molecule into a hydrophobic central cavity (202). Dialysate samples that contain cyclodextrin can be injected into an LC column without alteration to the chromatographic separation parameters, for example, plate number and peak width (203). Cyclodextrins are not selective, which for this enhancement approach is beneficial given that they can be applied to a wide variety of low molecular weight hydrophobic organic molecules (204,205). However, a difficulty with this approach is that cyclodextrins can diffuse out of the dialysis membrane that may complicate some applications. An additional difficulty is that cyclodextrins can interfere with affinity-based detection assays (immunoassays) due to competition between the analyte and cyclodextrin versus analyte and an antibody.

To overcome the free diffusion of cyclodextrin out of the dialysis tubing, different type of solid supports have been used for enhancement. Markides group has described the use of a solid-vehicle support for improving neuropeptide microdialysis relative recovery coupled with LC-MS detection (206,207). More specific enhancements can be

achieved using antibody-immobilized beads for flow cytometry (208). With the antibody-enhancement approach, increases in microdialysis sampling relative recovery of 4–12-fold were achieved for different cytokines.

Microdialysis sampling is already beginning to be used in metabolomic studies using LC-MS detection methods (209). With the creation of microcoil nuclear magnetic resonance (NMR) that can measure nanoliter samples (210,211) the detection possibilities for dialysate samples are greatly increased. This approach has been recently applied to metabolomic studies with microdialysis sampling in brain (212).

The combination of these new discoveries for microdialysis sampling shows the enormous potential for solving many clinical biomedical problems with this device. The future for microdialysis sampling and device spin-offs is quite bright. New developments in instrumentation and collection procedures will provide much clinical benefit.

Microdialysis sampling has moved from a sampling device exclusively used to collect low molecular weight hydrophilic neurotransmitters to applications requiring the collection of larger proteins. Many cellular signaling processes occur via small molecule (nitric oxide, norepinephrine, acetylcholine, eicosanoids, etc.), peptide (angiotensin, etc.) as well as proteins (cytokines). Cytokine profiling for different disease states has become quite important. For the applications of both neuropeptide and larger protein collection such as the cytokines, the principal limitation to collecting these molecules is the diffusion properties of these analytes through the dialysis membrane. Proteins are difficult to collect through dialysis membranes since they can exhibit both nonspecific adsorption to the polymeric materials as well as diffusion restrictions through the membrane pores. Despite the variety of applications of microdialysis sampling to medical and scientific research, there have been few new developments with respect to improving the overall sampling efficiency for difficult to dialyze samples. As clinical proteomics and biomarker collection becomes better understood for making clinical predictions, it will be necessary to have sampling methods that can meet these clinical needs.

ACKNOWLEDGMENTS

Microdialysis sampling research in the Stenzen laboratory is currently funded by NIH EB001441. The support from the John Wiley & Sons, Inc. editorial staff is greatly appreciated.

MICROFLUIDICS

GLENN M. WALKER
North Carolina State University
Raleigh, North Carolina

INTRODUCTION

Microfluidics is the study and application of fluids at the microscale. The most common definition of the microscale is that one or more device dimension be in the range of 1–1000 μm . For reference, the diameter of an average human head hair is $\sim 150 \mu\text{m}$, the average thickness of a human fingernail is $360 \mu\text{m}$, and the diameter of a human red blood cell is $\sim 7 \mu\text{m}$. Miniaturization technology, originally developed by the microelectronics industry, has been used to create microscale fluid components and complete microfluidic systems with pumps, valves, and filters, incorporated onto single microchips have been demonstrated.

By applying the analogy of the microelectronics industry (i.e., continuously incorporating more features into smaller areas) a logical application of microfluidics is to create lab-on-a-chip (LOC) systems. Lab-on-a-chip systems, also known as micro-total-analysis systems (μTAS), incorporate the functionality of biology or chemistry laboratories onto a single microfabricated chip. Ideally, a LOC system would be able to execute all of the tasks routinely performed in a biology or chemistry laboratory, such as sample preconditioning, mixing, reaction, separa-

tion, and analysis. Labor- and time-intensive procedures would be reduced to instant results derived from a series of automated steps performed on a LOC.

Microscale fluid handling confers many advantages over traditional lab operations (1). First, fluid quantities ranging from picoliters to microliters are used, thus reducing the amount of sample required for tests. Second, the amount of time required to perform some analyses (e.g., capillary electrophoresis) is reduced to seconds, which means analyses can be conducted many times faster than with traditional methods. Third, devices can be manufactured using microfabrication technology, which translates into reduced cost per device; disposable LOC systems can easily be envisioned.

In general, microfluidic devices are in early stages of development and are most often found in academic research laboratories. However, the benefits of these systems have been exploited to develop new medical devices for clinical diagnostics and point-of-care testing. Commercial examples of devices that make use of LOC concepts are discussed at the end of this article.

THEORY

Fluid Mechanics

The term microfluidics encompasses both liquid and gas behavior at the microscale, even though in most applications the working fluid is a liquid. All of the concepts discussed here are directed toward liquids. Other works are available which provide information on gas behavior at the microscale (2).

Fluid behavior at the microscale is different from that commonly observed in everyday experiences at the macroscale, owing primarily to the very low Reynolds (Re) numbers of the flow regime plus the large surface area/volume (SAV) ratios of the flow domain. As a consequence, viscous forces and surface tension effects become dominant over fluid inertia, and transport phenomena are purely diffusive.

Fluid flow at the microscale is typically laminar. Fluid flows are classified based on their flow regime, which can be predicted with the Re number. The Re number is the ratio of inertial forces to viscous forces and can be calculated with the equation

$$\text{Re} = \frac{\rho V D_h}{\mu} \quad (1)$$

where ρ is the fluid density, V is the characteristic fluid velocity, D_h is the hydraulic diameter of the microchannel, and μ is the fluid viscosity. Fully developed fluid flow in a channel of circular cross-section is considered laminar if the Re number is < 2100 . For Re numbers between 2100 and 2300, the flow is considered transitional: it shows signs of both laminar and turbulent flow. A Re number > 2300 indicates turbulent flow.

Laminar flow is predictable in the sense that the trajectories of microscopic particles suspended in it can be accurately predicted (Fig. 1a). Particles suspended in a turbulent fluid flow behave chaotically and their position as a function of time cannot be accurately predicted

Figure 1. (a) Particles suspended in a laminar flow within a straight microchannel follow straight trajectories. (b) Particles suspended in a turbulent flow within a straight microchannel do not follow straight trajectories unless they are very close to the wall.

(Fig. 1b). Fluid flow that has a Re number <1 is also known as viscous flow, creeping flow, boundary-layer flow, or Stokes flow.

Low Re number flow is best visualized by imagining how honey (or any viscous substance) behaves when poured or stirred. For example, water flowing in microchannels will generally have a Re number <1 . In this case, water will behave like a very viscous liquid (i.e., like honey). An important point to make here is that the properties of water do not change at the microscale; rather the microscale dimensions involved make the water *appear* more viscous than what we are accustomed to at the macroscale. An excellent description of low Re number environments has been given by Purcell (3). Very viscous fluid flows have certain characteristics: the flow is reversible, mixing is difficult, and flow separation does not occur (4).

Reversibility is the ability of a suspended particle in a fluid to retrace its path if the flow is reversed. This is a result of the minimal inertia (i.e., low Re number) present in fluid flows at the microscale. Figure 2 shows the path a suspended microscopic particle might take in forward and reverse flow.

Figure 2. (a) A suspended particle in laminar flow around an obstacle in a microchannel. (b) If the flow is reversed, the particle will retrace the same path.

Figure 3. (a) At low velocities (low Re numbers), flow separation will not occur in microchannels. (b) At higher velocities (larger Re numbers), flow separation may become apparent.

A second characteristic of microscale fluid flow is a lack of flow separation. Flow separation is commonly observed in the form of vortices, which are recirculating flows separate from the main flow. Because of the low Re number environment, vortices usually will not form within microfluidic channels, as shown in Fig. 3a. Separation will only occur in flows wherein inertial forces are significant relative to viscous forces ($Re > 1$). Figure 3b is a qualitative sketch of flow separation in a cavity.

The third characteristic of microscale fluid flows is inefficient mixing as a result of very low Re number flow, and thus negligible inertia. Low inertia means that stirring is not effective and that mixing must be accomplished by diffusion. At the macroscale, stirring minimizes the diffusion distances between two or more liquids by distributing “folds” of the liquids throughout the volume. Microscale methods of mixing have been developed that take advantage of the unique properties of the scale and improve the efficiency of mixing over simple diffusion; examples include using three-dimensional (3D) channel geometries, patterned channel surfaces, and pulsatile flow (5).

Figure 4 shows two streams flowing down a microchannel side-by-side. Because of the low Re number environment the streams will only mix by diffusion. If the flowrate is slow enough, the streams will eventually become uniformly mixed across the whole microchannel width.

The hydraulic diameter, D_h , of a microchannel is determined by its cross-sectional geometry and can be calculated with the equation

$$D_h = \frac{4A}{P} \tag{2}$$

Figure 4. Two streams flowing in a microchannel will only mix by diffusion. Note that the concentration across the width of each half of the main microchannel is not constant as diffusional mixing progresses.

Table 1. Diffusion Coefficients for Biologically Important Molecules in Water^a

Molecule	$T, ^\circ\text{C}$	$D, \text{cm}^2 \cdot \text{s}^{-1}$	Diffusion time, s
Cl^-	25	2.03×10^{-5}	0.02
O_2	18	2×10^{-5}	0.03
K^+	25	1.96×10^{-5}	0.03
Na^+	25	1.33×10^{-5}	0.04
Glucose	20	6×10^{-6}	0.08
Lactose	20	4.3×10^{-6}	0.12
Insulin	20	1.5×10^{-6}	0.33
Hemoglobin	20	6.3×10^{-7}	0.79
Urease	20	3.4×10^{-7}	1.47

^aAll values are from Ref. 6. The time for each particle to diffuse 10 μm is shown for comparison.

where A and P are the microchannel cross-sectional area and wetted perimeter, respectively. The hydraulic diameter is often used to calculate important flow characteristics for noncircular microchannel cross-sections.

At microscale dimensions diffusion is an effective mechanism for transporting molecules because of the relatively short distances involved. Particles diffuse from areas of high concentration to areas of low concentration and will eventually diffuse to uniform concentration throughout a given volume. The mean distance, d , a particle travels in a time, t , can be predicted with the equation

$$d^2 = 2Dt \quad (3)$$

where D is the diffusion coefficient of the particle. Diffusion times are proportional to the square of distance, which means that particles can diffuse across microscale distances within a particular medium in a matter of seconds. Table 1 lists representative molecules of biological significance and their diffusion coefficients.

The SAV ratios become very large at the microscale. Typical SAV ratios for macroscale containers such as Petri dishes or culture flasks are $\sim 10 \text{cm}^{-1}$, while they are $\sim 800 \text{cm}^{-1}$ for microfluidic channels. Increased SAV ratios allow diffusion-limited processes, such as immunoassays to become much more efficient at the microscale because of the increased surface area available for binding. Large SAV ratios also allow rapid heat radiation from microscale fluid volumes and efficient gas exchange with the ambient atmosphere and fluid in microchannels (assuming the microchannel is made of a gas-permeable material). Enhanced gas transport is a critical ingredient for cell culture in microscale environments. One drawback of large SAV ratios is that evaporation becomes a significant problem.

The surface tension of a liquid becomes increasingly important at very small dimensions. To visualize this, think of a liquid surface as an elastic skin. If a slit were made in that skin, a certain amount of force per unit length would be required to hold the two sides of the slit together. The amount of force required to hold the two sides together is called the surface tension. Because the liquid surface is under tension, liquid confined by the surface (e.g., a rain-

drop) will experience an internal pressure. This pressure is called the Young–LaPlace pressure. Smaller fluid volumes result in larger SAV ratios, thus increasing the internal pressure. The pressure within a drop of liquid can be calculated with the formula

$$\Delta P = \frac{2\gamma}{R} \quad (4)$$

where γ is the liquid surface energy and R is the radius of the drop. At microscale dimensions, significant pressures can be created by surface tension. A common result of the pressure difference of an air/liquid interface is the capillary effect: a pressure difference across the interface propels liquid through a small diameter capillary or microchannel.

The capillary effect also depends on the contact angle of the microchannel surface. Hydrophobic surfaces (e.g., polymers) have contact angles $>90^\circ$ and hydrophilic surfaces (e.g., glass) have contact angles $<90^\circ$. Microfluidic devices with hydrophilic surfaces can be filled via capillary action. The pressure difference at an air–liquid interface within a microchannel with square cross-sectional area can be calculated with the formula

$$\Delta P = 2\gamma \left(\frac{\cos(\theta_c)}{W} + \frac{\cos(\theta_c)}{H} \right) \quad (5)$$

where W and H are the microchannel width and height, respectively, and θ_c is the contact angle of the liquid on the internal microchannel walls. Conversely, equation 5 gives the pressure required to force water into a hydrophobic microchannel of rectangular cross-section.

Microfluidic Modeling

Microscale fluid flow can be modeled from either a macroscopic or microscopic vantage point. Macroscopic modeling treats the fluid as a well-mixed volume while the microscopic view looks at how particles suspended in the fluid would behave under different flow conditions.

Macroscopic modeling, also called lumped modeling, uses conservation of mass to predict microfluidic system behavior. A pressure drop, ΔP , applied across a microchannel (or other conduit) with fluidic resistance Z , will induce a volumetric flow rate Q :

$$\Delta P = QZ \quad (6)$$

All microchannels have a fluidic resistance associated with them that depends on the geometry of the microchannel and the viscosity of the fluid. The fluidic resistance of a microchannel with a circular cross-section is given by

$$Z = \frac{8\mu L}{\pi R^4} \quad (7)$$

where μ is the fluid viscosity, L is the microchannel length, and R is the microchannel radius. The fluidic resistance of a microchannel with a rectangular cross-section is given by

$$Z = \frac{4\mu L}{ab^3} f\left(\frac{a}{b}\right)^{-1} \quad (8)$$

where $f(a/b)$ is calculated with the formula

$$f\left(\frac{a}{b}\right) = \frac{16}{3} - \frac{1024b}{a\pi^5} \sum_{n=0}^{\infty} \frac{\tanh ma}{(2n+1)^5} \quad (9)$$

When calculating the resistance of microchannels with rectangular cross-section, μ is the fluid viscosity, L is the microchannel length, $2a$ and $2b$ are the microchannel width and height, respectively, and m is calculated with

$$m = \frac{\pi(2n+1)}{2b} \quad (10)$$

If the aspect ratio of the microchannel is very small (i.e., $2b \ll 2a$) then the simplified formula

$$Z = \frac{3\mu L}{4ab^3} \quad (11)$$

can be used. The general rule of thumb is that equation 11 should be used for microchannels with $b/a < 0.1$. The resistance of other geometries can be found elsewhere (7).

In predicting microfluidic system behavior, the analogies to Kirchhoff's laws are used. The sum of pressure drops in a fluidic loop must be equal to zero; the total volumetric flowrate entering a node must be equal to the total volumetric flowrate leaving a node.

In contrast to the macroscopic view, microscopic modeling allows fluid behavior to be predicted. Specifically, the microscopic view allows the velocity profiles of a fluid flow to be calculated. Velocity profiles are plots that show the relative velocities of different portions of a fluid within a microchannel. Figure 1a is an example of a velocity profile.

The velocity of flow in a microchannel with circular cross-section varies radially and can be predicted with the formula

$$v(r) = \frac{R^2 \Delta P}{4\mu L} \left(1 - \frac{r^2}{R^2}\right) \quad (12)$$

where μ is the fluid viscosity, L is the microchannel length, ΔP is the pressure drop, and R is the microchannel radius. The velocity profile of flow in a microchannel with rectangular cross-section varies along the height and width axes and can be predicted with the formula

$$v(x,y) = \frac{\Delta P}{2\mu L} \left(b^2 - y^2 - \frac{4}{b} \sum_{n=0}^{\infty} (-1)^n \frac{1}{m^3} \frac{\cos my \cosh mx}{\cosh ma} \right) \quad (13)$$

where μ is the fluid viscosity, L is the microchannel length, ΔP is the pressure drop, m is calculated from equation 10, and $2a$ and $2b$ are the microchannel width and height, respectively.

Microscopic modeling is performed when precise modeling of fluid behavior is needed. For example, cells attached to the wall of a microchannel might affect flow; modeling at the microscopic level would reveal any perturbations of the flow caused by the cell. In contrast, macroscopic modeling is performed when the behavior of the entire microfluidic system is needed. For example, fluid flow in many parallel microchannels might be required. Macroscopic modeling would reveal the relative flowrates through each microchannel and provide the microchannel dimensions needed to guarantee equal flow through each.

PUMPING FLUIDS

Fluids are pumped through microfluidic channels by creating gradients; the two most common types being pressure and electrical. Other types of gradients and their applications are discussed elsewhere (8).

Pressure gradients are the most common method used to pump fluid. Pressure is applied to one end of a microchannel which causes the fluid to flow down the pressure gradient. Common methods for creating a pressure gradient include pumps or gravity. Most methods for creating pressure-driven flow use macroscale pumps attached to the microfluidic device via tubing. Ideally, pumps should be incorporated on-chip to realize the ultimate vision for LOC devices. Many types of microfluidic pumps have been demonstrated and they presently constitute an active area of research (9).

Pressure-driven flow is attractive for use in microfluidics because it is easy to set up and model. Some drawbacks for using pressure-driven flow are sensitivity to bubbles, sensitivity to motion (via the tubing connecting pumps to the microfluidic device), and parabolic flow profiles. Shear stress is proportional to the pressure drop across a microchannel, which should be taken into account when manipulating cells.

The other common way to pump fluids is to use electrical gradients. This method of pumping fluid is only practical at the microscale level because of the large electric fields and SAV ratios required. Pumping via electric fields is called electrokinetic flow and is based on two phenomena: electrophoresis and electroosmosis. Electrophoresis operates on the principle that charged particles in an electric field will feel a force proportional to the field strength and their charge. The particles will move through the electric field toward the pole of opposite charge. Larger particles move slower than smaller particles because of the drag produced by moving through a fluid. Figure 5a shows an example of electrophoretic flow.

A charged particle in an electric field of strength E will travel with a velocity equal to

$$v = m_{ep} E \quad (14)$$

where m_{ep} is the electrophoretic mobility. Electrophoretic velocities are typically much smaller than the velocities caused by electroosmosis.

Electroosmosis will only function in the presence of an electric double layer at the surface of the microchannel.

Figure 5. (a) Electrophoresis. Charged particles will move toward oppositely charged poles in an electric field. (b) Electroosmosis. Charges lining a microchannel surface will move with an applied electric field, thus inducing bulk flow via momentum transfer within the liquid. (c) An electric double layer forms at charged microchannel surfaces; the layer thickness is called the Debye length.

An electric double layer forms at a charged surface when oppositely charged particles from an electrically neutral liquid gather at the surface. The thickness of the electric double layer is known as the Debye length; the concentration of charged particles at a surface falls off rapidly as a function of distance and is shown in Fig. 5c. When an electric field is applied across the length of the microchannel, the ions gathered at the microchannel surface begin to slide toward the oppositely charged pole, as shown in Fig. 5b. As the ions slide, they drag their neighbors within the bulk liquid, toward the middle of the microchannel. The friction between subsequent sliding layers of ions causes the bulk fluid to begin moving.

If the Debye length is much less than the characteristic dimensions of the microchannel, then the bulk fluid velocity can be predicted with the equation

$$v = m_{eo}E \quad (15)$$

where E is the electric field strength and m_{eo} is calculated with

$$m_{eo} = \frac{\varepsilon\zeta}{4\pi\mu} \quad (16)$$

where ε is the dielectric constant of the fluid, ζ is the zeta potential of the surface, and μ is the fluid viscosity.

Electrokinetic flow is attractive because it only requires the integration of electrodes in a microfluidic device, which is straightforward by microfabrication standards. Electrokinetic flow is therefore amenable to interfacing with electronic control circuitry. Electrokinetic flow also results in a blunt flow profile, which reduces the distortion of transported samples. Lastly, electrokinetic flow has

very rapid response times, since the electrodes are integrated on chip, and are generally insensitive to movement off chip. Drawbacks to electrokinetic flow include fouling of the electrodes, which reduces electric field strength and therefore flowrate. Also, protein adsorption to microchannel surfaces affects the Debye layer, and in turn flow. Unintended side effects from electric fields on biological cells within the microfluidic device may also exist. Figure 6 shows the difference between the parabolic flow profile of pressure-driven flow and the blunt profile of electrokinetic flow.

Other methods of fluid flow based on surface tension, heat, and evaporation, have also been demonstrated. However, these methods have yet to be widely adopted and it is

Figure 6. (a) Pressure-driven flow is parabolic; the middle of the stream moves faster than regions near the wall. (b) Electrokinetic flow is blunt; all parts of the stream move at equal velocity. Note that residual pressures can cause the profile to become slightly parabolic in the direction of the negative pressure gradient.

Figure 7. (a) Material is etched from a substrate and an enclosed structure is formed by bonding the etched substrate to a glass lid. (b) Walls of microchannels are built on top of a substrate and a glass lid is placed on top of the photoresist to form an enclosed structure.

unclear if they will prove more attractive than pressure-driven or electrokinetic flow.

FABRICATION

Fabricating microfluidic channels in traditional microfabrication materials, such as silicon and glass, can be achieved in two different ways. In the first, material is selectively removed, or etched, from a bulk substrate. The etched substrate is then bonded to another material (e.g., glass or silicon), which may have access holes or other features embedded in it. The result is an enclosed channel structure, as shown in Fig. 7a. The second method is to selectively add material to a substrate, and then bond another substrate to it. This method will also form enclosed channel structures as shown in Fig. 7b.

Photolithography is a fundamental part of all microfabrication (Fig. 8). Light is used to project patterns onto a photosensitive chemical, called a photoresist. The photoresist can be either positive or negative. Light chemically alters positive photoresist and makes it soluble in a developer. Negative photoresist is cross-linked by light, which makes it insoluble in developer. The patterned photoresist can be used as an etch mask for substrates, producing microchannels like those shown in Fig. 7a. Patterned photoresist can also be used in subsequent steps to direct the patterning of other materials that

cannot be directly patterned with light. In-depth treatments of microfabrication techniques can be found elsewhere (10,11).

Polymers have recently become popular alternatives to traditional (e.g., silicon or glass) microfabrication materials. Polymers can be used to make microchannels by using the same methods mentioned previously for silicon and glass. Polymers also have the advantage that they can be molded that makes them a cheaper alternative (relative to silicon or glass) for mass production.

Polymer microfluidic devices can be created by molding, hot embossing, injection molding, photopolymerization, and laser ablation or laser cutting. An attractive method for fabricating polymer microfluidic devices is to use a process known as micromolding (12). In this process, photolithography is used to make a pattern of the microchannels (called a master). The photoresist provides a positive relief from which a polymer mold can be cast. The polymer is poured over the master and allowed to cure. The polymer mold is then peeled from the master and either placed on a substrate or incorporated into a multilayer device. The two advantages of this microfabrication method are (1) no special microfabrication equipment is required, and (2) many inexpensive copies of a microfluidic device can be rapidly manufactured.

Drawbacks to using polymers include leaching of material into microfluidic channels, solvent incompatibility,

Figure 8. Photolithography requires an ultraviolet (UV) light source, a mask, and a photosensitive layer of material (i.e., photoresist). The photoresist is patterned with the UV light via a mask.

(Images courtesy of Agilent Technologies.)

and the ability of some substances to diffuse into the polymer. Also, surface treatments are occasionally required to make polymers compatible with electrokinetic flow; silicon or glass have an inherent surface charge that allows them to be used in electrokinetic flow applications.

BIOMEDICAL APPLICATIONS OF MICROFLUIDICS

Microfluidic concepts have already been incorporated in a variety of biomedical devices (13). One example of a microfluidic device now found in many biomedical labs is Agilent's Bioanalyzer. The Bioanalyzer system uses disposable chips etched in glass. The samples to be separated and reagents for the separation are loaded onto the chip via reservoirs. The chip is then placed in a reader, where electrokinetic flow is used to manipulate the samples in the reservoirs (Fig. 9).

Microfluidic capillary electrophoresis systems are becoming commonplace in laboratories. By using very small volumes for separation, joule heating from electrophoresis is rapidly radiated away from the gel.

Efficient heat radiation allows larger voltages to be used which translates into faster separations. The shorter separation distances used also contribute to reduced analysis times. Microfluidic capillary electrophoresis systems allow DNA to be rapidly analyzed, and have highly reproducible results since the entire process is automated. Lastly, contamination is minimized because the devices are disposable.

Because of their small size, another attractive aspect of capillary electrophoresis (CE) systems is that they can be incorporated into LOC devices and made part of a complete system. An example that has been demonstrated in several research labs is a system that takes cells as inputs, lyses them, performs all necessary preprocessing, DNA amplification, and so on, and then performs the DNA separations, all with no human intervention (14).

Microfluidics are also being used in clinical devices; devices for hematology and disposable assays for point-of-care diagnostics are among those now being researched and brought to market. A handheld point-of-care device made by i-STAT is an example of a clinical microfluidic device (Fig. 10). The handheld device quantifies analytes in

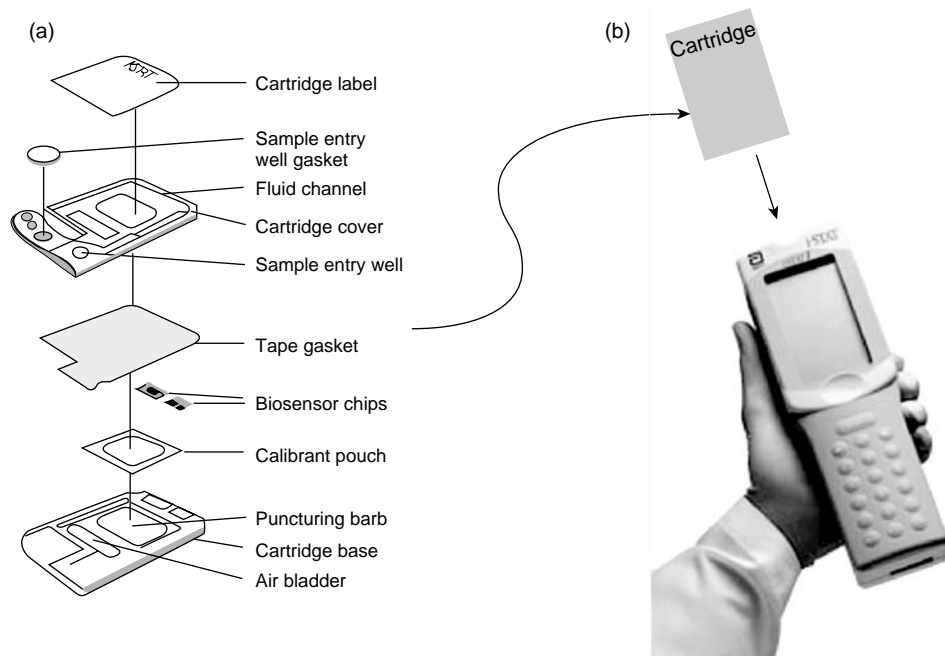

Figure 10. (a) The handheld point-of-care device manufactured by i-STAT performs analyses on blood samples contained in a disposable cartridge. Reprinted with permission from ACS (from Ref 15). Copyright 1998 American Chemical Sa. (b) Microfluidic cartridges are loaded with a sample and then plugged into the i-STAT handheld device. Image courtesy of Abbott Point-of-Care. The cartridge contains all necessary microfluidic control and sensing components that are then actuated by the handheld device.

blood samples that have been deposited on a disposable chip. The general procedure for operation is given below (15).

A patient's blood sample is deposited in a well on the disposable chip and then the well gasket is snapped shut (Fig. 10a). The microfluidic chip is then inserted into a handheld reader that performs an automated analysis of the blood sample, as shown in Fig. 10b. On-chip biosensors are automatically calibrated and checked for accuracy with an on-chip packet of calibrated solution. Once their accuracy has been determined, the calibration solution is flowed to the waste compartment. The blood sample is then flowed over the biosensors and the concentrations of different analytes are displayed on the handheld device screen within a few minutes. Diaphragm pumps are used to move the fluid. A variety of chips are available for different assays, including electrolytes and blood gases.

CONCLUSION

Microfluidics is the study and application of fluids at the microscale. Techniques used by the microelectronics industry have been adapted to facilitate the creation of micron-size channels capable of carrying fluid. The physical behavior of fluid at the microscale differs from behavior observed at the macroscale in everyday experience. The miniaturization of fluid handling has allowed LOC devices to be created in which all of the procedures of a traditional chemistry or biology lab are performed automatically in a single microfabricated chip. Lab-on-a-chip devices will allow new clinical and research tools to be developed.

Technology
Seoul, Korea

INTRODUCTION

Generally, micropower is the local generation of electricity by small-scale generators, which locates the end point. As the recent development of the microelectromechanical system (MEMS), as well as CMOS electronics technology, has been reducing the size and cost of biomedical devices, the research of micropower became important for implantable biomedical devices since they require internal self-sustained power sources.

As for biomedical devices, micropower is an internal or external power source to supply energy for active devices, which replaces an organ's function or treats diseases. The examples of active implantable devices that consume energy are cardiac pacemakers, cardiac defibrillators, muscle stimulators, neurological stimulators, cochlear implants, and drug pumps (1). Hence, in this article the term micropower describes rather tiny power supplying devices for miniaturized sensors, actuators, and electric devices, whose size is $>$ or $<$ 1 cm^3 .

The low power electrical actuator, such as a pacemaker or neuronal stimulator, requires tens of microwatts intermittently and their power source is usually a lithium iodine battery that lasts for 5–8 years. Usually, the stand-by current of a pacemaker is $\sim 1\ \mu\text{A}$ in waiting mode and its pulse current is $\sim 6\ \text{mA}$. One example of a specification for a pacemaker pulse is in the range of $25\ \mu\text{J}$ ($\sim 11\ \text{mA}$ at $2.2\ \text{V}$ with a $1\ \text{ms}$ discharge) and the capacity of the battery is $2\ \text{Ah}$ at typical rating (2). The volume of a pacemaker is $\sim 20\ \text{mL}$ and the volume occupied by the battery is about one-half of the total volume, $10\ \text{mL}$. Hence, the energy density (energy/volume) and reliability are important factors in the lifetime of the device.

An internal battery that is hermetically sealed in these devices can operate them with low power consumption; however, other implantable devices have radically different power requirements. Implantable cardioverter defibrillators demand the energy of $15\text{--}40\ \text{J}$ providing six orders of magnitude larger than that of a pacemaker even though the pulses are less frequent. The current from a lithium silver vanadium battery is charged in an internal capacitor and the pulse of $1\text{--}2\ \text{A}$ of current is fired. Electromechanical actuator like drug pumps demand more current than a lithium ion battery can deliver since it needs to overcome the high pressure in the chamber. The examples of drug pumps are insulin pumps, pain reliever, and an cerebrospinal fluid pump. A high current implantable battery should have low source impedance, such as lithium thionyl chloride, lithium carbon monofluoride, or lithium silver vanadium oxide.

Other future application are in wireless sensors, including physiological, chemical, or physical sensors embedded in an encapsulated environment. Miniaturized sensor

consumes $< 100\ \mu\text{W}$ and a radio frequency (rf) transmitter consumed $\sim 10\ \text{mW}$ intermittently. Since most of the power is used for communication, some research groups are developing several low power wireless transmission protocols (3,4). Hence, less power will be necessary for a sensor transmitter as technology evolves.

Some groups investigated more efficient and reliable batteries. To enhance their efficiency and lifetime, potential alternatives of the conventional batteries studied, such as a microfabricated battery, microfabricated fuel cell, and biofuel cell. Microelectrical system technology reduces the size of the primary battery and microfluidic galvanic cell (5), water activated microbatteries (6), and Li-ion microbatteries were demonstrated. The fuel cell attracts much attention since it has a high efficiency, high power, and low pollution rate. Research on fuel cells focus on high power applications, such as the automobile and portable electronics, like laptop computers and cellular phones (7). Recently, micromachining technologies employed as a method to fabricate miniature fuel cells (8–11) and their size became smaller than a button cell battery (12) with high power. Enzyme-based glucose/ O_2 biofuel cells were reported by several groups (13) and a miniaturized all (14) was reported that is $< 1\ \text{mm}^3$, with although a power of $4.3\ \mu\text{W}$. Since glucose is available in all tissues and organs, it is advantageous in implanted medical sensor transmitters.

Although a primary battery as well as a rechargeable battery is an important tool that supplies reliable power to implant devices, the continuous power of the battery decreases with time, and after 5 years they will not supply enough power (15). Power delivery with an rf transmission can extend the lifetime and continuously deliver high power. In the case of a cochlear implant, an external device provides power and data through electromagnetic field coupling; however, it needs accurate positioning of the external device and may cause rf interference and heating of the tissue.

Therefore, many research groups are paying attention to microfabricated power scavenging devices as an auxiliary power source to recharge the battery with no external power. Ambient energy sources are body heat or movement of the human body. Piezoelectric material (16–18), capacitance change (19–24), and inductive coil (25–27) convert vibration or human motion into electrical energy. The generation by high frequency vibration is not suitable for implant devices since vibration of the human body is in the range of tens of hertz. Hence, energy conversion using vibration of low frequency can be integrated with implant devices.

Thermoelectric generators that convert temperature differences of the human body or combustion engine to electricity were reported (28,29). Another conversion method is the thermophotovoltaic power generator (30,31), which combines the combustion engine and solar cell. However, integrating a power generation device into an implant device has some limitations due to biocompatibility. Power generation with a high temperature like the combustion engine or thermovoltaic method, cannot be implemented in the inside of the human body due to the heating of tissues. Thermoelectric generation using body heat is promising for the implantable device. However, this article includes the review on the other portable power sources like the micro-

combustion engine, because those are also useful for a portable diagnosis system. The recent development of microfluidics and miniaturized biosensors enables point-of-care testing devices to be on the market in the near future. A microheat engine is highly efficient in energy conversion and will be useful as a portable medical equipment.

A good review article on micropower for wireless sensor networks was reported (20,32). It lists the candidates of portable power sources and compares the energy density for the battery and power density for a power generator. This article reviews the existing and potential micropower sources in view of medical applications from tiny sensors embedded in the human body to portable medical electronic devices.

MICROBATTERY

For a long time, the battery was a major energy source in portable electronic devices and it has evolved from Zn/MnO₂ to the Zn/air cell since 1900. Electrochemical power sources were developed in response to the needs of the flashlight, automotive starter, mobile electronics, and laptop computers. These days, there is a tremendous need for portable electronics demanding smaller, lighter, and longer lived batteries. Hence, many researches are on the way to making microfuel cell or microfabricated batteries using various kinds of electrochemical power. This section will briefly review microbatteries including fuel cells, biofuel cells, and micromachined batteries.

Microfuel Cell

Although the energy density of conventional batteries has been increasing from 500 Wh · L⁻¹ for the Ni/Cd battery to 1500 Wh · L⁻¹ for the Li/C–CoO₂ battery, there is a large jump for the air-cathode fuel cells of 4500 Wh · L⁻¹ using hydrogen, hydrocarbon, and metals (7). The proton exchange membrane fuel cell (PEMFC) depicted in Fig. 1 is one of the promising techniques for fuel cell, which was

Figure 1. Schematic of a PEM fuel cell.

implemented in miniaturization. Power sources for the automobile or the portable electronics of a huge market have been a main concern of fuel cell research because of the advantage of high efficiency and easy rechargeability. However, these days, in response to the demand of low power application, many miniaturized fuel cells are under study. Miniature fuel cells with a series path in a flipflop configuration was fabricated in a planar array and a four-cell prototype was produced, 40 mW · cm⁻¹ (33). Yu (11) added microfluidic channels using anisotropic wet etching of silicon to the flipflop configuration and measured a peak power density of 190 mW · cm⁻². They also reported that the flipflop fuel cell was constructed on printed circuit board (PCB) and that they achieved the area power density of >700 mW · cm⁻². Wainright (12) fabricated on-board hydrogen storage with multiple coplanar fuel cells in series on ceramic substrates. They stored hydrogen in the form of the stabilized aqueous solutions of sodium borohydride (NaBH₄) or a metal hydride material, such as LaAl_{0.3}Ni_{4.7}. The energy density of microfabricated fuel cells did not exceed that of a Li/MnO₂ coin cell, but it had the advantage of higher power and compatibility with other microelectronic, microelectromechanical, or microfluidic devices. A polymer microfluidic channel was applied to a fuel cell using PDMS (10) and poly (methyl methacrylate) (PMMA) (8). They achieved a comparable area power density with a silicon based one. Whitesides and co-workers (9) also reported a membraneless vanadium redox fuel cell using a laminar flow property in a microfluidic channel with 200 mW · cm⁻². As for the commercialization, MTI microfuel cells and Manhattan Scientifics are making portable fuel cells using direct methanol fuel cell (DMFC) and Medis technology announced direct liquid fuel cell (DLFC) for handheld devices. Miniaturized fuel cells are promising for implantable medical devices with a high power requirement and it has the advantage of a longer lifetime and less charging time than a conventional battery.

However, PEM fuel cells do not fit well with the implantable microdevices with high power and a long life application because the refill of a hydrogen fuel cell is not easy when it is sealed in the human body. As an alternative fuel cell, the biofuel cell is a strong candidate for a low power embedded device like a microbiosensor. Although a biofuel cell is not capable of high power, the easy availability of fuel (glucose) gives it a long operation time. Enzyme-based glucose/O₂ biofuel cells were studied since 1980s (13) and Heller and co-worker (34) demonstrated the feasibility of a membraneless miniature biofuel cell as an implanted micropower source. Its chemical reaction is described in equations 1 and 2.

Some fuel cell components, such as case, membrane, ion conductive electrolyte, and plumbing was removed in the biofuel cell and its size became <1 mm². The power of the biofuel is 4.3 μW with 0.52 V and it is suitable for an implanted devices because of tiny volume and abundant glucose inside of human body. Moor et al. (35) developed a microfluidic chip based ethanol–oxygen biofuel cell, which

produced 18 μW with 0.34 V and is applicable to integrate the biofuel cell and the microfluidic chip.

Micromachined Battery

A microfabricated battery usually refers to a thin-film battery, however, recently some research groups are studying MEMS-based microbatteries. Integration of microbatteries with CMOS electronics or an MEMS device is easy and can be fabricated on a chip with a device. Since the microbatteries main concern is power output due to limitation of surface rather than the capacity, most research activities are focused on increasing power to out perform maintaining capacity.

As for thin-film batteries, Bates et al. (36) at Oak Ridge National Laboratory reported a thin-film secondary battery, which was made up of lithium and lithium ion. The thickness is tens of μm and the area is in the cm^2 range. Its continuous current output is $1 \text{ mA} \cdot \text{cm}^{-2}$. Pique et al. (37) constructed primary Zn–Ag₂O and secondary Li ion microbatteries in plane using laser direct-write with a capacity of $100 \mu\text{Ah} \cdot \text{cm}^{-2}$.

Other than classical thin-film batteries, several micromachined MEMS batteries were developed. They try to integrate power sources with microelectronic circuits and microsensors. Prof. Lin at UC Berkeley proposed a water-activated battery with 1.86 mWh in the area of $12 \times 12 \text{ mm}$ for lab-on-a-chip application (6) that overcomes the corrosiveness of the micromachined batteries with sulfuric acid and hydrogen peroxide (38). Andres (5) devised a pump integrated with a micropower source, in which microfluidic galvanic cells supplied power to heat up the two-phase fluid for pumping. The capacity of the micromachined battery is lower than that of a thin-film battery yet, its application is restricted to the integrated power for a micromachined implantable device.

MICROPOWER GENERATOR

A micropower generator scavenges energy from devices. The energy sources are mechanical (vibration and human body movement), thermal (temperature difference), and

solar energy. Thermoelectric devices convert the temperature difference to electricity and the photovoltaic cell collects solar energy. A MEMS-based power generator scavenges energy from the vibration in the mechanical structure or human body movements.

Thermoelectric Generator

Thermoelectric generation using the Seebeck effect was widely studied. This effect was discovered in 1821 by the physicist, Jonn Seebeck. It is the same phenomenon with a thermocouple where the temperature difference produces electricity or work. Although a thermoelectric power generator is an old technique and is commercially available in various sizes in the market, recent research focuses on making miniaturized low power thermoelectric microgenerators using microfabrication. Cost-effective fabrication technology was developed using electroplated structures with an epoxy film (28) and nanowire arrays by electrochemical deposition was implemented to improve thermoelectrical properties (29). Reportedly, several companies announced a thermoelectric generator using body heat. Applied Digital Solutions (39) announced a thermoelectric generator called ThermoLife, which produced a power of $49 \mu\text{W}$ from a temperature difference of 5°C in 0.5 cm^2 . Biophan technologies (40) also announced a biothermal power source as shown in Fig. 2 for implantable devices like a pacemaker and defibrillator (41). They aim to produce $100 \mu\text{W}$ at 3 V with 1°C temperature difference. A different scheme converting thermal energy to electricity is piezoelectric generator actuated by thermal expansion of two-phase working fluid (42). Although they produced up to $56 \mu\text{W}$ at its resonance frequency of 370 Hz, a practical application needs the careful design of a heat-transfer mechanism because the temperature is required to oscillate at a resonance frequency of structure. A thermoelectric generator has a well-established technology and its operation is relatively stable; however, note that the temperature difference inside the human body is $< 1^\circ\text{C}$. The temperature gradient is maximum at the skin surface and will limit the location of the thermoelectric power generator.

Figure 2. Principles of thermoelectric power source (Biophan).

Figure 3. Comparison of power density from vibrations, solar and batteries (21).

Power Generation with Ambient Vibration

Conversion of a mechanical vibration to electric power has been studied from the mid 1990s (43) using MEMS, while thermal and solar energy were exploited to generate electricity long ago. They changed vibration to electrical energy using piezoelectric, electromagnetic, and electrostatic generations.

The frequency of vibration in an ambient environment ranges from 60 to 400 Hz and for the microwave oven the acceleration was $2.25 \text{ m} \cdot \text{s}^{-2}$ at a resonance frequency of 120 Hz (15). Shad (21) suggested a graph comparing the power density of power scavenging and batteries as a function of time (Fig. 3). Power density in the vibration of machining center or microwave oven becomes larger than conventional batteries after 3 or 4 years, which means the waste vibration energy is not negligible. Williams and Yates (43) presented a general model in equation 3 for the power of external vibration as depicted in Fig. 4, when a mass is moved at a resonant frequency of ω_n .

$$P = \frac{\zeta_t m Y_o^2 \omega_n^3}{4(\zeta_t + \zeta_o)^2} \zeta \tag{3}$$

where m is mass, and Y_o is the maximum extent that the mass can move, ζ_t and ζ_o denote a damping factor both

Figure 4. Schematic analysis for mechanical movement of a power generator with external vibration.

in the transducer structure and in the environment (e.g., air).

Electromagnetic Conversion. Motion between the inductor and the permanent magnet induces an electromagnetic current in the inductor coil, as shown in Fig. 5 (25). The induced voltage, V , in the coil is given by equation 4.

$$V = NBl \frac{\omega_n}{2\zeta} \tag{4}$$

where N is the number of turns in the coil, B is the strength of the magnetic field, l is the length of coil, and z is the displacement of the magnet in the coil. This type of generator was fabricated with laser micromachining by Ching et al. (27) in 1 cm^3 volume and generated a 4.4 V peak-to-peak with a maximum rms power of $830 \mu\text{W}$. Glynne-Jones et al. (44) at the University of Southampton, derived $157 \mu\text{W}$ on average new car engine. Perpetuum Ltd., a spin-off company from the University of Southampton, produced an electromechanical microgenerator. That generated up to 4 mW and its operation frequency was 30–350 Hz. The vibration amplitude was $200 \mu\text{m}$ with 60–110 Hz and demonstrated a wireless temperature sensor transmitter system. This result showed electromagnetic conversion is feasible in low frequency vibration and is promising if it is compatible with silicon micromachining.

Figure 5. Schematic of an electromagnetic conversion device.

Figure 6. Structure of a piezoelectric cantilever for power generation.

Piezoelectric Conversion. The piezoelectric effect states that the deformation in the material produces an electrical charge due to the separation of charge within crystal structures. The most widely used piezoelectric material is PZT (lead zirconate titanate) in ceramic materials and PVDF [poly (vinylidene fluoride)] in polymers. Several groups are studying the piezoelectric cantilever with seismic mass (Fig. 6). The constitutive equations of piezoelectric materials are expressed in equation 5.

$$\sigma = Y(\delta - d_{31}E) \quad D = d_{31}\sigma + \varepsilon E \quad (5)$$

where σ is the mechanical stress, δ is the mechanical strain, Y is Young's modulus, d_{31} is the piezoelectric strain coefficient, D is the charge density, E is the electric field, and ε is the dielectric constant of the piezoelectric material. The piezoelectric coefficient links the mechanical stress-strain to the electrical charge equation. If the circuit is open ($D = 0$), the voltage across the piezoelectric layer is described in equation 6.

$$V = \frac{-d_{31}\sigma}{\varepsilon} t_{\text{piezo}} \quad (6)$$

where t_{piezo} is the thickness of the piezoelectric layer. The charge collected on the electrode is integrated on the area of the surface with no load condition as in equation 7

$$Q = \int D dA = \int d_{31}\sigma dA \quad (7)$$

When the impedance in the load circuit is pure resistance, the time-averaged power can be derived in Ref. 17 with the geometry of a cantilever. White and co-workers (16) presented a thick-film PZT generator, and the maximum power is $\sim 2 \mu\text{W}$. According to the analysis of Lu et al. (17), a 5 mm long PZT cantilever can generate $>100 \mu\text{W}$ with the amplitude of $>20 \mu\text{m}$ at $\sim 3 \text{ kHz}$ resonance. Roundy (15) demonstrated a piezoelectric converter of 1 cm^3 in volume, that is 1.75 cm in length. It generated $200 \mu\text{W}$ and is driven with vibrations of $2.25 \text{ m} \cdot \text{s}^{-2}$ at 120 Hz. A microfabricated PZT cantilever generator driven by a bubble was studied by Kang et al. (44), and a few picowatt was generated with one tiny cantilever at 30 Hz and tens of μW is expected on a 1 cm^2 surface (46). If the design, material, and fabrication are optimized, piezoelectric powergeneration will produce hundreds of microwatts with a volume of 1 cm^3 .

Figure 7. Circuit representation for an electrostatic converter (15).

Electrostatic Conversion. The electrical energy in a capacitor is given in equation 8.

$$E = \frac{1}{2} QV = \frac{1}{2} C_v V^2 = \frac{1}{2} \frac{Q^2}{C_v} \quad (8)$$

When the charge, Q , is constant, if the variable capacitance, C_v , is decreased the total energy E in the capacitor will increase. The MEMS structure can change the capacitance C_v with an external vibration, and stored energy in the capacitor transfers to energy storage. In the beginning, the external power source V_{in} initiates the charging process as in Fig. 7 (15). When C_v is maximum, SW1 is closed and the variable capacitance C_v is charged. While vibration changes capacitance C_v , all switches are open. When C_v reaches a minimum, SW2 is turned on and the energy in C_v is transferred to a storage capacitance C_{stor} . The disadvantage of electrostatic conversion is that it needs an external voltage source and switching circuit. The voltage across the storing capacitance is given in equation 9.

$$E_{\text{stor}} = \frac{1}{2} (C_{\text{max}} - C_{\text{min}}) V_{\text{max}} V_{\text{in}} \quad (\text{Ref. 47}) \quad (9)$$

where V_{max} is the maximum voltage across the capacitor C_v . Switching the circuit is realized using a diode and field effect transistor (FET) switch. Meninger et al. (47) made a comb-type variable capacitance with an in-plane overlap type with a $7 \mu\text{m}$ gap and a $500 \mu\text{m}$ depth using the $0.6 \mu\text{m}$ CMOS process. They produced a power of $8 \mu\text{W}$ with an ultralow power delay locked loop (DLL)-based system. Miao et al. (23) reported an out-of-plane variable capacitor with a gap closing type that varies from 100 pF to 1 pF. A periodic voltage output of 2.3 kV (10 Hz) was generated when the charging voltage was 26 V, which implies that a power of $24 \mu\text{W}$ ($2.4 \mu\text{J} \cdot \text{cycle}^{-1}$) can be produced. Mitchenson et al. analyzed architectures for vibration-driven micropower generators (26) and they fabricated a prototype of an electrostatic power generator producing $250 \text{ V} \cdot \text{cycle}^{-1}$ that corresponds to $0.3 \mu\text{J} \cdot \text{cycle}^{-1}$ (22). Other studies demonstrated polymer capacitor (24) and a liquid rotor power generator with a variable permittivity producing $10 \mu\text{W}$ (19). Recent developments in electrostatic generators

Figure 8. SEM of microturbine of MIT (52).

demonstrated that it is feasible and manufacturable with MEMS and that it has the advantage of a low frequency application like human body movement. However, the generated voltage is very high and should be managed for the implant application. Since it is compatible with the CMOS process and the variable capacitor is a well-established MEMS device, it is very promising as an integrated power generator with a sensor and transmitter.

Microheat Engine

A microheat engine is hard to be implanted in the human body, but it is promising as an external power source for portable medical equipment. A tiny internal combustion engine, made by precise machining, such as electrical discharge machining (EDM) or MEMS, may have a much higher density than a primary battery since the energy density of fossil fuel is $\sim 45 \text{ MJ} \cdot \text{kg}^{-1}$, while that of Li ion batteries are at most $0.5 \text{ MJ} \cdot \text{kg}^{-1}$ (48). Microturbine by EDM (48), Microrotors by deep reactive ion etching (DRIE) (49), heat engine (42) and reciprocating devices (50) was reported for electric power generation.

Several groups are working on a microheat engine, since fossil fuel offers a much higher energy density. Since the generated power is expected to generate 10–20 W, it is suitable for high power application. The Stirling engine (51), the reciprocal combustion engine (50), the Wankel motors, and gas turbines are reported. One of the first microengine projects was started at MIT (52) and the microfabricated turbine with a 4.2 mm diameter was illustrated in Fig. 8. Massachusetts Institute of Technology has been working on making microheat engines with a turbo charger and Georgia tech is collaborating with MIT on a magnetic generator (53). Allen and co-workers (54) at Georgia Institute of Technology generated a direct current (dc) electric power of 1.1 W with microfabricated windings at 120,000 rpm, although it was not integrated with a heat engine. Peirs et al. (48) made a microturbine by EDM and that tested to speeds of 160,000 rpm and produced a mechanical power of 28 W and an electrical power of 16 W. A miniaturized heat engine is still in the initial stage and no demonstration of power generation using a heat engine was reported. The heat engine would be very useful for high power applications such as portable

analytical equipment. Another scheme of a heat engine is thermophotovoltaic power generation (30,31). They converted the heat radiation in a SiC microcombustor to electric energy using photovoltaic cells, which is $<1 \text{ cm}^2$ and produced a power of 1.02 W with 2.28 V.

CONCLUSION

This article reviews micropower devices for medical implantable devices and portable medical device. Since the micropower devices have their own characteristics, there is no winner among them. When selecting a micropower system for a specific application, one should consider the energy capacity, power, volume, voltage, and compatibility of fabrication with microelectronic device.

Currently, primary or secondary batteries with external power transmission are a main power storage for a low power implanted device. As the application of implant devices is diversified and requires a high power output and longer lifetime, new battery like fuel cell, or biofuel will replace conventional battery system in the future. Furthermore, when power transmission through the skin is impossible due to the attenuation of transmission, integrated power generation device will be an alternative.

Most micropower generators are still in their infancy and they need much more study to be implemented in implant device. Research results on micropower generators showed only the feasibility of concept and their power is much less than the requirement. Hybrid micropower supplies (55) or integrated power system would be strong candidates for long battery life applications. The promising application of active implant device will be glucose sensor and the artificial pancreas for the treatment of diabetes and the ubiquitous bio- or environmental sensor network. Since there is strong demand in the market, it is believed that micropower system will be available in near future.

INTRODUCTION

The explosion of knowledge in life sciences is enabled by the ability to visualize beyond the capability of the human eye and by the capability to identify chemical compositions and the structure of matter. This was enabled by Levenhook's discovery of the new device for looking at the world of the small: the microscope. He found that by combining two lenses, it was possible to see much smaller objects than by the naked eye alone. This led to his subsequent discovery of the cell, which has spurred an explosion of knowledge in life science and medicine that continues at a dramatic rate of growth even today. Even 400 years after the Levenhook discovery, one of the first tools of choice for the visualization of small objects is the optical microscopy. What is known to a lesser extent is that the microscopic histochemical studies (i.e., staining of the tissues) with tissues and organelle-specific dyes in the late 1800s, initiated the modern pharmaceutical industry, when chemists and histologists alike envisioned an opportunity to selectively inhibit or kill pathogens by organic molecules in the same way organic dyes selectively label certain types of tissues, cells, and organelles. While the optical microscopy methods were able to uncover morphology and the structure and nature of the cells, they were faced with the ultimate physical limit of magnification, which is dictated by the spatial resolution limited by the diffraction limit. This limit was approximately the size of half of the wavelength of light used to perform the imaging.

The breakthrough in imaging small structures and further understanding the machinery of life and cell biology comes with the application of the deBroglie's postulate of particle-wave equality in order to use the electron beam with a shorter associated wavelength as an investigative imaging probe. Ruska's development of the first transmission electron microscope in late 1930s and the development of scanning electronic microscopies in the 1950s, opened the door to detailed investigations of the organization of subcellular assemblies, viruses, and even imaging of the individual biomolecules, at a resolution far beyond the diffraction limit of visible light. The rapid advances in the tools and techniques of ultramicroscopy, especially of scanning probe microscopies, which for the first time enabled routine molecular imaging, greatly contribute to enabling completely new multidisciplines, like nanoscience and nanotechnology, as well as an opening a door for an entirely new way of looking into the machinery of life.

While scanning probe microscopy in the 1990s allowed imaging at the unprecedented resolution of the unaltered samples; in general, it lacked the ability to uniquely identify the chemical composition of samples or unveil their physicochemical properties. For the investigation of chemical structures and fingerprinting the material composition, the tool of choice is optical spectroscopy. However,

the problem with classical optical spectroscopic techniques is that it provides average, bulk results with no specific information linking certain morphological features with spectra. This can ultimately identify chemical composition and/or physicochemical properties. The ability of doing molecular fingerprinting and, in a raster pattern, subsequent molecular specific imaging at the nanoscale with the spatial resolution of modern ultramicroscopy techniques is the holy grail for many aspects of today's life sciences disciplines.

This goal is partially fulfilled with electron microscopy combined with energy-dispersive X-ray analysis (EDX), wherein semiquantitatively, it is possible to associate topographical structures with elemental composition. However, for most of the problems in life and materials sciences, simple knowledge of elemental composition is not sufficient, as it is necessary to identify molecular structure. Plus, the electron microscopy is, in most cases, a destructive method of analysis, since the sample needs to be prepared to be vacuum compatible, and be either electrically conductive, in the case of scanning electron microscopy, or have contrasts with heavier metals, in the case of transmission or scanning transmission electron microscopy. Furthermore, the physics of generating characteristic X rays (i.e., the minimum size of the excitation volume from which the signal is emerging) is in the tens of micrometers, thereby limiting elemental compositional analysis with spatial resolution only for the large structure in the tens-of-microns-sized range. The ideal technique will be one that will allow imaging of the unaltered sample, in a way similar to the way atomic force microscopy (AFM) allows, while at the same time providing a way for spectroscopic identification of the chemical structure.

There are several techniques currently in their infancy that promise spectroscopic probing with electromagnetic spectroscopic information carrier signals imposed over topography. They are near-field scanning optical microscopy, microthermal analysis, scanning nuclear magnetic resonance (NMR) microscopy, and scanning electron paramagnetic resonance (EPR) microscopy.

However, for solving any of the practical problems, it will be of great benefit that the ultrastructure's information probes are photons of visible, and near-infrared (IR) and ultraviolet (UV) light, as a great deal of both morphological (based on the photon's position and intensity/count) and compositional (based on adsorption, fluorescence, Raman shift, etc.) information can be simultaneously obtained as optical microscopy relies on light as an information carrier. This is due to the fact that the same photons, which are in standard imaging configurations used to generate images, carry much more information on composition and the various physical and chemical properties of the observed spot on the sample that can be extracted through different spectroscopic methods.

The technique that has evolved over the last decade and promises to fulfill the above-goals at the nanoscale level, is near-field scanning optical microscopy (NSOM or SNOM), which effectively breaks the physical limits imposed by the optical-diffraction-limited resolution by using the near-field evanescent waves and scanning mechanisms similar to those in the scanning probe microscopies.

THEORETICAL PRINCIPLES OF NSOM MICROSCOPY

Abbe's equation (Eq. 1) describes the resolution of the classical, far-field optics, (i.e., the minimum separations between two points that can be distinguished) (1). From this equation it is easy to conclude that the maximum attainable resolution in the far field is $\sim \frac{1}{2}$ of the applied wavelength, which means that the best optical microscope cannot be used to visualize details smaller than 200–400 nm.

$$P_{\min} = \frac{\lambda}{2n \sin \alpha'} \quad (1)$$

In Abbe's equation, n is the refraction of the imaging index and α' is the aperture angle in the medium. While Abbe's equation describes the limiting resolution in the world of conventional optics, the Fourier optics approach can provide us with the same conclusion. Following Abbe's principle, Rayleigh (2) derived that the objects in a lens system in the far optical field are resolved only when the maximum of one pattern coincides with the first minimum of the neighboring features. What resulted was the discovery that the resolution criteria that describe the maximum resolution of the optical system based on the size of the numeric aperture was

$$d = 0.61 \lambda / \text{NA} \quad (2)$$

wherein λ is the applied wavelength and NA is the numerical aperture of the lens, again bringing the maximum theoretical resolution to ~ 200 nm.

A similar observation can be derived from the Fourier formalism in optics. In Fourier optics, the information content embedded in the spatial frequency f , in the case when f is higher than $1/\lambda$, decays rapidly toward zero from the object and thereby, no data on the subwavelength features can be efficiently collected with standard far-field optics. However, it is well known that it is possible to receive an electromagnetic signal with antenna that is smaller in size than the wavelength. The solution of the Maxwell equations that govern the behavior of electromagnetic radiation differs in the distance smaller than the wavelength than in the distance, much larger than the considered wavelengths. When the waves propagate within the distance much smaller than its wavelength, such situation is called the near field. The pragmatic definition of near-field optics will be a division of optics that deal with the elements of the subwavelength features scales, which are intended for passing the light through, from or near, to another element with subwavelength features positioned within the subwavelength distances. The spatial resolution in near-field optics depends on the feature's size and is limited to about one-half of the aperture size. Furthermore, the near-field system must be considered as a complete system consisting of two features (probe and sample in the case of microscopy) and the resolution of the system will be dependent on both sample and probe. Thus, it is impossible to speak of the unique or standard near-field resolution, as is done with a far-field instrument.

NEAR-FIELD IMAGING EQUIPMENT

The near-field scanning optical microscopy or scanning near-field optical microscopy (NSOM or SNOM) is a tech-

nique that enables users to work with standard optical tools that are integrated with scanning probe microscope (SPM) technology to obtain the optical image at a resolution in the range of tens of nanometers. This is quite comparable with the resolution of scanning electron or SPM. The integration of scanning probe and optical methods allows for the collection of optical information at resolutions well below the optical diffraction limit, which overlap real topography information obtained by scanning probe feedback. For spectroscopy applications, NSOM offers the potential for characterizing the spectroscopic signature of material on a submicron-to-nanometer scale, thereby affording new insights into nanoscopic structure and composition.

The principles of NSOM microscopy were theoretically founded by Synge in 1929 (2), and in his subsequent paper he described an imaginary device that closely resembles today's NSOM setup (3), including the use of piezoactuators. Due to technical difficulties at the time to implement such a device, the idea was forgotten until theoretician O'Keefe rediscovered the idea in 1956 (4). The first practical demonstration of the imaging of a structure smaller than the one-sixtieth of the applied wavelength was done in 1971 using the microwave in near-field scanning over the grid (5). The basic idea behind this method was to create evanescence, a standing wave, by light diffraction through an aperture that was much smaller than the wavelength, and then to use this evanescent light source to scan a sample in a raster-scan pattern in close proximity, and collect transmitted or reflected signal in the far field. The first demonstration of near-field optical imaging was implemented independently by Pohl (6) in 1982 and Lewis groups (7) in 1983, and described as an optical stethoscopy, in what is now considered the beginning of NSOM microscopy. The method grew rapidly during the 1990s and the trend is continuing to this day, as described in recent reviews (8–12). Furthermore, several companies are offering commercial instruments (13–16) that enable ordinary users, who are not inclined toward the instrumentation development, to apply NSOM in solving their research problems.

There are two fundamentally different ways to achieve near-field optical imaging. They are apertured-base and apertureless NSOMs with their principles of operation depicted in Fig. 1a and b (17). In the case of the apertured NSOM (Fig. 1a), the light passes through an aperture that is much smaller than the wavelength of applied light, and ultimately the resolution is defined by the size of the aperture. In the case of the apertureless NSOM (Fig. 1b), a sharp metallic tip is irradiated by a laser perpendicular (or as close as possible) to the tip along the axis. The irradiation excites the plasmons on the metallic surface of the tip and the field is concentrated by combining antenna and plasmonic effects at the top of the tip. The resolution of apertureless NSOM is thus defined by the size of the near-field excitation formed at the apex of the metallic tip, and is determined by tip sharpness, tip materials, and real and imaginary parts of the refraction index of the used metal.

The practical advantage of apertured NSOM is in its easy implementation. While the advantage of the apertureless

Figure 1. Two major principles of achieving the near-field scanning optical microscopy: (a) the aperture-based NSOM; (b) scatter-field, apertureless NSOM.

NSOM is theoretically a higher achievable resolution and possibly higher field strength, the technical difficulties in implementing the apertureless setup have not permitted those advantages to be realized. Thus, as of this writing, all of the existing commercial instruments are based on the apertured NSOM approach.

Regardless of the type of NSOM, the experimental setup always consists of a piezo X – Y scanner, whose role is to execute the raster-scan pattern scanning of the sample by the near-field probe; a Z piezo, whose role is to modulate the image by keeping the sample–tip distance; an optional, but for most cases necessary, noncontact modulation element, such as the tuning-fork for shear force feedback, or a piezo- or electromagnetic oscillator for AFM-like noncontact feedback; a near-field probe, which can be aperture or sharp tip; a laser light source; a far-field optical signal collection system, sample and sample holder; a system for coarse probe approach and sample–probe alignment; a scanner controller and computer for the image acquisition and reconstruction; and a vibration isolation system. In this manner, the NSOM most closely resembles the mechanism of the AFM, and almost all of the existing commercial setups, as well as many of the in-house, lab-made NSOMs, share these common components with the AFM and more general SPM platforms.

Piezo Scanner

The piezo scanner principle of work is based on the piezo effect, which is reversible internal stress induction within the crystal when exposed to the electric field (18). This stress induces crystal expansion. The piezo scanner in the NSOM is a more critical part than in the standard AFM. Ideally, it should be the perfect closed-loop scanner, due to stringent requirements of keeping the probe in a particular place during the raster scan, in order to achieve sufficient optical signal/noise ratio. Figure 2 depicts typical scanner configurations. The scanners are usually implemented in the form of the stacked piezo crystals (Fig. 2a), tube scanners (Fig. 2b), and bimorph (Fig. 2c) (19). Furthermore, scanners are often grouped into the so-called tripod configuration. The same material used for the SPM scanner, lead-zirconate-titanate ceramic (commonly referred as a PZT ceramic), is commonly used for the NSOM piezo scanner. The typical piezo-electric constant for PZT materials is about $-1.7 \text{ V} \cdot \text{nm}^{-1}$. However,

in order to practically achieve the linearity over the whole range of scan, it is necessary to calibrate each individual scanner periodically to compensate for crystal nonlinearity, creeping, and drift. Those effects are further minimized by using active, real-time feedback, which can be implemented either through some form of the strain gauge, capacitance, or by optical means. The active feedback adjusts the voltage applied to the scanner to keep linearity and to secure the probe above the scanning position within the raster scan.

Optical Signal Acquisition System

The optical signal collection system is made up of optical and optoelectronic parts. The optical portion usually consists of the far-field microscope objective with a high NA lens. The tip–sample working distance, as well as the sample thickness and sample holder accessibility, define the maximum NA of the objective that can be used. Oil immersion objectives are used to enhance the NA by many times. Besides the objective, the collection system may contain filters, notch-filters polarizers, and beam splitters, depending on the particular configuration and imaging mode. The optoelectronic part of the collection system converts optical information to an electrical signal for further processing. It is usually either a highly sensitive photomultiplier tube (PMT), or, for ultimate sensitivity and single-photon counting, an avalanche photodiode detector (APD) array. For the PMT tube, the output signal can be either voltage or counts, and for the APD, it is only TTL (transistor–transistor logic) counts. The high sensitivity PMT tubes can satisfy most of the imaging requirements, however, for extremely weak signals, such as in single-molecular imaging or single-molecular spectroscopy, an APD detector is more desirable. Due care does need to be paid when using the APD detector, as over-exposing the detector can damage it in an extremely short period of time. For the purpose of correlated experiments, many detectors are attached to the system. In the case of spectroscopy applications, the most commonly used dispersive detector is a highly sensitive CCD imaging camera, either solid-state or liquid-gas cooled. However, many setups use the other, more economical, wavelength or energy-dispersive detection systems, which are based on filters, prisms, or gratings in conjunction with either a PMT or APD detector.

Light Sources for Near-Field Imaging and Spectroscopy

Illumination sources for near-field microscopy are always lasers. Selection criteria for the laser depends on the desired wavelength(s). The most economical are the solid-state lasers, followed by ion lasers, such as the Ar laser, which can selectively produce multiple wavelengths of light from 450 to 514 nm (17). Besides the two most common types, many setups use liquid lasers as well as optical parametric oscillators to produce specific wavelengths that are not available with a standard laser. The transduction path can consist of mirrors or single-mode optical fibers. The mirror-based path has better throughput, however, it is more complex to adjust and requires periodic readjustment. The optical-fiber-based transduction path has some higher attenuation than the mirror-based path, but it is very convenient for use, especially if it is implemented with the standard FC or similar connectors.

Microscope Head

The NSOM head usually consists of a probe holder, one or more piezo scanners, a system for coarse probe approach, and a case. The head is positioned at the top of the sample holder. The probe holder is directly attached to the Z direction piezo. A video system, which shows the image of the approaching tip and substrate, and a software-controlled stepper motor with micrometric screws provide coarse approach of the probe to the sample surface. When the probe tip is brought to close proximity to the sample, the fine approach mechanism is engaged. The fine approach mechanism is essentially a stepped mechanism wherein the probe is brought in a small piezo steps in the vertical direction to close the gap between the tip of the probe and sample substrate. The contact is achieved when the signal indicates the deflection of the probe

in AFM-like setups, or, in shear-force mode, when its interaction with the sample reaches the user-prescribed “set point” voltage or current level. The determination of the appropriate set point varies for different samples and systems, and is more a result of art or tacit knowledge than an exact science. If the Z piezo is completely extended and contact has not been achieved, the piezo constricts to its neutral position and the stepper motor is activated to bring the probe to the approximate max extension distance of the piezo, and the process is repeated. Besides the Z piezo, sometimes the X–Y scanners can be positioned in the head.

Sample Holder/Stage

The sample holding stage can contain the X–Y piezo scanner, if it is not in the head. Its moving frame consists of micrometric screw positioners that push the sample holder in the X–Y direction under the probe, thus allowing sample “pan” operation. These screws can be manually or stepper-motor operated. The sample stage can be stand-alone, or it can be positioned at the top of an inverted, epi-fluorescence microscope. There are many advantages to having the NSOM sitting at the top of the standard inverted microscope. This configuration is able to combine far- and near-field microscopy, exploit the operation familiarity of the inverted fluorescence microscope, and deliver superior images to those acquired via a dedicated, stand-alone NSOM stage. However, a drawback of such a configuration is a larger mechanical circuit with a higher level of vibrational noise than in a dedicated system.

Controller

Controllers for NSOM are usually derived from the AFM/SPM controllers. In all of today’s setups, they are digital.

The controller's role is to generate the high voltage signals necessary to feed the piezo scanner and move the probe in the raster scan pattern. It also controls the vertical, Z position of the probe via the PID control-loop model mechanism (proportional-integral-differential), and thus topographically modulates the signal; it maintains the non-contact feedback; it controls the coarse probe approach, and in some instances coarse sample positioning; and it acquires the signals coming from the probe (both optical and topographical) and forwards them to the computer for further processing. The controller usually consists of a series of analog-to-digital and digital-to-analog converters, precision operational amplifiers, and high voltage amplifiers. Due to the complexity of the tasks, often the controller is designed using high end digital signal processors and other high end embedded systems.

The role of the control software is to control the controller, acquire the image, and store it in some of editable and exportable format. Furthermore, the control software almost always possesses image processing capabilities, such as different image filters, Fourier transform, 3D representations and rendering, and so on. All of the commercially available NSOMs share the same software with their AFM/SPM "cousins". Many of the homemade systems, on the other hand, have software modified from existing commercial SPM/AFM controller software, or software that is independently written, as in cases where the users have designed the whole control electronics by themselves. Many times, the results are processed in third party software. For example, for image processing a very popular solution is to use shareware NIH Image software or its PC cousin, Scion Image, and for advanced applications, to use scripts written for IgorPro, LabView, MathLab, or for spectroscopy experiments, WinSpec. Use of higher level software like Igor Pro dramatically reduces development time of applications, as compared to the time required to write the script in C or C++ code.

Apertured NSOM

The principle of the apertured NSOM is to use the aperture as a scanning probe. This is the first (5,6) and up-to-today most commonly implemented NSOM setup. In basic principle, the instrument consists of the XYZ piezo scanner(s) that moves the apertured probe over the raster scan pattern at the controlled aperture-sample height, and a non-contact feedback mechanism, the best-suited being the shear-force based one (20). An aperture in the tens of nanometer size can be formed by the tapering, heating, and pooling process borrowed from biophysics labs, where it is utilized for creating micropipettes (21) or for etching optical fibers (22). Additionally, as an aperture, it is possible to use the hollow cantilever (23).

Schematic representation of the instrument implementation, for both imaging and spectroscopy-hyperspectral imaging, is presented in Fig. 3a, configured for the most common, transmission mode (looking through the sample) operation. The laser light is coming from the optical fiber. Optical fiber is mounted on the tuning fork assembly, which is held onto the Z -piezo scanner and is constricted at the end to a tens of nanometer size range (see insert) and

Figure 3. Example of the aperture-based, straight-fiber NSOM: (a) schematics representation of the scanning probe and collection; (b) schematics representation of the tapered fiber NSOM probe, attached to the tuning fork; (c) photograph of the probe glued to the tuning fork; (d) SEM image of the end of the tapered, aluminum-coated fiber optic based NSOM probe. (Courtesy of Veeco Instruments Inc., Santa Barbara, CA.)

the evanescent field is formed at its aperture, as represented in the figure insert. The light is passing through the sample, interacting with sample matter, and is collected under the sample in the far-field with the high numerical aperture microscopy objective. Such a signal is further subjected to collection and processing. For the hyperspectral imaging or for the spectroscopy or spectral imaging purposes, the signal is first passed through the holographic notch filter, which eliminates excitation light and through the beam splitter is directed to the wavelength-dispersive detector, such as a CCD spectrometer, and to the summary, imaging detector, such as a PMT, or avalanche photodiode detector (APD). In the simplified setup, if the apparatus is used just for the optical imaging, the light is passed directly from the objective into the imaging detector, (i.e. APD or PMT).

Figure 3b schematically represents a typical apertured probe, mounted on the tuning fork. Micrographies at

Fig. 3c and d represent the frontal and lateral view of the metallic-coated, laser-pulled, tapered, fiber-based tip. An evanescent, standing wave is formed at the end of the aperture, and the size of the aperture approximately defines the optical resolution. Light is either brought through the aperture, as in transmission and reflection imaging mode, or collected through the aperture, as in the collection mode. The tip is scanned across the sample in a raster-scan pattern, and for imaging purposes; the signal is collected in the far field, either by sensitive photomultiplier tube, or by sensitive avalanche photo-diode counter.

The three distinctive different modes of operations of the aperture-based NSOM are illustrated in Fig. 4, which also graphically depicts the different kinds of information that can be extracted from the optical signal emanating from the sample. The origin of the optical contrast, as depicted in Fig. 4, can be due to topographic differences (different path length change the adsorption), material birefringence, reflectivity, sample extinction coefficients for the particular excitation wavelength, index of refraction, fluorescence emission properties, nonlinear spectroscopical properties of materials, and mechanical and magnetic stress in the sample. However, at the moment of this writing, for life sciences and biomedical applications, only transmittivity, reflectivity and fluorescence properties are of significance. The mode that is the most useful for biological applications is the transmission mode or the “looking through” mode, and is most similar to classical biological microscopy. In this case, as described above, light is brought through the fiber-based tip, the near field interacts with the sample, and the signal is collected in the far field as it passes through the sample. In this mode, it is possible to do transmission imaging, as well as fluorescence or other wavelength-resolved imaging, by application of adequate filters or wavelength-selective elements. In a reflection mode, which can be described as “looking on the surface mode”, the near field interrogates

Figure 4. Typical apertured NSOM configuration: (a) illustration of information that is carried and can be extracted from the optical signal; (b) transmission and reflection mode NSOM; (c) collection mode NSOM; (d) total internal reflection or dark field mode. (Figure 3b–d adapted from Ref. 17.)

the surface of the sample, and the scattered signal is collected in the far field. This mode allows imaging and spectroscopy of the nontransparent samples; however, the imaging efficiency is much lower than with transmission mode. In a collection mode, the light is passed either through the sample, or illuminated on the sample, and the signal is collected through the fiber in the near field. This mode is very burdensome to use, has low signal collection efficiency, and is used mainly in photonics research.

Besides these three modes, there are more exotic modes of operation, such as combined collection and illumination, where both sample illumination and resulting signal are passed and collected through the same probe; dark field imaging, where the probe tip is in close proximity to a sample that is illuminated from underneath with total internal reflection from the substrate, and wherein the probe acts as a second, tunneling prism. Besides pure optical operation modes, there are also a combined optomagnetic NSOM, which explores Kerr's effect (24); nano-mass spectroscopy (25), where near field is used for ablation; and optoelectrochemical NSOM (26). The later two modes have a lot of potential applications in physiology with their ability to simultaneously image and record potential at subwavelength resolution.

To secure the probe in a near field, the aperture must be kept in close proximity to the sample with a distance much smaller than the applied wavelength. The fiber is kept at the nanometer-range distance from the sample by means of noncontact feedback. There are several ways of achieving feedback, mainly shear force, AFM-like normal force contact, and noncontact force feedback. The shear-force feedback provides gentler, lateral touching of the sample, thereby reducing the possibility of aperture contamination or tip–aperture mechanical failure.

In shear-force feedback (20), the fiber tip is oscillated laterally to the sample surface. The NSOM tip is rigidly premounted on a quartz tuning fork (Fig. 3b and c), which is a few millimeters in size. The tuning fork is mechanically vibrated at resonance frequency, usually in tens to hundreds of kilohertz, resulting in a few nanometers of lateral motion at the distal end of the NSOM tip. When the tip is in a close lateral proximity to the sample, the resonance frequency of the tip-tuning fork system is disturbed due to electrostatic, van der Waals, hydrogen bonding, and other kinds of attractive and/or repulsive interactions between the tip and the sample. This disturbance is read as an electrical signal that is processed, and the tip is moved accordingly in the vertical direction to achieve its preset resonance frequency, thus keeping the same distance from the sample.

Optical resolution, which is typically achieved by fiber-based apertured NSOM, is in the range of 50 nm, with maximum resolution being in the range of 20 nm. The improvement in tip fabrication procedures and in the control of the tip-sample separation distance will ultimately lead to better resolution. For apertured NSOM, fiberoptic or pipette-based tips are fabricated by constricting the core of the optical fiber to a 50–20 nm diameter. This is achieved by a heating–pulling method (21), wherein the fiber is transversally irradiated by CO₂ laser and simultaneously

stretched on the pipette puller until the fiber is broken, or by chemical etching (22) at the phase boundaries using the HF solution with oil on the top. To enhance the efficiency of the light transmission and to avoid the light leakage through the fiber shell, the probes are usually coated with either aluminum or silver. The coating is done by vacuum evaporation, and its role is to prevent light leaking out of the probe. The metallic coating is especially beneficial in the near-field surface-enhanced Raman spectroscopy.

Another way of performing apertured NSOM is by bending the fiber or pipette. In this case, the force feedback can be achieved either by shear force, or by AFM-like normal force in both contact or noncontact mode. The disadvantage of this approach is that such bended fibers are more vulnerable to mechanical failure, and if used for spectroscopy purposes, there may be problems with Raman scattering lines coming from the fiber shell materials.

The other way of achieving apertured NSOM imaging is by using the hollow AFM cantilevers (23). In this kind of setup, the light from the excitation laser is focused on the top aperture on the center of the hollow AFM tip, and the near field is formed at its bottom. The feedback mechanism used therein is the same as in noncontact AFM. Presently, the resolution (in the range of 100 nm) of such hollow-cantilevered-based apertured NSOMs is inferior to that of pulled-fiber-based NSOMs. Another disadvantage of the AFM-like force-feedback setup in NSOM applications is in that the AFM uses a laser beam to follow the bending of the cantilever. In NSOM, when many applications are counting the individual photons, the optical noise introduced by the AFM-like laser-based feedback may be several folds stronger than the signal. Considerable improvement is to be expected with piezo-actuated hollow cantilevers, which will avoid using laser feedback.

Apertureless NSOM

In the apertureless NSOM (Figs. 1b and 5), a sharp metallic tip is irradiated by the laser light orthogonally to the long tip axis, and the near-field excitation is scattered from the

tip (27,28). The light scattering from the feature is much smaller than the applied wavelength, which also generates the strong evanescent field. The best strength of the scattering field is achieved if the excitation laser frequency corresponds to the surface-plasmon resonance of the metal from which the tip is made. Incoming beam scattering produces the evanescent field at the tip; however, the physics of the process is a combination of the near-field antenna effects and surface plasmon resonance. The laser induces the plasmons in the tip, which oscillates in parallel to the tip axis and amplifies the evanescent standing wave at the tip apex. The standing wave interacts with the sample and the signal is collected either in transmission or reflection mode in the far field. The tip is scanned across the sample in the same raster-pattern manner as with apertured NSOM. Feedback is provided in either the noncontact AFM manner, preferably with a tuning fork or some other nonlaser based Z-deflection feedback, and the signal collection is modulated by oscillating the probe in a vertical direction in order to avoid static and scattering artifacts. Furthermore, in modulated apertureless NSOM, the signal from the photodetector is also modulated with the same modulation signal source as a tip, in exactly the same frequency and phase (with possibilities of higher harmonics modulation. This is done in order to avoid inbound laser light nonnear-field induced scattering; static-scattering artifacts from sample features and to achieve optical signal acquisition always in a same sample-tip separation distance position.

In order to distinguish between the near-field scattering and inbound laser light, most of the apertureless NSOMs are used mainly for fluorescence, Raman, or for different nonlinear optical phenomena applications. Furthermore, because of the rapid decay of the scattered field, modulation of the scanning probe, and control of the sample-tip separation distance in the apertureless configuration is much more critical than in the aperture-based NSOM.

Figure 5 is a schematic representation of a typical, homemade, apertureless NSOM setup; in this particular case used for fluorescence and fluorescence-lifetime (FLIM)

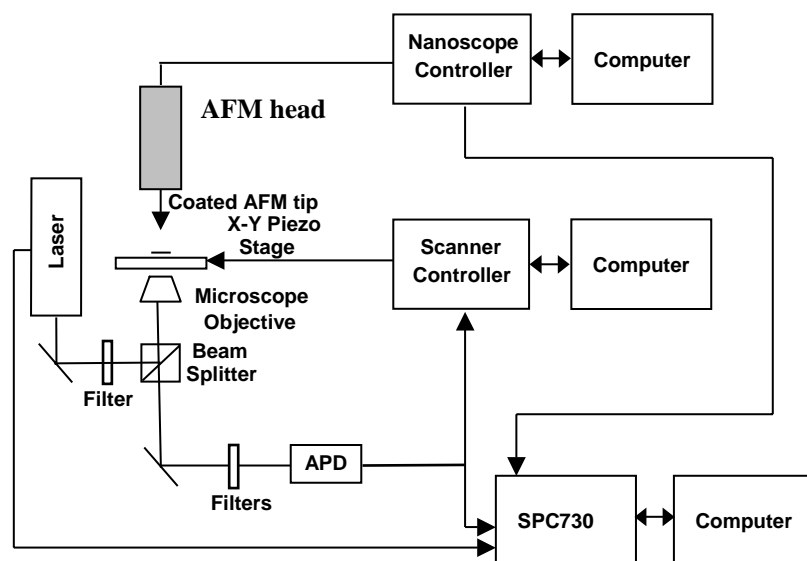

Figure 5. Schematic representation of the example of the apertureless NSOM. (Adapted from Ref. 29.)

near field imaging. It consists of a commercially available AFM head, mounted on the top of the inverted epi-fluorescence microscope, positioned at the optical table. The lateral irradiation of the tip, which is necessary in order to achieve the high intensity evanescent field generation, is produced by offsetting the position of the AFM tip in relationship to the high numerical apex microscope objective. In this particular case, the fluorescence imaging measurements were conducted in an inverted fluorescence-imaging microscope (Nikon Diaphot 300), the excitation light from a mode-locked YAG laser (Coherent Antares) at 532 nm wavelength, 10 ps pulse width, and 76 MHz repetition rate was focused on a diffraction-limited spot through an objective (Nikon 60X NA 1.4), and the emission from the sample was collected by the same objective, in the epi-fluorescence manner. The emission band-pass filters were HQ565/25 and D570/20 (Chroma Technology) to ensure that the excitation light and the feedback laser of AFM (650 nm) were both blocked. The emission was detected by an avalanche photodiode (APD) (Perkin Elmer, SPCM-AQR-15). The background photon counts with AFM feedback on were ~ 150 Hz. The sample cover slip was mounted on a closed-loop two-dimensional (2D) piezoelectric scanner (Polytec PI, P-731). The AFM (Veeco Instruments Inc, D3100) head and inverted microscope were coupled at an over-under position. The AFM tapping-mode tips used in this work are commercially available Si tips (Digital Instrument, OTESP7) coated with Au and Ag, by sputter coating. Image density of 128×128 pixels and scan rate of 1 Hz. As the quenching effect is highly distance dependent, the tip oscillation amplitude was reduced by reducing the driving voltage to the tip as much as possible without sacrificing image quality. Based on the force calibration curve, the tip oscillation amplitude during the imaging was estimated at ~ 30 nm.

The sample-scanning confocal fluorescence image was recorded by a home-built computer control interface that counted the APD signal and raster-scanned the piezoelectric scanner. The fluorescence decay traces were recorded by a time-correlated single photon counting (TCSPC) module (Becker & Hickl SPC730, Germany). The start signal was from the APD and the stop signal was from synchronization of the YAG laser at one-half of the laser repetition rate. For the lifetime imaging mode, the TCSPC module reads the line-synchronization signal of the Digital Instrument Nanoscope IIIa controller to achieve a synchronized recording of the AFM signals and fluorescence signals.

Figure 6 depicts the FEM simulation (30) of near-field enhancement around a metallic tip positioned in close proximity to the sample and irradiated with a laser beam. Figure 6 shows the rapid dependence of the near-field excitation on the sample-tip separation, and emphasizes necessity of accurate, sub nanometer sample-tip separation control mechanism for any widespread, commercial applications. This is even more important for the Raman spectroscopy or hyperspectral imaging (or in this sense for any other, nonlinear optical applications), as the strength of the Raman emission is proportional to the fourth power of the strength of the electric field of applied light the small changes in the strength of the local near-field enhancement

Figure 6. Finite-element methods (FEM) simulation of the electromagnetic field scattering and near field enhancement at the apex of the tip of the apertureless NSOM, and its behavior with change in tip-sample separation distance. (Adapted from Ref. 30.)

can produce the dramatic fluctuation in the strength of the optical signal.

Besides all of the difficulties in implementation, the advantage of the apertureless mode is in theoretically better resolution than the apertured mode, and in the higher surface-enhanced Raman signal, due to plasmon coupling, which makes this method, theoretically, an ideal molecular Raman nanoprobe, a “holy grail” for life scientists (31,32). The hyperspectral subwavelength Raman imaging is extremely important for further studies in system biology, proteomics, and metabolomics, as it is expected it will for the first time allow identification and spatial positioning of biomolecules within a cell, without the introduction of fluorescence labels. Aside from Raman imaging, this approach is expected to be better for the purpose of fluorescence lifetime imaging (FLIM) (29). The apertureless approach also has significant advantages because the surface plasmon enhancement is driven by the metallic tip and a higher local intensity of the scattered field.

However, to date, there is no commercial instrument available based on the apertureless NSOM principle, because of many technical problems, a significantly smaller photon flux, a low signal/noise ratio, and extreme signal dependence on the tip-sample separation distance. It is expected that with improvements in the control mechanism

for keeping the sample-tip separation in the subnanometer range, as well as improvements in laser positioning and further enhancement of the photodetector efficiencies, the apertureless NSOM will become more widespread, with the first commercial instruments expected to be introduced to the market in the near future.

The tip for the apertureless NSOM can be manufactured in three different ways. The simplest way is by electrochemically etching the metallic wire in the same way as for production of the STM tips. However, controlled and optimized shapes, which can provide more efficient field enhancement, can be better achieved by using the free ion bombardment (FIB) techniques for both tip growth and etching.

NSOM Operations

The typical operation of the NSOM consists of positioning the tip above the sample feature of interest, visually using the reflection and transmission video system, respectively. After executing a manual approach procedure, the tip is subsequently placed under PID control and is automatically maintained in the near-field region. The nonoptical, shear-force feedback relies on measuring the voltage generated by a quartz tuning fork onto which the NSOM tip is rigidly mounted, thus avoiding feedback laser. Having a feedback without the feedback laser is of great advantage, as avoidance of that voltage is a direct measure for the oscillation amplitude of the tip-tuning fork assembly, which varies with tip-to-sample distance over a range of ~ 25 nm.

Unlike conventional AFM cantilever designs, the spring constant of the straight-fiber NSOM tip in the vertical direction is extremely high, thus avoiding damaging snap-to-contact. A feedback algorithm monitors the amplitude of the tuning fork by appropriately adjusting the tip-sample distance. Using this method, the NSOM tip is engaged and maintained within ~ 5 nm of the surface in the near-field region throughout the NSOM scanning or spectroscopic measurements. Another advantage of using shear-force feedback is in the absence of a feedback laser, which is especially important in the low photon-count applications (e.g., in spectroscopy-hyperspectral imaging and single-molecular studies).

Other methods of maintaining the tip in the near field have not proven nearly as sensitive or reliable as tuning-fork-based shear-force feedback. Some methods originally developed for AFM applications may require actual surface contact and, consequently, possible surface or tip transformation, ultimately resulting in either damage or having to move the tip in and out of the near-field during data acquisition. The other disadvantage of AFM-like feedback is in the great technical difficulties to form a self-actuated, piezo-based AFM hollow tip, thus forcing the use of laser for feedback control. The AFM-like force feedback with pulled fiber tip requires a bent fiber, which is much less mechanically stable than a straight fiber. In addition, the bent fiber has problems associated with circular light paths and higher Raman scattering from glass-fiber substrates, interferences that carry especially negative consequences for near-field spectroscopy, as they can significantly increase the optical noise level.

The NSOM can be used both in air and in liquid. Most of the work to date has been done in air. While it has been demonstrated many times that the method can be successfully used in liquid operation, there are problems associated with the meniscus force formed between the probe and liquid surface. For work in air, shear force is the superior method of feedback. However, for work in liquid, the AFM-like noncontact feedback has advantages. With further improvements in the fiber-based probes coating in the near future, it is expected that shear-force-based topographic imaging and feedback will become equal with the AFM-like noncontact-based topographic imaging in liquid.

Near-Field Spectroscopy

For spectroscopic studies, NSOM can be considered as a controlled light collector, with tens-of-nanometer spatial positioning resolution. Thus, many of the standard spectroscopic techniques could be applied, depending on the amount of signal available. For example, it was successfully demonstrated that NSOM can be used for fluorescence and photoluminescence spectroscopy; electroluminescence spectroscopy, time-resolved spectroscopy; polarization studies, and in early stage infrared (IR) and Raman spectroscopies. The latter of the two has the greatest promise in becoming the ultimate molecular nanoprobe. Some of the applications of *in situ* hyperspectral, that is, composition-specific nanoscale studies include chemical identification of observed samples; studies of optical properties of materials at nano-scale levels; detection of phase differences and impurities in materials; protein studies, and many more. Ultimately, it opens the door for a plethora of both fundamental and applied studies in the fields of physics, material science, chemistry, life sciences, and nanotechnology.

Examples of a near-field spectroscopy application are shown in Fig. 7. While Fig. 7a represents the topography image of the PIC dye crystal (33), Fig. 7b is the NSOM fluorescence image of the same area. In order to explore the origin of inhomogeneities, near-field fluorescence spectroscopy, with spectra presented at Fig. 7c, has been done at different points, labeled 1–4, on Fig. 7b. Finally, fluorescence spectra resolved the inhomogeneities of emission sources, pointing to the two different allotropes of crystals having emissions peaking at 645 and 690 nm, respectively.

The near-field signal, which is by default very weak, gets even weaker if we want to do the wavelength-resolved spectroscopic analysis, or full hyperspectral cube imaging, so longer exposition time is necessary to acquire usable spectra. For a near-field spectroscopy system to be successful, it needs to have an extremely stable probe position control, in all three axes, to keep the optimal sample-probe distance, and to keep the probe above the point of interest, for a prolonged time of signal collection.

Figure 8 represents the typical modern commercial NSOM microscopy-spectroscopy setup, in this particular case, an Aurora-3 for spectroscopy made by Veeco Instruments Inc., Santa Barbara, CA (34). In general, such a near-field microscopy-spectroscopy package consists of the NSOM microscope, an objective lens for signal collection, optical filters for elimination of the excitation laser light,

Figure 7. Example of fluorescence-based hyperspectral near-field imaging. (a) Shear-force topography image; (b) NSOM fluorescence image; (c) spatially resolved fluorescence spectra, numbers 1–4 corresponds to the different position on the crystal, demonstrating chemically specific imaging and material inhomogeneities at the nanoscale. (Courtesy of David Vanden Bout and Paul Barbara, University of Minnesota, Minneapolis, MI.)

an optical pathway for signal transduction to the detector, and a wavelength dispersive detector. As the signal is generally very weak, the spectrometer needs to have a very sensitive detection system, in the best case, single-photon sensitivity. With today's solid-state detectors technology, the best detector to use is the CCD camera with a larger stack of sensitive pixels coupled to the imaging spectrometer. Depending on applications, either a Peltier cooled camera will be satisfactory (for most bright fluorescence samples) or a liquid-nitrogen-cooled camera for ultimate sensitivity, such as in single-molecular experiments and near-field Raman spectroscopy. Furthermore, interfacing and communication between spectrometer and NSOM scanning probe control software needs to be established.

Today, many spectrometers have semiopen control software, thus allowing triggering of the spectral acquisition with the TTL handshake signal, which can be produced by the NSOM microscope controller. In this way, the microscope controller initiates spectral acquisition and the system can be used with many different commercial spectrometers, allowing customization of the microprobe. Filtering out excitation photons is of extreme importance to increase the signal/noise ratio, and the best filters available today are notch, interferometric filters. Another consideration when designing the NSOM spectroscopy package is that not one formula will fit all of the requirements. Furthermore, virtually any application will require some special design consideration, so building the system

Figure 8. Typical, third generation commercially available NSOM setup, for imaging and spectroscopy: (a) photo of the NSOM head and sample holder; (b) complete system with attached spectrometer; (c) optical path schematics. (Courtesy of Veeco Instruments Inc., Santa Barbara, CA.)

as versatile and modular as possible is of the utmost importance. The ability to incorporate additional standard optical components and easy system reconfiguration should be first in the designer's mind. At the same time, once a system is set up for operation, it should allow for easy, straightforward, simple operation, and robustness, which are sometimes contradictory requirements. The design of the NSOM head, when having the spectroscopy package in mind, must incorporate extremely accurate closed-loop scan linearization. While shear-force feedback keeps superb control of sample-tip distance, the closed-loop X - Y scanning is necessary in order to keep the probe at the selected spatial position during sample collection.

The near-field spectroscopy package is an even more promising breakthrough technology for life sciences than for NSOM imaging alone. For the first time, it will allow qualitative identification of the composition of an observed sample, via optical spectroscopies, at the spatial resolution of scanning probe microscopy. The current commercial systems can distinguish differences in chemical composition of the samples, at the spatial resolution of 50 nm or better. For combined near-field spectroscopy and imaging, the signal may be split into the dual-beam path, wherein one path is used for the imaging detector and another one for spectroscopy. Such dual-beam solution minimizes removal, replacement, and realignment of components when a different mode is desired. The benefit is the ease of use and robust, reliable operation for separate or simultaneous transmission and reflection measurements.

In the example of the Aurora-3 optical path system, the light from both objectives is redirected out the side ports by two front-surface mirrors, which are reflection-coated for optimal visible/near-IR (NIR) operation. The near-field transmission and reflection light is collected in the far field by precisely aligned microscope objectives to provide high quality collimated (parallel) beams, with a nominal 7 mm diameter. This system design allows for NSOM spectroscopic operation with standard one-half in. diameter optics, though for ease of alignment and handling, 1 in. diameter optics is generally recommended. Furthermore, the reflection path is carefully aligned to match the transmission path. Such integrated solutions minimize removal, replacement, and realignment of components when a different mode is desired. The integrated reflection path is always available for use with any sample and never requires removal or realignment in the microscope with normal use. As there are many variations in the spectroscopy setup, it is important for an NSOM system that is intended for spectroscopic use to be capable of utilizing the standard optical element, so users can customize the system using standard optical poles and optical bench mounting systems.

Evaluation

While the first NSOM was invented just 2 years after the AFM, its widespread use has just started to pick up in the last several years. The reasons for this lag are several-fold: the first NSOM images were hard to interpret, and as they were achieved without topography modulation, the contrast in the images was not intuitive; there were no com-

mercial instruments available until the mid-1990s, thus all users needed to build their own systems; the use of the home-built and first commercial instrument and its alignment procedures were cumbersome and complicated for any user who was not skilled in optoelectronics development; and the resolution of the systems depended on each individual sample. However, the field is changing rapidly, and with introduction of the latest, third generation of commercial systems (13–16), such as the Aurora-3 from Veeco Instruments Inc., MultiView 400 from Nanonics Imaging Ltd, Smena from NT-MDT, and AlphaSNOM from WiTec GmbH, the ease of use is comparable with the standard scanning probe microscope and is within the skill set of average life sciences user. Furthermore, with improvement in the serial production of the probes and quality control in recent years, the resolution of the NSOM system is becoming more uniform, and resolution expectations can be met with most samples.

The way to evaluate and measure resolution of the NSOM instrument is by utilizing Fisher's projection masks (35). It is virtually accepted as a standard for evaluating NSOM resolution and quality of image topographic modulation, the latter one by comparing the topographic with the optical image. The Fisher project mask is a regular hexagonal array of metallic spikes (Fig. 9). It is produced by having the monolayer of the monodispersed polymer spheres coated with metallic coating, and the spheres subsequently dissolved with organic solvents. What is left is the regular, closed-packed hexagonal matrix of metallic spikes. In transmission mode, the spike is seen as a dark spot on the optical micrography, while in reflection mode, the spike is a bright spot, and the void space is dark.

The near-field optical imaging obviously provides two great advantages over other types of imaging: its ability to simultaneously acquire topography, in a scanning-force manner, and an optical image. The optical image carries a plethora of different information that can be furthermore extracted. The most important advantage is that there are many different ways to extract direct or indirect information on spatial distribution of chemical composition of the observed sample, even on the single molecular level. Furthermore, at current state-of-the-art commercial NSOM instrumentation, the near-field imaging and spectroscopy can be performed at a resolution at least four times as high as the resolution of the best optical confocal microscopes. The obvious applications in the biomedical field are all of the applications for which the standard confocal and inverted fluorescence microscope is used today, but at the same time, done at much higher resolution (36–40). Examples of life sciences and biomedical applications involve optical ultramicroscopy of cells; optical imaging of cell organelles; imaging and spectroscopy of individual molecules and macromolecules; *in vivo* tracking of molecular events and endocytosis; and high resolution chromosome labeling [i.e., high resolution fluorescence *in situ* hybridization (FISH) (39) applications]. Some of these applications, like molecular tracking, and high resolution FISH are unachievable with other methods.

The molecular tracking applications are based on fluorescence, and in the future, Raman SERS applications will revolutionize our way of understanding how cellular

Figure 9. Fisher mask, typical structure for NSOM evaluation and calibration: (a) topographic image produced with shear-force feedback; (b) NSOM transmission mode image of the same area. The images were produced on the Aurora-3 NSOM, (Courtesy of Veeco Instruments Inc., Santa Barbara, CA.)

mechanisms work, and will bring significant contributions to practical pharmacological applications, such as drug candidates, where their target will be able to be imaged, measured, and tracked during action. Additionally, this application will add considerably to the body of knowledge of macromolecular interactions and in the mapping of the interactome of proteins, enzymes, and nucleic acids within the cell. The simplest way will be by expressing differently colored fluorescence proteins, fused with ligand and target, and tracking their spatial positions within the cell, and from the fluorescence resonance energy transfer or fluorescence intermittency, following their interactions. No other method is capable of achieving the resolution necessary to understand molecular machines *in vivo*. Another futuristic application of NSOM is in the ultrahigh density genomics and proteomics array, which theoretically can be packed at the density range higher than the wavelengths.

Some of the more futuristic life science applications will come with the integration of NSOM with mass spectrometry. Zenobi's group (25) demonstrated that the apertured NSOM is capable of doing the nanoablation of structures and thus can feed the mass spectrometer with material ablated with the resolution of a few tens of nanometer. This can dramatically improve the knowledge of spatial locations of proteins, and protein-protein complexes and interactions.

The NSOM-based FISH (38) can have a large impact on the future of molecular *in vitro* diagnostics because it will allow FISH to be applied on the shorter segments of DNA. This will permit many additional applications by painting shorter genes of this simple, chromosome painting technique, which are unachievable with far-field fluorescence or confocal-fluorescence equipment. If designed in a simple and high throughput manner, this may become a standard diagnostic instrument for molecular cytogenetics diagnostics in pathology labs.

It is expected that the next, fourth-generation instrumentation, currently in the design stage, will allow more routine imaging with a level of technical expertise, which is

necessary for practical applications comparable with running today's confocal microscope.

Examples of the NSOMs biological applications are presented in Fig. 10a–c. Figure 10a is an example of the protein localization imaging beyond diffraction limit. In this particular image, the fibroblast cells were labeled with green fluorescence protein (GFP). The image on the left represents the shear-force micrography, which corresponds to the topographic image, while the image on the right is the GFP fluorescence image. Spatial distribution of the GFP can easily be observed within the cell at a resolution far exceeding the diffraction limits. This technique can be used to track the protein synthesis and trafficking within the cell if the targeted protein is fused with the fluorescence label, such as GFP or YFP. Another unique NSOM application is in optical characterization of the supramolecular and macromolecular assemblies. Figure 10b represents topographic, shear force (left) and NSOM transmission image (right) of the interband region of a polytene chromosome. In the optical image, the chromatin matter can be distinguished from the DNA based on the optical contrast, which is not possible based on the pure topography. Finally, Fig. 10c represents far-field optical transmission image of slice of the muscle tissue (left) and shear-force topography and near-field optical image, on the right top and bottom, respectively. The near-field imaging reveals the fine structure of the muscular fiber, its cell membrane, myofibrils, and endoplasmatic reticulum structure, in a similar manner as using the transmission electron microscopy.

Besides imaging, the near-field optical microscopy-like setup has promise for use in the nanoscale lithography (41), and for high density data storage (42). Nanoscale lithography will have applications in the preparation of tissue growth matrix and scaffolds, especially for the growth of neurons, while the high voluminous data storage will have a plethora of medical applications for storing ever-growing informational content of both imaging and high throughput diagnostics data.

In conclusion, near-field optical imaging is still a developing technique that shows much promise for biomedical

applications. This review presents the state-of-the-art NSOM technology up to the second quarter of 2005. It is certain that by the time of the next edition of this *Encyclopedia*, there will be many other technological and advancements in the field of biomedical applications of near-field optics.

INTRODUCTION

The technique of laser scanning and spinning disk confocal fluorescence microscopy has become an essential tool in biology and the biomedical sciences, as well as in materials science due to attributes that are not readily available using other contrast modes with traditional optical microscopy (1–12). The application of a wide array of new synthetic and naturally occurring fluorochromes has made it possible to identify cells and submicroscopic cellular components with a high degree of specificity amid nonfluorescing material (13). In fact, the confocal microscope is often capable of revealing the presence of a single molecule (14). Through the use of multiply labeled specimens, different probes can simultaneously identify several target molecules simultaneously, both in fixed specimens and living cells and tissues (15). Although both conventional and confocal microscopes cannot provide spatial resolution below the diffraction limit of specific specimen features, the detection of fluorescing molecules below such limits is readily achieved.

The basic concept of confocal microscopy was originally developed by Minsky in the mid-1950s (patented in 1961) when he was a postdoctoral student at Harvard University (16,17). Minsky wanted to image neural networks in unstained preparations of brain tissue and was driven by the desire to image biological events as they occur in living systems. Minsky's invention remained largely unnoticed, due most probably to the lack of intense light sources necessary for imaging and the computer horsepower required to handle large amounts of data. Following Minsky's work, Egger and Petran (18) fabricated a multiple-beam confocal microscope in the late-1960s that utilized a spinning (Nipkow) disk for examining unstained brain sections and ganglion cells. Continuing in this arena, Egger went on to develop the first mechanically scanned confocal laser microscope, and published the first recognizable images of cells in 1973 (19). During the late-1970s and the 1980s, advances in computer and laser technology, coupled to new algorithms for digital manipulation of images, led to a growing interest in confocal microscopy (20).

Fortuitously, shortly after Minsky's patent had expired, practical laser-scanning confocal microscope designs were translated into working instruments by several investigators. Dutch physicist Brakenhoff developed a scanning confocal microscope in 1979 (21), while almost simultaneously, Sheppard contributed to the technique with a theory of image formation (22). Wilson, Amos, and White nurtured the concept and later (during the late-1980s) demonstrated the utility of confocal imaging in the examination of fluorescent biological specimens (20,23). The first commercial instruments appeared in 1987. During the 1990s, advances in optics and electronics afforded more stable and powerful lasers, high efficiency scanning mirror

units, high throughput fiber optics, better thin-film dielectric coatings, and detectors having reduced noise characteristics (1). In addition, fluorochromes that were more carefully matched to laser excitation lines were beginning to be synthesized (13). Coupled to the rapidly advancing computer processing speeds, enhanced displays, and large-volume storage technology emerging in the late-1990s, the stage was set for a virtual explosion in the number of applications that could be targeted with laser scanning confocal microscopy.

Modern confocal microscopes can be considered as completely integrated electronic systems where the optical microscope plays a central role in a configuration that consists of one or more electronic detectors, a computer (for image display, processing, output, and storage), and several laser systems combined with wavelength selection devices and a beam scanning assembly. In most cases, integration between the various components is so thorough that the entire confocal microscope is often collectively referred to as a digital or video imaging system capable of producing electronic images (24). These microscopes are now being employed for routine investigations on molecules, cells, and living tissues that were not possible just a few years ago (15).

Confocal microscopy offers several advantages over conventional widefield optical microscopy, including the ability to control depth of field, elimination, or reduction of background information away from the focal plane (that leads to image degradation), and the capability to collect serial optical sections from thick specimens. The basic key to the confocal approach is the use of spatial filtering techniques to eliminate out-of-focus light or glare in specimens whose thickness exceeds the immediate plane of focus. There has been a tremendous explosion in the popularity of confocal microscopy in recent years (1–4,6,7), due in part to the relative ease with which extremely high quality images can be obtained from specimens prepared for conventional fluorescence microscopy, and the growing number of applications in cell biology that rely on imaging, both fixed and living cells and tissues. In fact, confocal technology is proving to be one of the most important advances ever achieved in optical microscopy.

In a conventional widefield optical epi-fluorescence microscope, secondary fluorescence emitted by the specimen often occurs through the excited volume and obscures resolution of features that lie in the objective focal plane (25). The problem is compounded by thicker specimens ($>2\ \mu\text{m}$), which usually exhibit such a high degree of fluorescence emission that most of the fine detail is lost. Confocal microscopy provides only a marginal improvement in both axial (z ; parallel to the microscope optical axis) and lateral (x and y ; dimensions in the specimen plane) optical resolution, but is able to exclude secondary fluorescence in areas removed from the focal plane from resulting images (26–28). Even though resolution is somewhat enhanced with confocal microscopy over conventional widefield techniques (1), it is still considerably less than that of the transmission electron microscope (TEM). In this regard, confocal microscopy can be considered a bridge between these two classical methodologies.

Illustrated in Fig. 1 are a series of images that compare selected viewfields in traditional widefield and laser

Comparison of Images Produced by Widefield and Confocal Microscopy

Figure 1. Comparison of widefield (upper row) and laser scanning confocal fluorescence microscopy images (lower row). Note the significant amount of signal in the widefield images from fluorescent structures located outside of the focal plane. (a) and (b) Mouse brain hippocampus thick section treated with primary antibodies to glial fibrillary acidic protein (GFAP; red), neurofilaments H (green), and counterstained with Hoechst 33342 (blue) to highlight nuclei. (c) and (d) Thick section of rat smooth muscle stained with phalloidin conjugated to Alexa Fluor 568 (targeting actin; red), wheat germ agglutinin conjugated to Oregon Green 488 (glycoproteins; green), and counterstained with DRAQ5 (nuclei; blue). (e) and (f) Sunflower pollen grain tetrad autofluorescence.

scanning confocal fluorescence microscopy. A thick (16 μm) section of fluorescently stained mouse hippocampus in widefield fluorescence exhibits a large amount of glare from fluorescent structures located above and below the focal plane (Fig. 1a). When imaged with a laser scanning confocal microscope (Fig. 1b), the brain thick section reveals a significant degree of structural detail. Likewise, widefield fluorescence imaging of rat smooth muscle fibers stained with a combination of Alexa Fluor dyes produce blurred images (Fig. 1c) lacking in detail, while the same specimen field (Fig. 1d) reveals a highly striated topography when viewed as an optical section with confocal microscopy. Autofluorescence in a sunflower (*Helianthus annuus*) pollen grain tetrad produces a similar indistinct outline of the basic external morphology (Fig. 1e), but yields no indication of the internal structure in widefield mode. In contrast, a thin optical section of the same grain (Fig. 1f) acquired with confocal techniques displays a dramatic difference between the particle core and the surrounding envelope. Collectively, the image comparisons in Fig. 1 dramatically depict the advantages of achieving very thin optical sections in confocal microscopy. The ability of this technique to eliminate fluorescence emission from regions removed from the focal plane offsets it from traditional forms of fluorescence microscopy.

PRINCIPLES OF CONFOCAL MICROSCOPY

The confocal principle in epi-fluorescence laser scanning microscope is diagrammatically presented in Fig. 2. Coherent light emitted by the laser system (excitation source) passes through a pinhole aperture that is situated in a conjugate plane (confocal) with a scanning point on the specimen and a second pinhole aperture positioned in front of the detector (a photomultiplier tube). As the laser is reflected by a dichromatic mirror, and scanned across the specimen in a defined focal plane, secondary fluorescence emitted from points on the specimen (in the same focal plane) pass back through the dichromatic mirror, and are focused as a confocal point at the detector pinhole aperture.

The significant amount of fluorescence emission that occurs at points above and below the objective focal plane is not confocal with the pinhole (termed out-of-focus light rays in Fig. 2) and forms extended Airy disks in the aperture plane (29). Because only a small fraction of the out-of-focus fluorescence emission is delivered through the pinhole aperture, most of this extraneous light is not detected by the photomultiplier and does not contribute to the resulting image. The dichromatic mirror, barrier filter, and excitation filter perform similar functions to identical components in a widefield epi-fluorescence microscope (30).

Figure 2. Schematic diagram of the optical pathway and principal components in a laser scanning confocal microscope.

Refocusing the objective in a confocal microscope shifts the excitation and emission points on a specimen to a new plane that becomes confocal with the pinhole apertures of the light source and detector.

In traditional widefield epi-fluorescence microscopy, the entire specimen is subjected to intense illumination from an incoherent mercury or xenon arc-discharge lamp, and the resulting image of secondary fluorescence emission can be viewed directly in the eyepieces or projected onto the surface of an electronic array detector or traditional film plane. In contrast to this simple concept, the mechanism of image formation in a confocal microscope is fundamentally different (31). As discussed above, the confocal fluorescence microscope consists of multiple laser excitation sources, a scan head with optical and electronic components, electronic detectors (usually photomultipliers), and a computer for acquisition, processing, analysis, and display of images.

The scan head is at the heart of the confocal system and is responsible for rasterizing the excitation scans, as well as collecting the photon signals from the specimen that are required to assemble the final image (1,5–7). A typical scan head contains inputs from the external laser sources, fluorescence filter sets and dichromatic mirrors, a galvanometer-based raster scanning mirror system, variable pinhole apertures for generating the confocal image, and photomultiplier tube detectors tuned for different fluorescence wavelengths. Many modern instruments include diffraction gratings or prisms coupled with slits positioned near the photomultipliers to enable spectral imaging (also referred to as emission fingerprinting) followed by linear unmixing of emission profiles in specimens labeled with combinations of fluorescent proteins or fluorophores having overlapping spectra (32–38). The general arrangement of scan head components is presented in Fig. 3 for a typical commercial unit.

Spectral Imaging Confocal Scan Head with SIM Laser Port

Figure 3. Three-channel spectral imaging laser scanning microscope confocal scan head with SIM scanner laser port. The SIM laser enables simultaneous excitation and imaging of the specimen for photobleaching or photoactivation experiments. Also illustrated are ports for a visible, ultraviolet (UV), and infrared (IR) laser, as well as an arc discharge lamp port for widefield observation.

In epi-illumination scanning confocal microscopy, the laser light source and photomultiplier detectors are both separated from the specimen by the objective, which functions as a well-corrected condenser and objective combination. Internal fluorescence filter components (e.g., the excitation and barrier filters and the dichromatic mirrors) and neutral density filters are contained within the scanning unit (see Fig. 3). Interference and neutral density filters are housed in rotating turrets or sliders that can be inserted into the light path by the operator. The excitation laser beam is connected to the scan unit with a fiber optic coupler followed by a beam expander that enables the thin laser beam waist to completely fill the objective rear aperture (a critical requirement in confocal microscopy). Expanded laser light that passes through the microscope objective forms an intense diffraction-limited spot that is scanned by the coupled galvanometer mirrors in a raster pattern across the specimen plane (point scanning).

One of the most important components of the scanning unit is the pinhole aperture, which acts as a spatial filter at the conjugate image plane positioned directly in front of the photomultiplier (39). Several apertures of varying diameter are usually contained on a rotating turret that enables the operator to adjust pinhole size (and optical section thickness). Secondary fluorescence collected by the objective is descanned by the same galvanometer mirrors that form the raster pattern, and then passes through a barrier filter before reaching the pinhole aperture (40). The aperture serves to exclude fluorescence signals from out-of-focus features positioned above and below the focal plane, which are instead projected onto the aperture as Airy disks having a diameter much larger than those forming the image. These oversized disks are spread over

Figure 4. Widefield versus confocal microscopy illumination volumes, demonstrating the difference in size between point scanning and widefield excitation light beams.

a comparatively large area so that only a small fraction of light originating in planes away from the focal point passes through the aperture. The pinhole aperture also serves to eliminate much of the stray light passing through the optical system. Coupling of aperture-limited point scanning to a pinhole spatial filter at the conjugate image plane is an essential feature of the confocal microscope.

When contrasting the similarities and differences between widefield and confocal microscopes, it is often useful to compare the character and geometry of specimen illumination utilized for each of the techniques. Traditional widefield epi-fluorescence microscope objectives focus a wide cone of illumination over a large volume of the specimen (41), which is uniformly and simultaneously illuminated (as illustrated in Fig. 4a). A majority of the fluorescence emission directed back toward the microscope is gathered by the objective (depending on the numerical aperture) and projected into the eyepieces or detector. The result is a significant amount of signal due to emitted background light and autofluorescence originating from areas above and below the focal plane, which seriously reduces resolution and image contrast.

The laser illumination source in confocal microscopy is first expanded to fill the objective rear aperture, and then focused by the lens system to a very small spot at the focal plane (Fig. 4b). The size of the illumination point ranges from ~ 0.25 to $0.8 \mu\text{m}$ in diameter (depending on the objective numerical aperture) and 0.5 to $1.5 \mu\text{m}$ deep at the brightest intensity. Confocal spot size is determined by the microscope design, wavelength of incident laser light, objective characteristics, scanning unit settings, and the specimen (41). Figure 4 presents a comparison between the typical illumination cones of a widefield (Fig. 4a) and point scanning confocal (Fig. 4b) microscope at the same numerical aperture. The entire depth of the specimen over a wide area is illuminated by the widefield microscope, while the sample is scanned with a finely focused spot of illumination that is centered in the focal plane in the confocal microscope.

In laser scanning confocal microscopy, the image of an extended specimen is generated by scanning the focused beam across a defined area in a raster pattern controlled by two high speed oscillating mirrors driven with galvanometer motors. One of the mirrors moves the beam from left to right along the x lateral axis, while the other translates the beam in the y direction. After each single scan along the x axis, the beam is rapidly transported back to the starting point and shifted along the y axis to begin a new scan in a process termed flyback (42). During the flyback operation, image information is not collected. In

this manner, the area of interest on the specimen in a single focal plane is excited by laser illumination from the scanning unit.

As each scan line passes along the specimen in the lateral focal plane, fluorescence emission is collected by the objective and passed back through the confocal optical system. The speed of the scanning mirrors is very slow relative to the speed of light, so the secondary emission follows a light path along the optical axis that is identical to the original excitation beam. Return of fluorescence emission through the galvanometer mirror system is referred to as descanning (40,42). After leaving the scanning mirrors, the fluorescence emission passes directly through the dichromatic mirror and is focused at the detector pinhole aperture. Unlike the raster scanning pattern of excitation light passing over the specimen, fluorescence emission remains in a steady position at the pinhole aperture, but fluctuates with respect to intensity over time as the illumination spot traverses the specimen producing variations in excitation.

Fluorescence emission that is passed through the pinhole aperture is converted into an analog electrical signal having a continuously varying voltage (corresponding to intensity) by the photomultiplier. The analog signal is periodically sampled and converted into pixels by an analog-to-digital (A/D) converter housed in the scanning unit or the accompanying electronics cabinet. The image information is temporarily stored in an image frame buffer card in the computer and displayed on the monitor. Note that the confocal image of a specimen is reconstructed, point by point, from emission photon signals by the photomultiplier and accompanying electronics, yet never exists as a real image that can be observed through the microscope eyepieces.

LASER SCANNING CONFOCAL MICROSCOPE CONFIGURATION

Basic microscope optical system characteristics have remained fundamentally unchanged for many decades due to engineering restrictions on objective design, the static properties of most specimens, and the fact that resolution is governed by the wavelength of light (1–10). However, fluorescent probes that are employed to add contrast to biological specimens and, and other technologies associated with optical microscopy techniques, have improved significantly. The explosive growth and development of the confocal approach is a direct result of a renaissance in optical microscopy that has been largely fueled by advances in modern optical and electronics technology. Among these are stable multiwavelength laser systems that provide better coverage of the uv, visible, and near-IR spectral regions, improved interference filters (including dichromatic mirrors, barrier, and excitation filters), sensitive low noise wide-band detectors, and far more powerful computers. The latter are now available with relatively low cost memory arrays, image analysis software packages, high resolution video displays, and high quality digital image printers. The flow of information through a modern confocal microscope is presented diagrammatically in Fig. 5 (2).

Figure 5. Confocal microscope configuration and information flow schematic diagram.

Although many of these technologies have been developed independently for a variety of specifically targeted applications, they have been incorporated gradually into mainstream commercial confocal microscopy systems. In current microscope systems, classification of designs is based on the technology utilized to scan specimens (7). Scanning can be accomplished either by translating the stage in the x , y , and z directions while the laser illumination spot is held in a fixed position, or the beam itself can be raster-scanned across the specimen. Because three-dimensional (3D) translation of the stage is cumbersome and prone to vibration, most modern instruments employ some type of beam-scanning mechanism.

In modern confocal microscopes, two fundamentally different techniques for beam scanning have been developed. Single-beam scanning, one of the more popular methods employed in a majority of the commercial laser scanning microscopes (43), uses a pair of computer-controlled galvanometer mirrors to scan the specimen in a raster pattern at a rate of approximately one frame per second. Faster scanning rates (to near video speed) can be achieved using acoustooptic devices or oscillating mirrors. In contrast, multiple-beam scanning confocal microscopes are equipped with a spinning Nipkow disk containing an array of pinholes and microlenses (44–46). These instruments often use arc-discharge lamps for illumination instead of lasers to reduce specimen damage and enhance the detection of low fluorescence levels during real-time image collection. Another important feature of the multiple-beam microscopes is their ability to readily capture images with an array detector, such as a charge-coupled device (CCD) camera system (47).

All modern laser scanning confocal microscope designs are centered on a conventional upright or inverted research level optical microscope. However, instead of the standard tungsten-halogen or mercury (xenon) arc-discharge lamp, one or more laser systems are used as a light source to excite fluorophores in the specimen. Image information is gathered point by point with a specialized detector, such as a photomultiplier tube or avalanche photodiode, and then digitized for processing by the host

computer, which also controls the scanning mirrors and/or other devices to facilitate the collection and display of images. After a series of images (usually serial optical sections) has been acquired and stored on digital media, analysis can be conducted utilizing numerous image processing software packages available on the host or a secondary computer.

ADVANTAGES AND DISADVANTAGES OF CONFOCAL MICROSCOPY

The primary advantage of laser scanning confocal microscopy is the ability to serially produce thin ($0.5\text{--}1.5\ \mu\text{m}$) optical sections through fluorescent specimens that have a thickness ranging up to $50\ \mu\text{m}$ or more (48). The image series is collected by coordinating incremental changes in the microscope fine focus mechanism (using a stepper motor) with sequential image acquisition at each step. Image information is restricted to a well-defined plane, rather than being complicated by signals arising from remote locations in the specimen. Contrast and definition are dramatically improved over widefield techniques due to the reduction in background fluorescence and improved signal to noise (48). Furthermore, optical sectioning eliminates artifacts that occur during physical sectioning and fluorescent staining of tissue specimens for traditional forms of microscopy. The noninvasive confocal optical sectioning technique enables the examination of both living and fixed specimens under a variety of conditions with enhanced clarity.

With most confocal microscopy software packages, optical sections are not restricted to the perpendicular lateral ($x\text{--}y$) plane, but can also be collected and displayed in transverse planes (1,5–8,49). Vertical sections in the $x\text{--}z$ and $y\text{--}z$ planes (parallel to the microscope optical axis) can be readily generated by most confocal software programs. Thus, the specimen appears as if it had been sectioned in a plane that is perpendicular to the lateral axis. In practice, vertical sections are obtained by combining a series of $x\text{--}y$ scans taken along the z axis with the software, and then projecting a view of fluorescence intensity as it would appear should the microscope hardware have been capable of physically performing a vertical section.

A typical stack of optical sections (often termed a z series) through a Lodgepole Pine tree pollen grain revealing internal variations in autofluorescence emission wavelengths is illustrated in Fig. 6. Optical sections were gathered in $1.0\ \mu\text{m}$ steps perpendicular to the z axis (microscope optical axis) using a laser combiner featuring an argon ion (488 nm; green fluorescence), a green helium–neon (543 nm; red fluorescence), and a red helium–neon (633 nm; fluorescence pseudocolored blue) laser system. Pollen grains from this and many other species range between 10 and $40\ \mu\text{m}$ in diameter and often yield blurred images in wide-field fluorescence microscopy (see Fig. 1c), which lack information about internal structural details. Although only 12 of the >36 images collected through this series are presented in the figure, they represent individual focal planes separated by a distance of $\sim 3\ \mu\text{m}$ and provide a good indication of the internal grain structure.

Confocal Optical Sections of Longhorn Pine Pollen Grains

Figure 6. Lodgepole pine (*Pinus contorta*) pollen grain optical sections. Bulk pollen was mounted in CytoSeal 60 and imaged with a $100\times$ oil immersion objective (no zoom) in $1\ \mu\text{m}$ axial steps. Each image in the sequence (1–12) represents the view obtained from steps of $3\ \mu\text{m}$.

In specimens more complex than a pollen grain, complex interconnected structural elements can be difficult to discern from a large series of optical sections sequentially acquired through the volume of a specimen with a laser scanning confocal microscope. However, once an adequate series of optical sections has been gathered, it can be further processed into a 3D representation of the specimen using volume-rendering computational techniques (50–53). This approach is now in common use to help elucidate the numerous interrelationships between structure and function of cells and tissues in biological investigations (54). In order to ensure that adequate data is collected to produce a representative volume image, the optical sections should be recorded at the appropriate axial (z step) intervals so that the actual depth of the specimen is reflected in the image.

Most of the software packages accompanying commercial confocal instruments are capable of generating composite and multidimensional views of optical section data acquired from z -series image stacks. The 3D software packages can be employed to create either a single 3D representation of the specimen (Fig. 7) or a video (movie) sequence compiled from different views of the specimen volume. These sequences often mimic the effect of rotation or similar spatial transformation that enhances the appreciation of the specimen's 3D character. In addition, many software packages enable investigators to conduct measurements of length, volume, and depth, and specific parameters of the images, such as opacity, can be interactively altered to reveal internal structures of interest at differing levels within the specimen (54).

Typical 3D representations of several specimens examined by serial optical sectioning are presented in Fig. 7. A series of sunflower pollen grain optical sections was combined to produce a realistic view of the exterior surface (Fig. 7a) as it might appear if being examined by a scanning electron microscope (SEM). The algorithm utilized to construct the 3D model enables the user to rotate the

3-D Volume Rendering in Confocal Microscopy

Figure 7. Three-dimensional volume renders from confocal microscopy optical sections. (a) Autofluorescence in a series of sunflower pollen grain optical sections was combined to produce a realistic view of the exterior surface. (b) Mouse lung tissue thick ($16\ \mu\text{m}$) section. (c) Rat brain thick section. These specimens were each labeled with several fluorophores (blue, green, and red fluorescence) and the volume renders were created from a stack of 30–45 optical sections. (d) Autofluorescence in a thin section of fern root.

pollen grain through 360° for examination. Similarly, thick sections ($16\ \mu\text{m}$) of lung tissue and rat brain are presented in Fig. 7b and 7c, respectively. These specimens were each labeled with several fluorophores (blue, green, and red fluorescence) and created from a stack of 30–45 optical sections. Autofluorescence in plant tissue was utilized to produce the model illustrated in Fig. 7d of a fern root section.

In many cases, a composite or projection view produced from a series of optical sections provides important information about a 3D specimen than a multidimensional view (54). For example, a fluorescently labeled neuron having numerous thin, extended processes in a tissue section is difficult (if not impossible) to image using wide-field techniques due to out-of-focus blur. Confocal thin sections of the same neuron each reveal portions of several extensions, but these usually appear as fragmented streaks and dots and lack continuity (53). Composite views created by flattening a series of optical sections from the neuron will reveal all of the extended processes in sharp focus with well-defined continuity. Structural and functional analysis of other cell and tissue sections also benefits from composite views as opposed to, or coupled with, 3D volume rendering techniques.

Advances in confocal microscopy have made possible multidimensional views (54) of living cells and tissues that include image information in the x , y , and z dimensions as a function of time and presented in multiple colors (using two or more fluorophores). After volume processing of individual image stacks, the resulting data can be displayed as 3D multicolor video sequences in real time. Note that unlike conventional widefield microscopy, all fluorochromes in multiply labeled specimens appear in register

using the confocal microscope. Temporal data can be collected either from time-lapse experiments conducted over extended periods or through real-time image acquisition in smaller frames for short periods of time. The potential for using multidimensional confocal microscopy as a powerful tool in cellular biology is continuing to grow as new laser systems are developed to limit cell damage and computer processing speeds and storage capacity improves.

Additional advantages of scanning confocal microscopy include the ability to adjust magnification electronically by varying the area scanned by the laser without having to change objectives. This feature is termed the zoom factor, and is usually employed to adjust the image spatial resolution by altering the scanning laser sampling period (1,2,8,40,55). Increasing the zoom factor reduces the specimen area scanned and simultaneously reduces the scanning rate. The result is an increased number of samples along a comparable length (55), which increases both the image spatial resolution and display magnification on the host computer monitor. Confocal zoom is typically employed to match digital image resolution (8,40,55) with the optical resolution of the microscope when low numerical aperture and magnification objectives are being used to collect data.

Digitization of the sequential analog image data collected by the confocal microscope photomultiplier (or similar detector) facilitates computer image processing algorithms by transforming the continuous voltage stream into discrete digital increments that correspond to variations in light intensity. In addition to the benefits and speed that accrue from processing digital data, images can be readily prepared for print output or publication. In carefully controlled experiments, quantitative measurements of spatial fluorescence intensity (either statically or as a function of time) can also be obtained from the digital data.

Disadvantages of confocal microscopy are limited primarily to the limited number of excitation wavelengths available with common lasers (referred to as laser lines), which occur over very narrow bands and are expensive to produce in the UV region (56). In contrast, conventional widefield microscopes use mercury- or xenon-based arc-discharge lamps to provide a full range of excitation wavelengths in the UV, visible, and near-IR spectral regions. Another downside is the harmful nature (57) of high intensity laser irradiation to living cells and tissues, an issue that has recently been addressed by multiphoton and Nipkow disk confocal imaging. Finally, the high cost of purchasing and operating multiuser confocal microscope systems (58), which can range up to an order of magnitude higher than comparable widefield microscopes, often limits their implementation in smaller laboratories. This problem can be easily overcome by cost-shared microscope systems that service one or more departments in a core facility. The recent introduction of personal confocal systems has competitively driven down the price of low end confocal microscopes and increased the number of individual users.

CONFOCAL MICROSCOPE LIGHT DETECTORS

In modern widefield fluorescence and laser scanning confocal optical microscopy, the collection and measurement of

secondary emission gathered by the objective can be accomplished by several classes of photosensitive detectors (59), including photomultipliers, photodiodes, and solid-state CCDs. In confocal microscopy, fluorescence emission is directed through a pinhole aperture positioned near the image plane to exclude light from fluorescent structures located away from the objective focal plane, thus reducing the amount of light available for image formation, as discussed above. As a result, the exceedingly low light levels most often encountered in confocal microscopy necessitate the use of highly sensitive photon detectors that do not require spatial discrimination, but instead respond very quickly with a high level of sensitivity to a continuous flux of varying light intensity.

Photomultipliers, which contain a photosensitive surface that captures incident photons and produces a stream of photoelectrons to generate an amplified electric charge, are the popular detector choice in many commercial confocal microscopes (59–61). These detectors contain a critical element, termed a photocathode, capable of emitting electrons through the photoelectric effect (the energy of an absorbed photon is transferred to an electron) when exposed to a photon flux. The general anatomy of a photomultiplier consists of a classical vacuum tube in which a glass or quartz window encases the photocathode and a chain of electron multipliers, known as dynodes, followed by an anode to complete the electrical circuit (62). When the photomultiplier is operating, current flowing between the anode and ground (zero potential) is directly proportional to the photoelectron flux generated by the photocathode when it is exposed to incident photon radiation.

In a majority of commercial confocal microscopes, the photomultiplier is located within the scan head or an external housing, and the gain, offset, and dynode voltage are controlled by the computer software interface to the detector power supply and supporting electronics (7). The voltage setting is used to regulate the overall sensitivity of the photomultiplier, and can be adjusted independently of the gain and offset values. The latter two controls are utilized to adjust the image intensity values to ensure that the maximum number of gray levels is included in the output signal of the photomultiplier. Offset adds a positive or negative voltage to the output signal, and should be adjusted so that the lowest signals are near the photomultiplier detection threshold (40). The gain circuit multiplies the output voltage by a constant factor so that the maximum signal values can be stretched to a point just below saturation. In practice, offset should be applied first before adjusting the photomultiplier gain (8,40). After the signal has been processed by the analog-to-digital converter, it is stored in a frame buffer and ultimately displayed on the monitor in a series of gray levels ranging from black (no signal) to white (saturation). Photomultipliers with a dynamic range of 10 or 12 bits are capable of displaying 1024 or 4096 gray levels, respectively. Accompanying image files also have the same number of gray levels. However, the photomultipliers used in a majority of the commercial confocal microscopes have a dynamic range limited to 8 bits or 256 gray levels, which in most cases, is adequate for handling the typical number of photons scanned per pixel (63).

Changes to the photomultiplier gain and offset levels should not be confused with postacquisition image processing to adjust the levels, brightness, or contrast in the final image. Digital image processing techniques can stretch existing pixel values to fill the black-to-white display range, but cannot create new gray levels (40). As a result, when a digital image captured with only 200 out of a possible 4096 gray levels is stretched to fill the histogram (from black to white), the resulting processed image appears grainy. In routine operation of the confocal microscope, the primary goal is to fill as many of the gray levels during image acquisition and not during the processing stages.

The offset control is used to adjust the background level to a position near 0 V (black) by adding a positive or negative voltage to the signal. This ensures that dark features in the image are very close to the black level of the host computer monitor. Offset changes the amplitude of the entire voltage signal, but since it is added to or subtracted from the total signal, it does not alter the voltage differential between the high and low voltage amplitudes in the original signal. For example, with a signal ranging from 4 to 18 V that is modified with an offset setting of 4 V, the resulting signal spans 0–14 V, but the difference remains 14 V.

Figure 8 presents a series of diagrammatic schematics of the unprocessed and adjusted output signal from a photomultiplier and the accompanying images captured with a confocal microscope of a living adherent culture of Indian Muntjac deer skin fibroblast cells treated with MitoTracker Red CMXRos, which localizes specifically in the mitochondria. Figure 8a illustrates the raw confocal image along with the signal from the photomultiplier. After applying a negative offset voltage to the photomultiplier, the signal and image appear in Fig. 8b. Note that as the signal is shifted to lower intensity values, the image becomes darker (upper frame in Fig. 8b). When the gain is adjusted to the full intensity range (Fig. 8c), the image exhibits a significant amount of detail with good contrast and high resolution.

The photomultiplier gain adjustment is utilized to electronically stretch the input signal by multiplying with a constant factor prior to digitization by the analog-to-digital converter (40). The result is a more complete representation of gray level values between black and white, and an increase in apparent dynamic range. If the gain setting is increased beyond the optimal point, the image becomes grainy, but this maneuver is sometimes necessary to capture the maximum number of gray levels present in the image. Advanced confocal microscopy software packages ease the burden of gain and offset adjustment by using a pseudocolor display function to associate pixel values with gray levels on the monitor. For example, the saturated pixels (255) can be displayed in yellow or red, while black-level pixels (0) are shown in blue or green, with intermediate gray levels displayed in shades of gray representing their true values. When the photomultiplier output is properly adjusted, just a few red (or yellow) and blue (or green) pixels are present in the image, indicating that the full dynamic range of the photomultiplier is being utilized.

Established techniques in the field of enhanced night vision have been applied with dramatic success to photomultipliers designed for confocal microscopy (63,64). Several manufacturers have collaborated to fabricate a head-on photomultiplier containing a specialized prism system that assists in the collection of photons. The prism operates by diverting the incoming photons to a pathway that promotes total internal reflection in the photomultiplier envelope adjacent to the photocathode. This configuration increases the number of potential interactions between the photons and the photocathode, resulting in an increase in quantum efficiency by more than a factor of 2 in the green spectral region, 4 in the red region, and even higher in the IR (59). Increasing the ratio of photoelectrons generated to the number of incoming photons serves to increase the electrical current from the photomultiplier, and to produce a higher sensitivity for the instrument.

Photomultipliers are the ideal photometric detectors for confocal microscopy due to their speed, sensitivity, high signal/noise ratio, and adequate dynamic range (59–61).

Gain and Offset Adjustment in Confocal Microscopy

The specimen is a living adherent culture of Indian Muntjac deer skin fibroblast cells treated with MitoTracker Red CMXRos. (a) The raw confocal image (upper frame) along with the signal from the photomultiplier. (b) Signal and confocal image after applying a negative offset voltage to the photomultiplier. (c) Final signal and image after the gain has been adjusted to fill the entire intensity range.

High end confocal microscope systems have several photomultipliers that enable simultaneous imaging of different fluorophores in multiply labeled specimens. Often, an additional photomultiplier is included for imaging the specimen with transmitted light using differential interference or phase-contrast techniques. In general, confocal microscopes contain three photomultipliers for the fluorescence color channels (red, green, and blue; each with a separate pinhole aperture) utilized to discriminate between fluorophores, along with a fourth for transmitted or reflected light imaging. Signals from each channel can be collected simultaneously and the images merged into a single profile that represents the real colors of the stained specimen. If the specimen is also imaged with a brightfield contrast-enhancing technique, such as differential interference contrast (65), the fluorophore distribution in the fluorescence image can be overlaid onto the brightfield image to determine the spatial location of fluorescence emission within the structural domains.

ACOUSTOOPTIC TUNABLE FILTERS IN CONFOCAL MICROSCOPY

The integration of optoelectronic technology into confocal microscopy has provided a significant enhancement in the versatility of spectral control for a wide variety of fluorescence investigations. The acoustooptic tunable filter (AOTF) is an electrooptical device that functions as an electronically tunable excitation filter to simultaneously modulate the intensity and wavelength of multiple laser lines from one or more sources (66). Devices of this type rely on a specialized birefringent crystal whose optical properties vary upon interaction with an acoustic wave. Changes in the acoustic frequency alter the diffraction properties of the crystal, enabling very rapid wavelength tuning, limited only by the acoustic transit time across the crystal.

An acoustooptic tunable filter designed for microscopy typically consists of a tellurium dioxide or quartz anisotropic crystal to which a piezoelectric transducer is bonded (67–70). In response to the application of an oscillating radio frequency (RF) electrical signal, the transducer generates a high frequency vibrational (acoustic) wave that propagates into the crystal. The alternating ultrasonic acoustic wave induces a periodic redistribution of the refractive index through the crystal that acts as a transmission diffraction grating or Bragg diffracter to deviate a portion of incident laser light into a first-order beam, which is utilized in the microscope (or two first-order beams when the incident light is nonpolarized). Changing the frequency of the transducer signal applied to the crystal alters the period of the refractive index variation, and therefore, the wavelength of light that is diffracted. The relative intensity of the diffracted beam is determined by the amplitude (power) of the signal applied to the crystal.

In the traditional fluorescence microscope configuration, including many confocal systems, spectral filtering of both excitation and emission light is accomplished utilizing thin-film interference filters (7). These filters are limiting in several respects. Because each filter has a fixed central wavelength and passband, several filters must be

utilized to provide monochromatic illumination for multi-spectral imaging, as well as to attenuate the beam for intensity control, and the filters are often mechanically interchanged by a rotating turret mechanism. Interference filter turrets and wheels have the disadvantages of limited wavelength selection, vibration, relatively slow switching speed, and potential image shift (70). They are also susceptible to damage and deterioration caused by exposure to heat, humidity, and intense illumination, which changes their spectral characteristics over time. In addition, the utilization of filter wheels for illumination wavelength selection has become progressively more complex and expensive as the number of lasers being employed has increased with current applications.

Rotation of filter wheels and optical block turrets introduces mechanical vibrations into the imaging and illumination system, which consequently requires a time delay for damping of perhaps 50 ms, even if the filter transition itself can be accomplished more quickly. Typical filter change times are considerably slower in practice, however, and range on the order of 0.1–0.5 s. Mechanical imprecision in the rotating mechanism can introduce registration errors when sequentially acquired multicolor images are processed. Furthermore, the fixed spectral characteristics of interference filters do not allow optimization for different fluorophore combinations, nor for adaptation to new fluorescent dyes, limiting the versatility of both the excitation and detection functions of the microscope. Introduction of the AOTF to confocal systems overcomes most of the filter wheel disadvantages by enabling rapid simultaneous electronic tuning and intensity control of multiple laser lines from several lasers.

As applied in laser scanning confocal microscopy, one of the most significant benefits of the AOTF is its capability to replace much more complex and unwieldy filter mechanisms for controlling light transmission, and to apply intensity modulation for wavelength discrimination purposes (67,70). The ability to perform extremely rapid adjustments in the intensity and wavelength of the diffracted beam gives the AOTF unique control capabilities. By varying the illumination intensity at different wavelengths, the response of multiple fluorophores, for example, can be balanced for optimum detection and recording (71). In addition, digital signal processors along with phase and frequency lock-in techniques can be employed to discriminate emission from multiple fluorophores or to extract low level signals from background.

A practical light source configuration scheme utilizing an acoustooptic tunable filter for confocal microscopy is illustrated in Fig. 9. The output of three laser systems (violet diode, argon, and argon–krypton) are combined by dichromatic mirrors and directed through the AOTF, where the first-order diffracted beam (green) is collinear and is launched into a single-mode fiber. The undiffracted laser beams (violet, green, yellow, and red) exit the AOTF at varying angles and are absorbed by a beam stop (not illustrated). The major lines (wavelengths) produced by each laser are indicated (in nm) beneath the hot and cold mirrors. The dichromatic mirror reflects wavelengths < 525 nm and transmits longer wavelengths. Two longer wavelength lines produced by the argon–krypton laser

Acousto-Optic Tunable Filters in Confocal Microscopy

Figure 9. Configuration scheme utilizing an AOTF for laser intensity control and wavelength selection in confocal microscopy.

(568 and 648 nm) are reflected by the hot mirror, while the output of the argon laser (458, 476, 488, and 514 nm) is reflected by the dichromatic mirror and combined with the transmitted light from the argon–krypton laser. Output from the violet diode laser (405 nm) is reflected by the cold mirror and combined with the longer wavelengths from the other two lasers, which are transmitted through the mirror.

Because of the rapid optical response from the AOTF crystal to the acoustic transducer, the acoustooptic interaction is subject to abrupt transitions resembling a rectangular rather than sinusoidal waveform (66). This results in the occurrence of sidelobes in the AOTF passband on either side of the central transmission peak. Under ideal acoustooptic conditions, these sidelobes should be symmetrical about the central peak, with the first lobe having 4.7% of the central peak's intensity. In practice, the sidelobes are commonly asymmetrical and exhibit other deviations from predicted structure caused by variations in the acoustooptic interaction, among other factors. In order to reduce the sidelobes in the passband to insignificant levels, several types of amplitude apodization of the acoustic wave are employed (66,67), including various window functions, which have been found to suppress the highest sidelobe by 30–40 dB. One method that can be used in reduction of sidelobe level with noncollinear AOTFs is to apply spatial apodization by means of weighted excitation of the transducer. In the collinear AOTF, a different approach has been employed, which introduces an acoustic pulse, apodized in time, into the filter crystal.

The effective linear aperture of an AOTF is limited by the acoustic beam height in one dimension (ID) and by the acoustic attenuation across the optical aperture (the acoustic transit distance) in the other dimension (67). The height of the acoustic beam generated within the AOTF crystal is determined by the performance and physical properties of the acoustic transducer. Acoustic attenuation in crystalline materials, such as tellurium dioxide, is proportional to the square of acoustic frequency, and is therefore a more problematic limitation to linear aperture size in the shorter wavelength visible light range, which requires higher RF frequencies for tuning. Near-IR and IR radiation produces

less restrictive limitations because of the lower acoustic frequencies associated with diffraction of these longer wavelengths.

The maximum size of an individual acoustic transducer is constrained by performance and power requirements in addition to the geometric limitations of the instrument configuration, and AOTF designers may use an array of transducers bonded to the crystal in order to increase the effective lateral dimensions of the propagating acoustic beam, and to enlarge the area of acoustooptic interaction (66,67,70). The required drive power is one of the most important variables in acoustooptic design, and generally increases with optical aperture and for longer wavelengths. In contrast to acoustic attenuation, which is reduced in the IR spectral range, the higher power required to drive transducers for infrared AOTFs is one of the greatest limitations in these devices. High drive power levels result in heating of the crystal, which can cause thermal drift and instability in the filter performance (66). This is particularly a problem when acoustic power and frequency are being varied rapidly over a large range, and the crystal temperature does not have time to stabilize, producing transient variations in refractive index. If an application requires wavelength and intensity stability and repeatability, the AOTF should be maintained at a constant temperature. One approach taken by equipment manufacturers to minimize this problem is to heat the crystal above ambient temperature, to a level at which it is relatively unaffected by the additional thermal input of the transducer drive power. An alternative solution is to house the AOTF in a thermoelectrically cooled housing that provides precise temperature regulation. Continuing developmental efforts promise to lead to new materials that can provide relatively large apertures combined with effective separation of the filtered and unfiltered beams without use of polarizers, while requiring a fraction of the typical device drive power.

In a noncollinear AOTF, which spatially separates the incident and diffracted light paths, the deflection angle (the angle separating diffracted and undiffracted light beams exiting the crystal) is an additional factor limiting the effective aperture of the device (67). As discussed previously, the deflection angle is greater for crystals having greater birefringence, and determines in part the propagation distance required for adequate separation of the diffracted and undiffracted beams to occur after exiting the crystal. The required distance is increased for larger entrance apertures, and this imposes a practical limit on maximum aperture size because of constraints on the physical dimensions of components that can be incorporated into a microscope system. The angular aperture is related to the total light collecting power of the AOTF, an important factor in imaging systems, although in order to realize the full angular aperture without the use of polarizers in the noncollinear AOTF, its value must be smaller than the deflection angle. Because the acoustooptic tunable filter is not an image-forming component of the microscope system (it is typically employed for source filtering), there is no specific means of evaluating the spatial resolution for this type of device (70). However, the AOTF may restrict the attainable spatial resolution of the imaging system

because of its limited linear aperture size and acceptance angle, in the same manner as other optical components. Based on the Rayleigh criterion and the angular and linear apertures of the AOTF, the maximum number of resolvable image elements may be calculated for a given wavelength, utilizing different expressions for the polar and azimuthal planes. Although diffraction limited resolution can be attained in the azimuthal plane, dispersion in the AOTF limits the resolution in the polar plane, and measures must be taken to suppress this factor for optimum performance. The dependence of deflection angle on wavelength can produce one form of dispersion, which is typically negligible when tuning is performed within a relatively narrow bandwidth, but significant in applications involving operation over a broad spectral range. Changes in deflection angle with wavelength can result in image shifts during tuning, producing errors in techniques, such as ratio imaging of fluorophores excited at different wavelengths, and in other multispectral applications. When the image shift obeys a known relationship to wavelength, corrections can be applied through digital processing techniques (1,7). Other effects of dispersion, including reduced angular resolution, may result in image degradation, such as blurring, that requires more elaborate measures to suppress.

SUMMARY OF AOTF BENEFITS IN CONFOCAL MICROSCOPY

Considering the underlying principles of operation and performance factors that relate to the application of AOTFs in imaging systems, a number of virtues from such devices for light control in fluorescence confocal microscopy are apparent. Several benefits of the AOTF combine to greatly

enhance the versatility of the latest generation of confocal instruments, and these devices are becoming increasingly popular for control of excitation wavelength ranges and intensity. The primary characteristic that facilitates nearly every advantage of the AOTF is its capability to allow the microscopist control of the intensity and/or illumination wavelength on a pixel-by-pixel basis while maintaining a high scan rate (7). This single feature translates into a wide variety of useful analytical microscopy tools, which are even further enhanced in flexibility when laser illumination is employed.

One of the most useful AOTF functions allows the selection of small user-defined specimen areas (commonly termed regions of interest; ROI) that can be illuminated with either greater or lesser intensity, and at different wavelengths, for precise control in photobleaching techniques, excitation ratio studies, resonance energy-transfer investigations, or spectroscopic measurements (see Fig. 10). The illumination intensity can not only be increased in selected regions for controlled photobleaching experiments (71–73), but can be attenuated in desired areas in order to minimize unnecessary photobleaching. When the illumination area is under AOTF control, the laser exposure is restricted to the scanned area by default, and the extremely rapid response of the device can be utilized to provide beam blanking during the flyback interval of the galvanometer scanning mirror cycle, further limiting unnecessary specimen exposure. In practice, the regions of excitation are typically defined by freehand drawing or using tools to produce defined geometrical shapes in an overlay plane on the computer monitor image. Some systems allow any number of specimen areas to be defined for laser exposure, and the laser intensity to be set to different levels for each area, in intensity increments as small as 0.1%. When the

AOTF Selection of Specific Regions for Excitation in Confocal Microscopy

Figure 10. AOTF selection of specific regions for excitation in confocal microscopy. (a) Region of Interest (ROI) selected for fluorescence recovery after photobleaching (FRAP) experiments. (b) Freehand ROIs for selective excitation. (c) ROI for fluorescence resonance energy transfer (FRET) analysis. (d) ROI for photoactivation and photoconversion of fluorescent proteins.

AOTF is combined with multiple lasers and software that allows time course control of sequential observations, time-lapse experiments can be designed to acquire data from several different areas in a single experiment, which might, for example, be defined to correspond to different cellular organelles.

Figure 10 illustrates several examples of several user-defined ROIs that were created for advanced fluorescence applications in laser scanning confocal microscopy. In each image, the ROI is outlined with a yellow border. The rat kangaroo kidney epithelial cell (PtK2 line) presented in Fig. 10a has a rectangular area in the central portion of the cytoplasm that has been designated for photobleaching experiments. Fluorophores residing in this region can be selectively destroyed by high power laser intensity, and the subsequent recovery of fluorescence back into the photobleached region monitored for determination of diffusion coefficients. Several freehand ROIs are illustrated in Fig. 10b, which can be targets for selective variation of illumination intensities or photobleaching and photoactivation experiments. Fluorescence resonance energy-transfer emission ratios can be readily determined using selected regions in confocal microscopy by observing the effect of bleaching the acceptor fluorescence in these areas (Fig. 10c; African green monkey kidney epithelial cells labeled with Cy3 and Cy5 conjugated to cholera toxin, which localizes in the plasma membrane). The AOTF control of laser excitation in selected regions with confocal microscopy is also useful for investigations of protein diffusion in photoactivation studies (74–76) using fluorescent proteins, as illustrated in Fig. 10d. This image frame presents the fluorescence emission peak of the Kaede protein as it shifts from green to red in HeLa (human

cervical carcinoma) cell nuclei using selected illumination (yellow box) with a 405 nanometer violet–blue diode laser.

The rapid intensity and wavelength switching capabilities of the AOTF enable sequential line scanning of multiple laser lines to be performed in which each excitation wavelength can be assigned a different intensity in order to balance the various signal levels for optimum imaging (77). Sequential scanning of individual lines minimizes the time differential between signal acquisitions from the various fluorophores while reducing crossover, which can be a significant problem with simultaneous multiple-wavelength excitation (Fig. 11). The synchronized incorporation of multiple fluorescent probes into living cells has grown into an extremely valuable technique for study of protein–protein interactions, and the dynamics of macromolecular complex assembly. The refinement of techniques for incorporating green fluorescent protein (GFP) and its numerous derivatives into the protein-synthesizing mechanisms of the cell has revolutionized living cell experimentation (78–80). A major challenge in multiple-probe studies using living tissue is the necessity to acquire the complete multispectral data set quickly enough to minimize specimen movement and molecular changes that might distort the true specimen geometry or dynamic sequence of events (32–34). The AOTF provides the speed and versatility to control the wavelength and intensity illuminating multiple specimen regions, and to simultaneously or sequentially scan each at sufficient speed to accurately monitor dynamic cellular processes.

A comparison between the application of AOTFs and neutral density filters (78) to control spectral separation of fluorophore emission spectra in confocal microscopy is presented in Fig. 11. The specimen is a monolayer culture

ND Filter versus AOTF Control of Bleedthrough in Confocal Microscopy

Figure 11. Fluorophore bleedthrough control with neutral density filters and sequential scanning using AOTF laser modulation. Adherent human lung fibroblast (MRC-5 line) cells were stained with Texas Red conjugated to phalloidin (actin; red) and counterstained with SYTOX green (nuclei; green). (a) Typical cell imaged with neutral density filters. (b) The same cell imaged using sequential line scanning controlled by an AOTF laser combiner. (c) and (d) Colocalization scatterplots derived from the images in (a) and (b), respectively.

of adherent human lung fibroblast (MRC-5 line) cells stained with Texas Red conjugated to phalloidin (targeting the filamentous actin network) and SYTOX Green (staining DNA in the nucleus). A neutral density filter that produces the high excitation signals necessary for both fluorophores leads to a significant amount of bleedthrough of the SYTOX Green emission into the Texas Red channel (Fig. 11a; note the yellow nuclei). The high degree of apparent colocalization between SYTOX Green and Texas Red is clearly illustrated by the scatterplot in Fig. 11b. The two axes in the scatterplot represent the SYTOX Green (abscissa) and the Texas Red (ordinate) channels. In order to balance the excitation power levels necessary to selectively illuminate each fluorophore with greater control of emission intensity, an AOTF was utilized to selectively reduce the SYTOX Green excitation power (Argon-ion laser line at 488 nm). Note the subsequent reduction in bleed-through as manifested by green color in the cellular nuclei in Fig. 11c. The corresponding scatterplot (Fig. 11d) indicates a dramatically reduced level of bleed-through (and apparent colocalization) of SYTOX Green into the Texas Red channel.

The development of the AOTF has provided substantial additional versatility to techniques, such as fluorescence recovery after photobleaching (FRAP; 81,82), fluorescence loss in photobleaching (FLIP; 83), as well as in localized photoactivated fluorescence (uncaging; 84) studies (Fig. 10). The FRAP technique (81,82) was originally conceived to measure diffusion rates of fluorescently tagged proteins in organelles and cell membranes. In the conventional FRAP procedure, a small spot on the specimen is continuously illuminated at a low light flux level and the emitted fluorescence is measured. The illumination level is then increased to a very high level for a brief time to destroy the fluorescent molecules in the illuminated region by rapid bleaching. After the light intensity is returned to the original low level, the fluorescence is monitored to determine the rate at which new unbleached fluorescent molecules diffuse into the depleted region. The technique, as typically employed, has been limited by the fixed geometry of the bleached region, which is often a diffraction-limited spot, and by having to mechanically adjust the illumination intensity (using shutters or galvanometer-driven components). The AOTF not only allows near-instantaneous switching of light intensity, but also can be utilized to selectively bleach randomly specified regions of irregular shape, lines, or specific cellular organelles, and to determine the dynamics of molecular transfer into the region.

By enabling precise control of illuminating beam geometry and rapid switching of wavelength and intensity, the AOTF is a significant enhancement to application of the FLIP technique in measuring the diffusional mobility of certain cellular proteins (83). This technique monitors the loss of fluorescence from continuously illuminated localized regions and the redistribution of fluorophore from distant locations into the sites of depletion. The data obtained can aid in the determination of the dynamic interrelationships between intracellular and intercellular components in living tissue, and such fluorescence loss studies are greatly facilitated by the capabilities of the AOTF in controlling the microscope illumination.

The method of utilizing photoactivated fluorescence has been very useful in studies, such as those examining the role of calcium ion concentration in cellular processes, but has been limited in its sensitivity to localized regional effects in small organelles or in close proximity to cell membranes. Typically, fluorescent species that are inactivated by being bound to a photosensitive species (referred to as being caged) are activated by intense illumination that frees them from the caging compound and allows them to be tracked by the sudden appearance of fluorescence (84). The use of the AOTF has facilitated the refinement of such studies to assess highly localized processes such as calcium ion mobilization near membranes, made possible because of the precise and rapid control of the illumination triggering the activation (uncaging) of the fluorescent molecule of interest.

Because the AOTF functions, without use of moving mechanical components, to electronically control the wavelength and intensity of multiple lasers, great versatility is provided for external control and synchronization of laser illumination with other aspects of microscopy experiments. When the confocal instrument is equipped with a controller module having input and output trigger terminals, laser intensity levels can be continuously monitored and recorded, and the operation of all laser functions can be controlled to coordinate with other experimental specimen measurements, automated microscope stage movements, sequential time-lapse recording, and any number of other operations.

RESOLUTION AND CONTRAST IN CONFOCAL MICROSCOPY

All optical microscopes, including conventional widefield, confocal, and two-photon instruments are limited in the resolution that they can achieve by a series of fundamental physical factors (1,3,5–7,24,85–89). In a perfect optical system, resolution is restricted by the numerical aperture of optical components and by the wavelength of light, both incident (excitation) and detected (emission). The concept of resolution is inseparable from contrast, and is defined as the minimum separation between two points that results in a certain level of contrast between them (24). In a typical fluorescence microscope, contrast is determined by the number of photons collected from the specimen, the dynamic range of the signal, optical aberrations of the imaging system, and the number of picture elements (pixels) per unit area in the final image (66,86–88).

The influence of noise on the image of two closely spaced small objects is further interconnected with the related factors mentioned above, and can readily affect the quality of resulting images (29). While the effects of many instrumental and experimental variables on image contrast, and consequently on resolution, are familiar and rather obvious, the limitation on effective resolution resulting from the division of the image into a finite number of picture elements (pixels) may be unfamiliar to those new to digital microscopy. Because all digital confocal images employing laser scanners and/or camera systems are recorded and processed in terms of measurements made within discrete pixels (66),

some discussion of the concepts of sampling theory is required. This is appropriate to the subject of contrast and resolution because it has a direct bearing on the ability to record two closely spaced objects as being distinct.

In addition to the straightforward theoretical aspects of resolution, regardless of how it is defined, the reciprocal relationship between contrast and resolution has practical significance because the matter of interest to most microscopists is not resolution, but visibility. The ability to recognize two closely spaced features as being separate relies on advanced functions of the human visual system to interpret intensity patterns, and is a much more subjective concept than the calculation of resolution values based on diffraction theory (24). Experimental limitations and the properties of the specimen itself, which vary widely, dictate that imaging cannot be performed at the theoretical maximum resolution of the microscope.

The relationship between contrast and resolution with regard to the ability to distinguish two closely spaced specimen features implies that resolution cannot be defined without reference to contrast, and it is this interdependence that has led to considerable ambiguity involving the term resolution and the factors that influence it in microscopy (29). As discussed above, recent advances in fluorescent protein technology have led to an enormous increase in studies of dynamic processes in living cells and tissues (71–76,78–83). Such specimens are optically thick and inhomogeneous, resulting in a far-from-ideal imaging situation in the microscope. Other factors, such as cell viability and sensitivity to thermal damage and photobleaching, place limits on the light intensity and duration of exposure, consequently limiting the attainable resolution. Given that the available timescale may be dictated by these factors and by the necessity to record rapid dynamic events in living cells, it must be accepted that the quality of images will not be as high as those obtained from fixed and stained specimens. The most reasonable resolution goal for imaging in a given experimental situation is that the microscope provides the best resolution possible within the constraints imposed by the experiment.

THE AIRY DISK AND LATERAL RESOLUTION

Imaging a point-like light source in the microscope produces an electromagnetic field in the image plane whose amplitude fluctuations can be regarded as a manifestation of the response of the optical system to the specimen. This field is commonly represented through the amplitude point spread function, and allows evaluation of the optical transfer properties of the combined system components (29,86–88). Although variations in field amplitude are not directly observable, the visible image of the point source formed in the microscope and recorded by its imaging system is the intensity point spread function, which describes the system response in real space. Actual specimens are not point sources, but can be regarded as a superposition of an infinite number of objects having dimensions below the resolution of the system. The properties of the intensity point spread function (PSF; see Fig. 12) in the image plane as well as in the axial direction are major factors in determining the resolution of a microscope (1,24,29,40,85–89).

It is possible to experimentally measure the intensity point spread function in the microscope by recording the image of a subresolution spherical bead as it is scanned through focus (a number of examples may be found in the literature). Because of the technical difficulty posed in direct measurement of the intensity point spread function, calculated point spread functions are commonly utilized to evaluate the resolution performance of different optical systems, as well as the optical-sectioning capabilities of confocal, two-photon, and conventional widefield microscopes. Although the intensity point spread function extends in all three dimensions, with regard to the relationship between resolution and contrast, it is useful to consider only the lateral components of the intensity distribution, with reference to the familiar Airy disk (24).

The intensity distribution of the point-spread function in the plane of focus is described by the rotationally symmetric Airy pattern. Because of the cylindrical symmetry of the microscope lenses, the two lateral components

Figure 12. Schematic diagram of an Airy disk diffraction pattern and the corresponding three-dimensional point spread functions for image formation in confocal microscopy. Intensity profiles of a single Airy disk, as well as the first and higher order maxima are illustrated in the graphs.

(x and y) of the Airy pattern are equivalent, and the pattern represents the lateral intensity distribution as a function of distance from the optical axis (24). The lateral distance is normalized by the numerical aperture of the system and the wavelength of light, and therefore is dimensionless. Figure 12 (Airy disk and intensity function) illustrates diagrammatically the formation and characteristics of the Airy disk, the related 3D point spread function, and Airy patterns in the fluorescence microscope. Following the excitation of fluorophores in a point-like specimen region, fluorescence emission occurs in all directions, a small fraction of which is selected and focused by the optical components into an image plane where it forms an Airy disk surrounded by concentric rings of successively decreasing maximum and minimum intensity (the Airy pattern). The Airy pattern intensity distribution is the result of Fraunhofer diffraction of light passing through a circular aperture, and in a perfect optical system exhibits a central intensity maximum and higher order maxima separated by regions of zero intensity (85). The distance of the zero crossings from the optical axis, when the distance is normalized by the numerical aperture and wavelength, occur periodically (Fig. 12). When the intensity on the optical axis is normalized to one (100%), the proportional heights of the first four higher order maxima are 1.7%, 0.4%, 0.2%, and 0.08%, respectively.

A useful approach to the concept of resolution is based on consideration of an image formed by two point-like objects (specimen features), under the assumption that the image-forming process is incoherent, and that the interaction of the separate object images can be described using intensity point spread functions. The resulting image is then composed of the sum of two Airy disks, the characteristics of which depend on the separation distance between the two points (24,86). When sufficiently separated, the intensity change in the area between the objects is the maximum possible, cycling from the peak intensity (at the first point) to zero and returning to the maximum value at the center of the second point. At decreased distance in object space, the intensity distribution functions of the two points, in the image plane, begin to overlap and the resulting image may appear to be that of a single larger or brighter object or feature rather than being recognizable as two objects. If resolution is defined, in general terms, as the minimum separation distance at which the two objects can be sufficiently distinguished, it is obvious that this property is related to the width of the intensity peaks (the point spread function). Microscope resolution is directly related, therefore, to the full-width at half maximum (fwhm) of the instrument's intensity point spread function in the component directions (29,86,87).

Some ambiguity in use of the term resolution results from the variability in defining the degree of separation between features and their point spread functions that is sufficient to allow them to be distinguished as two objects rather than one. In general, minute features of interest in microscopy specimens produce point images that overlap to some extent, displaying two peaks separated by a gap (1,24,29,40,86). The greater the depth of the gap between the peaks, the easier it is to distinguish, or resolve, the two

objects. By specifying the depth of the dip in intensity between two overlapping point spread functions, the ambiguity in evaluating resolution can be removed, and a quantitative aspect introduced.

In order to quantify resolution, the concept of contrast is employed, which is defined for two objects of equal intensity as the difference between their maximum intensity and the minimum intensity occurring in the space between them (55,86,89). Because the maximum intensity of the Airy disk is normalized to one, the highest achievable contrast is also one, and occurs only when the spacing between the two objects is relatively large, with sufficient separation to allow the first zero crossing to occur in their combined intensity distribution. At decreased distance, as the two point spread functions begin to overlap, the dip in intensity between the two maxima (and the contrast) is increasingly reduced. The distance at which two peak maxima are no longer discernible, and the contrast becomes zero, is referred to as the contrast cut-off distance (24,40). The variation of contrast with distance allows resolution, in terms of the separation of two points, to be defined as a function of contrast.

The relationship between contrast and separation distance for two point-like objects is referred to as the contrast/distance function or contrast transfer function (31,90). Resolution can be defined as the separation distance at which two objects are imaged with a certain contrast value. It is obvious that when zero contrast exists, the points are not resolved; the so-called Sparrow criterion defines the resolution of an optical system as being equivalent to the contrast cut-off distance (24). It is common, however, to specify that greater contrast is necessary to adequately distinguish two closely spaced points visually, and the well-known Rayleigh criterion (24) for resolution states that two points are resolved when the first minimum (zero crossing) of one Airy disk is aligned with the central maximum of the second Airy disk. Under optimum imaging conditions, the Rayleigh criterion separation distance corresponds to a contrast value of 26.4%. Although any contrast value >0 can be specified in defining resolution, the 26% contrast of the Rayleigh criterion is considered reasonable in typical fluorescence microscopy applications, and is the basis for the common expression defining lateral resolution according to the following equation (24), in which the point separation (r) in the image plane is the distance between the central maximum and the first minimum in the Airy disk:

$$r_{\text{lateral}} = 1.22 \lambda / (2 \cdot \text{NA}) = 0.6 \lambda / \text{NA}$$

where λ is the emitted light wavelength and NA is the numerical aperture of the objective.

Resolution in the microscope is directly related to the fwhm dimensions of the microscope's point spread function, and it is common to measure this value experimentally in order to avoid the difficulty in attempting to identify intensity maxima in the Airy disk. Measurements of resolution utilizing the fwhm values of the point spread function are somewhat smaller than those calculated employing the Rayleigh criterion. Furthermore, in confocal fluorescence configurations, single-point illumination scanning and

single-point detection are employed, so that only the fluorophores in the shared volume of the illumination and detection point spread functions are able to be detected. The intensity point spread function in the confocal case is, therefore, the product of the independent illumination intensity and detection intensity point spread functions. For confocal fluorescence, the lateral (and axial) extent of the point spread function is reduced by $\sim 30\%$ compared to that in the wide-field microscope. Because of the narrower intensity point spread function, the separation of points required to produce acceptable contrast in the confocal microscope (29,31) is reduced to a distance approximated by

$$r_{\text{lateral}} = 0.4\lambda/\text{NA}$$

If the illumination and fluorescence emission wavelengths are approximately the same, the confocal fluorescence microscope Airy disk size is the square of the wide-field microscope Airy disk. Consequently, the contrast cut-off distance is reduced in the confocal arrangement, and equivalent contrast can be achieved at a shorter distance compared to the widefield illumination configuration. Regardless of the instrument configuration, the lateral resolution displays a proportional relationship to wavelength, and is inversely proportional to the objective lens numerical aperture.

As noted previously, lateral resolution is of primary interest in discussing resolution and contrast, although the axial extent of the microscope intensity point spread function is similarly reduced in the confocal arrangement as compared to the widefield fluorescence configuration (86,89). Reasonable contrast between point-like objects lying on the optical axis occurs when they are separated by the distance between the central maximum and the first minimum of the axial point spread function component.

Figure 13 presents the axial intensity distributions (89) for a typical widefield (Fig. 13a) and confocal (Fig. 13b) fluorescence microscope. Note the dramatic reduction in intensity of the wings in the confocal distribution as a function of distance from the central maximum.

A variety of equations are presented in the literature that pertains to different models for calculating axial resolution for various microscope configurations. The ones

most applicable to fluorescence emission are similar in form to the expressions evaluating depth of field, and demonstrate that axial resolution is proportional to the wavelength, and refractive index of the specimen medium, and inversely proportional to the square of the numerical aperture. Consequently, the NA of the microscope objective has a much greater effect on axial resolution than does the emission wavelength. One equation (89) commonly used to describe axial resolution for the confocal configuration is given below, with η representing the index of refraction, and the other variables as specified previously:

$$r_{\text{axial}} = 1.4 \lambda \cdot \eta / \text{NA}^2$$

Although the confocal microscope configuration exhibits only a modest improvement in measured axial resolution over that of the widefield microscope, the true advantage of the confocal approach is in the optical sectioning capability in thick specimens, which results in a dramatic improvement in effective axial resolution over conventional techniques. The optical sectioning properties of the confocal microscope result from the characteristics of the integrated intensity point spread function, which has a maximum in the focal plane when evaluated as a function of depth. The equivalent integral of intensity point spread function for the conventional widefield microscope is constant as a function of depth, producing no optical sectioning capabilities.

FLUOROPHORES FOR CONFOCAL MICROSCOPY

Biological laser scanning confocal microscopy relies heavily on fluorescence as an imaging mode, primarily due to the high degree of sensitivity afforded by the technique coupled with the ability to specifically target structural components and dynamic processes in chemically fixed as well as living cells and tissues. Many fluorescent probes are constructed around synthetic aromatic organic chemicals designed to bind with a biological macromolecule (e.g., a protein or nucleic acid) or to localize within a specific structural region, such as the cytoskeleton, mitochondria, Golgi apparatus, endoplasmic reticulum, and nucleus (90). Other probes are employed to monitor dynamic processes and localized environmental variables, including concentrations of inorganic metallic ions, pH, reactive oxygen species, and membrane potential (91). Fluorescent dyes are also useful in monitoring cellular integrity (live versus dead and apoptosis), endocytosis, exocytosis, membrane fluidity, protein trafficking, signal transduction, and enzymatic activity (92). In addition, fluorescent probes have been widely applied to genetic mapping and chromosome analysis in the field of molecular genetics.

The history of synthetic fluorescent probes dates back over a century to the late-1800s when many of the cornerstone dyes for modern histology were developed. Among these were pararosaniline, methyl violet, malachite green, safranin O, methylene blue, and numerous azo (nitrogen) dyes, such as Bismarck brown (93). Although these dyes were highly colored and capable of absorbing selected bands of visible light, most were only weakly fluorescent and would not be useful for the fluorescence microscopes that would be developed several decades later. However,

Axial Point Spread Function Intensity Profiles

Figure 13. Comparison of axial (x - z) point spread functions for widefield (left) and confocal (right) microscopy.

several synthetic dye classes synthesized during this period, based on the xanthene and acridine heterocyclic ring systems, proved to be highly fluorescent and provided a foundation for the development of modern synthetic fluorescent probes. Most notable among these early fluorescent dyes were the substituted xanthenes, fluorescein and rhodamine B, and the biaminated acridine derivative, acridine orange.

Fluorochromes were introduced to fluorescence microscopy in the early twentieth century as vital stains for bacteria, protozoa, and trypanosomes, but did not see widespread use until the 1920s when fluorescence microscopy was first used to study dye binding in fixed tissues and living cells (7,93). However, it was not until the early 1940s that Coons developed a technique for labeling antibodies with fluorescent dyes, thus giving birth to the field of immunofluorescence (94). Over the past 60 years, advances in immunology and molecular biology have produced a wide spectrum of secondary antibodies and provided insight into the molecular design of fluorescent probes targeted at specific regions within macromolecular complexes.

Fluorescent probe technology and cell biology were dramatically altered by the discovery of the GFP from jellyfish and the development of mutant spectral variants, which have opened the door to noninvasive fluorescence multicolor investigations of subcellular protein localization, intermolecular interactions, and trafficking using living cell cultures (79,80,95). More recently, the development of nanometer-sized fluorescent semiconductor quantum dots has provided a new avenue for research in confocal and widefield fluorescence microscopy (96). Despite the numerous advances made in fluorescent dye synthesis during the past few decades, there is very little solid evidence about molecular design rules for developing new fluorochromes, particularly with regard to matching absorption spectra to available confocal laser excitation wavelengths. As a result, the number of fluorophores that have found widespread use in confocal microscopy is a limited subset of the many thousands that have been discovered.

BASIC CHARACTERISTICS OF FLUOROPHORES

Fluorophores are catalogued and described according to their absorption and fluorescence properties, including the spectral profiles, wavelengths of maximum absorbance and emission, and the fluorescence intensity of the emitted light (92). One of the most useful quantitative parameters for characterizing absorption spectra is the molar extinction coefficient (denoted with the Greek symbol ϵ , see Fig. 14a), which is a direct measure of the ability of a molecule to absorb light. The extinction coefficient is useful for converting units of absorbance into units of molar concentration, and is determined by measuring the absorbance at a reference wavelength (usually the maximum, characteristic of the absorbing species) for a molar concentration in a defined optical path length. The quantum yield of a fluorochrome or fluorophore represents a quantitative measure of fluorescence emission efficiency, and is expressed as the ratio of the number of photons emitted to the number of photons absorbed. In other words, the quantum

Figure 14. Fluorescent spectral profiles, plotted as normalized absorption or emission as a function of wavelength, for popular synthetic fluorophores emitting in the blue, green, and red regions of the visible spectrum. Each profile is identified with a colored bullet in (a), which illustrates excitation spectra. (b) The emission spectra for the fluorophores according to the legend in (a).

yield represents the probability that a given excited fluorochrome will produce an emitted (fluorescence) photon. Quantum yields typically range between a value of 0 and 1 and fluorescent molecules commonly employed as probes in microscopy have quantum yields ranging from very low (0.05 or less) to almost unity. In general, a high quantum yield is desirable in most imaging applications. The quantum yield of a given fluorophore varies, sometimes to large extremes, with environmental factors, such as metallic ion concentration, pH, and solvent polarity (92).

In most cases, the molar extinction coefficient for photon absorption is quantitatively measured and expressed at a specific wavelength, whereas the quantum efficiency is an assessment of the total integrated photon emission over the entire spectral band of the fluorophore (Fig. 14b). As opposed to traditional arc-discharge lamps used with the shortest range (10–20 nm) bandpass interference filters in wide-field fluorescence microscopy, the laser systems used for fluorophore excitation in scanning confocal microscopy restrict excitation to specific laser spectral lines that encompass only a few nanometers (1,7). The fluorescence emission spectrum for both techniques, however, is controlled by similar bandpass or longpass filters that can cover tens to hundreds of nanometers (7). Below saturation levels, fluorescence intensity is proportional to the product of the molar extinction coefficient and the quantum yield of the fluorophore, a relationship that can be utilized to judge the effectiveness of emission as a function of excitation wavelength(s). These parameters display an approximate 20-fold range in variation for the popular fluorophores commonly employed for investigations in confocal microscopy with quantum yields ranging from 0.05 to 1.0, and extinction coefficients ranging from 10,000 to 0.25 million ($L \cdot mol^{-1}$). In general, the absorption spectrum of a fluorophore is far less dependent on environmental conditions than the fluorescence emission characteristics (spectral wavelength profile and quantum yield; 92).

Fluorophores chosen for confocal applications must exhibit a brightness level and signal persistence sufficient for the instrument to obtain image data that does not suffer from excessive photobleaching artifacts and low signal/noise ratios. In widefield fluorescence microscopy, excitation illumination levels are easily controlled with neutral

Table 1. Laser and Arc-Discharge Spectral Lines in Widefield and Confocal Microscopy

Laser Type	Ultraviolet	Violet	Blue	Green	Yellow	Orange	Red

density filters (40), and the intensity can be reduced (coupled with longer emission signal collection periods) to avoid saturation and curtail irreversible loss of fluorescence. Excitation conditions in confocal microscopy are several orders of magnitude more severe, however, and restrictions imposed by characteristics of the fluorophores and efficiency of the microscope optical system become the dominating factor in determining excitation rate and emission collection strategies (1,7,92).

Because of the narrow and wavelength-restricted laser spectral lines employed to excite fluorophores in confocal microscopy (Table 1), fluorescence emission intensity can be seriously restricted due to poor overlap of the excitation wavelengths with the fluorophore absorption band. In addition, the confocal pinhole aperture, which is critical in obtaining thin optical sections at high signal/noise ratios, is responsible for a 25–50% loss of emission intensity, regardless of how much effort has been expended on fine-tuning and alignment of the microscope optical system (7). Photomultiplier tubes are the most common detectors in confocal microscopy, but suffer from a quantum efficiency that varies as a function of wavelength (especially in the red and IR regions), further contributing to a wavelength-dependent loss of signal across the emission spectrum (59–62). Collectively, the light losses in confocal microscopy can result in a reduction of intensity exceeding 50 times of the level typically observed in widefield fluorescence instruments. It should be clear from the preceding argument that fluorophore selection is one of the most critical aspects of confocal microscopy, and instrumental efficiency must be carefully considered, as well, in order to produce high quality images.

In confocal microscopy, irradiation of the fluorophores with a focused laser beam at high power densities increases the emission intensity up to the point of dye saturation, a condition whose parameters are dictated by the excited state lifetime (97). In the excited state, fluorophores are unable to absorb another incident photon until they emit a lower energy photon through the fluorescence process. When the rate of fluorophore excitation exceeds the rate of emission decay, the molecules become saturated and the ground state population decreases. As a result, a majority of the laser energy passes through the specimen undiminished and does not contribute to fluorophore excitation. Balancing fluorophore saturation with laser light intensity

levels is, therefore, a critical condition for achieving the optimal signal/noise ratio in confocal experiments (1,7,92,97). The number of fluorescent probes currently available for confocal microscopy runs in the hundreds (90,93), with many dyes having absorption maxima closely associated with common laser spectral lines (90). An exact match between a particular laser line and the absorption maximum of a specific probe is not always possible, but the excitation efficiency of lines near the maximum is usually sufficient to produce a level of fluorescence emission that can be readily detected.

Instrumentally, fluorescence emission collection can be optimized by careful selection of objectives, detector aperture dimensions, dichromatic and barrier filters, as well as maintaining the optical train in precise alignment (63). In most cases, low magnification objectives with a high numerical aperture should be chosen for the most demanding imaging conditions because light collection intensity increases as the fourth power of the numerical aperture, but only decreases as the square of the magnification. However, the most important limitations in light collection efficiency in confocal microscopy arise from restrictions imposed by the physical properties of the fluorophores themselves. As previously discussed, fluorescent probe development is limited by a lack of knowledge of the specific molecular properties responsible for producing optimum fluorescence characteristics, and the design rules are insufficiently understood to be helpful as a guide to the development of more efficient fluorophores. The current success in development of new fluorescent probes capable of satisfactory performance in confocal microscopy is a testament to the progress made through use of empirical data and assumptions about molecular structure extrapolated from the properties of existing dyes, many of which were first synthesized over a hundred years ago.

TRADITIONAL FLUORESCENT DYES

The choice of fluorescent probes for confocal microscopy must address the specific capabilities of the instrument to excite and detect fluorescence emission in the wavelength regions made available by the laser systems and detectors. Although the current lasers used in confocal microscopy (Table 1) produce discrete lines in the UV, visible, and

near-IR portions of the spectrum, the location of these spectral lines does not always coincide with absorption maxima of popular fluorophores. In fact, it is not necessary for the laser spectral line to correspond exactly with the fluorophore wavelength of maximum absorption, but the intensity of fluorescence emission is regulated by the fluorophore extinction coefficient at the excitation wavelength (as discussed above). The most popular lasers for confocal microscopy are air-cooled argon and krypton-argon ion lasers, the new blue diode lasers, and a variety of helium-neon systems (7,40). Collectively, these lasers are capable of providing excitation at 10–12 specific wavelengths between 400 and 650 nm.

Many of the classical fluorescent probes that have been successfully utilized for many years in widefield fluorescence (92,93), including fluorescein isothiocyanate, Lissamine rhodamine, and Texas red, are also useful in confocal microscopy. Fluorescein is one of the most popular fluorochromes ever designed, and has enjoyed extensive application in immunofluorescence labeling. This xanthene dye has an absorption maximum at 495 nm, which coincides quite well with the 488 nm (blue) spectral line produced by argon-ion and krypton-argon lasers, as well as the 436 and 467 principal lines of the mercury and xenon arc-discharge lamps, respectively. In addition, the quantum yield of fluorescein is very high and a significant amount of information has been gathered on the characteristics of this dye with respect to the physical and chemical properties (98). On the negative side, the fluorescence emission intensity of fluorescein is heavily influenced by environmental factors (e.g., pH), and the relatively broad emission spectrum often overlaps with those of other fluorophores in dual and triple labeling experiments (92,98,99).

Tetramethyl rhodamine (TMR) and the isothiocyanate derivative (TRITC) are frequently employed in multiple labeling investigations in widefield microscopy due to their efficient excitation by the 546 nm spectral line from mercury arc-discharge lamps. The fluorochromes, which have significant emission spectral overlap with fluorescein, can be excited very effectively by the 543 nm line from helium-neon lasers, but not by the 514 or 568 nanometer lines from argon-ion and krypton-argon lasers (99). When using krypton-based laser systems, Lissamine rhodamine is a far better choice in this fluorochrome class due to the absorption maximum at 575 nm and its spectral separation from fluorescein. Also, the fluorescence emission intensity of rhodamine derivatives is not as dependent upon strict environmental conditions as that of fluorescein.

Several of the acridine dyes, first isolated in the nineteenth century, are useful as fluorescent probes in confocal microscopy (93). The most widely utilized, acridine orange, consists of the basic acridine nucleus with dimethylamino substituents located at the 3 and 6 positions of the tricyclic ring system. In physiological pH ranges, the molecule is protonated at the heterocyclic nitrogen and exists predominantly as a cationic species in solution. Acridine orange binds strongly to DNA by intercalation of the acridine nucleus between successive base pairs, and exhibits green fluorescence with a maximum wavelength of 530 nm (92,93,100). The probe also binds strongly to ribonucleic acid (RNA) or single-stranded deoxyribonucleic

acid (DNA), but has a longer wavelength fluorescence maximum (~640 nm; red) when bound to these macromolecules. In living cells, acridine orange diffuses across the cell membrane (by virtue of the association constant for protonation) and accumulates in the lysosomes and other acidic vesicles. Similar to most acridines and related polynuclear nitrogen heterocycles, acridine orange has a relatively broad absorption spectrum, which enables the probe to be used with several wavelengths from the argon-ion laser.

Another popular traditional probe that is useful in confocal microscopy is the phenanthridine derivative, propidium iodide, first synthesized as an antitrypanosomal agent along with the closely related ethidium bromide). Propidium iodide binds to DNA in a manner similar to the acridines (via intercalation) to produce orange-red fluorescence centered at 617 nm (101,102). The positively charged fluorophore also has a high affinity for double-stranded RNA. Propidium has an absorption maximum at 536 nm, and can be excited by the 488 or 514-nm spectral lines of an argon-ion (or krypton-argon) laser, or the 543 nm line from a green helium-neon laser. The dye is often employed as a counterstain to highlight cell nuclei during double or triple labeling of multiple intracellular structures. Environmental factors can affect the fluorescence spectrum of propidium, especially when the dye is used with mounting media containing glycerol. The structurally similar ethidium bromide, which also binds to DNA by intercalation (102), produces more background staining, and is therefore not as effective as propidium.

The DNA and chromatin can also be stained with dyes that bind externally to the double helix. The most popular fluorochromes in this category are 4',6-diamidino-2-phenylindole (DAPI) and the bis (benzimidazole) Hoechst dyes that are designated by the numbers 33258, 33342, and 34580 (103–106). These probes are quite water soluble and bind externally to AT-rich base pair clusters in the minor groove of double-stranded DNA with a dramatic increase in fluorescence intensity. Both dye classes can be stimulated by the 351 nm spectral line of high power argon-ion lasers or the 354 nm line from a helium-cadmium laser. Similar to the acridines and phenanthridines, these fluorescent probes are popular choices as a nuclear counterstain for use in multicolor fluorescent labeling protocols. The vivid blue fluorescence emission produces dramatic contrast when coupled to green, yellow, and red probes in adjacent cellular structures.

ALEXA FLUOR DYES

The dramatic advances in modern fluorophore technology are exemplified by the Alexa Fluor dyes (90,107,108) introduced by Molecular Probes (Alexa Fluor is a registered trademark of Molecular Probes). These sulfonated rhodamine derivatives exhibit higher quantum yields for more intense fluorescence emission than spectrally similar probes, and have several additional improved features, including enhanced photostability, absorption spectra matched to common laser lines, pH insensitivity, and a high degree of water solubility. In fact, the resistance to photobleaching of Alexa Fluor dyes is so dramatic (108)

that even when subjected to irradiation by high intensity laser sources, fluorescence intensity remains stable for relatively long periods of time in the absence of antifade reagents. This feature enables the water soluble Alexa Fluor probes to be readily utilized for both live-cell and tissue section investigations, as well as in traditional fixed preparations.

Alexa Fluor dyes are available in a broad range of fluorescence excitation and emission wavelength maxima, ranging from the UV and deep blue to the near-IR regions (90). Alphanumeric names of the individual dyes are associated with the specific excitation laser or arc-discharge lamp spectral lines for which the probes are intended. For example, Alexa Fluor 488 is designed for excitation by the blue 488 nm line of the argon or krypton-argon ion lasers, while Alexa Fluor 568 is matched to the 568 nm spectral line of the krypton-argon laser. Several of the Alexa Fluor dyes are specifically designed for excitation by either the blue diode laser (405 nm), the orange/yellow helium-neon laser (594 nm), or the red helium-neon laser (633 nm). Other Alexa Fluor dyes are intended for excitation with traditional mercury arc-discharge lamps in the visible (Alexa Fluor 546) or UV (Alexa Fluor 350, also useful with high power argon-ion lasers), and solid-state red diode lasers (Alexa Fluor 680). Because of the large number of available excitation and emission wavelengths in the Alexa Fluor series, multiple labeling experiments can often be conducted exclusively with these dyes.

Alexa Fluor dyes are commercially available as reactive intermediates in the form of maleimides, succinimidyl esters, and hydrazides, as well as prepared cytoskeletal probes (conjugated to phalloidin, G-actin, and rabbit skeletal muscle actin) and conjugates to lectin, dextrin, streptavidin, avidin, biocytin, and a wide variety of secondary antibodies (90). In the latter forms, the Alexa Fluor fluorophores provide a broad palette of tools for investigations in immunocytochemistry, neuroscience, and cellular biology. The family of probes has also been extended into a series of dyes having overlapping fluorescence emission maxima targeted at sophisticated confocal microscopy detection systems with spectral imaging and linear unmixing capabilities. For example, Alexa Fluor 488, Alexa Fluor 500, and Alexa Fluor 514 are visually similar in color with bright green fluorescence, but have spectrally distinct emission profiles. In addition, the three fluorochromes can be excited with the 488 or 514 nm spectral line from an argon-ion laser and are easily detected with traditional fluorescein filter combinations. In multispectral ($x-y-l$; referred to as a lambda stack) confocal imaging experiments, optical separation software can be employed to differentiate between the similar signals (32–35). The overlapping emission spectra of Alexa Fluor 488, 500, and 514 are segregated into separate channels and differentiated using pseudocolor techniques when the three fluorophores are simultaneously combined in a triple label investigation.

CYANINE DYES

The popular family of cyanine dyes, Cy2, Cy3, Cy5, Cy7, and their derivatives, are based on the partially saturated

indole nitrogen heterocyclic nucleus with two aromatic units being connected via a polyalkene bridge of varying carbon number (92,109). These probes exhibit fluorescence excitation and emission profiles that are similar to many of the traditional dyes, such as fluorescein and tetramethylrhodamine, but with enhanced water solubility, photostability, and higher quantum yields. Most of the cyanine dyes are more environmentally stable than their traditional counterparts, rendering their fluorescence emission intensity less sensitive to pH and organic mounting media. In a manner similar to the Alexa Fluors, the excitation wavelengths of the Cy series of synthetic dyes are tuned specifically for use with common laser and arc-discharge sources, and the fluorescence emission can be detected with traditional filter combinations.

Marketed by a number of distributors, the cyanine dyes are readily available as reactive dyes or fluorophores coupled to a wide variety of secondary antibodies, dextrin, streptavidin, and eggwhite avidin (110). The cyanine dyes generally have broader absorption spectral regions than members of the Alexa Fluor family, making them somewhat more versatile in the choice of laser excitation sources for confocal microscopy (7). For example, using the 547 nm spectral line from an argon-ion laser, Cy2 is about twice as efficient in fluorescence emission as Alexa Fluor 488. In an analogous manner, the 514 nm argon-ion laser line excites Cy3 with a much higher efficiency than Alexa Fluor 546, a spectrally similar probe. Emission profiles of the cyanine dyes are comparable in spectral width to the Alexa Fluor series.

Included in the cyanine dye series are the long-wavelength Cy5 derivatives, which are excited in the red region (650 nm) and emit in the far-red (680 nm) wavelengths. The Cy5 fluorophore is very efficiently excited by the 647 nm spectral line of the krypton-argon laser, the 633 nm line of the red helium-neon laser, or the 650 nm line of the red diode laser, providing versatility in laser choice. Because the emission spectral profile is significantly removed from traditional fluorophores excited by UV and blue illumination, Cy5 is often utilized as a third fluorophore in triple labeling experiments. However, similar to other probes with fluorescence emission in the far-red spectral region, Cy5 is not visible to the human eye and can only be detected electronically (using a specialized CCD camera system or photomultiplier). Therefore, the probe is seldom used in conventional widefield fluorescence experiments.

FLUORESCENT ENVIRONMENTAL PROBES

Fluorophores designed to probe the internal environment of living cells have been widely examined by a number of investigators, and many hundreds have been developed to monitor such effects as localized concentrations of alkali and alkaline earth metals, heavy metals (employed biochemically as enzyme cofactors), inorganic ions, thiols, and sulfides, nitrite, as well as pH, solvent polarity, and membrane potential (7,90–93,111,112). Originally, the experiments in this arena were focused on changes in the wavelength and/or intensity of absorption and emission spectra exhibited by fluorophores upon binding calcium

ions in order to measure intracellular flux densities. These probes bind to the target ion with a high degree of specificity to produce the measured response and are often referred to as spectrally sensitive indicators. Ionic concentration changes are determined by the application of optical ratio signal analysis to monitor the association equilibrium between the ion and its host. The concentration values derived from this technique are largely independent of instrumental variations and probe concentration fluctuations due to photobleaching, loading parameters, and cell retention. In the past few years, a number of new agents have been developed that bind specific ions or respond with measurable features to other environmental conditions (7,90).

Calcium is a metabolically important ion that plays a vital role in cellular response to many forms of external stimuli (113). Because transient fluctuations in calcium ion concentration are typically involved when cells undergo a response, fluorophores must be designed to measure not only localized concentrations within segregated compartments, but should also produce quantitative changes when flux density waves progress throughout the entire cytoplasm. Many of the synthetic molecules designed to measure calcium levels are based on the nonfluorescent chelation agents EGTA and BAPTA, which have been used for years to sequester calcium ions in buffer solutions (7,114,115). Two of the most common calcium probes are the ratiometric indicators fura-2 and indo-1, but these fluorophores are not particularly useful in confocal microscopy (7,116). The dyes are excited by UV light and exhibit a shift in the excitation or emission spectrum with the formation of isosbestic points when binding calcium. However, the optical aberrations associated with UV imaging, limited specimen penetration depths, and the expense of ultraviolet lasers have limited the utility of these probes in confocal microscopy.

Fluorophores that respond in the visible range to calcium ion fluxes are, unfortunately, not ratiometric indicators and do not exhibit a wavelength shift (typical of fura-2 and indo-1) upon binding, although they do undergo an increase or decrease in fluorescence intensity. The best example is fluo-3, a complex xanthene derivative, which undergoes a dramatic increase in fluorescence emission at 525 nm (green) when excited by the 488 nm spectral line of an argon-ion or krypton-argon laser (7,117). Because isosbestic points are not present to assure the absence of concentration fluctuations, it is impossible to determine whether spectral changes are due to complex formation or a variation in concentration with fluo-3 and similar fluorophores.

To overcome the problems associated with using visible light probes lacking wavelength shifts (and isosbestic points), several of these dyes are often utilized in combination for calcium measurements in confocal microscopy (118). Fura red, a multinuclear imidazole and benzofuran heterocycle, exhibits a decrease in fluorescence at 650 nm when binding calcium. A ratiometric response to calcium ion fluxes can be obtained when a mixture of fluo-3 and fura red is excited at 488 nm and fluorescence is measured at the emission maxima (525 and 650 nm, respectively) of the two probes. Because the emission intensity of fluo-3 increases monotonically while that of fura red simultaneously

decreases, an isosbestic point is obtained when the dye concentrations are constant within the localized area being investigated. Another benefit of using these probes together is the ability to measure fluorescence intensity fluctuations with a standard FITC/Texas red interference filter combination.

Quantitative measurements of ions other than calcium, such as magnesium, sodium, potassium, and zinc, are conducted in an analogous manner using similar fluorophores (7,90,92). One of the most popular probes for magnesium, mag-fura-2 (structurally similar to fura red), is also excited in the ultraviolet range and presents the same problems in confocal microscopy as fura-2 and indo-1. Fluorophores excited in the visible light region are becoming available for the analysis of many monovalent and divalent cations that exist at varying concentrations in the cellular matrix. Several synthetic organic probes have also been developed for monitoring the concentration of simple and complex anions.

Important fluorescence monitors for intracellular pH include a pyrene derivative known as HPTS or pyranine, the fluorescein derivative, BCECF, and another substituted xanthene termed carboxy SNARF-1 (90,119–122). Because many common fluorophores are sensitive to pH in the surrounding medium, changes in fluorescence intensity that are often attributed to biological interactions may actually occur as a result of protonation. In the physiological pH range (pH 6.8–7.4), the probes mentioned above are useful for dual-wavelength ratiometric measurements and differ only in dye loading parameters. Simultaneous measurements of calcium ion concentration and pH can often be accomplished by combining a pH indicator, such as SNARF-1, with a calcium ion indicator (e.g., fura-2). Other probes have been developed for pH measurements in subcellular compartments, such as the lysosomes, as described below.

ORGANELLE PROBES

Fluorophores targeted at specific intracellular organelles, such as the mitochondria, lysosomes, Golgi apparatus, and endoplasmic reticulum, are useful for monitoring a variety of biological processes in living cells using confocal microscopy (7,90,92). In general, organelle probes consist of a fluorochrome nucleus attached to a target-specific moiety that assists in localizing the fluorophore through covalent, electrostatic, hydrophobic, or similar types of bonds. Many of the fluorescent probes designed for selecting organelles are able to permeate or sequester within the cell membrane (and therefore, are useful in living cells), while others must be installed using monoclonal antibodies with traditional immunocytochemistry techniques. In living cells, organelle probes are useful for investigating transport, respiration, mitosis, apoptosis, protein degradation, acidic compartments, and membrane phenomena. Cell impermeant fluorophore applications include nuclear functions, cytoskeletal structure, organelle detection, and probes for membrane integrity. In many cases, living cells that have been labeled with permeant probes can subsequently be fixed and counterstained with additional fluorophores in multicolor labeling experiments.

Mitochondrial probes are among the most useful fluorophores for investigating cellular respiration and are often employed along with other dyes in multiple labeling investigations. The traditional probes, rhodamine 123 and tetramethylrosamine, are rapidly lost when cells are fixed and have largely been supplanted by newer, more specific, fluorophores developed by Molecular Probes (90,123,124). These include the popular MitoTracker and MitoFluor series of structurally diverse xanthene, benzoxazole, indole, and benzimidazole heterocycles that are available in a variety of excitation and emission spectral profiles. The mechanism of action varies for each of the probes in this series, ranging from covalent attachment to oxidation within respiring mitochondrial membranes.

MitoTracker dyes are retained quite well after cell fixation in formaldehyde and can often withstand lipophilic permeabilizing agents (123). In contrast, the MitoFluor probes are designed specifically for actively respiring cells and are not suitable for fixation and counterstaining procedures (90). Another popular mitochondrial probe, entitled JC-1, is useful as an indicator of membrane potential and in multiple staining experiments with fixed cells (125). This carbocyanine dye exhibits green fluorescence at low concentrations, but can undergo intramolecular association within active mitochondria to produce a shift in emission to longer (red) wavelengths. The change in emission wavelength is useful in determining the ratio of active to nonactive mitochondria in living cells.

In general, weakly basic amines that are able to pass through membranes are the ideal candidates for investigating biosynthesis and pathogenesis in lysosomes (90–92,112). Traditional lysosomal probes include the non-specific phenazine and acridine derivatives neutral red and acridine orange, which are accumulated in the acidic vesicles upon being protonated (92,93). Fluorescently labeled latex beads and macromolecules, such as dextran, can also be accumulated in lysosomes by endocytosis for a variety of experiments. However, the most useful tools for investigating lysosomal properties with confocal microscopy are the LysoTracker and LysoSensor dyes developed by Molecular Probes (90,92,126). These structurally diverse agents contain heterocyclic and aliphatic nitrogen moieties that modulate transport of the dyes into the lysosomes of living cells for both short- and long-term studies. The LysoTracker probes, which are available in a variety of excitation and emission wavelengths (91), have high selectivity for acidic organelles and are capable of labeling cells at nanomolar concentrations. Several of the dyes are retained quite well after fixing and permeabilization of cells. In contrast, the LysoSensor fluorophores are designed for studying dynamic aspects of lysosome function in living cells. Fluorescence intensity dramatically increases in the LysoSensor series upon protonation, making these dyes useful as pH indicators (91). A variety of Golgi apparatus specific monoclonal antibodies have also been developed for use in immunocytochemistry assays (90,127–129).

Proteins and lipids are sorted and processed in the Golgi apparatus, which is typically stained with fluorescent derivatives of ceramides and sphingolipids (130). These agents are highly lipophilic, and are therefore useful as markers for the study of lipid transport and metabolism in

live cells. Several of the most useful fluorophores for Golgi apparatus contain the complex heterocyclic BODIPY nucleus developed by Molecular Probes (90,92,131). When coupled to sphingolipids, the BODIPY fluorophore is highly selective and exhibits a tolerance for photobleaching that is far superior to many other dyes. In addition, the emission spectrum is dependent upon concentration (shifting from green to red at higher concentrations), making the probes useful for locating and identifying intracellular structures that accumulate large quantities of lipids. During live-cell experiments, fluorescent lipid probes can undergo metabolism to derivatives that may bind to other subcellular features, a factor that can often complicate the analysis of experimental data.

The most popular traditional probes for endoplasmic reticulum fluorescence analysis are the carbocyanine and xanthene dyes, DiOC (6) and several rhodamine derivatives, respectively (90,92). These dyes must be used with caution, however, because they can also accumulate in the mitochondria, Golgi apparatus, and other intracellular lipophilic regions. Newer, more photostable, probes have been developed for selective staining of the endoplasmic reticulum by several manufacturers. In particular, oxazole members of the Dapoxyl family produced by Molecular Probes are excellent agents for selective labeling of the endoplasmic reticulum in living cells, either alone or in combination with other dyes (90). These probes are retained after fixation with formaldehyde, but can be lost with permeabilizing detergents. Another useful probe is Brefeldin A (131), a stereochemically complex fungal metabolite that serves as an inhibitor of protein trafficking out of the endoplasmic reticulum. Finally, similar to other organelles, monoclonal antibodies (127–129) have been developed that target the endoplasmic reticulum in fixed cells for immunocytochemistry investigations.

QUANTUM DOTS

Nanometer-sized crystals of purified semiconductors known as quantum dots are emerging as a potentially useful fluorescent labeling agent for living and fixed cells in both traditional widefield and laser scanning confocal fluorescence microscopy (132–136). Recently introduced techniques enable the purified tiny semiconductor crystals to be coated with a hydrophilic polymer shell and conjugated to antibodies or other biologically active peptides and carbohydrates for application in many of the classical immunocytochemistry protocols (Fig. 15). These probes have significant benefits over organic dyes and fluorescent proteins, including long-term photostability, high fluorescence intensity levels, and multiple colors with single-wavelength excitation for all emission profiles (136).

Quantum dots produce illumination in a manner similar to the well-known semiconductor light emitting diodes, but are activated by absorption of a photon rather than an electrical stimulus. The absorbed photon creates an electron-hole pair that quickly recombines with the concurrent emission of a photon having lower energy. The most useful semiconductor discovered thus far for producing biological quantum dots is cadmium selenide (CdSe), a material in

Figure 15. Anatomy and spectral profiles of quantum dot conjugates. The cadmium selenide core is encapsulated with zinc sulfide, and then a polymer coating is applied followed by a hydrophilic exterior to which the biological conjugate is attached (left). The absorption profile displays a shoulder at 400 nm, while the emission spectra all feature similar symmetrical profiles.

which the energy of the emitted photons is a function of the physical size of the nanocrystal particles. Thus, quantum dots having sizes that differ only by tenths of a nanometer emit different wavelengths of light, with the smaller sizes emitting shorter wavelengths, and vice versa.

Unlike typical organic fluorophores or fluorescent proteins, which display highly defined spectral profiles, quantum dots have an absorption spectrum that increases steadily with decreasing wavelength (Fig. 15). Also, in contrast, the fluorescence emission intensity is confined to a symmetrical peak with a maximum wavelength that is dependent on the dot size, but independent of the excitation wavelength (135). As a result, the same emission profile is observed regardless of whether the quantum dot is excited at 300, 400, 500, or 600 nm, but the fluorescence intensity increases dramatically at shorter excitation wavelengths. For example, the extinction coefficient for a typical quantum dot conjugate that emits in the orange region (605 nm) is approximately five-fold higher when the semiconductor is excited at 400 versus 600 nm. The fwhm value for a typical quantum dot conjugate is ~ 30 nm (135), and the spectral profile is not skewed towards the longer wavelengths (having higher intensity tails), such is the case with most organic fluorochromes. The narrow emission profile enables several quantum dot conjugates to be simultaneously observed with a minimal level of bleed through.

For biological applications, a relatively uniform population of cadmium selenide crystals is covered with a surrounding semiconductor shell composed of zinc sulfide to improve the optical properties. Next, the core material is coated with a polymeric film and other ligands to decrease hydrophobicity and to improve the attachment efficiency of conjugated macromolecules. The final product is a biologically active particle that ranges in size from 10 to 15 nm, somewhere in the vicinity of a large protein (133). Quantum dot conjugates are solubilized as a colloidal suspension in common biological buffers and may be incorporated into existing labeling protocols in place of classical staining reagents (such as organic fluorochrome-labeled secondary antibodies).

In confocal microscopy, quantum dots are excited with varying degrees of efficiency by most of the spectral lines produced by the common laser systems, including the

argon-ion, helium-cadmium, krypton-argon, and the green helium-neon. Particularly effective at exciting quantum dots in the UV and violet regions are the new blue diode and diode-pumped solid-state lasers that have prominent spectral lines at 442 nm and below (135,136). The 405 nm blue diode laser is an economical excitation source that is very effective for use with quantum dots due to their high extinction coefficient at this wavelength. Another advantage of using these fluorophores in confocal microscopy is the ability to stimulate multiple quantum dot sizes (and spectral colors) in the same specimen with a single excitation wavelength, making these probes excellent candidates for multiple labeling experiments (137).

The exceptional photostability of quantum dot conjugates is of great advantage in confocal microscopy when optical sections are being collected. Unlike the case of organic fluorophores, labeled structures situated away from the focal plane do not suffer from excessive photobleaching during repeated raster scanning of the specimen and yield more accurate 3D volume models. In widefield fluorescence microscopy, quantum dot conjugates are available for use with conventional dye-optimized filter combinations that are standard equipment on many microscopes. Excitation can be further enhanced by substituting a shortpass filter for the bandpass filter that accompanies most filter sets, thus optimizing the amount of lamp energy that can be utilized to excite the quantum dots. Several of the custom fluorescence filter manufacturers offer combinations specifically designed to be used with quantum dot conjugates.

FLUORESCENT PROTEINS

Over the past few years, the discovery and development of naturally occurring fluorescent proteins and mutated derivatives have rapidly advanced to center stage in the investigation of a wide spectrum of intracellular processes in living organisms (75,78,80). These biological probes have provided scientists with the ability to visualize, monitor, and track individual molecules with high spatial and temporal resolution in both steady-state and kinetic experiments. A variety of marine organisms have been the source of >100 fluorescent proteins and their analogs, which arm the investigator with a balanced palette of noninvasive biological probes for single, dual, and multispectral fluorescence analysis (75). Among the advantages of fluorescent proteins over the traditional organic and new semiconductor probes described above is their response to a wider variety of biological events and signals. Coupled with the ability to specifically target fluorescent probes in subcellular compartments, the extremely low or absent photodynamic toxicity, and the widespread compatibility with tissues and intact organisms, these biological macromolecules offer an exciting new frontier in live-cell imaging.

The first member of this series to be discovered, GFP, was isolated from the North Atlantic jellyfish, *Aequorea Victoria*, and found to exhibit a high degree of fluorescence without the aid of additional substrates or coenzymes (138–142). In native green fluorescent protein, the fluorescent moiety is a tripeptide derivative of serine, tyrosine, and glycine that requires molecular oxygen for activation, but no additional cofactors or enzymes (143). Subsequent

investigations revealed that the GFP gene could be expressed in other organisms, including mammals, to yield fully functional analogs that display no adverse biological effects (144). In fact, fluorescent proteins can be fused to virtually any protein in living cells using recombinant complementary DNA cloning technology, and the resulting fusion protein gene product expressed in cell lines adapted to standard tissue culture methodology. Lack of a need for cell-specific activation cofactors renders the fluorescent proteins much more useful as generalized probes than other biological macromolecules, such as the phycobiliproteins, which require insertion of accessory pigments in order to produce fluorescence.

Mutagenesis experiments with green fluorescent protein have produced a large number of variants with improved folding and expression characteristics, which have eliminated wild-type dimerization artifacts and fine tuned the absorption and fluorescence properties. One of the earliest variants, known as enhanced green fluorescence protein (EGFP), contains codon substitutions (commonly referred to as the S65T mutation) that alleviates the temperature sensitivity and increases the efficiency of GFP expression in mammalian cells (145). Proteins fused with EGFP can be observed at low light intensities for long time periods with minimal photobleaching. Enhanced green fluorescent protein fusion products are optimally excited by the 488 nm spectral line from argon and krypton–argon ion lasers in confocal microscopy. This provides an excellent biological probe and instrument combination for examining intracellular protein pathways along with the structural dynamics of organelles and the cytoskeleton.

Additional mutation studies have uncovered GFP variants that exhibit a variety of absorption and emission characteristics across the entire visible spectral region, which have enabled researchers to develop probe combinations for simultaneous observation of two or more distinct fluorescent proteins in a single organism (see the spectral profiles in Fig. 16). Early investigations yielded the blue fluorescent protein (BFP) and cyan fluorescent protein (CFP) mutants from simple amino acid substitutions that shifted the absorption and emission spectral profiles of wild-type GFP to lower wavelength regions (146–148). Used in combination with GFP, these derivatives are useful in resonance energy transfer (FRET) experiments and other investigations that rely on multicolor fluorescence imaging (73). Blue fluorescent protein can be efficiently excited with the 354 nm line from a high power argon laser, while the more useful cyan derivative is excited by a number of violet and blue laser lines, including the

405 nm blue diode, the 442 nm helium–cadmium spectral line, and the 457 nm line from the standard argon-ion laser.

Another popular fluorescent protein derivative, the yellow fluorescent protein (YFP), was designed on the basis of the GFP crystalline structural analysis to red-shift the absorption and emission spectra (148). Yellow fluorescent protein is optimally excited by the 514 nm spectral line of the argon-ion laser, and provides more intense emission than enhanced green fluorescent protein, but is more sensitive to low pH and high halogen ion concentrations. The enhanced yellow fluorescent protein derivative (EYFP) is useful with the 514 argon-ion laser line, but can also be excited with relatively high efficiency by the 488 nm line from argon and krypton–argon lasers. Both of these fluorescent protein derivatives have been widely applied to protein–protein FRET investigations in combination with CFP, and in addition, have proven useful in studies involving multiprotein trafficking.

Attempts to shift the absorption and emission spectra of *Aequorea Victoria* fluorescent proteins to wavelengths in the orange and red regions of the spectrum have met with little success. However, fluorescent proteins from other marine species have enabled investigators to extend the available spectral regions to well within the red wavelength range. The DsRed fluorescent protein and its derivatives, originally isolated from the sea anemone *Discosoma striata*, are currently the most popular analogs for fluorescence analysis in the 575–650 nm region (149). Another protein, HcRed from the *Heteractis crispa* purple anemone, is also a promising candidate for investigations in the longer wavelengths of the visible spectrum (150). Newly developed photoactivation fluorescent proteins, including photoactivatable green fluorescent protein (PA-GFP; 74), Kaede (76), and kindling fluorescent protein 1 (KFP1; 151), exhibit dramatic improvements over GFP (up to several 1000-fold) in fluorescence intensity when stimulated by violet laser illumination. These probes should prove useful in fluorescence confocal studies involving selective irradiation of specific target regions and the subsequent kinetic analysis of diffusional mobility and compartmental residency time of fusion proteins.

QUENCHING AND PHOTBLEACHING

The consequences of quenching and photobleaching are suffered in practically all forms of fluorescence microscopy, and result in an effective reduction in the levels of emission (152,153). These artifacts should be of primary

Figure 16. Fluorescent spectral profiles, plotted as normalized absorption or emission as a function of wavelength, for fluorescent proteins emitting in the blue to orange-red regions of the visible spectrum. Each profile is identified with a colored bullet in (a), which illustrates excitation spectra. (b) The emission spectra for the proteins according to the legend in (a).

consideration when designing and executing fluorescence investigations. The two phenomena are distinct in that quenching is often reversible whereas photobleaching is not (154). Quenching arises from a variety of competing processes that induce nonradiative relaxation (without photon emission) of excited-state electrons to the ground state, which may be either intramolecular or intermolecular in nature. Because nonradiative transition pathways compete with the fluorescence relaxation, they usually dramatically lower or, in some cases, completely eliminate emission. Most quenching processes act to reduce the excited state lifetime and the quantum yield of the affected fluorophore.

A common example of quenching is observed with the collision of an excited state fluorophore and another (non-fluorescent) molecule in solution, resulting in deactivation of the fluorophore and return to the ground state. In most cases, neither of the molecules is chemically altered in the collisional quenching process. A wide variety of simple elements and compounds behave as collisional quenching agents, including oxygen, halogens, amines, and many electron-deficient organic molecules (154). Collisional quenching can reveal the presence of localized quencher molecules or moieties, which via diffusion or conformational change, may collide with the fluorophore during the excited state lifetime. The mechanisms for collisional quenching include electron transfer, spin-orbit coupling, and intersystem crossing to the excited triplet state (154,155). Other terms that are often utilized interchangeably with collisional quenching are internal conversion and dynamic quenching.

A second type of quenching mechanism, termed static or complex quenching, arises from nonfluorescent complexes formed between the quencher and fluorophore that serve to limit absorption by reducing the population of active, excitable molecules (154,156). This effect occurs when the fluorescent species forms a reversible complex with the quencher molecule in the ground state, and does not rely on diffusion or molecular collisions. In static quenching, fluorescence emission is reduced without altering the excited state lifetime. A fluorophore in the excited state can also be quenched by a dipolar resonance energy transfer mechanism when in close proximity with an acceptor molecule to which the excited-state energy can be transferred nonradiatively. In some cases, quenching can occur through non molecular mechanisms, such as attenuation of incident light by an absorbing species (including the chromophore itself).

In contrast to quenching, photobleaching (also termed fading) occurs when a fluorophore permanently loses the ability to fluoresce due to photon-induced chemical damage and covalent modification (153–156). Upon transition from an excited singlet state to the excited triplet state, fluorophores may interact with another molecule to produce irreversible covalent modifications. The triplet state is relatively long lived with respect to the singlet state, thus allowing excited molecules a much longer timeframe to undergo chemical reactions with components in the environment (155). The average number of fluorophore before photobleaching is dependent on the molecular structure and the local environment (154,156).

Some fluorophores bleach quickly after emitting only a few photons, while others that are more robust can undergo thousands or even millions of cycles before bleaching.

Figure 17 presents a typical example of photobleaching (fading) observed in a series of digital images captured at different time points for a multiply stained culture of normal Tahr ovary (HJ1.Ov line) fibroblast cells. The nuclei were stained with DAPI (blue fluorescence), while the mitochondria and actin cytoskeleton were stained with MitoTracker Red CMXRos (red fluorescence) and an Alexa Fluor phalloidin derivative (Alexa Fluor 488; green fluorescence), respectively. Time points were taken in 2 min intervals using a fluorescence filter combination with bandwidths tuned to excite the three fluorophores simultaneously while also recording the combined emission signals. Note that all three fluorophores have a relatively high intensity in Fig. 17a, but the DAPI (blue) intensity starts to drop rapidly at two min and is almost completely gone at six min (Fig. 17f). The mitochondrial and actin stains are more resistant to photobleaching, but the intensity of both drops dramatically over the course of the timed sequence (10 min).

An important class of photobleaching events is represented by events that are photodynamic, meaning they involve the interaction of the fluorophore with a combination of light and oxygen (157–161). Reactions between fluorophores and molecular oxygen permanently destroy fluorescence and yield a free-radical singlet oxygen species that can chemically modify other molecules in living cells. The amount of photobleaching due to photodynamic events is a function of the molecular oxygen concentration and the proximal distance between the fluorophore, oxygen molecules, and other cellular components. Photobleaching can be reduced by limiting the exposure time of

Differential Photobleaching Rates in Multiply Stained Specimens

Figure 17. Photobleaching in multiply stained specimens. Normal Tahr ovary fibroblast cells were stained with MitoTracker Red CMXRos (mitochondria; red fluorescence), Alexa Fluor 488 conjugated to phalloidin (actin; green fluorescence), and subsequently counterstained with DAPI (nuclei; blue fluorescence). Time points were taken in two-minute intervals over a 10 min period using a fluorescence filter combination with bandwidths tuned to excite the three fluorophores simultaneously while also recording the combined emission signals. (a–f) Time = 0, 2, 4, 6, 8, 10 min, respectively.

fluorophores to illumination or by lowering the excitation energy. However, these techniques also reduce the measurable fluorescence signal. In many cases, solutions of fluorophores or cell suspensions can be deoxygenated, but this is not feasible for living cells and tissues. Perhaps the best protection against photobleaching is to limit exposure of the fluorochrome to intense illumination (using neutral density filters) coupled with the judicious use of commercially available antifade reagents that can be added to the mounting solution or cell culture medium (153).

Under certain circumstances, the photobleaching effect can also be utilized to obtain specific information that would not otherwise be available. For example, in FRAP experiments, fluorophores within a target region are intentionally bleached with excessive levels of irradiation (82). As new fluorophore molecules diffuse into the bleached region of the specimen (recovery), the fluorescence emission intensity is monitored to determine the lateral diffusion rates of the target fluorophore. In this manner, the translational mobility of fluorescently labeled molecules can be ascertained within a very small (2–5 μm) region of a single cell or section of living tissue.

Although the subset of fluorophores that are advantageous in confocal microscopy is rapidly growing, many of the traditional probes that have been useful for years in widefield applications are still of little utility when constrained by fixed-wavelength laser spectral lines. Many of the limitations surrounding the use of fluorophores excited in the ultraviolet region will be eliminated with the introduction of advanced objectives designed to reduce aberration coupled to the gradual introduction of low cost, high power diode laser systems with spectral lines in these shorter wavelengths. The 405 nm blue diode laser is a rather cheap alternative to more expensive ion and Noble gas based ultraviolet lasers, and is rapidly becoming available for most confocal microscope systems. Helium–neon lasers with spectral lines in the yellow and orange region have rendered some fluorophores useful that were previously limited to widefield applications. In addition, new diode-pumped solid-state lasers are being introduced with emission wavelengths in the UV, violet, and blue regions.

Continued advances in fluorophore design, dual-laser scanning, multispectral imaging, endoscopic instruments, and spinning disk applications will also be important in the coming years. The persistent problem of emission crossover due to spectral overlap, which occurs with many synthetic probes and fluorescent proteins in multicolor investigations, benefits significantly from spectral analysis and deconvolution of lambda stacks. Combined, these advances and will dramatically improve the collection and analysis of data obtained from complex fluorescence experiments in live-cell imaging.
