INTRODUCTION

Tissue transplantation and synthetic devices have been utilized in order to substitute the function of lost

or damaged hard tissue, such as bone and tooth. Tissue transplants can be autologous, allogeneic, or xenogeneic. However, the use of autologous tissue involves additional surgery and donor site morbidity while the use of allogeneic or xenogeneic tissue involves the risks of immune rejection and disease transmission. Therefore, synthetic hard tissue implants are very necessary. Metals, ceramics, composites, and even polymers are investigated as candidates for the hard tissue replacements. For heavy loaded applications, such as hip prostheses, metals (e.g., Ti-alloys, Co-Cr), and strong inert ceramics (e.g., alumina, zirconia) are extensively studied. Unfortunately, various problems related to both the metallic materials and the bioinert ceramics, for example, corrosion, elastic modulus mismatch (stress concentration and shielding), and bioinertness (only physical connection with host) with metals, and brittle, elastic modulus mismatch, and bioinertness with bioinert ceramics. For these reasons, bioceramics are showing very promising results in the high bioactivity and the formation of interfacial chemical bond with host tissue, which was called osseointegration (1). So far, several bioactive ceramics have been proposed for hard tissue replacements, hydroxyapatite (HA) and bioactive glasses are the most acceptable materials for hard tissue applications (2). The advantages of bioceramics over inert ceramics and metals allow for developing better hard tissue replacements with the characteristics of bioactive and elastic modulus more close to that of bone (2). On the other hand, the mechanical properties of bioceramics are fairly poor when compared with their replaced natural hard tissues. The poor mechanical properties, especially inside the body aqueous environments, limit their applications to only small, unloaded, and low loaded implants, powders, coatings, composites, porous scaffolds for tissue engineering, and so on. Bioceramic coatings and porous scaffold are showing the most promising results for the future hard tissue replacements (3–5). There are various methods developed to produce HA coatings (3–5). Among these techniques, plasma spraying has widely been used. However, this method is not applicable for deposition HA films onto a porous substrate.

In order to obtain a bone substitute possessing both desirable mechanical properties and bioactivity, two major deposition routes in coating the bioactive HA on a highly porous alumina substrate with the similar range of tensile and compressive strength as natural bone were developed. Coated reticulated bioactive substrates can provide the needed mechanical strength for the replacement of the bear-loading functions. The first one is a suspension method in which the ceramic substrates are first coated with a suspension containing the HA powder followed by a sintering with an appropriate time-temperature cycle to densify the HA coating. The second one is a synthesis route or called thermal deposition.

The techniques of coating uniformly thin layers of bioactive HA onto highly porous alumina substrate, the structural properties, especially the interfaces between the coating and the substrate, and the bioactive behavior of the coated substrate in the simulated body fluid (SBF) will be presented in this article.

Figure 1. Cross-section of reticulated alumina substrate, showing the interconnected porosity.

MATERIALS AND METHODS

Reticulated alumina Al_2O_3 was used as the substrate materials. Figure 1 is the gross morphology of the substrate; and Fig. 2 is the cross-section showing the interconnected pores. The average size of the pores is $500\ \mu\text{m}$, which are large enough to allow the ingrowth of bone tissue. Substrates were cleaned using ultrasonic cleaner in acetone and dried at 100°C before applying the coating.

Suspension Method

The coating suspension was made up of finely milled ceramic powders, an organic solvent, and a binder. The binder was used to prevent the precipitation of particles and to provide bonding strength to the coating after drying. One important property of the suspension is its viscosity. Specifically, when the porous substrate was immersed in the coating suspension, the suspension must be fluid enough to enter, fill, and uniformly coat the substrate skeleton. Low viscosity could result in undesirable thin films while highly viscous slurry would block the pore, thus impairing the interconnectivity of the pores. The viscosity

Figure 2. Cross-section of reticulated alumina substrate, showing the interconnected porosity.

Table 1. Sample Group Assignment

Sample	Source and Treatment	SSA, m ² · g ⁻¹
HA	Commercial	63.02
HA600	HA heated at 600 °C, 30 min	40.92
HA900	HA heated at 900 °C, 30 min	17.45
SHA700	Synthesized HA heated at 700 °C, 4 h	15.19
SHA800	Synthesized HA heated at 800 °C, 4 h	1.49
SHA900	Synthesized HA heated at 900 °C, 4 h	1.23
No. 1	HA heated at 700 °C, 3.5 h, particle size: 40–100 mesh	24.38
No. 2	HA heated at 700 °C, 3.5 h, particle size: 100–200 mesh	25.70
No. 3	HA heated at 700 °C, 3.5 h, particle size: > 200 mesh	27.02

was controlled by the relative amount of solvent, binder, and particles. The porous substrates were subsequently immersed into the mixture. After the porous substrates were completely infiltrated, they were spun briefly in a high speed centrifuge for removal of excess solution. Coated substrates were dried in an oven at 100 °C. The dried specimens were heated in air to 400 °C for 1 h to burn out the organic binder from suspension. During the burnout process, a slow and controlled heating rate was necessary to avoid bubbling in the coating. Then the samples were subject to sintering at different temperatures. Two types of suspension were developed for coating. One was prepared by suspending HA particles (300 mesh) (Chemat Technology, Inc.) in an organic binder–solvent system without glass sintering aid, glass frits. The other was prepared by partially substitution of HA by sintering aid, glass frits (65%), which have good adhesion to the Al₂O₃ substrate and a weak reaction with HA during firing. The glass frits used in this work were borosilicate glasses containing ~75% of a mixture of SiO₂ and B₂O₃, and 20 wt% alkali metal oxides. After melting, the glass was quenched in water and ground in a ball mill into a glass frit of the desired particle size (325 mesh).

Thermal Deposition

Mixing calcium 2-ethyl hexanoate with bis(2-ethylhexyl) phosphite stoichiometrically in ethanol. The viscosity of the solution was controlled by the quantity of ethanol added. The mixture was stirred for 2 days at room temperature. Then mixture was used to coat porous substrates. The coating method used is the same as used in suspension method described earlier. Coated substrates were air-dried and calcinated up to 1000 °C at a heating rate of 2 °C/min. Then the samples were subject to sintering at different temperatures. For phase analysis purpose, the HA was prepared in the powder form as well through same procedures. Briefly, the solution was open to the air and stirred to vaporize the solvent in chemical hood. Finally, a highly viscous, translucent mixture was obtained and then subject to calcinations at desirable temperatures.

Mechanical strength measurements were carried out on an Instron testing unit. Bars of the porous substrate (5×5×60 mm³) were cut using a diamond saw. Tension tests were performed in three-point bending. Compression tests were made on cylinder-shaped sample of 10-mm height and 23 mm diameter. X-ray diffraction (XRD), Scanning electron microscopy (SEM) with an energy dis-

persive spectrometer (EDS) was utilized to study the coating structure, surface morphology, and the interface structure. The coating bonding strength was measured through tape test (ASTM D 3359), which was originally designed for organic coatings on metallic substrates. This method was used to find the relative bonding strength. All the tests were performed on dense alumina substrates with one or multilayer HA coatings. Permacel 670 tape (Permacel) was used in the test. After removal from the coating, the tape was examined under a light microscope. Sintering process and chemical bonding of the sintering products were examined using differential thermal analysis (DTA) and Fourier transform infrared spectroscopy (FTIR).

The *in vitro* tests were conducted to evaluate the bioactivity of the synthetic HA produced by thermal deposition method (commercial HA as control). All the samples were tested in the powder form (Table 1). Table 1 summarizes the different treatments used to obtain a variety of crystalline structures in the materials; and also names the samples according to the treatment conditions, such as HA, HA600, HA900, SHA700, SHA800, SHA900, No. 1, No. 2, and No. 3. The HA sample group refers to commercial hydroxyapatite samples. HA600 and HA 900 groups refer to commercial HA samples treated for 30 min under 600 and 900 °C, respectively. The SHA700, SHA800, SHA900 conditions refer to synthesized HA using the thermal deposition method described earlier and heated for 4 h at 700, 800, and 900 °C, respectively. Sample No. 1, No. 2, and No. 3 refer to commercial HA and are heat-treated at 700 °C for 3.5 h and with different specific surface area (SSA). Sample No. 3 has the highest SSA; Sample No. 1 has the lowest SSA; and Sample No. 2 is in the middle. The simulated body fluid (SBF) solution that had ionic concentrations close to human blood plasma, as shown in Table 2, was prepared by dissolving reagent grade NaCl, NaHCO₃, KCl, K₂HPO₄·3H₂O, MgCl₂·3H₂O, CaCl₂, and Na₂SO₄ in ion-exchanged distilled water. The solution was buffered at pH 7.4 with 1 M HCl and tris(hydroxymethyl) aminomethane, (CH₂OH)₃CNH₂ at 37 °C. Powders were immersed into solution at 1 mg/mL ratio and maintained at 37 °C at periods ranging from 15 min to 9 weeks. The calcium concentrations in the solutions were measured by inductively coupled plasma (ICP). Subsequent to immersion, the solutions were vacuum filtered. The powders were gently rinsed with alcohol, ion-exchanged distilled water and then dried at room temperature. The surface microstructures before and after immersion of SBF solution were analyzed via scanning electron microscope (SEM). Both

Table 2. Ionic Concentration of SBF in Comparison With Those of Human Blood Plasma

	Concentration, mM							
	Na ⁺	K ⁺	Ca ²⁺	Mg ²⁺	HCO ₃ ⁻	Cl ⁻	HPO ₄ ²⁻	SO ₄ ⁻
Blood plasma	142.0	5.0	2.5	1.5	27.0	103.0	1.0	0.5
SBF	142.0	5.0	2.5	1.5	4.2	147.8	1.0	0.5

XRD and FTIR determined the contents of the phases that were present in the coatings. Measurements were obtained on a Philips X-ray diffractometer with CuK-radiation at 35 kV and 23 mA.

RESULTS

Suspension Method

The phase diagram for anhydrous calcium phosphates (Fig. 3) shows that the liquid phase appears at a temperature > 1500 °C, and presumably the induced liquid could improve the bonding between HA and the Al₂O₃ substrate during sintering. However, such as liquid-enhanced bonding process was not experimentally observed. Meanwhile, XRD analysis of the coating made from HA solution (without glass additive) showed that HA was decomposed, and in turn, the bioactivity of the coating was changed. A high density of cracks was found to exist in the coating. The adherence of the coating to the Al₂O₃ substrate was low and the coating layer could be peeled off by scraping. These results indicated that HA solution without sintering aid, such as glass frits, was not suitable for this particular application.

Using the sintering aid, glass frits, a well-bonded HA coating was produced. Figures 4–6 are SEM photographs of the surfaces and interfaces of the coatings made from solution with glass frits. As is apparent from Figs. 5 and 6, the glass–HA ceramic layer is firmly attached to the alumina substrate. An average coating thickness is 15 μm. The interfacial strength between the coating and the

Figure 6. The SEM photograph of the coating interface for porous alumina. The interface is indicated by arrows.

Figure 7. Aluminum content profile along the interface. The solid line is a guide to the eye.

substrate depends on the adherence of the glass to the Al_2O_3 . Figure 7 is the aluminum compositional profile across the interface. The data showed that the aluminum concentration decreased when scanning from the substrate to the outer surface of the coating. It was concluded that aluminum ions diffused during sintering, and consequently bonded the glass to the alumina substrate by ion diffusion. This diffusion bonding is attributed to the formation of a eutectic compound at the interface during the sintering, and thus ensures the strong bonding between the coating and the substrate.

The above results indicate that the development of glass frits is essential for having an excellent adhesion of HA coating to the alumina substrate. Great efforts were therefore made in the preparation of the glass frits. As a sintering aid, the glass must wet the substrate and HA, and its melting point should be lower than the decomposing temperature of HA (1300°C). Furthermore, for successful coating, optimizing the coefficient of thermal expansion of the glass to match the substrate is critical. It has been known that the mismatch in expansion coefficients between the coating and the substrate materials will give rise to interfacial stress that weakens the bonding strength or leads to the cracking and spalling of the coating. The magnitude of this stress is proportional to the difference between the thermal expansion coefficients of the coating and the substrate. The expansion coefficient of HA ($13.3 \times 10^{-6}/^\circ\text{C}$) is relatively higher than that of alumina ($8.0 \times 10^{-6}/^\circ\text{C}$). The expansion coefficient of the selected glass should then be an intermediate one to reduce this difference. Another important aspect of the glass is chemical durability. For biological applications, it is essential for glass to be nontoxic and stable in the body fluid. The dissolution of the glass will lead to the degradation of the coating. The HA particles will escape from the coating, and this will have an extremely negative effect, such as interfacial loosening and tissue inflammation, on the bone regeneration. The optimal properties of the glass can be achieved by adjusting the glass compositions. The glass selected in this work was borosilicate glass. Its expansion coefficient is compatible with that of Al_2O_3 substrate. No crack was found in the coating

Figure 8. The XRD spectra showing a typical HA pattern of the coating surface.

(Fig. 4). The XRD pattern of the coating (Fig. 8) shows that there is no negative reaction between the glass and HA. Figure 8 is a typical HA diffraction pattern. Mechanical properties of HA-coated reticulated alumina are ~ 7 – 10.35 MPa for compressive strength and 5 – 8 MPa for tensile strength. Compared to previously reported porous materials, such as porous HA (1.3 MPa for compressive strength and 2.5 MPa for tensile strength) and coralline ceramic (5.8 MPa for compressive strength and 1.3 MPa for tensile strength) (6), a substantial increase in strength was obtained. These values are comparable to those of cancellous bone (2 – 12 MPa for compressive strength and 10 – 20 for tensile strength) (2). Some much stronger substrate materials, such as fiber reinforced composites, are excellent candidates for the HA coating using the developed approaches discussed in this article. The mechanical properties of the substrate can also be significantly improved by other ceramics routes. In addition, after bone ingrowth, the strength of the implant (bone composites) will be expected to further increase by a factor of 2 – 7 as previously demonstrated (7).

Thermal Deposition Method

Figure 9 shows the FTIR spectra of an unfired sample and samples fired at 500 , 600 , 700 , and 900°C . According to standard IR transmission spectra, peaks observed at 3573 and 631 cm^{-1} are assigned to OH stretching and librational modes. Peaks ~ 600 and 1100 cm^{-1} are due to the bending and stretching modes of PO bonds in the phosphate groups (8). These are characteristic peaks of HA. At a sintering temperature of 500°C , PO bonds formed, but hydroxyl groups were not detected. Compared with the spectra of the unfired sample, most organic groups were burned out by this temperature. At 600°C , all the characteristic lines of HA were recorded, but some organic residual could still be seen. At 700°C and higher the peak positions match all those of standard HA, and the organic groups were not detectable.

Figure 10 shows the XRD spectra of HA sintered at different temperatures in the range of 600 – 900°C . The results of the XRD are quite consistent with that of the FTIR. The crystalline phase started to form at 600°C , and

Figure 9. The FTIR spectra of HA-coated samples sintered for 4 h at the temperature indicated (thermal deposition).

all peaks were attributed to the HA phase. According to the Scherrer equation,

$$\Delta(2\theta) = K\lambda/D \quad (1)$$

where D is the crystallite dimension; K is the Scherrer constant (here $K=0.9$); λ is the X-ray wavelength in angstroms; $\Delta(2\theta)$ is the true broadening of the diffraction peak at half-maximum intensity. The crystallite size is inversely proportional to the peak width. The broadening of peaks was evident at lower sintering temperatures, indicating the initial state of crystal formation. At higher sintering temperatures, the sharpening of peaks evidenced the growth of crystals. The peak shift could also be noted by comparing it with the standard XRD spectra of HA. At lower temperatures the shift was considerable, suggesting great lattice distortion.

Figure 10. The XRD spectra of HA samples sintered at the temperatures indicated.

Figure 11. The DTA profile of the HA-coated sample showing a reaction near 300 °C.

Monitoring the sintering process and the evolution of chemical bonds is important in determining the bioactivity of the sintered products. The material with more lattice defects would be expected to be more reactive (2). This assumption will be experimentally verified later in *in vitro* tests. The high temperature and long sintering time will result in well-crystallized products. Therefore, to enhance the bioactivity, low temperature and short sintering time is preferred. It is critical to find an optimal sintering procedure so that the sintered HA is poorly crystallized but with no organic residuals. The DTA profile (Fig. 11) shows that burn-out of organic residuals occurs over the temperature range of 300–350 °C. In the current work, the samples were baked at 500 °C to burn out the organic groups. At this temperature, the structure of the sample is amorphous and most of the organic groups can be easily removed. This procedure will be helpful in eliminating residual carbon in the coating. Without this treatment, some organics could be incorporated in the final crystal lattice. It was found that the carbon disappeared at much lower temperatures than those samples treated in a rapid sintering process because most organic groups were not burned out at low temperatures. Therefore, a higher temperature is needed to remove them. However, the reactivity of HA is considerably reduced. It should be noted that the removal of the organic residue is not only related to the microstructure, but also to the macrostate of the samples. For example, for a thick and dense coating, a high temperature is needed to remove the residual carbon.

The bonding strength between the HA coating and the substrate was determined using the tape test. No peeling of the coating film was observed for all samples, indicating a strong bonding between the HA coating and the substrate. Figure 12 is the SEM micrographs showing the surfaces of the HA coating on dense alumina. As can be seen in this figure, the coating is fairly porous, which contributes to the bioactivity when immersed in SBF. Figure 13 is an SEM image of HA-coated reticulated alumina with significant open pores in the matrix. Figure 13b is the X-ray map recorded with Ca K_{α} lines for coated porous alumina. As can be seen in Fig. 13b, the distribution of calcium demonstrated that HA is uniformly coated on the skeleton of the

Figure 12. The SEM photographs showing the coated surface for a dense alumina substrate.

substrate. Figure 14 is the SEM micrograph showing the interface between the HA coating and the substrate. The coating thickness was $\sim 1 \mu\text{m}$, which can also be altered by a second or third coating.

Bioactivity Test

Due to bioactivity of HA, dissolution occurs after the sample is immersed in SBF. Consequently, some of the elements such as calcium in the solution are expected to change. The elemental-concentration changes of calcium in the SBF solution as a function of time are given in Figs. 15,16. As can be seen in Fig. 15, both HA and HA600 exhibit an immediate uptake of the Ca concentration. Initially, there is a high rate of ion uptake, suggesting the formation of a new phase on the HA surface in supersaturated solution. After 24 h, with the depletion of supersaturation, the reaction proceeds at a lower rate of uptake. For HA900, there is an induction time of 60 min prior to a detectable decrease in Ca concentration, and the initial rate of Ca uptake is much lower than those of HA and HA600. The SHA700 behaves similarly to HA and HA600 with a slow reaction rate, as can be seen in Fig. 16. However, the reaction behaviors of SHA800 and SHA900 significantly differ from the HA samples. During the first hour, an increase of Ca concentration was measured, indicating that dissolution of SHA800 and SHA900 has surpassed the new

Figure 13. The SEM photographs showing (a) porous alumina substrate and (b) an X-ray map recorded with Ca K_{α} lines.

phase formation. Note that the rise in supersaturation for SHA900 is greater than that for SHA800. The ion uptake takes place after this initial dissolution. Another difference between HA and SHA series is that the latter took longer to reach the solid–solution equilibrium stage, clearly indicating a slower reaction rate in the HA series. These results suggest that the dissolution and precipitation rates are

critically dependent on the crystal structures developed in the HA samples.

Figure 17 represents the Ca concentration in the solution as a function of immersion time for samples Nos. 1, 2, and 3. All these samples are commercial HA heat treated at 700 °C for 30 min. Therefore, these samples are of the same structural crystallinity, but with different specific surface areas. Sample No. 3 has the highest SSA; Sample No. 1 has the lowest SSA; and Sample No. 2 is in the middle. They were tested at a ratio of 1 mg · mL⁻¹ SBF. It is apparent in Fig. 17 that the rates of precipitation are highly dependent on the surface area. From these kinetic curves, the initial

Figure 17. The Ca concentration in the solution as a function of immersion time for samples No. 1, No. 2, and No. 3.

Figure 18. Initial reaction rate versus specific area for the samples showing in Fig. 17.

rate of precipitation, R_0 , was determined by the slope of the first two data points. As shown in Fig. 18, there is a linear relationship between the initial precipitation rate and the surface area.

Figure 19 is a plot of Ca concentration versus immersion time for HA, HA600, SHA800, and SHA900. Samples of each group have been selected to have the same surface area. As can be seen, the initial rates of HAs and SHAs separate into two branches. The HA group exhibits an initial gradual decrease, while that of SHA group increases quite rapidly. However, as can also be seen in this figure, calcium concentration of SHA800 initially increases, but reaches a peak at 3 h, and thereafter decreases. In SHA900, although with a different rate, the calcium concentration always increases up to 9 h. Therefore, it can be concluded that the specific surface area is not the only factor that affects the reaction behavior of various HA samples. As discussed later, the degree of crystallinity in fact plays an even more important role in the reaction rates. The SHA700 sample behaves similarly to HA and HA600 with a slow reaction rate as can be seen in (Fig. 19). However, the reaction behaviors of SHA800 and SHA900 significantly differ from the HA samples. During the first hour, an increase of Ca concentration was measured indicating that dissolution of SHA800 and SHA900 has surpassed the new phase formation. It is noted that the rise in super-

Figure 19. The Ca concentration versus immersion time for some of the typical HA and SHA samples.

Figure 20. The SEM photograph showing the surface morphology of the SHA700 immersed in SBF for 1 week.

saturation for SHA900 is greater than that for SHA800. The ion uptake takes place after this initial dissolution. Another difference between HA and SHA series is that the latter took longer time to reach the solid–solution equilibrium stage, clearly indicating a slower reaction rate in the HA series. These results suggest that the dissolution and precipitation rates are critically dependent on the crystal structures developed in the HA samples.

Figures 20 and 21 are surfaces of SHA700 and SHA900 coatings after immersion in SBF for 1 week and 9 weeks, respectively. As can be seen, the morphology of these two surfaces is quite different. The SHA700 coating is fully converted to flake shape with an average diameter of 1–10 μm . The surface of the flakes exhibits fine, needle-like structures within 1 week, which have been identified to be HCA by IR analysis. For SHA900 coating, after 9 weeks of immersion in SBF, a layer of precipitation has been observed under high magnification, which is shown to be amorphous or poorly crystallized new phase instead of HCA.

Figure 21. The SEM photograph showing the surface morphology of the SHA900 immersed in SBF for 9 weeks.

Figure 22 shows the FTIR spectra of HA and SHA samples after immersion in SBF at time periods up to 1 week. The absorption bands at 1460 cm^{-1} (high C=O region) and 872 cm^{-1} (low CO region) are characteristic features of HCA (8). As can be seen from spectrum of HA (Fig. 22a), these bands became significantly greater after 76 h of immersion indicating an increase in carbonate content. A gradual reduction of the splitting of the major PO_4^{3-} absorption bands ($1100\text{--}1000$ and $600\text{--}550\text{ cm}^{-1}$) with immersion time is also observed, suggesting the formation of amorphous or fine, poorly crystallized new phases. For HA900, a broad band appears in the high energy C=O region (Fig. 22b). However, the low energy C=O band at 872 cm^{-1} is not recorded. At the same time, a gradual reduction of the splitting of the major PO_4^{3-} bands is observed, indicating again the formation of amorphous or fine, poorly crystallized new phases. The HCA phase cannot be identified from these weak bands, and it is likely that some intermediate phases other than HCA have formed. The HCA peaks have appeared in the spectra of SHA700 within 7 days (Fig. 22c). A time-dependent increase in the carbonate band intensities accompanied by a reduction of splitting of the major PO_4^{3-} bands is again recorded. Similar changes have occurred in the spectra of immersed SHA800 (Fig. 22d). However, no characteristic HCA peaks are recorded for SHA900 up to 3 weeks, only a broad band has appeared in the high energy C=O region (Fig. 22c). This trend seems to indicate that the reactivity of HA is considerably reduced at higher temperatures.

DISCUSSION

Structural Effects

The results indicate that *in vitro* behavior of the HA coatings is strongly affected by the structural characteristics induced by heat treatment. The SBF used in this work represents physiological ion concentration in human body, and it is supersaturated with respect to HA. In this chemical environment, HA is the most stable phase among all the calcium phosphate phases, thus the HCA formation is thermodynamically possible. However, only HA, HA600, and SHA700 have led to immediate Ca ions uptake. The HA900, SHA800, and SHA900 samples show a partial dissolution prior to precipitation. The difference in the dissolution ability of the HA samples is not the only factor in bioactivity. Figure 10 shows XRD spectra of HA sintered at different temperatures in the range of $600\text{--}900\text{ }^\circ\text{C}$. The structural evolution begins from an amorphous state in the commercial HA. Crystalline phase started to form at $600\text{ }^\circ\text{C}$, and all peaks were attributed to the HA phase. In addition, relative peak intensities are in agreement with the expected values for HA. Therefore, it can be decided that the structure consists primarily of crystalline HA, no additional peaks were observed to appear at any firing temperatures. However, the peak shift could be noted by comparing with the standard XRD spectra of HA. At lower temperatures, the shift was considerable suggesting great lattice distortion. The breadth of the peaks was used as an indicator of crystal dimension in the direction perpendicular to the diffracting plane hkl . The crystal size D is

Figure 22. The FTIR spectra of HA and SHA samples after immersion in SBF for the time indicated.

inversely proportional to the peak breadth according to the Scherer equation. The contribution to the peak breadth from instrumental broadening was determined to be $\sim 0.12^\circ\text{C}$ (0.002 rad), independent of 2θ . This amount subtracted from the total experimental width is the value of true broadening, assuming the two contributions add linearly. The peak breadth (D002) is given as a function of temperature in (Fig. 23). It can be seen that the peak breadth decreases with sintering temperature, indicating that the crystal size increases with increasing sintering temperature, from 600 to 900°C . On the basis of above analysis, the important difference with annealing temperature was the size of the individual crystals and the amount of crystal defects.

It is possible that the crystal growth rate is controlled by more than one of the elementary rate controlling mechanisms. The rate controlling process can change depending on particle size, solution concentration, and surface properties of the crystallites. The mechanisms of crystal growth are usually interpreted from measured reaction rates at different driving forces or from the activation energies of reactions. It is common practice to fit the data to an empirical rate law, which is represented by simple empirical kinetics (9):

$$R_g = k_g s \sigma^n \quad (2)$$

where k_g is the rate constant for crystal growth, s is a function of the total number of available growth sites, σ is the degree of supersaturation, and n is the effective order of reaction. A broad empirical test for growth mechanism can be achieved from a logarithmic plot of Eq. 2. From the n

value, the probable mechanism can be deduced. It is possible that the crystal growth rate is controlled by more than one of the elementary rate controlling mechanisms listed above. Under these circumstances, the rate-limiting steps are dependent on the jump frequency of lattice ions: (1) through the solution for mass transport control; (2) to the crystal surface for adsorption control, or (3) along the crystal surface or into a crystal lattice kink site for spiral and polynuclear control. The rate controlling process can change depending on particle size, solution concentration, and surface properties of the crystallites. A broad empirical

Figure 23. The X-ray diffraction peak breadth versus processing temperature for the HA synthesized in this study.

test for growth mechanism can be achieved by plotting the data according to Eq. 2. An effective order reaction in the range $0 < n < 1.2$, $n \sim 2$, or $n > 2.5$ indicates that the rate controlling process is one of adsorption and/or mass transport, surface spiral, or polynucleation, respectively (9). Experimentally, it is found that the growth rates of the calcium phosphates are insensitive to changes in fluid dynamics indicating surface controlling mechanisms rather than mass transport of ions to the crystal surfaces. A dynamic fluid may effect the growth rate, but not in a pronounced fashion. However, in our experiment, we found the growth to be insensitive. But we have no comparison of growth rates in both static and dynamic fluids.

Temperature Dependence of Activation Energy

Activation energies, obtained from experiments at different temperatures, can be used to differentiate between volume diffusion and surface controlled processes. The activation energy for volume diffusion, reflecting the temperature dependence of the diffusion coefficient, usually lies between 16 and 20 $\text{kJ} \cdot \text{mol}^{-1}$, while for a surface reaction the value may be in excess of 35 $\text{kJ} \cdot \text{mol}^{-1}$. If a reaction has activation energy of $< 20 \text{ kJ} \cdot \text{mol}^{-1}$, it is safe to assume that it is overwhelmingly controlled by volume diffusion. However, if the activation energy is higher than 35 $\text{kJ} \cdot \text{mol}^{-1}$, it is quite certain that an adsorption process predominates. In all other cases, both adsorption and volume diffusion mechanisms may participate for a first-order reaction (10).

Figure 17 represents the Ca concentration in solutions as a function of immersion time at different surface areas. These samples were the same kind of powders to ensure that they have the same crystal structure and surface morphology; while the ratio of surface area to volume of SBF was different. It is apparent in Fig. 17 that the rates of precipitation were highly dependent on the surface area. Based on the empirical kinetics in Eq. 2, to build a relationship between the reaction rate R_g and surface area s , the degree of supersaturation σ should be kept at a constant value. The corresponding reaction rates were calculated by a simple fitting procedure from the above kinetic plots. As shown in Fig. 18, there was a linear relationship between the precipitation rates and the total surface area, which is in agreement with the above empirical kinetics equation. This result also showed that crystallization occurred only on the added seed materials without any secondary nucleation or spontaneous precipitation. Furthermore, the advantage of porous bioceramics over dense bioceramics was proved by this relationship.

The initial precipitation rate was not used here because of the following considerations. First, the empirical fitting procedure used to calculate R_0 is greatly affected by the slower rates occurring after the initial fast stage of the precipitation process. Thus, the fitting data could not represent the true initial rate. Second, initial rate was a complicated factor. Rapid adjustment of surface composition usually happened when the solids were introduced into the growth or dissolution media. In the case of HA, initial uptaking surges were observed, which might be attributed to calcium ion adsorption. Therefore, considerable uncertainties can arise if too much emphasis is placed upon initial rates of reaction.

Another point needed to be noted was that in this test, the different surface areas were not originated from the distribution of particle sizes, considering that different particle sizes might bring in the factor of surface morphology, which has great influence on the reaction rate. The effect of particle size would be demonstrated later. In the current method, the same powders were used, so that the factor of morphology was eliminated and a linear relationship was obtained.

The particles of different sizes behaved differently under the same surface area to volume (SA/V) test conditions. When comparing the 40–100-mesh and < 200 -mesh particles at SA/V of $0.02 \text{ m}^2 \cdot \text{mL}^{-1}$, it is apparent that the Ca adsorption rate is slower for the smaller particles. This may be attributed to physical differences such as the radius of curvature and surface roughness.

Figure 19 is a plot of Ca concentration verses immersion time for HA, HA600, and SHA800, SHA900. Samples of each group were tested under the same SA/V ratio. As can be seen, the initial rate of HA was greater than that of HA600; the behavior of SHA800 differed from the one of SHA900. Therefore, it is concluded that the specific surface area is not the only reason that affects the reaction behavior of various HA powders, the degree of crystallinity also plays an important role in their reaction rates.

Chemical reactions, specifically in this case, the process of nucleation and crystal growth from solution, is described as an activated process with temperature, which is represented by the following relationship:

$$\text{rate} \propto \exp\left(-\frac{E_a}{kT}\right) \quad (3)$$

where E_a is the activation energy, so that reaction rate increases exponentially with temperature increase. The reaction rate constant K is related to temperature by an Arrhenius equation:

$$K = K_0 \exp\left(-\frac{E_a}{kT}\right) \quad (4)$$

By keeping σ at a constant value, plot $\ln R$ versus $1/T$, the slope of the curve will be E_a/k , and consequently E_a can be calculated.

According to the procedures described above, the activation energy for HA, HA600, HA900, and SHA700 was calculated. The parameter σ was selected at $\Delta\text{Ca} = -8\text{mM}$ for all the reaction temperatures. The computed activation energy was listed in Table 3. The above results showed that the activation energy increased with the sintering temperature for HA powders. The activation energy of synthesized HA700 was much higher than those of HA and HA600.

In Vitro Biochemistry Behavior of Hydroxyapatite

The formation of biological apatite on the surface of implanted synthetic calcium phosphate ceramics goes

Table 3. Activation Energies for the Samples Indicated

Samples	Activation energy, $\text{kJ} \cdot \text{mol}^{-1}$
HA	66.3
HA600	80.3
HA900	172.7
SHA700	130.4

through a sequence of chemical reactions. It has been shown that the reaction rate *in vitro* appears to correlate with the rate of apatite mineral formation *in vivo*.

Therefore, the laboratory observations can be projected to the *in vivo* situation. The *in vitro* behavior of bioceramics is determined by its stability at ambient and body temperatures. Many factors have significant influence on their stability, including the pH and supersaturation of the solution, crystallinity, structure defects, and porosity of the material (11,12). Driessens (13) showed that, among the phases composed of calcium and phosphate, hydroxyapatite is the most stable at room temperature when in contact with SBF, which was used to represent the ionic concentrations of plasma. Generally, SBF will initiate a partial dissolution of the HA material causing the release of Ca^{2+} , HPO_4^{2-} , and PO_4^{3-} , and increasing the supersaturation of the microenvironment with respect to HA phase that is stable in this environment. Following this initial dissolution is the reprecipitation. Carbonate ions, together with other electrolytes, which are from the biological fluids, become incorporated in the new apatite microcrystals forming on the surfaces of the HA.

Since any clinical use of calcium phosphate bioceramics involves contact with water, it is important to understand the stability of HA in the presence of water at ambient temperatures. As Driessens showed (13), there were only two classes of calcium phosphate materials that were stable at room temperature when in contact with aqueous solution. Temperature, ionic strength, and pH are major parameters influencing the stability of calcium phosphate. In the body, temperature and ion strength are constant, therefore, the pH value at the local tissue determines which form of calcium phosphate is the most stable. At a pH < 4.2, the component $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ was the most stable, while at higher pH (> 4.2), HA was the stable phase. However, HA does not form at the first place. Other mineral phases such as dicalcium phosphate dihydrate (DCPD), octacalcium phosphate (OCP), and amorphous tricalcium phosphate (TCP) form as precursor phases that transform to HA.

Therefore, in this *in vitro* test, at biological pH value, only HA or its precursor phase can be found in contact with SBF. It is believed that synthetic HA ceramic surfaces can be transformed to biological apatite through a set of reactions including dissolution, precipitation, and ion exchange. Following the introduction of HA to SBF, a partial dissolution of the surface is initiated causing the release of Ca^{2+} , HPO_4^{2-} , and PO_4^{3-} , which increases the supersaturation of the microenvironment with respect to the stable (HA) phase. Carbonated apatite can form using the calcium and phosphate ions released from partially dissolving ceramic HA and from the biological fluids that contain other electrolytes, such as CO_3^{2-} and Mg^{2+} . These become incorporated in the new CO_3 -apatite microcrystals forming on the surfaces of ceramic HA crystals. The *in vitro* reactivity of HA is governed by a number of factors, which can be considered from the two aspects: *in vitro* environment and properties of HA material.

CONCLUSIONS

In order to produce highly strengthened porous bioactive materials for bone substitutes, suspension method and

thermal deposition method, were employed to coat the inner-pore surfaces of a porous ceramic substrate. A thin layer of HA has been uniformly coated onto inner-pore surfaces of reticulated alumina substrates. The *in vitro* bioactivity of HA coatings was found to be strongly affected by structure characteristics, which are a combination of crystallinity and specific surface area. The bioactivity is reduced at a higher degree of crystallinity, which is likely related to the higher driving force for the formation of a new phase, and the reaction rate was proportional to the surface area. The surface morphology and HA treating temperature also have a direct affect on the reaction rates of the HA coatings. The calcium absorption rate is slower for smaller particles; this could be attributed to physical differences including radius of curvature and surface roughness. The activation energy increased with the heat-treatment temperature for HA powders.

INTRODUCTION

Tissue engineering offers an alternative to whole organ and tissue transplantation for diseased, failed, or abnormally functioning organs. Millions suffer from end-stage organ failure or tissue loss annually. In the United States alone, at least 8 million surgical operations are carried out each year at a total national healthcare cost exceeding \$400 billion annually (1–4). Approximately 500,000 coronary artery bypass surgeries are conducted in the United States annually (5). Autologous and allogenic natural tissue, such as the saphenous vein or the internal mammary artery, is generally used for coronary artery replacement. The results have been favorable for these procedures with patency rates generally ranging from 50–70%. Failures are caused by intimal thickening due largely to adaptation of the vessel in response to increased pressure and wall shear stress, compression, inadequate graft diameter, and disjunction at the anastomosis. Also, successful treatment has been limited by the poor performance of the synthetic materials used, such as polyethyleneterephthalate (PET, Dacron) and expanded polytetrafluoroethylene (ePTFE, Gore-Tex), which are used for tissue replacement due to plaguing problems (6). For example, in cases of tumor resection in the head, neck, and upper and lower extremities, as well as in cases of trauma and congenital abnormalities, there are often outline defects due to the loss of soft tissue, this tissue is largely composed of subcutaneous adipose tissue (7). The defects lead to abnormal cosmesis, affect the emotional comfort of patients, and may impair function. A surgeon would prefer to use an autologous adipose tissue to sculpt contour deformities. Because mature adipose tissue does not transplant effectively, numerous natural, synthetic, and hybrid materials have been used to act as adipose surrogates. Despite improved patient outcomes, the use of many of these materials results in severe problems, such as unpredictable outcomes, fibrous capsule contraction, allergic reactions, suboptimum mechanical properties, distortion, migration, and long-term resorption.

To offset the short supply of donor organs as well as the problems caused by the poor biocompatibility of the biomaterials used, a new hybridized method of “tissue engineering”, which combines both cells and biomaterials has been introduced (8). To reconstruct new tissue by tissue engineering, a triad of components are required: (1) harvested and dissociated *cells* from the donor tissue including nerve, liver, pancreas, cartilage, and bone as well as embryonic stem, adult stem, or precursor cell; (2) *scaffolds*

made of biomaterials on which cells are attached and cultured, then implanted at the desired site of the functioning tissue; (3) *growth factors* that promote and/or prevent cell adhesion, proliferation, migration, and differentiation by up-regulating or down-regulating the synthesis of protein, growth factors, and receptors (see Fig. 1). In a typical application for cartilage regeneration, donor cartilage is harvested from the patient and dissociated into individual chondrocyte cells using enzymes as collagenase, and then mass cultured *in vitro*. The chondrocyte cells are then seeded onto a porous and synthetic biodegradable scaffold. This cell–polymer structure is massively cultured in a bioreactor. The abnormal tissue is removed and the cell–polymer structure is then implanted in the patient. Finally, the synthetic biodegradable scaffold resorbs into the body and the chondrocyte cell produces collagen and glycosaminoglycan as its own natural extracellular matrix (ECM), which results in regenerated cartilage. This approach can theoretically be applied to the manufacture of almost all organs and tissues except for organs such as the brain (3).

In this section, a review is given of the biomaterials and procedures used in the development of tissue-engineered scaffolds, including: (1) natural and synthetic biomaterials, (2) natural–synthetic hybrid scaffolds, (3) the fabrication methods and techniques for scaffolds, (4) the required physicochemical properties for scaffolds, and (5) cytokine-released scaffolds.

Figure 1. Tissue engineering triad. The combination of three key elements, cells, biomaterials, and signaling molecules, results in regenerated tissue-engineered neo-organs.

BIOMATERIALS FOR TISSUE ENGINEERING

The Importance of Scaffold Matrices in Tissue Engineering

Scaffolds play a very critical role in tissue engineering. Scaffolds direct the growth (1) of cells seeded within the porous structure of the scaffold, or (2) of cells migrating from surrounding tissue. Most mammalian cell types are anchorage dependent; the cells die if an adhesion substrate is not provided. Scaffold matrices can be used to achieve cell delivery with high loading and efficiency to specific sites. Therefore, the scaffold must provide a suitable substrate for cell attachment, cell proliferation, differentiated function, and cell migration. The prerequisite physicochemical properties of scaffolds are (1) to support and deliver the cells; (2) to induce, differentiate, and promote conduit tissue growth; (3) to target the cell-adhesion substrate, (4) to stimulate cellular response; (5) to create a wound healing barrier; (6) to be biocompatible and biodegradable; (7) to have relatively easy processability and malleability into the desired shapes; (8) to be highly porous with large surface-volume; (9) to have mechanical strength and dimensional stability; and (10) to have sterilizability (9–16). Generally, three-dimensional (3D) porous scaffolds can be fabricated from natural and synthetic polymers (Fig. 2 shows these chemical structures), ceramics, metal, and in a very few cases, composite biomaterials and cytokine-releasing materials.

Natural Polymers

Many naturally occurring scaffolds can be used for tissue engineering purposes. One such example is the ECM, which is composed of very complex biomaterials and controls cell function. For the ECM used in tissue engineering, natural and synthetic scaffolds are designed to mimic specific function. The natural polymers used are alginate, proteins, collagens (gelatin), fibrins, albumin, gluten, elastin, fibroin, hyaluronic acid, cellulose, starch, chitosan (chitin), sclerolucan, elsinan, pectin (pectinic acid), galactan, curdlan, gellan, levan, emulsan, dextran, pullulan, heparin, silk, chondroitin 6-sulfate, polyhydroxyalkanoates, and others. Much of the interest in these natural polymers comes from their biocompatibility, relatively abundance and commercial availability, and ease of processing (17).

Alginate. Alginate (from seaweed) is composed of two repeating monosaccharides: L-guluronic acid and D-mannuronic acid. Repeating strands of these monomers form linear, water-soluble polysaccharides. Gelation occurs by interaction of divalent cations (e.g., Ca^{2+} , Mg^{2+}) with blocks of guluronic acid from different polysaccharide chains (as shown in Fig. 3). From this gelation property, the encapsulation of calcium alginate beads impregnated with various pharmaceuticals, cytokines, or cultured cells, has been extensively investigated. Varying the preparation conditions of the gelation can control structure and physicochemical properties. Calcium alginate scaffolds do not degrade by hydrolytic reaction, whereas they can be degraded by a chelating agent such as ethylenediaminetetraacetic acid (EDTA) or by an enzyme. Also, the diffusion

of calcium ions from an alginate gel can cause dissociation between alginate chains, which results in a decrease of mechanical strength over time. One of the disadvantages of an alginate matrix is a potential immune response and the lack of complete degradation, since alginate is produced in the human body (10). For these reasons, the chemical modification and incorporation of biological peptides, such as Arg-Gly-Asp cell adhesion peptides, have been used to improve the functionality and flexibility of natural scaffolds and their potential application (18).

Many researchers have studied the encapsulation of chondrocytes. Growth plate chondrocytes, fetal chondrocytes, and mesenchymal stem cells derived from bone marrow have been encapsulated in alginate (19). In each system, the chondrocytes demonstrated a differentiated phenotype, producing an ECM and retaining the cell morphology of typical chondrocytes. In addition, novel hybrid composites, such as alginate/agarose (a thermosensitive polysaccharide), alginate/fibrin, alginate/collagen and alginate/hyaluronic acid, and different gelling agents (water, sucrose, sodium chloride, and calcium sulfate) were investigated to optimize the advantages of each component material for tissue engineered cartilage (20–22). It was found that this hybrid material provides a reason why the microenvironments of composite materials affect chondrogenesis.

Collagen. At least 22 types of collagen exist in the human body. Among these, collagen types I, II, and III are the most abundant and ubiquitous. Conformation of the collagen chain consists of triple helices that are packed or processed into microfibrils. Molecularly, the three repeating amino acid sequences, such as glycine, proline, and hydroxyproline, form protein chains resulting in the formation of a triple helix arrangement. Type I collagen is the most abundant and is the major constituent of bone, skin, ligament, and tendon, whereas type II collagen is the collagen in cartilage. Collagen can promote cell adhesion as demonstrated by the Asp-Gly-Glu-Ala peptide in type I collagen, which functions as a cell-binding domain. Due to the abundance and ready accessibility of these tissues, they have been used frequently in the preparation of collagen (23).

The purified collagen materials obtained from either molecular or fibrillar technology are subjected to additional processing to fabricate the materials into useful scaffold types for specific tissue-engineered organs. Collagen can be processed into several types such as membrane (film and sheet), porous (sponge, felt, and fiber), gel, solution, filamentous, tubular (membrane and sponge), and composite matrix for the application of tissue repair, patches, bone and cartilage repair, nerve regeneration, and vascular and skin repair with/without cells (24). The Physicochemical properties of collagen can be improved by the addition of a variety of homogeneous and heterogeneous composites. Homogeneous composites can be formed between ions, peptides, proteins, and polysaccharides in a collagen matrix by means of ionic and covalent bonding, entrapment, entanglement, and coprecipitation. Heterogeneous composites, such as collagen-synthetic polymers, collagen-biological polymers, and collagen-ceramic hybrid

polymers (collagen–nano-hydroxyapatite and collagen–calcium phosphate) have been investigated for use in tissue-engineered products (10).

Fibrin. Fibrin plays a major role during wound healing as a hemostatic barrier to prevent bleeding and to support a natural scaffold for fibroblasts. Actual polymerization is triggered by the conversion of fibrinogen to fibrin monomer by thrombin, and gelation occurs within 30–60 s. One advantage of using fibrin in this manner is its ability to completely fill the defect by gelling in situ. Fibrin sealant composed of fibrinogen and thrombin in addition to antifibrinolytic agents has been used already in such surgical applications as sealing lung tears, cerebral spinal fluid leaks, and bleeding ulcers, because of its natural role in wound healing. Fibrin sealant might be made from autologous blood or from recombinant proteins (22). Fibrin gels can degrade either through hydrolytic or proteolytic means. Fibrinogen is commercially available from several manufacturers, so the cost of the fabrication of fibrin gels is relatively low. Recently, much work has been done to develop fibrin as a potential tissue-engineered scaffold matrix, especially for cartilage, which is formed from a fibrin/chondrocyte construct. Biochemical and mechanical analysis has demonstrated its cartilage-like properties. In neural tissue engineering, fibrin modified the incorporation of bioactive peptide in fibrin gels (25). Also, fibrin/hydroxyapatite hybrid composites have been investigated to optimize the mechanical strength of tissue-engineered subchondral bone substitutes.

Hyaluronan. Hyaluronic acid, a natural glycosaminoglycans polymer, can be found in abundance within cartilaginous ECM. It has some disadvantages in its natural form, such as high water solubility, fast resorption, and fast tissue clearance times, which are not conducive to biomaterials. To overcome these undesirable characteristics,

chemical modifications were made to increase biocompatibility, tailor the degradation rate, control water solubility, and to fit the mechanical property. To increase hydrophobicity, esterification was carried out to increase the hydrocarbon content of the added alcohol, which resulted in tailored degradation rates since hydrophobicity directly influences hydration and the deesterification reaction (10). Another approach, the condensation reaction between the carboxylic group of unmodified hyaluronan molecules with the hydroxyl group of other hyalunonic acid molecules, was used to fabricate the sponge form. Then, bone marrow-derived mesenchymal progenitor cells were seeded to induce chondrogenesis and osteogenesis on this scaffold. Results from animal studies indicate that modified hyaluronic acid can successfully support mesenchymal stem cell proliferation and differentiation for osteochondral application (15). Also, a sulfate reaction on a hyaluronan gel created a variety of sulfate derivatives, ranging from one-to-four sulfate groups per disaccharide subunit. A crosslinking network hydrogel can be formed by using diamines from individual hyaluronic acid chains. Chondrocytes seeded on sulfated hyaluronic acid hydrogels appear to have good cell compatibility with the tissue-engineered cartilage. The benzyl ester hyaluronan products HYAFF-11 and LaserSkin (Fidia Advanced Biopolymers, FAB, Abano Terme, Italy) have been introduced to engineer skin bilayers *in vitro* (26).

Chitosan. Chitosan, a polysaccharide derived from chitin, is composed of a simple glucosamine monomer and has physicochemical properties similar to many glycosaminoglycans. Chitosan is relatively biocompatible and biodegradable; it does not evoke a strong immune response. It is relatively cheap due to its abundance and good reactivity with diverse methods of chemical processing. Chitin is typically extracted from arthropod shells by means of acid–alkali treatment to hydrolyze acetamido groups from the *N*-acetylglucosamine resulting in the production chitosan. It has a molecular weight of 800,000–1,500,000 g·mol⁻¹ and dissolves easier than the native chitin polymer (27). For its use in the tissue-engineered cartilage, a 3D composite, such as a chondroitin sulfate A/chitosan hydrogel scaffold, was prepared. This hydrogel supported a differentiated phenotype of seeded articular chondrocytes and type II collagen and proteoglycan production (28). Also, the organic–inorganic hybrid scaffold, used as a chitosan/tricalcium phosphate scaffold, was fabricated for tissue-engineered bone. When osteoblast cells collected from rat fetal calvary were seeded onto a chitosan/tricalcium phosphate scaffold, the cells proliferated in a multiplayer manner and deposited a mineralized matrix (29).

Agarose. Agarose is another type of marine source polysaccharide purified extract from sea creatures, such as agar or agar-bearing algae. One of the unique properties of agarose is the formation of a thermally reversible gel, which starts to set at a concentration in excess of 0.1% at a temperature ~40 °C and a gel melting temperature of 90 °C. Agarose gel is widely used in the electrophoresis of proteins and nucleic acid. Its good gelling behavior could make it a suitable injectable bone substitute and cell

carrier matrix (17). Allogenic chondrocyte-seeded agarose gels have been used as a model to repair osteochondral defects *in vivo*. The repaired tissues were scored histologically based on the intensity and extent of the proteoglycan and the type II collagen immunoassay, the structural features of the various cartilaginous zones, integration with host cartilage, and the morphological features and arrangement of chondrocytic cells. The allogenic chondrocyte–agarose-grafted repairs had a higher semiquantitative score than control grafts. These results showed a good potential for use in tissue engineering (30). More detailed studies, such as the *in vivo* mechanical properties, biocompatibility and toxicity, and the balance degradation and synthesis kinetics of agarose-based tissue-engineered products, must be undertaken to further successful agarose applications (31).

Small Intestine Submucosa. Porcine small intestine submucosa (SIS) is an important material for natural ECM scaffolds (15). Many experiments have shown systematically that an acellular resorbable scaffold material, derived from SIS, is rapidly resorbed, supports early and abundant new blood vessel growth, and serves as a template for the constructive remodeling of several body tissues including musculoskeletal structures, skin, body wall, dura mater, urinary bladder, and blood vessels (32). The SIS material consists of a naturally occurring ECM, rich in components that support angiogenesis, including fibronectin, glycosaminoglycans including heparin, several collagens (including types I, III, IV, V, and VI), and angiogenic growth factors such as basic fibroblast growth factor and vascular endothelial cell growth factor (33). For these reasons, SIS scaffolds have been successfully used to reconstruct the urinary bladder, for vascular grafts, to reconstruct cartilage and bone alone or as a composite with synthetic polymers and inorganic biomaterials (34).

Acellular Dermis. Acellular human skin, that is skin removed of all cellular components, may be one of the most significant ECMs. An acellular dermis can be seeded with fibroblasts and keratinocytes to fabricate a dermal–epidermal composite for the regeneration of skin. AlloDerm (LifeCell, Branchburgh, NJ) is a typical commercialized product, a split-thickness acellular allograft prepared from human cadaver skin and cryopreserved for off-shelf use (35). Alloderm has been successful in the treatment of burn patients because of its nonantigenic dermal scaffold that includes elastin, proteoglycan, and basement membrane.

Poly(hydroxyalkanoates). Poly(hydroxyalkanoates) are entirely natural and are obtained from the microorganism *Alcaligen eutrophus* as Gram-negative bacteria. The physical properties of polyhydroxybutyrate (PHB) are similar to nondegradable polypropylene. Its copolymers with hydroxyvalerate [poly(hydroxybutylate-*co*-hydrovalerate); PHBV] have a modest range of mechanical properties and a correspondingly modest range of chemical compositions for monomers and processing conditions. Due to their good processability, these polymers can be manufactured into many forms, such as fibers, meshes, sponges, films, tubes, and matrices through standard processing techniques.

The family of poly(hydroxyalkanoates) does not appear to cause any acute inflammation, abscess formation, or tissue necrosis in whethers in the form of nonporous disks or cylinders, adjacent tissues (36). To optimize the mechanical property of PHBV, organic–inorganic hybrid composites such as PHBV–hydroxyapatite were developed for the tissue engineering of bone; hydroxyapatite promotes osteoconductive activity (13). Also, Schwann cell-seeded PHB was applied to regenerate a nerve in the shape of a conduit to guide and induce neonerve tissue at the nerve ends. Good nerve regeneration in PHB conduits as compared to nerve grafts was observed. The shape, mechanical strength, porosity, thickness, and degradation rate of PHB and its copolymers can be engineered.

Other Natural Polymers. Excluding those polymers discussed in the Natural Polymers section above, other natural polymers, are proteins, albumin, gluten, elastin, fibroin, cellulose, starch, sclerolucan, elsinan, pectin (pectinic acid), galactan, curdlan, gellan, levan, emulsan, dextran, pullulan, heparin, silk, and chondroitin 6-sulfate. Although they are not discussed here, these biopolymers are of interest because of their unusual and useful functional properties as well as their abundance. This group of natural polymers are (1) biocompatible and nontoxic, (2) easily processed as film and gel, (3) heat stable and thermal processable over a broad temperature range, and (4) water soluble (17). *In vivo* and *in vitro* experiments, and physicochemical modifications should be performed in the near future to promote the use of these natural polymers in tissue-engineered scaffolds.

Synthetic Polymers

Natural polymers are not used more extensively because they are expensive, differ from batch to batch, and there is a possibility of cross-contamination from unknown viruses or unwanted diseases due to their isolation from plant, animal, and human tissue. Alternatively, synthetic polymeric biomaterials have easily controlled physicochemical properties and quality, and no immunogenicity. Also, they can be processed by various techniques and supplied consistently in large quantities. To adjust the physical and mechanical properties of a tissue-engineered scaffold at a desired place in the human body, the molecular structure, and molecular weight are adjusted during the synthetic process. Synthetic polymers are largely divided two categories: biodegradable, and nonbiodegradable. Some nondegradable polymers include poly(vinylalcohol) (PVA), poly(hydroxyethylmethacrylate), and poly(*N*-isopropylacrylamide). Some synthetic degradable polymers are in the family of poly(α -hydroxy ester)s, such as polyglycolide (PGA), polylactide (PLA) and its copolymer poly(lactide-*co*-glycolide) (PLGA), polyphosphazene, polyanhydride, poly(propylene fumarate), polycyanoacrylate, polycaprolactone, polydioxanone and biodegradable polyurethanes.

Between these two polymers, synthetic biodegradable polymers are preferred for use in tissue-engineered scaffolds because they have minimal chronic foreign body reactions and they promote the formation of completely natural tissue. That is, they can form a temporary scaffold

for mechanical and biochemical support. More detailed polymer fabrication methods are discussed in the section, Scaffold Fabrication and Characterization.

Poly(α -Hydroxy Ester)s. The family of poly(α -hydroxy acid)s, such as PGA, PLA, and its copolymer PLGA, are among the few synthetic polymers approved for human clinical use by the U.S. Food and Drug Administration (FDA). These polymers are extensively used or tested as scaffold materials, because they are as bioerodible with good biocompatibility, have controllable biodegradability, and relatively good processability (37). This family of poly(α -hydroxy ester)s has been used for three decades: PGA as a suture; PLA in bone plate, screw and reinforced materials; and PLGA in surgical and drug delivery devices. The safety of these materials has been proved for many medical applications (38–47).

These polymers degrade by nonspecific hydrolytic scission of their ester bonds. Polyglycolide biodegrades by a combination of hydrolytic scission and enzymatic (esterase) action producing glycolic acid, which can either enter the tricarboxylic acid (TCA) cycle or be excreted in urine and eliminated as carbon dioxide and water. The hydrolysis of PLA yields lactic acid, which is a normal byproduct of anaerobic metabolism in the human body and is incorporated in the TCA cycle to be excreted finally by the body as carbon dioxide and water. With the addition of a methyl group to glycolide, PLA is much more hydrophobic than the highly crystalline PGA. As a result, PLA has a slower degradation rate over a year's time. The degradation time of PLGA as a copolymer can be controlled from weeks to over a year by varying the ratio of monomers, its molecular weight, and the processing conditions. The synthetic methods and physicochemical properties, such as melting temperature, glass transition temperature, tensile strength, Young's modulus, and elongation, were reviewed elsewhere (48).

The mechanism of biodegradation of poly(α -hydroxy acid)s is bulk degradation, which is characterized by a loss in polymer molecular weight, while its mass is maintained. Mass maintenance is useful for tissue-engineering applications that require a specific shape. However, a loss in molecular weight causes a significant decrease in mechanical properties. Degradation depends on its chemical history, porosity, crystallinity, steric hindrance, molecular weight, water uptake, and pH. Degradable products, such as lactic acid and glycolic acid, decrease the pH in the surrounding tissue resulting in inflammation and potentially poor tissue development. The PGA, PLA, and PLGA scaffolds are applied for the regeneration of all tissue, including skin, cartilage, blood vessel, nerve, liver, dura mater, bone, and other tissue (10,12,17). For the application of these polymers as scaffolds, the development of fabrication methods for porous structures is also important.

The hybrid structure of chondrocytes and fibroblast/PGA fiber felts was successfully tested in the regeneration of cartilage and skin, respectively (49). Also, porous PLGA scaffolds with an average pore sizes of 150–300 or 500–710 μm were seeded with osteoblast cells, which resulted in good bone generation. Composites of PLA/tricalcium phos-

phate and PLA/hydroxyapatite were attempted to induce bone formation both *in vitro* and *in vivo* (13,50). Porous PLA tubes with an inside diameter of 1.6 mm, an outside diameter of 3.2 mm, and lengths of 12 mm, were implanted into 12 mm gaps in the rat sciatic nerve model. Compared to control grafts, both the number and density of axons were significantly less for the tabulated implants. The PGA tube was also tested for the regeneration of vascular grafts, and showed good *in vivo* results.

To improve the physicochemical properties of poly(α -hydroxy acid)s for use as scaffold materials, the chemical modification of both end groups of PLA and PGA was undertaken; the additional reaction of the moieties helps to control the biological and/or physical properties of biomaterials (17). For example, poly(lactic acid-*co*-lysine-*co*-aspartic acid) (PLAL-ASP) was synthesized to add a cell adhesion property. Similarly, a copolymer of lactide and ϵ -caprolactone was synthesized to improve the elastic property of PLA. The PLA-poly(ethylene oxide) (PEO) copolymers were synthesized to have the degradative and mechanical properties of PLA and the biological control offered by PEO and its functionalization (51). One of the unique characteristics of PLA-PEO block copolymers is its temperature sensitivity. Because of the hydrophobicity of PLA and hydrophilicity of PEO, the sol-gel property can be applied to injectable cell carriers. Also, a nano-hybrid composite with other materials has been developed for application to all organs in the body.

Poly(vinyl Alcohol). Poly(vinyl alcohol) is synthesized from poly(vinyl acetate) by saponification. The result is a hydrogel that contains some water, which is similar to cartilage. It is relatively biocompatible, swells with a large amount of water, easily sterilized, and easily fabricated and molded into desired shapes. It has a reactive pendant alcohol group that can be modified by chemical cross-linking, physical cross-linking, or by incorporating an acrylate group, which results in improvement of its mechanical properties. A typical commercialized PVA gel is Salubria (Salumedia, Atlanta, GA), which was created by completing a series of freeze-thaw cycles with PVA polymers and 0.9% saline solution. By changing the ratio of PVA and H_2O , the molecular weight of PVA, and the quantity and duration of the freeze-thaw cycles, the physical properties of the PVA hydrogel can be controlled. Poly(vinyl alcohol) has been used in cartilage regeneration; it has similar mechanical properties needed in breast augmentation, diaphragm replacement, and bone replacement (10). One significant drawback is that it is not fully biodegradable because of the lack of labile bonds within the polymer backbone. So, it is recommended that low molecular weight PVA, $\sim 15,000 \text{ g} \cdot \text{mol}^{-1}$, which can be absorbed through the kidney, might be applied to tissue-engineered scaffolds.

Polyanhydride. Polyanhydride is synthesized by the reaction of diacids with anhydride to form acetyl anhydride prepolymers. High molecular weight anhydrides are synthesized from the anhydride prepolymer in a melt condensation. Polyanhydrides are modified to increase their physical properties by a reaction with imides (17). A typical example of this is copolymerization with an

aromatic imide monomer that results in the polyanhydride-*co*-imide used in hard tissue engineering. To control degradability and to enhance mechanical properties, photo-crosslinkable functional groups were introduced by the substituted methacrylate groups on polyanhydrides for orthopedic tissue engineering (48,50). The degradation mechanism of polyanhydrides is a highly predictable and controlled, surface erosion whereas that of poly(α -hydroxy ester) is bulk erosion. To optimize the degradation behavior of anhydride-based copolymers, the polymer backbone chemistry needs to be controlled to achieve a ratio of monomer and molecular weight.

Poly(Propylene Fumarate). Poly(propylene fumarate) and its copolymer, a biodegradable and unsaturated linear polyester, were synthesized as potential scaffold biomaterials. The degradation mechanism is a hydrolytic chain scission similar to poly(α -hydroxy ester). The mechanical strength and degradable behaviors were controlled by crosslinking with a vinyl monomer at the unsaturated double bonds. The physical properties are enhanced by a composite with degradable bioceramic β -tricalcium phosphate, which is used as injectable bone (52). Copolymerization of propylene fumarate with ethylene glycol can be made elastic with poly(propylene fumarate) and used as a cardiovascular stent. New materials for propylene fumarate polymers are continually being investigated through copolymer synthesis, hybrid composites, and blends.

PEO and Its Derivatives. Poly(ethylene oxide) is one of the most important and widely used polymers in biomedical applications because of its excellent biocompatibility (51,53,54). It can be produced by anionic or cationic polymerization from ethylene oxide by initiators. Poly(ethylene oxide) is used to coat materials used in medical devices to prevent tissue and cell adhesion, as well as in the preparation of biologically relevant conjugates, and in induction cell membrane fusion. These PEO hydrogels can be fabricated by crosslinking reactions which gamma rays, electron beam irradiation, or chemical reactions. This hydrogel can be used for drug delivery and tissue engineering. Vigilon (C.R. Bard, Inc., Murray Hill, NJ) is a radiated crosslinked, high molecular weight PEO, which swells with water and is used as a wound-covering material. The hydroxyl in the glycol end group is very active, making it appropriate for chemical modification. The attachment of bioactive molecules, such as cytokines and peptides to PEO or poly(ethylene glycol) (PEG) promotes the efficient delivery of bioactive molecules. See the section, Cytokine Release System for Tissue Engineering, for a more detailed explanation.

To synthesize biodegradable PEO, block copolymerization with PGA or PLA degradable units has been carried out. The hydrogel can be polymerized into two- or three-block copolymers such as PEO-PLA, PEO-PLA-PEO, and PLA-PEO-PLA. For the biodegradable block, ϵ -caprolactone, δ -valerolactone, and PLGA can be used (50). A characteristic of this series of hydrogels is a temperature-sensitive phenomena. A solid state at room temperature changes to a gel state at body temperature. Hence, biodegradable hydrogels are very useful in injectable cell loading

scaffolds (55). After injection of the chondrocyte cell hybrid structure and biodegradable hydrogels, the hydrogels degrade in vivo and neocartilage tissue remains.

Also, the copolymers of PEO and poly(propylene oxide) (PPO), including PPO-PEO-PPO or PEO-PPO-PEO block copolymers, are the basis for the commercially available Pluronics and Tetronics. Pluronics form a thermosensitive gel by shrinking hydrophobic segments of the copolymer PPO (54). The physicochemical property of the hydrogel can be varied with the composition and structure of the ratio of PPO and PEO. Some have been approved by the FDA and EPA for use as food additives, pharmaceutical ingredients, and agricultural products. Although the polymer is not degraded by the body, the gels dissolve slowly and the polymer is eventually cleared. Chondrocyte-loaded Pluronics, when directly injected at the injured site containing tissue-engineered cartilage, maintained its original shape in the developing neocartilage (56). Also, these polymers are used in the treatment of burn patients and for protein delivery. The advantages of these injectable hydrogels include: (1) no need for surgical intervention, (2) easy pore-size manipulation, and (3) no need for complex shape fabrication.

Polyphosphazene. Polyphosphazene consists of an inorganic backbone of alternating single and double bonds between phosphorous and nitrogen atoms, while most of the polymer is made up of a carbon-carbon organic backbone (10,12,17). It has side groups that can react with other functional groups which result in block or star polymers. Biological and physical properties can be controlled by the substitution of functional side groups. For example, the rate of degradation can be varied by controlling the proportion of hydrolytically labile side groups. The wettability such as hydrophilicity, hydrophobicity, and amphiphilicity, of polyphosphazene might be dependent on the properties of the side group. It can be made into films, membranes, and hydrogels for scaffold applications by cross-linking or grafting modifications (48). The cytocompatibility of highly porous polyphosphazene scaffolds offers possibilities for skeletal tissue engineering. Also, the blend of polyphosphazene with PLGA may be modified and its miscibility and degradability determined (57).

Biodegradable Polyurethane. Polyurethane is one of the most widely used polymeric biomaterials in biomedical fields due to its unique physical properties, such as durability, elasticity, elastomer-like character, fatigue resistance, compliance, and tolerance. Moreover, the reactivity of the functional group of the polyurethane backbone can be achieved by the attachment of biologically active biomolecules and the adjustment of their hydrophilicity-hydrophobicity (58). Recently, the synthesis of a new generation of nontoxic biodegradable peptide-based polyurethanes was achieved. Typical biodegradable polyurethane is composed of an amino acid-based hard segment (such as lysine diisocyanate), a polyol soft segment (such as a hydroxyl donor-like polyester), and sugar (59). Hence, the degradation products of these nontoxic lysine diisocyanate-based urethane polymers are nontoxic lysine and the polyol. If the covalent bonding of various proteins, such

as cytokines, growth factors, and peptides, are introduced in the polymer backbone, the controlled release of the bioactive molecules can be achieved in a degradable manner using polyurethane scaffolds. The mechanisms of degradation are hydrolysis, oxidation—both thermal, and enzymatic. Both the chemistry and the composition of soft and hard segments play an important role in the degradability of polyurethane. Poly(urethane-urea) matrices with lysine diisocyanate as the hard segment and glucose, glycerol, or PEG as the soft segments have been studied. In the application of biodegradable polyurethane as a scaffold various types of cells, such as chondrocytes, bone marrow stromal cells, endothelial cells, and osteoblast cells, were successfully adhered and proliferated. Also, toxicity, induction of a foreign body reaction, and antibody formation were not observed in *in vivo* experiments. The long-term safety and biocompatibility of biodegradable polyurethane must be continuously monitored for use in tissue-engineered scaffold substrates.

Other Synthetic Polymers. Besides the synthetic polymers already introduced in the above sections, many other synthetic polymers, either degradable or nondegradable, are being developed and tested to mimic the natural tissue and wound-healing environment. Examples are poly(2-hydroxyethylmethacrylate) hydrogel, injectable poly(*N*-isopropylacrylamide) hydrogel, and polyethylene for neocartilage; poly(iminocarbonates) and tyrosine-based poly(iminocarbonates) for bone and cornea; crosslinked collagen–PVA films and an injectable biphasic calcium phosphate–methylhydroxypropylcellulose composite for bone regeneration materials; a polyethylene oxide-*co*-polybutylene terephthalate for bone bonding; poly(orthoester) and its composites with ceramics for tissue-engineered bone; synthesized conducting polymer polypyrrole–hyaluronic acid composite films for the stimulation of nerve regeneration; and peptide-modified synthetic polymers for the stimulation of cell and tissue.

It is very important for the design and synthesis of more biodegradable and biocompatible scaffold biomaterials to mimic the natural ECM in terms of bioactivity, mechanical properties, and structures. The more biocompatible biomaterials tend to elicit less of an immune response and reduce an inflammatory response at the implantation site.

Bioceramic Scaffolds

Bioceramic is a term used for biomaterials that are produced by sintering or melting inorganic raw materials to create an amorphous or a crystalline solid body that can be used as an implant. Porous final products have been used mainly as scaffolds. The components of ceramics are calcium, silica, phosphorous, magnesium, potassium, and sodium. Bioceramics used in tissue engineering might be classified as non-resorbable (relatively inert), bioactive, or surface active (semi-inert), and biodegradable or resorbable (non-inert). Alumina, zirconia, silicone nitride, and carbons are inert bioceramics. Certain glass ceramics are dense hydroxyapatites [$9\text{CaO} \cdot \text{Ca}(\text{OH})_2 \cdot 3\text{P}_2\text{O}_5$] and semi-inert (bioactive). Calcium phosphates, aluminum–calcium–phosphates, coralline, tricalcium phosphates ($3\text{CaO} \cdot \text{P}_2\text{O}_5$), zinc-calcium-

phosphorous oxides, zinc-sulfate-calcium-phosphates, ferric–calcium–phosphorous–oxides, and calcium aluminates are resorbable ceramics (60). Among these bioceramics, synthetic apatite and calcium phosphate minerals, coral-derived apatite, bioactive glass, and demineralized bone particles are widely used in the hard tissue engineering area, hence, they will be discussed in this section.

Synthetic crystalline calcium phosphate can be crystallized into salts such as hydroxyapatite and β -whitlockite, depending on the Ca/P ratio. These salts are very tissue compatible and are used as bone substitutes in a granular, sponge form or as a solid block. The apatite formed with calcium phosphate is considered to be closely related to the mineral phase of bone and teeth. The chemical composition of crystalline calcium phosphate is a mixture of $3\text{CaO} \cdot \text{P}_2\text{O}_5$, $9\text{CaO} \cdot \text{Ca}(\text{OH})_2 \cdot 3\text{P}_2\text{O}_5$ and calcium pyrophosphate ($4\text{CaO} \cdot \text{P}_2\text{O}_5$). The active exchange of ions occurs on the surface and leads to the exchange composition of minerals (9,61). When porous ceramic scaffolds were implanted in the body, both with or without cells for tissue-engineered bone, the delivery of some elements to the new bone was at the interface between the materials and the osteogenic cells.

Tricalcium phosphate is the rapidly resorbable calcium phosphate ceramic resulting in resorption 10–20 times faster than hydroxyapatite (13). Porous tricalcium phosphate may stimulate local osteoblasts for new bone formation. Injectable calcium phosphate cement containing β -tricalcium phosphate, dibasic dicalcium phosphate, and tricalcium phosphate monoxide, was investigated for the treatment of distal radius fractures. Calcium sulfate hemihydrate (plaster of Paris), as a synthetic graft material, was also tested for tissue-engineered bone.

Coral-derived apatite (Interpore; Interpore international, Irvine, CA) is a natural substance made by marine vertebrate (62). The porous structure of coral, which is structurally similar to bone, is a unique physicochemical property that promotes its use as a scaffold matrix for bone. The main component of natural coral is calcium carbonate or aragonite, the metastable form of calcium carbonate. This compound can be converted to hydroxyapatite by a hydrothermal exchange process, which results in a mixture of hydroxyapatites, $9\text{CaO} \cdot \text{Ca}(\text{OH})_2 \cdot 3\text{P}_2\text{O}_5$, and fluoroapatite, $\text{Ca}_5(\text{PO}_4)_3\text{F}$. For tissue-engineered bone, the hybrid structure of porous coral-derived scaffolds and mesenchymal stem cells were demonstrated *in vitro*. The results showed the differentiation of bone marrow derived from stem cells to osteoblasts; successive mineralizations were successfully accomplished (63).

Glass ceramics are polycrystalline materials manufactured by controlled crystallization of glasses using nucleating agents, such as small amounts of metallic agent Pt groups, TiO_2 , ZrO_2 , and P_2O_5 , which result in a fine-grained ceramic that possesses excellent mechanical and thermal properties (60,61). Typical bioglass ceramics developed for implantations are SiO_2 -CaO- Na_2O - P_2O_5 and Li_2O -ZnO- SiO_2 systems. These bioglass scaffolds are suitable for inducing direct bonding with bone. Bonding to bone is related to the composition of each component.

One significant natural bioactive material is the demineralized bone particle, which is a powerful inducer of new

bone growth (38,41). Demineralized bone particles contain many kinds of osteogenic and chondrogenic cytokines such as bone morphogenetic protein, and are widely used as filling agent for bony defects. Because of their improved availability through the tissue bank industry, demineralized bone particles are widely used in clinical settings. To achieve more optimal results in the application of demineralized bone particles to tissue engineering, nanohybridization with synthetic (PLGA/demineralized bone particle hybrid scaffolds) and with natural organic compounds (collagen/demineralized bone particle hybrid scaffolds), has been carried out.

Porosity—the size of the mean diameter and the surface area—is a critical factor for the growth and migration of tissue into bioceramic scaffolds (60). Several methods have been introduced to optimize the fabrication of porous ceramics, such as dip casting, starch consolidation, the polymeric sponge method, the foaming method, organic additives, gel casting, slip casting, direct coagulation consolidation, hydrolysis-assisted solidification, and freezing methods. Therefore, it is very important to choose an appropriate method of preparation based on the physical properties of the desired organs.

A CYTOKINE-RELEASE SYSTEM FOR TISSUE ENGINEERING

Growth factors, a type of cytokine, are polypeptides that transmit signals to modulate cellular activity and tissue development including cell patterning, motility, proliferation, aggregation, and gene expression. As in the development of tissue-engineered organs, regeneration of functional tissue requires maintenance of cell viability and differentiated function, encouragement of cell proliferation, modulation of the direction and speed of cell migration, and regulation of cellular adhesion. For example, transforming growth factor- β_1 (TGF- β_1) might be required to induce osteogenesis and chondrogenesis from bone marrow derived mesenchymal stem cells. Also, brain-derived neurotrophic factor (BDNF) can be enhanced to regenerate the spinal cord after injury. The easiest method for the delivery of growth factor is injection near the site of cell differentiation and proliferation (4). The most significant problems associated with the direct injection method are that the growth factors have a relatively short half-life, have a relatively high molecular weight and size, display very low tissue penetration, and have potential toxicity at systemic levels (4,10,11,16).

A promising technique for the improvement of their efficacy is to locally control the release of bioactive molecules for a specified release period to promote impregnation into a biomaterial scaffold. Through impregnation into the scaffold carrier, protein structure and biological activity can be stabilized to a certain extent, resulting in prolonging the release time at the local site. The duration of cytokine release from a scaffold can be controlled by the types of biomaterials used, the loading amount of cytokine, the formulation factors, and the fabrication process. The release mechanisms are largely divided into three categories: (1) diffusion controlled, (2) degradation controlled, and (3) solvent controlled. The mechanism of biodegrad-

Figure 4. (a) Bone marrow-derived mesenchymal stem cells impregnated TGF- β_1 loaded alginate beads (original magnifications 40 \times), and (b) inner structure of alginate beads (original magnifications 100 \times).

able scaffold materials was regulated by degradation control, whereas that of the nondegradable material was regulated by diffusion and/or solvent control. The desired release pattern, such as a constant, pulsatile, and time programmed behavior over the specific site and injury can be achieved by the appropriate combination of these mechanisms. Also, the cytokine-release system's geometries and configurations can be altered to produce the necessary scaffold, tube, microsphere, injectable form or fiber (46,51,54).

Figures 4–6 show the TGF- β_1 loaded alginate bead and the release pattern of TGF- β_1 from alginate beads for the chondrogenesis from bone marrow-derived mesenchymal stem cells (64). The pore structure of 10 μm width and 100 μm length, was well suited to promote cell proliferation (Fig. 4); TGF- β_1 released at a near zero-order rate for 35 days (Fig. 5). By using the alginate bead with TGF- β_1 delivery system, chondrogenesis was successfully attained, as shown in Fig. 6.

To fabricate a new sustained delivery device for nerve growth factor (NGF), we developed NGF-loaded biodegradable PLGA films by a novel and simple sandwich solvent casting method for possible applications in the central nervous system (45). The release of NGF from the NGF-loaded PLGA films was prolonged > 35 days with a zero-order rate, without initial burst, and controlled by variation of different molecular weights and different NGF loading amounts as shown in Fig. 7. After 7 days, NGF

Figure 5. Release pattern of TGF- β_1 from TGF- β_1 loaded alginate beads; (■) 0.5 μg TGF- β_1 , (●) 0.5 μg TGF- β_1 with heparin, (▲) 1.0 μg TGF- β_1 , and (▼) 1.0 μg TGF- β_1 with heparin.

was released in a phosphate buffered saline solution (PBS; pH 7.0) and rat pheochromocytoma (PC-12) cells were cultured on the NGF-loaded PLGA film for 3 days. The released NGF stimulated neurite sprouting in the cultured

Figure 7. (a) Release profiles and (b) logarithmic plot of release rate for NGF from NGF-loaded PLGA films of 43,000 g/mol. (●) 25.4 ng, and (■) 50.9 ng NGF/cm² PLGA.

PC-12 cells; the remaining NGF in the NGF/PLGA film at 37°C for 7 days was still bioactive, as shown in Fig. 8. These studies suggest that NGF-loaded PLGA sandwich film can be released in the delivery system over the desired time period, thus, it can be a useful neuronal growth culture serving as a nerve contact guidance tube for applications in neural tissue engineering.

One serious problem during the fabrication of cytokine-loaded scaffolds is the denaturation and deactivation of cytokines, which result in loss of biological activity (65,66). Hence, the optimized method must be developed for stabilized cytokine-release scaffolds. For example, the release of NGF from a PLGA matrix was investigated using codispersants, such as polysaccharides (dextran) and proteins (albumin and β -lactoglobulin), with different molecular weights and charges. Negatively charged codispersants stabilized NGF in the PLGA system. Similarly, albumin stabilized epidermal growth factor (EGF) and heparin stabilized other growth factors.

Another available emerging technology is the “tethering of protein”, that is, immobilization of protein on the surface

Figure 8. Effect of NGF released on neurites formation of PC-12 cells for 3-day cultivation on control (a) PLGA, (b) 25.4 ng, and (c) 50.9 ng NGF/cm² PLGA just after 7 days. There were total medium changes (Molecular weight of PLGA; 83,000 g/mol, original magnification; 400 \times).

of a scaffold matrix. Immobilization of insulin and transferrin to the poly(methylmetacrylate) films stimulates the growth of fibroblast cells compared to the same concentrations of soluble or physically adsorbed proteins (67). For the enhancement of cytokine activity, the PEO chain was applied as a short spacer between the surface of the scaffold and the cytokine. Tethered EGF, immobilized to the scaffold through the PEO chain, showed better DNA synthesis or cell rounding compared to the physically adsorbed EGF surface (68).

Conjugation of cytokine with an inert carrier prolongs the short half-life of protein molecules. Inert carriers are albumin, gelatin, dextran, and PEG. In PEGylation, PEG conjugated cytokine is most widely used for the release. This carrier appears to decrease the rate of cytokine degradation, attenuate the immunological response, and reduce clearance by the kidneys (69). Also, this PEGylated cytokine can be impregnated into scaffold materials by physical entrapment for sustained release. For example, the NGF-conjugated dextran (70,000 g · mol⁻¹) impregnated polymeric device was implanted directly into the brain of adult rats. Conjugated NGF could penetrate into the brain tissue 8 times faster than the unconjugated NGF. This conjugation method can be applied to the delivery of proteins and peptides. Immobilized RGD (arginin-glycine-aspartic acid) and YIGSR (tyrosin-leucine-glycine-serine-arginine), which are typical ECM proteins, can enhance cell viability, function, and recombinant products in the cell (70).

Gene-activating scaffolds are being designed to deliver the targeted gene that results in the stimulation of specific cellular responses at the molecular level (4,3,11). Modification of bioactive molecules with resorbable biomaterial systems obtain specific interactions with cell integrins resulting in cell activation. These bioactive bioglasses and macroporous scaffolds also can be designed to activate genes that stimulate regeneration of living tissue (9). Gene delivery would be accomplished by complexation with positively charged polymers, encapsulation, and gel by means of the scaffold structure (51). Methods of gene delivery for gene-activating scaffolds are almost the same methods as for those with protein, drug, and peptides.

SCAFFOLD FABRICATION AND CHARACTERIZATION

Scaffold Fabrication Methods

Engineered scaffolds may enhance the functionalities of cells and tissues to support the adhesion and growth of a large number of cells because they provide a large surface area and pore structure within a 3D structure. The pore structure needs to provide enough space, permit cell suspension, and allow penetration of the 3D structure. Also, these porous structures help to promote ECM production, transport nutrients from nutrient media, and excrete waste products (10,12,15). Therefore, an adequate pore size and a uniformly distributed, and an interconnected pore structure, which allow for easy distribution of cells

throughout the scaffold structure, are very important. Scaffold structures are directly related to their fabrication methods; over 20 methods have been proposed (10,71).

The most common and commercialized scaffold is the PGA nonwoven sheet (Albany International Research Co., Mansfield, MA; porosity $\sim 97\%$, $\sim 1\text{--}5$ mm thick); it is one of the most tested scaffolds for tissue-engineered organs. To stabilize dimensionally and provide mechanical integrity, fiber-bonding technology was developed using heat and PLGA or PLA solution spray coating methods (72).

Porogen leaching methods have been combined with polymerization, solvent casting, gas foaming, or compression molding of natural and synthetic scaffolds biomaterials. The leaching of pore-generating particles such as sodium chloride crystal, sodium tartrate, and sodium citrate were sieved using a molecular sieve (10,71). PLGA, PLA, collagen, poly(orthoester), or SIS-impregnated PLGA scaffolds were successfully fabricated into a biodegradable sponge structure by this method with $> 93\%$ porosity and a desired pore size of $1000\ \mu\text{m}$. By using the solvent casting/particulate leaching method, complex geometries, such as tube, nose, and specific organ types (e.g., nano-composite hybrid scaffolds), could be fabricated by means of conventional polymer-processing techniques, such as calendaring, extrusion, and injection. Complex geometry can be fabricated from porous film lamination (33,39,42,47). The advantage of this method is its easy control of porosity and geometry. However, the disadvantages include: (1) the loss of water-soluble biomolecules or cytokines during the leaching porogen process, (2) the possibility that the remaining porogen as a salt can be harmful to the cell culture, and (3) the different geometry surface and cross-section that results.

The gas-foaming method consists of a solid scaffold matrix exposed to a sudden expansion of CO_2 gas under high pressure, which results in the formation of a sponge structure due to nucleation and expansion in a dissolved CO_2 scaffold matrix. The PLGA scaffolds with $> 93\%$ porosity and $\sim 100\ \mu\text{m}$ median pore size were developed by this method (71). A significant advantage is that there is no loss of bioactive molecules in the scaffold matrix, since there is no more need for the leaching process and there is no residual organic solvent. The disadvantage is the presence of a skin layer on the scaffold surface, which results in a need for an additional process to remove the skin layer.

The phase-separation method is divided into the freeze-drying, freeze-thaw, freeze-immersion precipitation, and emulsion freeze-drying techniques (37,72,73). Phase separation by freeze-drying can be induced by the appropriate concentration of polymer solution obtained by rapid freezing. Then, the used solvent is removed by freeze-drying, leaving in porous structure made up of a portion of the solvent. These can be collagen scaffolds with pores $\sim 50\text{--}150\ \mu\text{m}$; collagen-glycosaminoglycan blend scaffolds with an average pore size $\sim 90\text{--}120\ \mu\text{m}$; or chitosan scaffolds with a pore size $\sim 1\text{--}250\ \mu\text{m}$, dependent on the freezing conditions (71). Also, scaffold structures of synthetic polymers, such as PLA or PLGA, have been successfully made much $> 90\%$ porosity and $\sim 15\text{--}250\ \mu\text{m}$ size by this method. The freeze-thaw technique induces phase separation between a solvent and a hydrophilic monomer upon freezing, followed by the polymerization of the hydro-

philic monomer by means of ultraviolet (UV) irradiation and removal of the solvent by thawing. This technique leads to the formation of a macroporous hydrogel. A similar method is the freeze-immersion precipitation technique. The polymer solution is cooled, immersed in a nonsolvent, and then the vaporized solvent leads to a porous scaffold structure. Also, the emulsion freeze-drying method is used to fabricate a porous structure. Mixtures of polymer solution and nonsolvent are thoroughly sonicated, frozen quickly in liquid nitrogen at -198°C , and then freeze-dried, resulting in a sponge structure. The advantage of these techniques is that they result in the loading of hydrophilic or hydrophobic bioactive molecules, whereas the disadvantages are relatively small pore sized scaffolds with precise pore structures that are hard to control (73).

Nano-electrospinning of PGA, PLA, PLGA, caprolactone copolymers, collagen, and elastin, has been extensively developed (74). For example, electrostatic processing can consistently produce PGA fiber diameters $\leq 1\ \mu\text{m}$. By controlling the pick-up of these fibers, the orientation and mechanical properties can be tailored to the specific needs of the injured site. Also, collagen electrospinning was performed utilizing type I collagen dissolved in 1,1,1,3,3,3-hexafluoro-2-propanol with a concentration of $0.083\ \text{g}\cdot\text{mL}^{-1}$. The optimally electrospun type I collagen nonwoven fabric appeared with an average diameter of $100 \pm 40\ \text{nm}$, which resulted in biomimicking fibrous scaffolds.

Injectable gel scaffolds have also been reported (10,16,51,54). An injectable, gelforming scaffold offers several advantages: (1) it can fill any space based on its ability to flow; (2) it can load various types of bioactive molecules and cells by simple mixing; (3) it does not contain residual solvents that may be present in a preformed scaffold; and (4) it does not require a surgical procedure for placement. Typical examples are thermosensitive gels such as Pluronic and PEG-PLGA-PEG triblock copolymer, pH sensitive gels such as chitosan and its derivatives, an ionically cross-linked gel such as alginate, and fibrin and hyaluronan gels, as well as others previously introduced in the Natural Polymers section. In the near future, multifunctional gels which are tissue-specific, have a very fast sol-gel transition, are fully degradable over the necessary time period will be available.

Newly hybridized fabrication techniques such as organic-inorganic and synthetic-natural techniques at the nanosize level that biomimic, are also being developed for use in engineered scaffolds.

Physicochemical Characterization of Scaffolds

For the successful achievement of 3D scaffolds, several characterization methods are needed. These methods can be divided into four categories. (1) Morphology—porosity, pore size, and surface area; (2) mechanical properties—compressive and tensile strength; (3) bulk properties—degradation and its relevant mechanical properties; and (4) surface properties—surface energy, chemistry, and charge.

Porosity is defined as the fraction of the total volume occupied by voids that appear as percentages. The most widely used methods for the measurement of porosity are mercury porosimetry, scanning electron microscopy (SEM), and confocal laser microscopy.

Mechanical properties are extremely important when designing tissue-engineered products. Conventional testing instruments can be used to determine the mechanical properties of a porous structure. Mechanical tests can be divided into (1) creep tests, (2) stress–relaxation tests, (3) stress–strain tests, and (4) dynamic mechanical tests. These test methods are similar to those used for conventional biomaterials.

The rate of degradation of manufactured scaffolds is a very important factor in the design of tissue-engineered products. Ideally, the scaffold constructs provide mechanical and biochemical supports until the entire tissue regenerates, then the scaffold completely biodegrades at a rate consistent with tissue generation. Immersion studies are commonly conducted to track the degradation of the biodegradable matrix. Changes in weight loss and molecular weight can be evaluated by the chemical balance of the matrix, by SEM, and by gel permeation chromatography. These results produce the mechanism of biodegradation.

It is generally recognized that the adhesion and proliferation of different types of cells on polymeric materials depend largely on the materials' surface characteristics, such as wettability (hydrophilicity/hydrophobicity of surface free energy), chemistry, charge, roughness, and rigidity (37,40,41,44,45). The 3D aspects of tissue engineering are more important for cell migration, proliferation, DNA/RNA synthesis, and phenotype presentation on the scaffold materials. Surface chemistry and charge can be analyzed by electron scanning chemical analysis and streaming potential, respectively. Also, wettability of the scaffold surface can be measured by the contact angle using static and dynamic methods.

SURFACE MODIFICATION OF SCAFFOLDS FOR THE IMPROVEMENT OF BIOCOMPATIBILITY

As explained above, the surface properties of scaffold materials are very important. For example, the hydrophobic surfaces of PLA, PGA, and PLGA possess high interfacial free energy in aqueous solutions, which tends to unfavorably influence their cell, tissue, and blood compatibility in the initial stage of contact. Moreover, it does not allow the nutrient media to permeate into the center of the scaffolds. For these reasons, a surface treatment is applied by several methods: (1) chemical treatment using oxidants, (2) physical treatment using glow discharge, and (3) a blend with hydrophilic biomaterials or bioactive molecules.

The physicochemical treatment has been demonstrated to improve the wetting property and hydrophilicity of PLGA porous scaffolds fabricated by the emulsion freeze–drying method (37,45). The chemical treatments were 70% perchloric acid, 50% sulfuric acid, and 0.5 *N* sodium hydroxide solution. The physical methods included corona and plasma treatments generated by a radiofrequency glow discharge. After treatment, water contact angles decreased (Fig. 9). The wetting property of chemically treated PLGA scaffolds also ranked in the order of perchloric acid, sulfuric acid, and sodium hydroxide solution by blue dye intrusion experiment, whereas phy-

Figure 9. Changes of water contact angles after physicochemical treatment. The significant decreasing of water contact angle, that is, increased hydrophilicity, was observed.

sical methods had no effect, as shown in Fig. 10. Thus, the chemical treatment method may be useful in uniform cell seeding into porous biodegradable PLGA scaffolds. Wettability plays an important role in cell adhesion, spreading, and growth on the PLGA surface, and the intrusion of nutrient media into the PLGA scaffold.

Scaffolds impregnated with bioactive and hydrophilic material might be better for cell proliferation, differentiation, and migration due to cell stimulation. To give scaffolds new bioactive functionality from SIS powder as a natural source, scaffolds consisting of porous SIS/PLA and SIS/PLGA as a natural–synthetic composite, were prepared by the solvent casting–salt leaching method for use in tissue-engineered bone. A uniform distribution of good interconnected pores from the surface-to-core region was observed (pore size 40–500 μm), independent of the SIS amount, by using the solvent casting–salt leaching method. Porosities, specific pore areas as well as pore size distribution were also similar. After the fabrication of SIS/PLGA hybrid scaffolds, the wetting properties were greatly improved resulting in more uniform cell seeding and distribution, as shown in Fig. 11. Five different scaffolds, a PGA nonwoven mesh scaffold without glutaraldehyde (GA) treatment, PLA scaffolds without and with GA treatment, PLA/SIS scaffolds without and with GA treatment, were implanted into the back of nude mouse to observe the effect of SIS on the induction of cell proliferation by hematoxylin and eosin using von Kossa staining, for 8 weeks. It was observed that the effect of PLA/SIS scaffolds with GA treatment on bone induction is stronger than PLA scaffolds, that is the effects of PLA/SIS scaffolds with GA treatment > PLA/SIS scaffolds without GA treatment > PGA nonwoven > PLA scaffolds only with GA treatment = PLA scaffolds only without GA treatment for osteoinduction activity (Fig. 12).

STERILIZATION METHODS FOR SCAFFOLDS

The sterilizability of polymeric scaffold biomaterials is an important property, since polymers have lower thermal and chemical stability than other materials, such as ceramics and metals. Consequently, polymers are more difficult to sterilize using conventional techniques. Commonly used sterilization techniques are dry heat, autoclaving, radiation, and ethylene oxide gas (EOG). In addition, plasma glow discharge and electron beam sterilization recently were proposed due to their convenience (6,75).

In dry heat sterilization, the temperature varies between 160 and 190 °C. This temperature is above the melting and softening temperatures of many linear polymers, such as PLGA, resulting in the shrinking of the scaffold dimension. The PLA scaffolds were sterilized at 129 °C for 60 s, resulting in a minimal change in tensile properties. One of the significant problems was a decrease in molecular weight, which might have an affect on the

degradation kinetics of the polymers. In the case of polyamide (Nylon) used as a nonbiodegradable polymer, oxidation occurs at the dry sterilization temperature, even though this is below its melting temperature. The only polymers that can safely be dry sterilized are polytetrafluoroethylene (PTFE) and silicone rubber. However, ceramic and metallic scaffolds were safe in this temperature range.

Steam sterilization (autoclaving) is performed under high steam pressure at a relatively low temperature (125–130 °C). However, if the polymer is subjected to attack by water vapor, this method cannot be employed. The PVC, polyacetals, PE (low density variety), and polyamides belong to this category. In the poly(α -hydroxy ester) family, a trace of water can deteriorate the PLGA backbone.

Chemical agents such as EOG and propylene oxide gases, and phenolic and hypochloride solutions are used widely for sterilizing all biomaterials, since they can be used at relatively low temperatures. Chemical agents

Figure 11. Wetting properties of SIS impregnated PLGA scaffolds by red dye intrusion methods. We observed the rapid penetration of water into SIS/PLGA scaffolds compared to the control PLGA scaffolds; (a) control PLGA, (b) 40% SIS/PLGA, and (c) 160% SIS/PLGA scaffolds.

Figure 12. Photomicrographs of von Kossa and H&E histological sections of implanted (a) PGA nonwoven, (b) PLA scaffold only without GA treatment, (c) PLA scaffold only with GA treatment, (d) SIS/PLA scaffold without GA treatment, (e) SIS/PLA scaffold with GA treatment, and (f) SIS/PLA scaffold with GA treatment (H&E) (Original magnification 100 \times).

sometimes cause polymer deterioration even when sterilization takes place at room temperature. However, the time of exposure is relatively short (overnight), and most scaffolds can be sterilized with this method. The cold EOG sterilization method is the most widely used, with conditions of 35°C and 95% humidity. While the hot EOG method, which uses 60°C and 95% humidity, can cause shrinkage of the PLGA scaffold. One significant problem is residual EOG, which is harmful on the surface and within the polymer. Therefore, it is important that the scaffolds are subjected to adequate degassing or aeration subsequent to EOG sterilization, so that the concentration of residual EOG can be reduced to acceptable levels.

Radiation sterilization using isotopic ^{60}Co can also deteriorate polymers, since at high dosages the polymer chains can be dissociated or crosslinked according to the characteristics of the chemical structures. At a 2.5 Mrad dose, the tensile strength and molecular weight of PLGA decreases. Also, there is a rapid decrease in the molecular weight of the PGA nonwoven felt with increasing doses of radiation. It is important to remember that the properties and useful lifetime of the PLGA implant can be significantly affected by irradiation. In the case of polyethylene, it becomes a brittle and hard material at doses as high as 25 Mrad; This is due to a combination of random chain scission crosslinking. Polypropylene will often discolor during irradiation giving the product an undesirable tint, but a more severe problem is the embrittlement resulting in flange breakage, luer crack-

ing, and tip breakage. The physical properties continued to deteriorate with time following irradiation.

Sterilization methods might significantly affect the physicochemical properties of the scaffold matrix. The specific effects with various methods are determined by the kinds of scaffold materials themselves, the scaffold preparation methods, and the sterilization factors. It is essential that a new standard for sterilizing scaffold devices be designed and established.

CONCLUSIONS

Tissue engineering, including regenerative medicine in recognition of its tremendous potential, has received a revolutionary "research push." As a result, there have been many reports on the successful regeneration of tissues and organs including skin, bone, cartilage, the peripheral and central nerves, tendon, muscle, cornea, bladder and urethra, and liver as well as composite systems like the human phalanx and joint, using scaffold biomaterials from polymers, ceramic, metal, composites and its hybrids. As previously emphasized, scaffold materials must contain a site of cellular and molecular induction and adhesion, and must allow for the migration and proliferation of cells through porosity. They must also maintain strength, flexibility, biostability, and biocompatibility to mimic a more natural, 3D environment. From this standpoint, control over a precise biochemical signal must be fostered by the combination

of a scaffold matrix and bioactive molecules including genes, peptide molecules, and cytokines. Moreover, the combination of cells and redesigned bioactive scaffolds should expand to a tissue level of hierarchy. To achieve this goal, novel scaffold biomaterials, scaffold fabrication methods, and characterization methods must be developed.

INTRODUCTION

Normal human development spans a lifetime from infancy to old age. Modern civilization is confronted with the lengthening of that time and its effect on the individual and society. Housing improvements, employment alterations, labor saving devices, and modern medicine are but a few of the factors protecting humanity from those instances which previously shortened life. While many of the difficult, threatening experiences have been eliminated or reduced in severity, problems remain to be solved. Concerns for the quality of life as people become older include maintaining self-sufficiency. Many solutions conflict with beliefs generally termed "current wisdom" in areas, such as training, dieting, exercising, and aging. While society ages, the challenge for each individual is to strive to retain the lowest "biological" age while their "chronological" birthdays increase. The dilemma concerns the best way to accomplish this task.

The main purpose of this article is to focus on the biomechanical principles of movement, the scientific bases of training and fitness, and the optimization of human performance at any age. These are not just nonsense concepts added to the quantities of known theories, but are objectively quantifiable procedures that encompass our understandings and can produce precise conclusions. Mathematical principles and gravitational formulations provide the cornerstones for optimizing human performance. Biological, anatomical, physiological, and medical discoveries are always under investigation, challenge, and improvement and these findings will be incorporated into many of the current theories. Figure 1 illustrates just part of the anatomy and its complicated structure. The struggle will continue among scientists to establish new principles for revolutionizing the world of gerontology, diet, physical fitness and training, and amplifying those factors necessary for extending life not only in length, but also in quality. Scientists with expertise in many different areas will be addressing the problems associated with aging from their specialized perspective.

In order to address the optimization of human movement and performance, the underlying philosophical premise metaphorically compares life with sport. The goal is that everyone should be a gold medalist in their own body regardless of age. Most people, however, do not achieve their Gold Medal because their goals, potential, and/or timing are uncoordinated or nonexistent. For example, an individual may envision themselves as a tennis champion, yet lack the requisite physical and physiological traits of the greatest players. Given this situation, can a person's potential be maximized? Achieving one's maximum potential necessitates tools applicable to everyone for improving their performance, whether in tennis, fitness, overcoming physical handicaps, or fighting disease. Useful tools must be based, however, on correct, substantive scientific principles.

SCIENTIFIC PRINCIPLES FOR QUANTIFYING MOTION

Human movement has fascinated humans for centuries including some of the world's greatest thinkers, such as Leonardo da Vinci, Giovanni Borelli, Wilhelm Braune, and others. Many questions posed by these stellar geniuses have been or can be addressed by the relatively new area of Biomechanics. Biomechanics is the study of the motion of living things, primarily, and it has evolved from a fusion of the classic disciplines of anatomy, physiology, physics, and engineering. Bio refers to the biological portion, incorporating muscles, tendons, nerves, and so on, while mechanics is associated with the engineering concepts based upon the laws described by Sir Isaac Newton. Human bodies consist of a set of levers that are powered by muscles. Quantification of movements, whether human, animal, or inanimate objects, can be treated within biomechanics according to Newtonian equations. It may seem obvious, with the perfect vision of hind sight, that humans and their activities, such as the wielding of tools (e.g., hammer, axe) or implements (e.g., baseball bat, golf club, discus), must obey the constraints of gravitational bodies, just as bridges, buildings, and cars do. For some inexplicable reason, humans and their activities had not been subjected to the appropriate engineering concepts that architects would use when determining the weight of books to be housed in a new library or engineers would apply to designing a bridge to span a wide, yawning abyss. It was not until Newton's

Figure 1. The human structure.

Figure 2. The modern coach and his tools.

apple fell again during the twentieth century that biomechanics was born.

Biomechanics, then, is built on a foundation of knowledge and the application of the basic physical laws of gravitational effects as well as those of anatomy, chemistry, physiology, and other human sciences. Early quantification efforts of human movement organized the body as a system of mechanical links. Activities were recorded on movie film that normally consisted of hundreds of frames for each of the desired movement segment. Since each frame of the activity had to be processed individually, the task was excessively lengthy, tedious, and time intensive. Figure 2 illustrates an abstract of today's sophisticated coaching tools in athletics. The hand calculations of a typical 16 segment biomechanical human required many hours for each frame, necessitating either numerous assistants or an individual investigator's labor-of-love and, frequently, both. Unfortunately, these calculations were susceptible to numerical errors.

The introduction of large, main-frame computers improved reliability and reasonableness of the results, replacing much of the skepticism or distrust associated with the manually computed findings. Computerization accelerated the calculations of a total movement much more rapidly than had been previously possible, but presented new difficulties to overcome. Many of the early biomechanical programs were cumbersome, time intensive main-frame endeavors with little appeal except to the obsessed, devotee of computers, and movement assessment. However, even these obstacles were conquered in the ever expanding computerization era. The computerized hardware/software system provides a means to objectively quantify the dynamic components of movement in humans regardless of the nature of the event. Athletic events, gait analyses, job-related actions as well as motion by inanimate objects, including machine parts, air bags, and auto crash dummies are all reasonable analytic candidates. Objectivity replaces mere observation and supposition.

One of the most important aspects included in the Bio portion of biomechanics is the musculoskeletal system.

Voluntary human movement is caused by muscular contractions that move bones connected at joints. The neuromuscular system functions as a hierarchical system with autonomic and basic, life sustaining operations, such as heart rate and digestion, controlled at the lowest, noncognitive levels and with increasing complexities and regulatory operations, such as combing the hair or kicking a ball, controlled by centers that are further up the nervous system. Interaction of the various control centers is regulated through two fundamental techniques each governed like a servosystem.

The first technique equips each level of decision making with subprocessors that accept the commands from higher levels as well as accounting for the inputs from local feedback and environmental information sensors. Thus, a descending pyramid of processors is defined that can accept general directives and execute them in the presence of varying loads, stresses, and other perturbations. This type of input-output control is used for multimodal processes, such as maintaining balance while walking on an uneven terrain, but would be inappropriate for executing deliberate, volitional, complex tasks like the conductor using the baton to coordinate the music of the performing musicians.

The second technique utilized by the brain to control muscular contractions applies to the operation of higher level systems that generate output strategies in relation to behavioral goals. These tasks use information from certain sensory inputs, including joint angle, muscle loading, and muscular extension or flexion that are assessed, transmitted to higher centers for computation, which then executes the set of modified neural transmissions received. Cognitive tasks requiring the type of informational input that influences actions are the ones with which humans are most familiar since job execution requires more thought than breathing or standing upright. A frequently misunderstood concept is that limb movement is possible only through contractions of individual muscle fibers. For most cases of voluntary activity, muscles work in opposing pairs with one set of muscles opening or extending the joint (extensors) while the opposite muscle group closes or flexes the joint. The degree of contraction is proportional to the frequency of signals from the nerve as signaled from the higher centers. Movement control is provided by a programmable mechanism so that when flexors contract, the extensors relax, and vice versa. The motor integration programmed generated in the higher, cognitive levels regulates not only the control of the muscle groups around a joint, but also those necessary actions by other muscles and limbs to redistribute weight, to counteract shifts in the center of gravity.

One of the most important, but frequently misunderstood, concepts of the nervous system is the control and regulation of coordinated movement. When a decision is made to move a body segment, the prime muscles or agonists receive a signal to contract. The electrical burst stimulates the agonist muscular activity causing an acceleration of the segment in the desired direction. At the same time, a smaller signal is transmitted to the opposite muscle group, or antagonist, which causes it to function as a joint stabilizer. With extremely rapid movements, the antagonist is frequently stimulated to slow the limb in time to

Figure 3. Feedback control mechanism of movement.

protect the joint from injury. It is the strength and duration of the electrical signal to both the agonist and antagonist that govern the desired action. The movement of agonists and antagonists, whether a cognitive process, such as throwing a ball, or an acquired activity, such as postural control, is controlled by the nervous system. Figure 3 illustrates a flowchart for the control system for movement. Many ordinary voluntary human activities resulting from agonist–antagonist muscular contraction are classified by different terms, isotonic, variable resistance, and ballistic. Slower movements, demonstrating smaller, more frequent, electrical signal alterations, are intricately controlled by both agonist and antagonist. These types of motion are tracking movements.

One control mechanism available involves the process of information channeled between the environment and the musculature. Closed-loop control involves the use of feedback whereby differences between actual and desired posture are detected and subsequently corrected, whereas open-loop control utilizes feed forward strategies that involve the generation of a command based on prior experience rather than on feedback. Braitenberg and Onesto (ARBIB) proposed a network for converting space into time by providing that the position of an input would determine the time of the output. This open loop system would trigger a preset signal from the nervous system to the muscle generating a known activity. Kicking a ball, walking, throwing a baseball, swinging a golf club, and hand writing are considered ballistic movements.

When a limb moves, a sophisticated chain of events occurs before, during, and after the movement is completed. The fineness of control depends on the number of muscle fibers innervated by each motor neuron. A motor unit is generally defined as a single motor neuron and the number of muscle fibers it innervates. Fine control is achieved when a single motor neuron innervates just a few fibers. Less fine control, as in many large muscle groups, is attained when individual motor units innervate hundreds or even thousands of fibers. The more neurons there are, the finer the ability to maneuver, as with eye movements or delicate hand manipulations. In contrast to the high innervations ratio of the eye, the biceps of the arm has a very low rate of nerve-to-muscle fiber resulting in correspondingly more coarse movements.

While the amount of nervous innervations is important when anticipating the precision of control, the manner of interaction and timing between muscles, nerves, and desired outcome is probably more important when evaluat-

ing performance. Recognizable actions elicit execution of patterned, synchronous nervous activity. Frequently repeated movements are usually performed crudely in the beginning stages of learning, but become increasingly more skilled with use and/or practice. Consider the common activity of handwriting and the execution of one's own signature. The evolution from a child's irregular, crude printing to an adult's recognizable, consistently repeatable signature is normal. Eventually, the individual's signature begins to appear essentially the same every time and is uniquely different from any other person. Not only can the person execute handwritten signatures consistency, but can use chalk to sign the name in large letters on a blackboard producing a recognizably similar appearance. The individuality of the signature remains whether using the fine control of the hand or recruiting the large shoulder and arm muscles not normally required for the task. Reproduction of recognizable movements occurs from preprogrammed control patterns stored in the brain and recruited as necessary. Practicing a golf swing until it results in a 300 yard drive down the middle of the fairway, getting the food-laden fork from the plate into the mouth, and remembering how to ride a bike after a 30 year hiatus illustrate learned behavior that has become "automatic" with practice and can be recalled from the brain's storage for execution.

Volitional tasks require an integration of neurological, physiological, biochemical, and mechanical components. There are many options available when performing a task, such as walking, but eventually, each person will develop a pattern that will be recognizable as that skill, repeatable, and with a certain uniqueness associated with that particular individual. Although any person's movement could be quantified with biomechanical applications and compared to other performers in a similar group, for example, the gold, silver, and bronze medalists in an Olympic event, perhaps it will be the ability to compare one person to themselves that will provide the most meaningful assistance in the assault on aging.

There are many areas of daily living in which biomechanical analyses could be useful. Biomechanics could be utilized to design a house or chair to suit the body or to lift bigger, heavier objects with less strain. This science could be useful in selecting the most appropriate athletic event for children or for improving an adult's performance. With increasing international interest in competitive athletics, it was inevitable that computers would be used for the analysis of sports techniques. Computer calculations can provide information that surpasses the limits of what the

human eye can see and intuition can deduce. Human judgment, however, is still critically important. As in business and industry, where decisions are based ultimately upon an executive's experience and interpretive ability, the coach or trainer is, and will remain, the ultimate decision maker in athletic training. Rehabilitation and orthopedic specialists can assess impaired movement relative to normal performance and/or apply computerized biomechanical techniques to the possibilities of achieving the restoration of normal activities. With the increase in the population of older citizens, erotological applications will increase. The computer should be regarded as one more tool, however, complex, which can be skillfully used by humans in order to achieve a desired end.

One factor that humans have lived with is change. The environment in which we live is changing during every one of the ~ 35 million min of our lives. The human body itself changes from birth to maturity and from maturity to death. The moment humans first picked up a stone to use as a tool, the balance between humans and the environment was altered. After that adaptation, the ways in which the surrounding world changed resulted in different effects and these were no longer regular or predictable. New objects were created from things that otherwise would have been discounted. These changes were made possible by humans due to the invention of tools. The more tools humans created, the faster was the rate of environmental change. The rate of change due to tools has reached such a magnitude that there is danger to the whole environment and frequently to the people who use the tools, such as occurred during the Industrial Revolution, as well as in our own times with such problems as carpal tunnel syndrome. Human beings seem to have become so infatuated with their ability to invent things that they have concentrated almost exclusively upon improving the efficiency, safety, durability, cost, or aesthetic appeal of the device. It is ironic that with all of the innovative development, little consideration has been given to the most complex system with the most sophisticated computer in the world: the human body.

When they talk about their physical goals in work or in sports, people usually say they would like to do their best, meaning, reach their maximum output. It is a matter of achieving their absolute limit in speed, strength, endurance or skill and combining the elements with accuracy. This is no different than an athlete training for maximum performance in the Olympic games. The difficulty with focusing everything on maximum performance is that only a single goal, getting the highest results—fastest, biggest, quickest, longest, or most graceful—is considered a superlative or acceptable achievement. Maximums do not take into consideration other aspects of body performance that often prove to be just as important to the individual. Emphasis upon the demands for maximum performance is frequently portrayed with the thought that Winning isn't everything, it's the only thing. Figure 4 illustrates today's sophisticated biomechanical system to quantify human performance.

Imagine for a moment a maximum performance in the car industry—the perfect automobile. It is incredibly graceful and the aerodynamic, functional lines make it a thing of beauty. It accelerates from 0 to 60 miles \cdot h⁻¹ within a few

Figure 4. The modern biomechanical system.

seconds. It brakes, corners, and steers with a fineness that would permit a shortsighted 75-year old to compete at Le Mans. The suspension is so smooth that a passenger can pour liquids without spilling a drop. The car requires only minimal maintenance while averaging 50 miles \cdot gal⁻¹ in city driving. Best of all, it is the vehicle of the common man at a price of \$5000. If all that sounds impossible—it is. Incorporating all of these maximums into a single automobile exceeds the ability of any designer or manufacturer. Instead, the individual shopping for a car must choose the attributes he or she feels are most important.

Therein lies the problem, some goals are partly, if not wholly, incompatible with others. An automatic transmission uses more gas than a standard shift, but it does make driving easier. Sleek aerodynamic lines add grace and reduce drag, but they can also lessen head room. High performance engines provide power, but require constant care. The solution is a compromise, a willingness to make tradeoffs.

This same spirit of compromise, of accepting something less than a single maximum, should govern the operation of the most important machine in our lives—our body. Reality must be applied when comparing ourselves to Olympic athletes or, with the progression of age, mimicking various youthful physical activities. For example, there is no need to have an endurance capacity equal to the current gold medalist or the strength level equivalent to the World heavyweight record holder. Likewise, senior citizens may resist relinquishing their drivers' licenses despite their slower reaction times, poorer eyesight, and/or hearing, as well as frequently suffering from some type of chronic disease that may further reduce their strength, joint mobility, or even cognitive processes, such as memory or decision making.

Instead of a maximum, what most people really want from their bodies is to optimize their performances and lives. They seek the most efficient use of energy, of bodily action consonant with productive output, health, and enjoyment. Many people are beginning to appreciate that certain types of exercise add to the vitality of the

cardiovascular system, lessen the risk of heart attack, and make it possible to live longer and more active lives. In other words, the willingness to sacrifice 20 yards on a drive off the golf tee may mean that the golfer's feet will be able to walk the entire course without being tortured during every step. The desire is to play a couple of hours of winning tennis, stroking the ball with pace and purpose, but not if the extra zing means a tennis elbow that will be sore for several weeks. Sensible joggers prefer to run 6 rather than 10 miles a day in 40 min, if the latter leads to tender knees and shin splints. In other words, human beings must compromise between anatomy (the structural components) and physiology (the bodily processes). A correct balance between the two, at all ages, will assist in optimizing bodily efficiency.

In addition to the desire for our internal environment to be physical fit, pertinent questions should be posed about our external environment. For example, is it really necessary for that designer chair to cause a bone ache deep in the buttocks after sitting for 5 min? Can a person not spend a day laboring over a desk or piece of machinery without feeling as if a rope had been tightly tied around the shoulders at the end of the project? Why must a weekend with shovel or rake inevitably produce lower back pain on Monday? Why is it that some individuals who are 50 years old seem able to work and play as if 10–20 years younger, while some 30 year olds act as if infected with a malignant decrepitude? The answer is that, as with the anatomy and physiology achieving optimal coordination, so should the whole human organism coordinate better with its environment.

Perhaps these examples could be dismissed as the minor aches of a hypochondriac society overly concerned with its comfort. But the overall health facts for the United States and many other modern civilizations appall even those jaded by constant warnings of disaster. The American Heart Association, in urging the 2005 Congress to fund prevention programs, contends that the Number One killer of Americans is heart disease, stroke, and other cardiovascular diseases. In addition, a total of 75 million Americans are afflicted with chronic disease. On any given day, > 1 million workers do not show up for their jobs because of illness, and sickness prevents a million of these from returning in < 1 week. Twenty-eight million Americans have some degree of disability. Perhaps not coincidentally, a quarter of the population is classified as overweight. At least 3 million citizens have diabetes, and one-half are unaware of the problem, and the United States accounts for most of the deaths due to cardiovascular disease. The health profile of the future, the condition of the youth of today, offers no comfort. About 1 in 5 youngsters still cannot pass even a simple test of physical performance. More than 9 million American children under the age of 15 have a chronic ailment. From one-third to one-half of U.S. children are overweight and one-third of America's young men fail to meet military physical fitness requirements.

In pursuit of technological achievement, Americans have almost ignored the one major element besides food and rest needed to sustain the human body: physical activity. This has lent impetus to a subtle yet deadly disease that has reached epidemic proportions in this

country and others. Cardiovascular disease is often referred to as hypokinetic disease or lack-of-motion disease. Unfortunately, degeneration with Americans begins earlier rather than later. One study indicates that middle age characteristics start to show at approximately age 26. The peak age for heart disease among American men is 42 years. In Europe, it is 10 years later. A corporate wide employee health survey conducted by a large computer manufacturer indicated that smokers have 25% higher healthcare costs and 114% longer hospital stays than nonsmokers. People who did not exercise have 36% higher healthcare costs and 54% longer hospital stays than people who did exercise. Overweight people have 7% higher healthcare costs and 85% longer hospital stays than people who are not. In general, people with poor health habits have higher healthcare costs, longer hospital stays, lower productivity, more absenteeism, and more chronic health problems than those who do not. Some questions both workers and their companies should ask are (1) How many heart attacks, strokes, cancers, or coronary by-pass operations did your company pay for last year? (2) How much better would profits have been if heart diseases had been reduced 10, 20, or 30%? (3) How much would corporate profits increase if employee healthcare costs were reduced by 10%?

One large U.S. corporation developed a comprehensive wellness program at numerous sites. During the first year, grievances decreased by 50%, on-the-job accidents by 50%, lost time by 40%, and sickness and accident payments by 60%. The corporation estimated at least a 3:1 return per dollar invested.

The requirement for such an optimum way of life is a scientific analysis of the way people live and use their bodies. Only after such a quantitative examination can a concept of cost be determined or a better way of doing something that is more efficient and less damaging to the body, discovered. For example, rapid weight loss may result from running long distances, such as 15 miles a day, fasting drastically, or performing aerobics for 5 h a day. However, such excessive training regimens may be as detrimental to the body as sitting all day in an easy chair and simply ignoring one's obesity.

Evolution, culture, and the changing demands of existence have tended to develop forces and stresses upon the body that are not necessarily in harmony with the basic design and structure of the human equipment. Standing upright, humans employ one pair of extremities for support and the other pair capable of tremendous versatility. It would seem that of all animals, humans, fortuitously assisted by the evolution of their brain and other organs, optimized the use of their body. Unfortunately, the human body has had to pay a stiff price for its upright posture. Human vertical posture is inherently unstable; therefore, humans must devote more neuromuscular effort and control to maintain balance, than four-legged animals. There is a tendency to lean forward, which adds to the ability to move in that direction, but increases the risk of falling.

A complex neuromuscular process is constantly at work to prevent humans from toppling. Many things may interfere with this balancing act, such as consuming too much whiskey or walking on an icy sidewalk. These interruptions

of the flow of information to and from the brain centre which coordinates the balancing process can result in staggering or falling. This postural condition creates a constant strain on all the muscles employed to retain balance and upon the set of bones forming the spine. The spine is basically a tower of I-beams supports the skeletal frame and, in order to remain in good health, proper mechanical alignment is essential. Any deviation from this mechanical alignment will result in pain relating to non-alignment, such as low back or neck pain. The vulnerability of the back is threatened frequently by work, recreation situations, and furnishings, since their uses subject an already tenuous upright position to undergo increased stresses. As the body compensates for alignment problems by creating excess bone tissue and neural pain, certain arthritic conditions may be the result.

Correction or prevention in tools or activities may assist in the optimization of performance and in more closely aligning the biological with the chronological age. Clearly, optimization and compensation may conflict within the human mechanism since a logical idea may violate physical principles. Based on this introduction of merely a few of the internal and external challenges to the human organism, the need for adequate and accurate assessments, improved tools, and human behavioral modifications becomes more apparent.

With each passing year, the composition of the population in America and probably many other modern societies is becoming older. This population increase of older citizens appears to be due, in part, to the large number of individuals of all ages who are experiencing modifications of lifestyle in a variety of ways, including better working conditions, improved health-medical opportunities, and changing activity levels. Pollock et al. (1) noted that the activity levels of elderly people have increased during the previous 20 years. However, it was estimated that only 10% of elderly individuals participate in regular vigorous physical activity and that 50% of the population who are 60 or more years of age described their lifestyles as sedentary.

Scientific studies and personal experiences continue to link many of the health problems and physical limitations found in the aged to lifestyle. Sedentary living appears to be a major contributor to the significantly adverse effect on health and physical well being. Certainly, there is increasing evidence indicating the vital need for improved national and international policies for better fitness, health, and sports for older individuals. In order to address some of these indicators, new attitudes and policies must emphasize activities and resources to meet the minimal requirements for keeping older people in good health, preventing their deterioration with age, and meeting the special interests of individuals with various disorders. In addition to the difficulties that hospitals, insurance companies, children of the elderly, and legislators face, the medical and scientific communities require time to determine the most appropriate solutions for improving the quality of these lengthening lives.

Many of the myths about aging are being disproved while the true nature of age-related changes appears to be less bleak than previously thought. Disuse and disease, not age alone, are increasingly, revealed as culprits. There is an increasing awareness of the need for more emphasis on

fitness to maintain wellness and prevent degenerative illness, for more research to understand the aging body of the healthy older person, and to determine the exercise needs of the ill and/or the handicapped. Pollock et al. (1) noted that physical capacity decrements are normally associated with the aging process. This loss has been attributed to the influence of disease, medication, age, and/or sedentary lifestyle. Additionally, it was noted that the majority of the elderly do not exercise and that it is unclear whether the reduced state of physical conditioning associated with aging results from the deconditioning due to sedentary living, age, or both.

It is a fact of life that muscle tissue suffers some diminution from age. Age-associated changes in organ and tissue function, such as a decline in fat-free mass, total body and intracellular water, and an increase in fat mass (2) may alter the physiological responses to exercise or influence the effect(s) of medication. However, any discussion about age realistically utilizes arbitrary time periods apportioned eons ago by men who evaluated time relative to the number of revolutions of the earth around the sun and the rotation of the earth on its own axis. These predetermined periods may or may not have any relationship with the aging of the cells in the body. The linkage between the chronological age and the biological age of people is imprecise. Perhaps a more accurate consideration of the relationship between chronological and biological age would be one that is nonlinear, may differ with gender, or be dependent on other factors.

It is an inevitable evolutionary consequence that individuals within a species differ in many ways. The characterization of an individual on the basis of a chronological age scale may be practical, but biologically inappropriate. It may be that use or functional activities may have a greater influence on determining biological age rather than the number of times the earth has revolved around the sun. It appears that biological age can be affected by genetic code, nutrition and, most physical activity. Astrand (3) suggested that as an individual ages, the genetic code may have more of an effect on the function of systems with key importance in physical performance. He also noted that a change in lifestyle, at almost any chronological age, can definitely modify the biological age, either upward or downward. It has been suggested that the disparity of older persons is a hallmark of aging itself (4). It is important to determine how much age variance is due to the passage of time and how much is caused by the accumulation of other, nontime dependent, alterations. Previous attitudes towards physical adversities observed in the elderly were that they were attributable to disease. More recently, a third dimension associated with poor health in older persons has been described by Bortz and Bortz (4) as The Disuse Syndrome. For example, one of the most common markers of aging was thought to be a decreased lean body mass. However, analysis of 70 year old weight lifters revealed no such decline. The components of the Disuse Syndrome have been similarly grouped by Kraus and Raab (5) in their book, *Hypokinetic Disease*, and are (1) cardiovascular vulnerability; (2) musculoskeletal fragility; (3) obesity; (4) depression; (5) premature aging.

Use is a universal characteristic of life. When any part of the body has little or no use, it declines structurally and

functionally. The effects of disuse can be observed on any body part, such as atrophied intestinal mucosa, when a loop is excluded from digestive functions or the lung becomes atelectatic when not aerated. A lack of adequate conditioning and physical activity causes alterations in the heart and circulatory system, as well as the lungs, blood volume, and skeletal muscle (6–9). During prolonged bed rest, blood volume is reduced, heart size decreases, myocardial mass falls, blood pressure response to exercise increases, and physical performance capability is markedly reduced. On the other hand, although acute changes within the cardiovascular system result in response to increased skeletal muscle demands during exercise, there is evidence that chronic endurance exercise produces changes in the heart and circulation that are organic adaptations to the demands of chronic exercise (10–15).

Cardiac performance undergoes direct and indirect age-associated changes. There is a reduction in contractility of the myocardium (16) and this increased stiffness impairs ventricular diastolic relaxation and increases end diastolic pressure (17). This suggests that exercise-induced increases in heart rate would be less well tolerated in older individuals than in younger populations. The decline in maximal heart rate is known and the cause is multifactorial, but is mostly related to a decrement in sympathetic nervous system response. Fifty percent of Americans who are > 65 years of age have a diagnostically abnormal resting electrocardiogram (18). Another factor associated with aging is a progressive increase in rigidity of the aorta and peripheral arteries due to a loss of elastic fibers, increase in collagenous materials, and calcium deposits (19). When aortic rigidity increases, the pulse generated during systole is transmitted to the arterial tree relatively unchanged. Therefore, systolic hypertension predominates in elderly hypertensive patients.

Other bodily systems demonstrate age-related alterations. Baroreceptor sensitivity decreases with age and hypertension (20,21) such that rapid adjustment of the cerebral circulation to changes in posture may be impaired. Kidney function reveals a defect in renal concentrating ability and sluggish renal conservation of sodium intake causes elderly patients to be more susceptible to dehydration (22). Hyaline cartilage on the articulator surface of various joints shows degenerative changes and clinically represents the fundamental alteration in degenerative osteoarthritis (23). A decrease in bone mineral density (osteoporosis) can reduce body stature as well as predispose the individual to spontaneous fractures. Older women are more prone to osteoporosis than older men and this may reflect hormonal differences (23). Older persons are less tolerant of high ambient temperatures than younger people (24) due to a decrease in cardiovascular and hypothalamic function which compromises the heat dissipating mechanisms. Heat dissipation is further compromised by the decrease in fat-free mass, intracellular and total body water, and an increase in body fat.

Unfortunately, the effects of disuse on the body manifest themselves slowly since humans normally have redundant organs that can compensate for ineffectiveness or disease. In addition, humans are opaque so that disease or deterioration are externally unobservable and, thus, go

unheeded (e.g., the early changes in bones due to osteoporosis are subclinical and are normally detected only after becoming so pronounced that fractures ensue). Cummings et al. (25) mentioned the difficulty of distinguishing manifestations in musculoskeletal changes due to disease related to aging. Muscle mass relative to total body mass begins decreasing in the fifth decade and becomes markedly reduced during the seventh decade of life. This change results in reduced muscular strength, endurance, size, as well as a reduction in the number of muscle fibers. Basmajian and De Luca (26) reported numerous alterations in the electrical signals associated with voluntary muscular contractions with advancing age. As yet, there are no findings published that have definitively located age-related musculoskeletal changes in either the nervous or the muscular system. The diaphragm and cardiac muscle do not seem to incur age changes. Perhaps this is due to constant use, from exercise, or possibly a genetic survival mechanism.

There is growing consensus that many illnesses are preventable by good health practices including physical exercise. Milliman and Robertson (27) reported that, of the 15,000 employees of a major computer company, the non-exercisers accounted for 30% more hospital stays than the exercisers. Lane et al. (28) reported that regular runners had only two-thirds as many physician visits as community matched controls. The beneficial effect of exercise on diabetes has long been recognized and is generally recommended as an important component in the treatment of diabetes (29). Regular endurance exercise favorably alters coronary artery disease risk factors, including hypertension, triglyceride and high density lipoprotein cholesterol concentrations, glucose tolerance, and obesity. In addition, regular exercise raises the angina threshold (30).

Jokl (31) suggested three axioms of gerontology that are affected by exercise. He contents that sustained training results in the following: (1) decline of physique with age; (2) decline of physical fitness with age; (3) decline of mental functions with age.

Health in older people is best measured in terms of function, mental status, mobility, continence, and a range of activities of daily living. Preventive strategies appear to be able to forestall the onset of disease. Whether exercise can prevent the development of atherosclerosis, delay the occurrence of coronary artery disease, or prevent the evolution of hypertension is at present debatable. But moderate endurance exercise significantly decreases cardiovascular mortality (32). Endurance exercise can alter the contributions of stress, sedentary lifestyle, obesity, and diabetes to the development of coronary artery disease (33).

For example, the four-time Olympic discus champion, Al Oerter, at the age of 43, focused his training to qualify for the 1980 Olympic Games that would have been his fifth consecutive Olympiad. Oerter threw his longest throw [220 f (67.05 m)] but, since the United States boycotted the 1980 Moscow Olympic Games, his chance was denied. By the time of the 1984 Los Angeles Games, Oerter was 47 years old. Even at an age well beyond most Olympic competitors, he again threw his best, exceeding 240 f (73.15 m) in practice sessions. Oerter's physique and strength suggested that his biological age was less than his chronological age.

Biologically, he was probably between 25 and 30, although chronologically he was 15–20 years older. Unfortunately, in the competition that determined which athletes would represent the United States, Oerter suffered an injury that precluded him from trying to achieve an unprecedented fifth consecutive Olympic Gold medal.

PRINCIPLES FOR EXERCISE AND TRAINING

Physical fitness and exercise have become, as previously discussed, an increasing concern at nearly all levels of American society. The goal of attaining peak fitness has existed for centuries, yet two problems continue to obfuscate understanding. The ability to assess strength and/or to exercise has occupied centuries of thought and effort. For examples, Milo the Greek lifted a calf each day until the baby grew into a bull. Since this particular procedure is not commonly available, humans have attempted to provide more suitable means to determine strength levels and ways to develop and maintain conditioning. Technology for assessing human performance in exercise and fitness evaluations, in both theory and practice, exhibits two problems. First, a lack of clearly defined and commonly accepted standards results in conflicting claims and approaches to both attaining and maintaining fitness. Second, a lack of accurate tools and techniques for measuring and evaluating the effectiveness of a given device designed to diagnose present capabilities for exercising or even to determine which exercises are appropriate to provide “fitness”, regardless of age or gender. Vendors and consumers of fitness technology have lacked sound scientific answers to simple questions regarding the appropriateness of exercise protocols.

Reviewing studies conducted to determine the effects of strength training on human skeletal muscle suggests many benefits with appropriate exercise. In general, strength training that uses large muscle groups in high resistance, low repetition efforts increases the maximum work output of the muscle group stressed (34). Since resistance training does not change the capacity of the specific types of skeletal muscle fibers to develop different tensions, strength is generally seen to increase with the cross-sectional area of the fiber (35). The human body can exercise by utilizing its own mass (e.g., running, climbing, sit ups). These and other forms of nonequipment based exercises can be quite useful. In addition, there are various types of exercise equipment that allow selection of a weight or resistance and then the exercise against that machine resistance is performed.

The relationship between resistance exercises and muscle strength has been known for centuries. Milo the Greek’s method of lifting a calf each day until it reached its full growth probably provides the first example of progressive resistance exercises. It has been well-documented in the scientific literature that the size of skeletal muscle is affected by the amount of muscular activity performed. Increased work by a muscle can cause that muscle to undergo compensatory growth (hypertrophy), whereas disuse leads to wasting of the muscle (atrophy).

The goal of developing hypertrophy has stimulated the medical and sports professions, especially coaches and ath-

Figure 5. Integration of our muscular system.

letes, to try many combinations and techniques of muscle overload. Attempts to produce a better means of rehabilitation, an edge in sporting activities, as a countermeasure for the adverse effects of space flight, or as a means to improve or enhance bodily performances throughout a lifetime have only scratched the surface of the cellular mechanisms and physiological consequences of muscular overload.

Muscular strength can be defined as the force that a muscle group can exert against a resistance in a maximal effort. In 1948, Delorme and Watkins (36) adopted the name “progressive resistance exercise” for his method of developing muscular strength through the utilization of counter balances and weight of the extremity with a cable and pulley arrangement. This technique gave load-assisting exercises to muscle groups that did not perform antigravity motions. McQueen (37) distinguished between exercise regimes for producing muscle hypertrophy and those for producing muscle power. He concluded that the number of repetitions for each set of exercise determines the different characteristics of the various training procedures. Figure 5 illustrates the complexity of the skeletal-muscular structure.

When muscles contract, the limbs may appear to move in unanticipated directions. One type of motion is a static contraction, known as an isometric type of contraction. Another type of contraction is a shortening or dynamic contraction that is called an isotonic contraction. Dynamic contractions are accompanied by muscle shortening and by limb movement. Dynamic contractions can exhibit two types of motion. One activity is a concentric contraction in which the joint angle between the two bones become smaller as the muscular tension is developed. The other action is an eccentric contraction in which, as the muscles contract, the joint angle between the bones increases. Owing to ambiguity in the literature concerning certain physiologic terms and differences in laboratory procedures, the following terms are defined below.

1. *Muscular strength*: the contractile power of muscles as a result of a single maximum effort.
2. *Muscular endurance*: ability of the muscles to perform work by holding a maximum contraction for a given length of time or by continuing to move submaximal load to a certain level of fatigue.

3. *Isometric*: a muscular contraction of total effort but with little or no visible limb movement (sometimes referred to as static or anaerobic).
4. *Isotonic*: a muscular contraction of less than total effort with visible limb movement (sometimes called dynamic or aerobic).
5. *Isokinetic training (accommodating resistance)*: muscular contraction at a constant velocity. In other words, as the muscle length changes, the resistance alters in a manner that is directly proportional to the force exerted by the muscle.
6. *Concentric contraction*: an isotonic contraction in which the muscle length decreases (that is, the muscle primarily responsible for movement becomes shorter).
7. *Eccentric contraction*: an isotonic contraction in which the muscle length of the primary mover and the angle between the two limbs increases during the movement.
8. *Muscle overload*: the workload for a muscle or muscle group that is greater than that to which the muscle is accustomed.
9. *Variable resistance exercise*: as the muscle contracts, the resistance changes in a predetermined manner (linear, exponentially, or as defined by the user).
10. *Variable velocity exercise*: as the muscle contracts with maximal or submaximal tension, the speed of movement changes in a predetermined manner (linear, exponentially, or as defined by the user).
11. *Repetitions*: the number of consecutive times a particular movement or exercise is performed.
12. *Repetition maximum (1 RM)*: the maximum resistance a muscle or muscle group can overcome in a maximal effort.
13. *Sets*: the number of groups of repetitions of a particular movement or exercise.

Based on evidence presented in these early studies (36–38), hundreds of investigations have been published relative to techniques for muscular development, including isotonic exercises, isometric exercises, eccentric contractions, and many others. The effectiveness of each exercise type has been supported and refuted by numerous investigations, but no definitive, irrefutable conclusions have been established.

Hellebrandt and Houtz (38) shed some light on the mechanism of muscle training in an experimental demonstration of the overload principle. They found that the repetition of contractions that place minimal stress on the neuromuscular system had little effect on the functional capacity of the skeletal muscles. They also found that the amount of work done per unit of time is the critical variable upon which extension of the limits of performance depends. The speed with which functional capacity increases suggests that the central nervous system, as well as the contractile tissue, is an important contributing component of training.

Results from the work of Hellebrandt and Houtz (38) suggest that an important consideration in both the design of equipment for resistive exercise and the performance of an athlete or a busy executive is that the human body relies on preprogrammed activity by the central nervous system. Since most human movements are ballistic and the neural control of these patterns differs from slow controlled movements, it is essential that training routines employ programmable motions to suit specific movements. This control necessitates exact precision in the timing and coordination of both the system of muscle contraction and the segmental sequence of muscular activity. Research has shown that a characteristic pattern of motion is present during any intentional movement of body segments against resistance. This pattern consists of reciprocally organized activity between the agonist and antagonist. These reciprocal activities occur in consistent temporal relationships with the variables of motion, such as velocity, acceleration, and forces.

In addition to the control by the nervous system, the human body is composed of linked segments, and rotation of these segments about their anatomic axes is caused by force. Both muscle and gravitational forces are important in producing these turning effects, which are fundamental in body movements in all sports and daily living. Pushing, pulling, lifting, kicking, running, walking, and all human activities result from the rotational motion of the links which, in humans, are the bones. Since force has been considered the most important component of athletic performance, many exercise equipment manufacturers have developed various types of devices employing isometrics and isokinetics. When considered as a separate entity, force is only one factor influencing successful athletic performance. Unfortunately, these isometric and isokinetic devices inhibit the natural movement patterns of acceleration and deceleration.

The three factors underlying all athletic performances and the majority of routine human motions are force, displacement, and the duration of movement. In all motor skills, muscular forces interact to move the body parts through the activity. The displacement of the body parts and their speed of motion are important in the coordination of the activity and are also directly related to the forces produced. However, it is only because of the control provided by the brain that the muscular forces follow any particular displacement pattern and, without these brain centre controls, there would be no skilled athletic performances. In every planned human motion, the intricate timing of the varying forces is a critical factor in successful performances. In any human movement, the accurate coordination of the body parts and their velocities is essential for maximizing performances. This means that the generated muscular forces must occur at the right time for optimum results. For this reason, the strongest weightlifter cannot put the shot as far as the experienced shot-putter, although the weightlifter possesses greater muscular force, he has not trained his brain centers to produce the correct forces at the appropriate time. Older individuals may be unable to walk up and down stairs or perform many of the daily, routine functions that had been virtually automatic before the deterioration produced by weakness, disease, or merely age.

There are significant differences in the manner of execution of the various resistive training methods. In isotonic exercises, the inertia, which is the initial resistance, must be overcome before the execution of the movement progresses. The weight of the resistance cannot be heavier than the maximum strength of the weakest muscle acting in a particular movement or the movement cannot be completed. Consequently, the amount of force generated by the muscles during an isotonic contraction does not maintain maximum tension throughout the entire range of motion. In an isokinetically loaded muscle, the desired speed of movement occurs almost immediately and the muscle is able to generate a maximal force under a controlled and specifically selected speed of contraction.

The use of the isokinetic principle for overloading muscles to attain their maximal power output has direct applications in the fields of sport medicine and athletic training. Many rehabilitation programmes utilize isokinetic training to recondition injured limbs of athletes to their full range of motion. The unfortunate drawback to this type of training is that the speed is constant and there are no athletic activities that are performed at a constant velocity. The same disadvantage applies to normal human activities.

In isotonic resistive training, if more than one repetition is to be used, a submaximal load must be selected for the initial contractions in order to complete the required repetitions. Otherwise, the entire regimen would not be completed, owing to fatigue or, the inability to perform. A modality that can adjust the resistance so that it parallels fatigue to allow a maximum effort for each repetition would be a superior type of equipment. This function could be accomplished by manually removing weight from the bar while the subject trained. This is neither convenient nor practical. With the aid of the computer, the function can be performed automatically.

Another drawback with many isotonic types of resistive exercises is that the inertia resulting from the motion changes the resistance depending on the acceleration of the weight and of the body segments. In addition, since overload on the muscle changes due to both biomechanical levers and the length-tension curve, the muscle is able to achieve maximal overload only in a small portion of the range of motion. To overcome this shortcoming in resistive training, some strength training devices have been introduced that have "variable resistance" mechanisms, such as a cam, in them. However, these variable resistance systems increase the resistance in a linear fashion and this linearity may not truly accommodate the individual. When including inertial forces to the variable resistance mechanism, the accommodating resistance can be canceled by the velocity of the movement.

There seem to be unlimited training methods and each is supported and refuted by as many "experts". In the past, the problem of accurately evaluating the different modes of exercise was rendered impossible because of the lack of adequate diagnostic tools. For example, when trying to evaluate isotonic exercises, the investigator does not know exactly the muscular effort nor the speed of movement, but knows only the weight that has been lifted. When a static weight is lifted, the force of inertia provides a significant

contribution to the load and cannot be quantified by feel or observation alone. In the isokinetic mode, the calibration of the velocity is assumed, but has been poorly verified since the mere rotation of a dial to a specific speed setting does not guarantee the accuracy of subsequently generated velocity. In fact, discrepancies as great as 40% have been observed when verifying the bar velocity.

Most exercise equipment currently available lack intelligence. In other words, the equipment is not aware that a subject is performing an exercise or how it is being conducted. Verification of the speed is impossible since a closed-loop feedback and sensors are absent. However, with the advent of miniaturized electronics in computers, it became possible to unite exercise equipment with the computer's artificial intelligence. In other words, it became possible for exercise equipment to adapt to the user rather than forcing the user to adapt to the equipment.

HIGH TECHNOLOGY TOOLS

High technology refers to the use of advanced, sophisticated, space age mathematical and electronic methods and devices for creating tools that can enhance human activities as well as expanding the horizons for future inventions. NASA put a man on the moon, sent exploratory spacecraft to Mars and beyond, and is sending shuttle missions to the Space Station. Polymer science invented plastics, mechanical science produced the automobile, and aeronautical engineering developed the airplane. Despite all of the knowledge and explosive developments since the rock became a tool, few advances have considered first the most important component in a complicated system, the human body.

The usual developmental cycle creates something and humans must adapt to it rather than the reverse. Computers can provide precise computations rapidly for complex problems that would otherwise require enormous quantities of time, talent, and energy to complete. The strength of these electronic wizards to follow instructions exactly, remember everything, and perform calculations within thousandths of a second has made them indispensable in finance, industry, and government. Application of the computer was a perfect enhancement for the human mind in order to quantify and evaluate movement performances. Used in conjunction with the human mind's ability to deduce, interpret, and judge, the computer provides the necessary enhancement to surpass the limits of what the eye can see or what intuition can surmise. Technological advances, such as these, can assist humans irrespective of their age.

For good health, it is necessary to follow a training method that incorporates all of the various bodily systems. In other words, the body should be treated as a complex, but whole, entity rather than as isolated parts. While it is not wrong to evaluate one's diet, an assessment of health would be incomplete without consideration of physical training, stress reduction, and other components that constitute the integrated organism of the human body. For a person to be able to jog 5 miles it is not important only to

run, but to develop the cardiovascular system in a systematic way to achieve a healthy status. Strength exercise, flexibility routines, proper nutrition and skill are necessary to achieve this goal.

Two sophisticated systems have been developed to analyze human performance and both are appropriate for the assault on aging. These systems include tools to (1) assess movements of the human body and (2) assist in exercising human beings. The first one is the biomechanical system that was developed to analyze movement performance. Currently, biomechanical analyses are routinely performed on a wide range of human motions in homes, work settings, recreation, hospitals, and rehabilitation centers. The second system, which incorporates space age technology, allows diagnoses and training of the musculoskeletal system. Each of these systems will be discussed subsequently in detail. Both of these technologies and the scientific principles and techniques discussed may help achieve physical and mental goals. The technological advances provide tools for quantification of the results and to analyze the potential of a person. With this information and these tools, it should be possible to train the various body systems for optimal results at any age.

The first commercially available computerized biomechanical system was described in 1973 (39) and that system can serve to illustrate the general concepts and procedures associated with biomechanical quantification of movement. Figure 6 illustrates device system. The computerized hardware–software system provides a means to objectively

quantify the dynamic components of movement in humans, such as athletic events, gait analyses, work actions, as well as motion by inanimate objects, including such items as machinery actions, air bag activation, and auto crash dummies. This objective technique replaces mere observation and supposition. This system provides a means to quantify motion utilizing input information from any or all of the following mediums: visual (video), electromyography (EMG), force platforms, or other signal processing diagnostic equipment.

The Ariel Performance Analysis System provides a means of measuring human motion based on a proprietary technique for the processing of multiple high speed video recordings of a subject's performance (40–42). This technique demonstrates significant advantages over other common approaches to the measurement of human performance. First, except in those specific applications requiring EMG or kinetic (force platform) data, it is non-invasive. No wires, sensors, or markers need be attached to the subject. Second, it is portable and does not require modification of the performing environment. Cameras can be taken to the location of the activity and positioned in any convenient manner so as not to interfere with the subject. Activities in the workplace, home, hospital, therapist's office, health club, or athletic field can be studied with equal ease. Third, the scale and accuracy of measurement can be set to whatever levels are required for the activity being performed. Camera placement, lens selection, shutter and film speed may be varied within wide limits to collect data on motion of only a few centimeters or of many meters, with a duration from a few milliseconds to a number of seconds. Video equipment technology currently available is sufficiently adequate for most applications requiring accurate motion analysis. Determination of the problem, error level, degree of quantification, and price affect the input device selection.

A typical kinematic analysis consists of four distinct phases: data collection (filming); digitizing; computation; and presentation of the results. Data collection is the only phase that is not computerized. In this phase, video recordings of an activity are made using two or more cameras with only a few restrictions: (1) all cameras must record the action simultaneously. (2) If a fixed camera is used, it must not move between the recording of the activity and the recording of the calibration points. These limiting factors are not necessary when a panning camera and associated mechanism are used. A specialized device accompanied by specialized software was developed to accommodate camera movement particularly for use with gait analysis and some longer distance sporting events, such as skiing or long jumping. (3) The activity must be clearly seen throughout its duration from at least two camera views. (4) The location of at least six fixed noncoplanar points visible from each camera view (calibration points) must be known. These points need not be present during the activity as long as they can be seen before or after the activity. Usually they are provided by some object or apparatus of known dimensions that is placed in the general area of the activity, filmed and then removed. (5) The speed of each of the cameras (frames/second) must be accurately known, although the speeds do not have to be identical. (6) Some

Figure 6. Analyses of vertical jump.

Figure 7. Digitizing system.

event or time signal must be recorded simultaneously by all cameras during the activity in order to provide synchronization.

These rules for data collection allow great flexibility in the recording of an activity. Figure 7 illustrates a modern digitizing system to quantify human movement. Information about the camera location and orientation, the distance from camera to subject, and the focal length of the lens is not needed. The image space is self-calibrating through the use of calibration points that do not need to be present during the actual performance of the activity. Different types of cameras and different film speeds can be used and the cameras do not need to be mechanically or electronically synchronized. The best results are obtained when camera viewing axes are orthogonal (90° apart), but variations of $20\text{--}30^\circ$ can be accommodated with negligible error. Initially, the video image is captured by the computer and stored in memory. This phase constitutes the "Grabbing" mode. Brightness, contrast, saturation, and color can be adjusted so that the grabbed picture may, in fact, be better than the original. Grabbing the image and storing it on computer memory eliminates any further need for the video apparatus.

Digitizing is the third step in biomechanical quantification. The image sequence is retrieved from computer memory and displayed, one frame at a time, on the digitizing monitor. Using a video cursor, the location of each of the subject's body joints (e.g., ankle, knee, hip, shoulder, elbow) is selected and stored in computer memory. In addition, a

fixed point, which is a point in the field of view that does not move, is digitized for each frame as an absolute reference. The fixed point allows for the simple correction of any registration or vibration errors introduced during recording or playback. At some point during the digitizing of each view, a synchronizing event must be identified and, additionally, the location of the calibration points as seen from that camera must be digitized. This sequence of events is repeated for each camera view. This type of digitizing is primarily a manual process.

An alternative digitizing option permits the procedure to proceed automatically using any number of marker sets. This requires that the subject have the markers placed on the body prior to the filming phase. The types of markers and their placements have a substantial number of adherents particularly in the rehabilitation, gait measurement, and computer game communities. This type of digitizing combines manual and automatic, so that the activity progresses under manual control with computer-assisted selection of the joint segments or points. User participation in the digitizing process provides an opportunity for error checking and visual feedback which rarely slows the digitizing process adversely. A trained operator, with reasonable knowledge about digitizing and anatomy, can rapidly produce high quality digitized images. It is essential that the points are selected precisely because all subsequent information is based on the data provided in this phase.

The computation phase of analysis is performed after all camera views have been digitized. At this point in the procedures, the three-dimensional (3D) coordinates of the joints centers of a body are calculated. The transformation methods for transforming the data to two-dimensional (2D) or 3D coordinates are Direct Linear Transformation, Multiplier, and Physical Parameters Transformation. This phase computes the true 3D image space coordinates of the subject's body joints from the 2D digitized coordinates obtained from each camera's view. The Direct Linear Transformation Computation is determined by first relating the known image space locations of the calibration points to the digitized coordinate locations of those points. The transformation is then applied to the digitized body joint locations to yield true image space locations. This process is performed under computer control with some timing information provided by the user. The information needed includes, for example, starting and ending points if all the data are not to be used, as well as a frame rate for any image sequence that differs from the frame rate of the cameras used to record the sequence. The Multiplier technique for transformation is less rigorous mathematically and is utilized for those situations when no calibration device was used and only a few objects in the background are available to calibrate the area. This situation usually occurs when a nonscientific, third-party recorded the pictures such as a home video or even a televised sporting event. The third type of transformation, the Physical Parameters Transformation, is primarily applied with panning camera views or when greater accuracy is required on known image sources.

Following data transformation, a smoothing or filtering operation is performed on the image coordinates to remove small random digitizing errors and to compute body joint

velocities and accelerations. Smoothing options include polynomial, cubic and quintic splines, a Butterworth second-order digital and fast Fourier filters (43–45). Smoothing may be performed automatically by the computer or interactively with the user controlling the amount of smoothing applied to each joint. Error measurements from the digitizing phase may be used to optimize the amount of smoothing selected. Another unique feature is the ability to display the Power Spectrum for each of the x , y , and z coordinates. This enhancement permits the investigator to evaluate the effect of the smoothing technique and the chosen value selected for that curve by examining the Power Spectrum. Thus, the investigator can determine the method and level of smoothing that best meets the requirements of the specific research. After smoothing, the true 3D body joint displacements, velocities, and accelerations will have been computed on a continuous basis throughout the duration of the sequence.

Analogue data can be obtained from as many as 256 channels for input into the analogue-to-digital (A/D) system. Processing of the analogue signals, such as those obtained from transducers, thermistors, accelerometers, force platforms, EMG, ECG, EEG, or others, can be recorded for analysis and, if needed, synchronized with the video system. The displayed video picture and the vectors from the force plate can be synchronized so that the force vectors appear to be “inside the body”. At this point, optional kinetic calculations can be performed to provide for measurement and analysis of the external forces that are applied to the body during movement. Inverse Dynamics are used to compute joint forces and torques as well as energy and momentum parameters of single or combined segments. External forces include anything external to the body that is applying force or resistance such as a golf club held in the hand. The calculations that are performed are made against the force distribution of the body.

The presentation phase of analysis allows computed results to be viewed and recorded in a number of different formats. Body position and motion can be presented in both still frame and animated stick figure format in 3D. Multiple stick figures may be displayed simultaneously for comparison purposes. Joint velocity and acceleration vectors may be added to the stick figures to show the magnitude and direction of body motion parameters. Copies of these displays can be printed for reporting and publication. Results can also be reported graphically. Plots of body joints and segments, linear and angular displacements, velocities, accelerations, forces, and moments can be produced in a number of format options. An interactive graphically oriented user interface allows the selection and plotting of such results to be simple and straightforward. In addition, body motion parameter results may also be reported in numerical form and printed as tables.

Utilizing this computerized system for biomechanical quantification of various movements performed by the elderly may assist in developing strategies of exercise, alterations in lifestyle, modifications in environmental conditions, and interventions to ease and/or extend independence. For example, rising from a chair is a challenging task for many elderly persons and getting up quickly is

associated with a particularly high risk for falling. Hoy and Marcus (46) observed that older women moved more slowly and altered their posture to a greater extent than younger women. The strength levels were greater for the younger subjects, but it could not be concluded that strength was the causal mechanism for the slower speed. Following an exercise program affecting a number of muscle groups, younger and older women significantly increased in strength. Results of this study suggest that age-associated changes in muscle strength have an important effect on movement strategies used during chair rising. Following participation in a strength-training program, biomechanical assessment revealed changes in movement strategies that increased both static and dynamic stability. Other areas appropriate for biomechanical assessment would be on the well-known phenomenon of increased postural sway (47) and problems with balance (48–50) in the aged.

It is also important to study the motor patterns used by older persons while performing locomotor tasks associated with daily life such as walking on level ground and climbing or descending stairs. Craik (51) demonstrated that older subjects walking at the same speed as younger ones exhibited similar movement characteristics. Perhaps the older subjects selected slower movement speeds that produced apparent rather than real reductions in performance. These types of locomotor studies are easily assessed by biomechanical procedures. A biomechanical inquiry by Williams (52) examined the age-related differences of intralimb coordination by young and old individuals. Williams observed a similarity of general intralimb coordination for both old and young participants for level ground motions. One age-related change was suggested with regard to the additional balance constraints required for going up stairs because of adjustments not required on level ground. More profound differences were observed by Light et al. (53) with complex, multilimb coordinated movements performed in a standing position which necessitated dynamic balance control. These types of tasks showed significant age-dependent changes. Compared with younger subjects, the older participants were slower in all timing components, had less predominance in their movement patterns, less coupling of their limbs for movement end-points, and were more susceptible to environmental uncertainties. The alterations in movement performance reflected age-related loss in the ability to coordinate fast, multilimb movements performed from an upright stance suggesting that older individuals may have uncoordinated and unpredictable movement patterns when required to move quickly. Additionally, it was suggested that the more uncertain the environment, the greater the disturbance on the movement, thus, increasing the risk of falling. These studies provide realistic examples of one role biomechanics can perform by not only specifically identifying the locus of change but also providing objective quantification.

Another interesting application of the biomechanical system involves a multidimensional study of Alzheimer's disease currently in progress at a leading medical school. The study's strength is similar to the blind men who must integrate all of the information each has gathered in order to accurately describe the elephant. Examination of the

brain's response to specific drugs and at varying dosages, magnetic resonance imaging (MRI), thermographic, endocrine, and hormonal changes, vascular chemistry, as well as other aspects are being evaluated for each patient and their specific motor performances are being quantified biomechanically with the Ariel Performance Analysis system. Preliminary evidence indicates that performance on a simple bean-bag tossing skill improves daily although there is no cognitive recognition of the task. The activity of tossing a bean bag into a target circle from a standing position employs postural adjustments as well as coordinated arm and hand directed skills. Skill acquisition, or motor learning, involves both muscular capability and neural control mechanisms. Both activities involve closed- and open-loop mechanisms. The goal-directed movements needed to perform the bean-bag toss require the anticipatory postural adjustments that are inherent in an open-loop control. Because these findings suggest that muscular control and skill acquisition remain viable, this enables investigators to narrow the direction of the research and continue the study while continuously honing the focus. With each scientific finding, the research can be directed toward identification of the underlying cause.

The preceding discussion has described a computerized biomechanical system that can be utilized for the quantification of activities and performance levels particularly where appropriate for gerontological issues. Following the identification and definition of an activity, a second and equally necessary component follows. This is the ability to evaluate, test, and/or train the musculoskeletal components of the body in a manner appropriate to the specifically identified task(s) and according to the capabilities of the age and health of the individual. The integration of both technological assessment tools should assist the individual and others involved in their daily life to identify and measure those portions of an exercise program that can enhance performance, fitness status, or exercise capabilities for each gender and at different ages. In other words, one of the principles should be remembered is the goal of optimizing performance at every age.

For centuries, many devices have been created specifically for strength development. These devices include treadmills, bicycle ergometers, rowing machines, skiing simulators, as well as many of the more traditional resistive exercises with dumbbells, bar bells, and commercially available weight equipment. Figure 8 illustrates one of these equipment. Each type of exercise has some advantages, but none are designed to cope with the difficulties inherent with the gravitational effects that affect the multilinked human body performing on various exercise equipment.

All systems that employ weights as the mechanism for resistance have major drawbacks in four or more areas, as follows: (1) biomechanical considerations; (2) inertia; (3) risk of injury; (4) unidirectional resistance.

The biomechanical parameters are extremely important for human performance and should be incorporated into exercise equipment. The biomechanical factors were discussed previously. Inertia is the resistance to changes in motion. In other words, a greater force is required to begin moving weights than is necessary to keep them moving.

Figure 8. The computerized exercise equipment.

Similarly, when the exercising person slows at the end of a movement, the weights tend to keep moving until slowed by gravity. This phenomenon reduces the force needed at the end of a motion sequence. Inertia becomes especially pronounced as acceleration and deceleration increase, effectively reducing the useful range of motion of weight-based exercise equipment.

The risk of injury is obvious in most weight-based exercise equipment. When weights are raised during the performance of an exercise, they must be lowered to their original resting position before the person using the equipment can release the equipment and stop exercising. If the person exercising loses their grip, or is unable to hold the weights owing to exhaustion or imbalance, the weights fall back to their resting position; serious injuries can, and have, occurred. Finally, while being raised or lowered, weights, whether on exercise equipment or free standing, offer resistance only in the direction opposite to that of gravity. This resistance can be redirected by pulleys and gears but still remains unidirectional.

In almost every exercise performed, the muscle or muscles being trained by resistance in one direction are balanced by a corresponding muscle or muscles that could be trained by resistance in the opposite direction. With weight-based systems, a different exercise, and often a different mechanism, is necessary to train these opposing muscles. Exercise mechanisms that employ springs, torsion bars, and the like are able to overcome the inertia problem of weight-based mechanisms and, partially, to compensate the unidirectional force restriction by both expanding and compressing the springs. However, the serious problem of safety remains. An additional problem is the fixed, nonlinear resistance that is characteristic of springs and is usually unacceptable to most exercise equipment users.

The third resistive mechanism commonly employed in existing exercise equipment is a hydraulic mechanism. Hydraulic devices are able to overcome the inertial problem of weights, the safety problem of both weights and springs, and, with the appropriate selection or configuration, the unidirectional problem. However, previous applications of the hydraulic principle have demonstrated a serious

deficiency that has limited their popularity in resistive training. This deficiency is that of a fixed or a preselected flow rate through the hydraulic system. With a fixed-flow rate, it is a well established fact that resistance is a function of the velocity of the piston and, in fact, varies quite rapidly with changes in velocity. It becomes difficult for a person exercising to select a given resistance for training due to the constraint of moving either slower or faster than desired in order to maintain the resistance. Additionally, at any given moment, the user is unsure of just what the performing force or velocity actually is.

In the field of rehabilitation (54) especially, isokinetic or constant velocity training equipment is a technology that has enjoyed wide acceptance. These mechanisms typically utilize active or passive hydraulics or electric motors and velocity-controlling circuitry. The user or practitioner selects a constant level of velocity for exercise and the mechanism maintains this velocity while measuring the force exerted by the subject. Although demonstrating significant advantages over weight-based systems, isokinetic systems possess a serious limitation. There are virtually no human activities that are performed at a constant velocity. Normal human movement consists of patterns of acceleration and deceleration. When a person learns to run, ride a bike, or write, an acceleration-deceleration sequence is established that may be repeated at different rates and with different levels of force, but always with the pattern unique to that activity. To train, rehabilitate, or diagnose at a constant velocity is to change the very nature of the activity being performed and to violate most biomechanical performance principles.

FEEDBACK CONTROL OF EXERCISE

A newer form of exercise equipment can determine the level of effort by the person, compare it to the desired effort, and then adjust accordingly. The primary advantage of this resistive mechanism is that the pattern of resistance or the pattern of motion is fully programmable. The concept of applying a pattern of resistance or motion to training and rehabilitation was virtually impossible until the invention of computerized feedback control. Prior to the introduction of computerized feedback control, fitness technology could provide only limited modes of resistance and motion. Bar bells or weights of any type provide an isotonic or constant resistance type of training only when moved at a constant velocity. Typically, users are instructed to move the weights slowly to avoid the problem of inertia resulting from the acceleration or deceleration of mass. Weights used with cams or linkages that alter the mechanical advantage can provide a form of variable resistance. However, the pattern is always fixed and the varying mechanical advantage causes a variation in velocity that increases inertial effects. Users must move the weights slowly to preserve the resistance pattern. Another deficiency with these types of equipment is that they do not approximate the body or limb movement pattern of a normal human activity.

An exercise machine controlled by a computer possesses several unique advantages over other resistive exercise mechanisms, both fixed and feedback controlled. The most

significant of these advances is the introduction of software to the human/computer feedback loop. The computer and its associated collection of unique programs can regulate the resistance to vary with the measured variables of force and displacement as well as modify the resistance according to data obtained from the feedback loop while the exercise progresses. This modification can, therefore, reflect changes in the pattern of exercise over time. The unique programmed selection can effect such changes in order to achieve a sequential or patterned progression of resistance for optimal training effect. The advantage of this capability over previous systems is that the user can select the overall pattern of exercise and the machine assumes responsibility for changing the precise force level, the speed of movement, and the temporal sequence to achieve that pattern.

There are a wide range of treadmills, bikes, and exercise devices currently available that employ electrical control features. These include such options as fat burn, up hill training, or cardiac modes. These types of equipment change the speed or elevations with preprogrammed actions that are determined at the manufacturing center when the machines are made rather than by the person exercising. The exerciser can select the programs presented on the control panel, but the response by the machine to the user is not at all related to the performance but rather to the preset events stored in the memory. Therefore, the person may be running "uphill" on the treadmill as determined by the imbedded system, but not with responsive interaction between the equipment and the individual moment by moment. This is a limitation of most of the exercise equipment available in the marketplace of the twenty-first century.

In the early 1980s, the first resistive training and rehabilitation device to employ computerized feedback control of both resistance and motion during exercise was introduced to overcome the lack of machine-human interactivity (55). For the first time, a machine dynamically adapted to the activity being performed rather than the traditional approach of modifying the activity to conform to the limitations of the machine. Biomechanical results previously calculated could be used to program the actual patterns of motion for training or rehabilitation. The equipment utilizes a passive hydraulic resistance mechanism operating in a feedback-controlled mode under control of the system's computer.

A simplified functional description of this mechanism, the Ariel Computerized Exercise System, and its operation is described. A hydraulic cylinder is attached to an exercise bar through a mechanical linkage. As the bar is moved, the piston in the hydraulic cylinder moves which pushes oil from one side of the cylinder, through a valve, and into the other side of the cylinder. When the valve is fully open there is no resistance to the movement of oil and, thus, no resistance in the movement of the bar. As the valve is closed, it becomes harder to push the oil from one side of the cylinder to the other and, thus, harder to move the bar. When the valve is fully closed, oil cannot flow and the bar will not move. In addition to the cylinder, the resistance mechanism contains sensors to measure the applied force on the bar and the motion of the bar. To describe

the operation of the computerized feedback loop, assume the valve is at some intermediate position and the bar is being moved at some velocity with some level of resistance. If the computer senses that the bar velocity is too high or that bar resistance is too low, it will close the valve by a small amount and then check the velocity and resistance values again. If the values are incorrect, it will continue to regulate the opening of the valve and continually check the results until the desired velocity or resistance is achieved. Similar computer assessments and valve adjustments are made for every exercise. Thus, an interactive feedback loop between the computer and the valve enable the user to exercise at the desired velocity or resistance. The feedback cycle occurs hundreds of times a second so that the user experiences no perceptible variations from the desired parameters of exercise.

There are a number of advantages in a computerized feedback controlled resistance mechanism over devices that employ weights, springs, motors, or pumps. One significant advantage is safety. The passive hydraulic mechanism provides resistance only when the user pushes or pulls against it. The user may stop exercising at any time and the exercise bar will remain motionless. Another advantage is that of bidirectional exercise. The hydraulic mechanism can provide resistance with the bar moving in each direction, whereas weights and springs provide resistance in only one direction. Opposing muscle groups can be trained in a single exercise. Two additional problems associated with weight training, noise and inertia, are also eliminated because the hydraulic mechanism is virtually silent and full resistance can be maintained at all speeds. Figure 9 illustrates an olympic training system utilized by the olympic athletes.

The Ariel Computerized Exercise System allows the user to set a pattern of continuously varying velocity or resistance. The pattern can be based on direct measurements of that individual's motion derived from the biomechanical analysis or can be designed or created by the user with a goal of training or rehabilitation. During exercise, the computer uses the pattern to adjust bar velocity or bar resistance as the subject moves through the full range of motion. In this manner, the motion parameters of almost any activity can be closely duplicated by the exercise system allowing training or rehabilitation using the same pattern as the activity itself.

The software consists of two levels. One level of software is invisible to the individual using the equipment since it controls the hardware components. The second level of software allows interaction between the user and the computer. The computer programs necessary to provide the real-time feedback control, the data program and storage, and the additional performance manipulations are extensive. The software provides computer interaction with the individual operator by automatically presenting a menu of options when the system is activated. Selection of the diagnostics option allows several parameters about that person to be evaluated and stored if desired. Some of the diagnostic parameters available include range of motion, maximum force, and maximum speed that the individual can move the bar for the specific activity selected. The maximum force and maximum speed data

Figure 9. Olympic training on the computerized exercise system.

can be determined at each discrete point in the range of movement as well as the average across the entire range. The diagnostic data can be used solely as isolated pre- and post-test measurements. However, the data can also be stored within the person's profile so that subsequent actions and tests performed on the equipment can be customized to adjust to that specific individual's characteristics.

The controlled velocity option permits the individual to control the speed of bar movement. The pattern of the velocity can be determined by the person using the equipment and these choices of velocity patterns include: (1) isokinetic, which provides a constant speed throughout the range of motion; (2) variable speed, in which the speed at the beginning of the motion and the speed at the end of the stroke are different with the computer regulating a smooth transition between the two values; and (3) programmed speed, which allows the user to specify a unique velocity pattern throughout the range of movement. For each of the choices, determination of the initial and final velocities is at the discretion of the individual through an interactive menu. The number of repetitions to be performed can be indicated by the person. Also, it is possible to designate different patterns of velocity for each direction of bar movement.

The controlled resistance option enables the person to control the resistance or amount of force required to move the bar. The alternatives include (1) isotonic, which provides a constant amount of force for the individual to overcome in order to move the bar; (2) variable resistance, in which the force at the beginning of the motion and the force at the end of the movement are different with the computer regulating a smooth transition between the two values; (3) programmed resistance, which permits the individual to specify a unique force pattern throughout the range of movement. An interactive menu enables the person to indicate the precise initial and final values, the number of repetitions to be used, and each direction of bar motion for the three choices. The controlled work option allows the individual to determine the amount of work, in Newton/meters or joules, to be performed rather than the number of repetitions. In addition, the person can choose either velocity or resistance as the method for controlling the bar movement. As with the previous options, bidirectional control is possible. The data storage capability is useful in the design of research protocols. The software allows an investigator to program a specific series of exercises and the precise manner in which they are to be performed, for example, number of repetitions and amount of work, so that the user need only select their name from the graphic menu and the computer will then guide the procedures. Data gathered can be stored for subsequent analysis. The equipment is fully operational for all options irrespective of whether the data storage option is activated.

Numerous features further enhance the application of this advanced fitness technology. Individual exercise programs can be created and saved on the computer, a CD, an internet file, or a USB disk. Users can perform their individual program at any time merely by loading it from any of the memory options used. Measurements of exercise results can be automatically saved and progress monitored by comparing current performance levels to previous ones. Performance can be measured in terms of strength, speed, power, repetitions, quantity of work, endurance and fatigue. Comparison of these quantities can be made for flexors versus extensors, right limb versus left limb, as well as between different dates and different individuals. Visual and audio feedback are provided during exercise to ensure that the subject is training in the proper manner and to provide motivation for optimal performance. Accuracy of measurement is essential and it is deemed as one of the most important considerations in the software. Calibration of the equipment is performed dynamically and is a unique feature that the computerization and the feedback system allow. Calibration is performed using weights with known values and the procedure can be performed for both up and down directions. This type of calibration is unique since the accuracy of the device can be ascertained throughout the range of motion.

FUTURE DEVELOPMENTS

As discussed previously, a large diagnostic and/or exercise system exists, but sheer bulk precludes its convenient use at home or in small spaces. One future goal is to develop

Figure 10. Motion analysis in space.

a computerized, feedback-controlled, portable, battery-powered, hydraulic musculoskeletal exercise assessment and training equipment based on the currently available full-sized system. The device will be portable, compact, and operate at low voltage. Although physical fitness and good health have become increasingly more important to the American public, no compact, affordable, accurate device either for measurement or conditioning human strength or performance exists. This deficit hinders both America's ability to provide convenient, affordable, and accurate diagnostic and exercise capabilities for hospital or home-bound patients, children or elderly, to adequately perform within small-spaced military areas, as would be found in submarines, or in NASA shuttle projects to explore the frontiers of space. Figure 10 illustrates an astronaut running on a computerized treadmill in a zero gravity environment.

The frame will be compact and light-weight with a target weight of < 10 kg. This is an ambitious design goal that will require frame materials to have maximum strength/weight ratios and the structure must be engineered with attention directed toward compactness, storage size, and both ease and versatility of operation. The design of a smaller and lighter hydraulic valve, pack, and cylinder assembly is envisioned. Software can be tailored to specific applications such as for the very young or the aged, specific orthopedic and/or disease training, or other applications.

Another future development will be the ability to download programs through the Internet. For example, each patient could have one of the small exercise devices at home. His/her doctor can prescribe certain diagnostic activities and exercise regiments and transmit them via the Internet. The individual can perform the exercises at home and then submit the results to the doctor electronically. Biomechanical quantification of performances will become available electronically by downloading the software and executing the procedures on the individual's personal computer. Parents will be able to assist their child's athletic and

growth performances, doctors or physical therapists can compare normal gait with their patient's, and many other uses which may not be apparent at this time. The Internet can also function as a conduit between a research site and a remote location. Consider a hypothetical example of the National Institute of Health conducting a study on the effects of exercise on various medical, chemical, neural, and biomechanical factors for a large number of subjects around the world. The exercise equipment could be linked directly with Internet sources; the other data could be collected, and sent to the appropriate participating institutes. Findings from each location could then be transmitted to the main data collection site for integration.

CONCLUSION

National and international attitudes and policies focused on improving the health of children, workers, and the elderly must be directed towards good nutrition and improving lifestyles. It is made abundantly clear in print and televised media, that obesity has become a severe threat to the health and well being of Americans. That this problem is or will become an international epidemic may depend on the manner in which it is addressed. Exercise is no substitute for poor lifestyle practices, such as excessive alcohol consumption, smoking, overeating, and poor dietary practices. Attention must be directed to the importance of creative movements, posture, perceptual motor stimulation, body awareness, body image, and coordination. However, the importance of physical activity is too valuable to be limited to the young and healthy. Exercise, sports, and other physical activities must include all ages without regard to their frailty or disabilities.

The laws of nature rule the human body. Chemical and biological laws affect food metabolism, neurological transmissions within the nervous system and the target organs, hormonal influences, and all other growth, maintenance, and performance activities. Mechanical influences occur at the joints according to the same laws that return the pole vaulter to earth. Food, water, air, and environmental factors interact with work and societal demands. Human life is an interplay of external and internal processes and energy and, according to the second law of thermodynamics, the system will move toward increased disorder over time (56).

In terms of the universe, the first law of thermodynamics states that the total energy of the universe is constant. The second law states that the total entropy of the universe is increasing. The measure of a system's disorder is referred to as entropy and Eddington said, Whenever you conceive of a new theory of unusually attractiveness, but it does not in some way conform to the second law, then that theory is most certainly wrong (57). Everyone inevitably grows older. Delaying the process of disorder by keeping the subsystems of the organism at a low level of entropy does not flaunt the second law, but rather exploits it.

Science and technology have afforded us the ability to quantify movement so that humans can use their bodies more efficiently. Normal movement of small children can be reflected in improved diapers that do not alter their gait.

Figure 11. The EMG analysis of a tennis stroke.

Assessment of workplace activities can identify movements that are biomechanically inappropriate for healthy workers. Changing the design of the work bench, providing variable height stools for the conveyor belt operators, and evaluating the job requirements to assist in matching the employee to the work, improved wheelchair design, and adaptations in housing for the elderly are just a few examples of how biomechanical analysis can be applied. Figure 11 shows how athletic performance and equipment are assessed scientifically.

Not only has scientific and technological means provided quantitative assessment abilities, but has also allowed the development of improved means for exercising. Exercise equipment has become so sophisticated that it is appropriate for all ages. The youngest and the oldest can benefit from improved muscular health; the weakest and the strongest can always improve or, at the very least, sustain, healthy muscles; and those with compromised health or bodily functions should enjoy the opportunities to improve their musculature.

Logically, consumption of proper food, sleeping or resting sufficiently, and engaging in an appropriately amount of intense physical activity should keep the tissues and organs functioning maximally. To extend and improve the length and the quality of life depends on an increased awareness of human anatomy, biology, and physiology with continuous research efforts in these and other areas which impact human life. The aging process cannot be overcome, but it should be possible to negate many of the debilitating aspects of it. The Declaration of the United States of America is the only document of any country in history which includes the statement of "pursuit of happiness" and this concept should apply to the health and quality of life for all peoples, regardless of location, and at every age: from infancy to the twilight years.

BIOMEDICAL ENGINEERING EDUCATION

PAUL BENKESER
Georgia Institute of Technology
Atlanta, Georgia

INTRODUCTION

Biomedical engineering is that interdisciplinary field of study combining engineering with life sciences and medicine. It is a relatively new field of study that has only recently experienced sufficient maturity to enable it to establish its own identity. Often, this field will be described

using the term bioengineering. In 1997, the Bioengineering Definition Committee of the National Institutes of Health released the following definition of the field (1): “Bioengineering integrates physical, chemical, mathematical, and computational sciences and engineering principles to study biology, medicine, behavior, and health. It advances fundamental concepts; creates knowledge from the molecular to the organ systems level; and develops innovative biologics, materials, processes, implants, devices and informatics approaches for the prevention, diagnosis, and treatment of disease, for patient rehabilitation, and for improving health.”

While many use biomedical engineering and bioengineering interchangeably, it is generally accepted today that bioengineering is a broader field that combines engineering with life sciences, but is not necessarily restricted to just medical applications.

The Biomedical Engineering Society further elaborated on the definition of biomedical engineering as part of a guide on careers in the field. In it is stated (2): “A Biomedical Engineer uses traditional engineering expertise to analyze and solve problems in biology and medicine, providing an overall enhancement of health care. Students choose the biomedical engineering field to be of service to people, to partake of the excitement of working with living systems, and to apply advanced technology to the complex problems of medical care. The biomedical engineer works with other health care professionals including physicians, nurses, therapists and technicians. Biomedical engineers may be called upon in a wide range of capacities: to design instruments, devices, and software, to bring together knowledge from many technical sources to develop new procedures, or to conduct research needed to solve clinical problems.”

Educational programs in the field of biomedical engineering had their origins in a handful of specialized graduate training programs in the 1950s focusing primarily on diagnostic and therapeutic devices and instrumentation. By 2004, there were undergraduate and graduate programs in biomedical engineering at ~100 universities in the United States. The diversity in the content of undergraduate educational programs that was commonplace in its early years is gradually diminishing as the field has matured. While the current undergraduate programs still maintain their own unique identity, there has been a steady movement toward the definition of a core curriculum in the field.

The purpose of this article is to give the reader some historical perspective on the origins of educational programs in the field, the challenges associated with preparing bachelor-level graduates for careers in the field, and the current state-of-the-art in undergraduate biomedical engineering curriculums.

HISTORY

The first steps toward establishing biomedical engineering as a discipline occurred in the 1950s as several formalized training programs were created. Their establishment was significantly aided by the National Institutes of Health

creation of training grants for doctoral studies in biomedical engineering. The Johns Hopkins University, the University of Pennsylvania, the University of Rochester, and Drexel University were among the first to be awarded these grants.

During the late 1960s and early 1970s, growing opportunities in the field helped prompt the development of a second generation of biomedical engineering programs and departments. These included Boston University in 1966; Case Western Reserve University in 1968; Northwestern University in 1969; Carnegie Mellon University, Duke University, Rensselaer Polytechnic Institute and a joint program between Harvard and the Massachusetts Institute of Technology in 1970; Ohio State University and University of Texas, Austin, in 1971; Louisiana Tech, Texas A&M and the Milwaukee School of Engineering in 1972; and the University of Illinois, Chicago in 1973 (3). Many of these first and second generation of programs were concentrating the training of their students in areas defined either using quasiclassical engineering terminology, such as bioinstrumentation, biomaterials and biomechanics, or by application area, such as rehabilitation engineering or clinical engineering.

The late 1990s witnessed a substantial increase in the growth of the number of departments and programs in biomedical engineering, especially at the undergraduate level. The growth of this third generation of programs was fueled in part by grants from The Whitaker Foundation to help institutions establish or develop biomedical engineering departments or programs. In 2004, ~100 universities have programs or departments in biomedical engineering, including 33 offering undergraduate degree programs accredited by the Engineering Accreditation Commission of the Accreditation Board for Engineering and Technology (ABET) (4). The growth in the numbers of ABET accredited degree programs is illustrated in Fig. 1.

The arrival of the third generations of programs coincided with the development of several new areas of training in biomedical engineering, such as systems biology–physiology, and tissue, cellular, and biomolecular engineering. These areas typically require significantly more training in life sciences than was present in the first and second

generation biomedical engineering training programs. This presented significant challenges for undergraduate programs trying to add this life science content to their curricula without increasing the number of credit hours required for the programs. Many of these programs accomplished this by creating a new generation of courses in which the engineering and life science concepts are integrated together within courses. The integration of such courses into the curriculum is discussed in more detail in the Curriculum section.

CAREER PREPARATION

The design of a high quality educational program should always start with its educational objectives. By using the definition established by ABET, these program educational objectives are statements that describe the expected accomplishments of graduates during the first several years following graduation (5). This requires programs to be cognizant of the needs of prospective employers of its graduates and design learning environments and curricula to meet those needs. This is particularly challenging task for a relatively new and evolving field like biomedical engineering.

Biomedical engineers are employed in industry, in research facilities of educational and medical institutions, in teaching, in government regulatory agencies, and in hospitals. They often serve as integrators or facilitators, using their skills in both the engineering and life science fields. They may work in teams in industry to help design devices, systems, and processes that require an in-depth understanding of both living systems and engineering. Frequently, biomedical engineers will be found in technical sales and marketing positions in companies seeking to provide their customers with technically trained individuals who are capable of better understanding their needs and communicating those needs back to product development teams. Government regulatory positions, such as those with the Food and Drug Administration, often involve testing medical devices for performance and safety. In research institutions, biomedical engineers participate in or direct research activities in collaboration with other

Figure 1. Number of ABET accredited programs in biomedical engineering.

researchers with such backgrounds as medicine, biology, chemistry, and a variety of engineering disciplines.

According to the U.S. Department of Labor's Bureau of Labor Statistics, manufacturing industries employed 38% of all biomedical engineers, primarily in the pharmaceutical and medicine manufacturing and medical instruments and supplies industries (6). Others worked in academia, hospitals, government agencies, or as independent consultants. Employment of biomedical engineers is expected to increase faster than the average for all occupations through 2012 (6). The demand for better and more cost-effective medical devices and equipment designed by biomedical engineers is expected to increase with the aging of the population and the associated increased focus on health issues. Most of these employment opportunities will be filled with graduates from B.S. and M.S. degree programs. However, for research-oriented jobs, like faculty positions in academia and research and development positions in industry, employers typically require their employees to possess a Ph.D. degree.

The needs of the employers that hire biomedical engineers undoubtedly vary by industry and job title. However, there are some skills that appear to be in universal demand by all employers of biomedical engineers. They include proficient oral and written communication skills, the ability to speak the languages of engineering and medicine, a familiarity with physiology and pathophysiology, and teamwork skills (6).

In spite of this seemingly impressive list of career paths and options, one of the most significant challenges facing entry-level biomedical engineers are prospective employers who complain that they do not understand what skill sets biomedical engineers possess (7). The perception is that the skills possessed by engineers from other disciplines, like electrical or mechanical engineering, are more predictable and in large part are independent of the university where the engineer was educated. It is likely that this perception is a result of a combination of two factors. First, often the individuals responsible for making the hiring decisions in companies did not receive their degrees in biomedical engineering, and thus do not have first-hand experience with the training received by biomedical engineers. Second, until relatively recently, many undergraduate biomedical engineering programs lacked a substantive core curriculum and were structured in such a way that students had to select from one of several "tracks" offered by the program. These tracks were typically patterned along traditional engineering lines, such as bioelectronics and biomechanics, in an attempt to address another concern expressed by prospective employers—that graduates of bachelor degree programs in biomedical engineering were too broadly trained and thus lacked sufficient depth of engineering skills. Due to this perceived lack of depth, it is not uncommon to find employers for which the entry-level degree for biomedical engineering positions is the masters degree. Undoubtedly the presence of these tracks, and their variability from program to program, contributed to the confusion in industry over the what skill sets they should expect from a biomedical engineer.

As a result of these concerns over depth, breadth, and uniformity of curriculum, the biomedical engineering

education community has recognized the need to reach consensus on what constitutes a core undergraduate curriculum in biomedical engineering. This has become one of the major initiatives of the National Science Foundation (NSF) sponsored VaNTH Engineering Research Center (ERC) for Biomedical Engineering Educational Technologies. This ERC, a collaboration of teams from Vanderbilt University, Northwestern University, The University of Texas at Austin, Harvard University, and the Massachusetts Institute of Technology, was created in 1999. Its vision is to transform bioengineering education to produce adaptive experts by developing, implementing and assessing educational processes, materials, and technologies that are readily accessible and widely disseminated (8). The Whitaker Foundation has also sponsored workshops at its 2000 and 2005 Biomedical Engineering Summit meetings with the goal of delineating the core topics in biomedical engineering that all biomedical engineering students should understand. White papers from these meetings can be found at the Foundation's web site (9).

In spite of the movement toward the creation of a common core curriculum in undergraduate programs of study in biomedical engineering, there will undoubtedly continue to be some differences in curricula between programs. This is not only permitted in the current accreditation review process of ABET, but in some sense encouraged. Within the past decade this process has changed from a prescriptive evaluation to an outcomes-based assessment centered on program-defined missions and objectives (10). Thus, it will be incumbent on programs to work closely with the prospective employers of their graduates to ensure that the programs provide the graduates with the skills the employers desire. For example, Marquette University's biomedical engineering program has an established industrial partners program with >30 companies participating (11).

THE UNDERGRADUATE CURRICULUM

Contained within this section is a description of a core undergraduate curriculum that the author believes the biomedical engineering educational community is converging upon. The contents are based upon reviews of curriculums from biomedical engineering programs (12) and information disseminated by the Curriculum Project of the VaNTH ERC (13). It is important to note that the core described herein is not being presented as the prescription for what a biomedical engineering curriculum should look like, but rather a reflection of the current trends in the field.

Course Requirements

To be accredited by ABET, the curriculum must include the following:

- One year of an appropriate combination of mathematics and basic sciences.
- One-half year of humanities and social sciences.
- One and one-half years of engineering topics and the requirements listed in ABET's Program Criteria for bioengineering.

A year is defined as 32 semester or 48 quarter hours.

The typical math and science content of biomedical engineering curriculums, as described in Table 1, are similar to those of other engineering disciplines. The notable exceptions are courses in biology and organic chemistry. In general, most programs rely on other departments within their university to provide the instruction for these courses. Some programs with large enrollments have been successful in collaborating with faculty in their university's science departments to create biology and chemistry courses for biomedical engineering students. For example, the School of Chemistry and Biochemistry at the Georgia Institute of Technology has created organic and biochemistry courses specifically designed for biomedical engineering students.

Table 1. Mathematics and Science Core Curriculum Subjects

Subject	Sampling of Topical Coverage
Math	Linear algebra Differential, integral, multivariable calculus Differential equations Statistics
Physics	Classical mechanics, oscillations and waves Electromagnetism, light and modern physics
Computer Science	Algorithms, data structures, program design and flow control Graphics and data visualization Higher level programming language (e.g., Matlab, Java, C++)
Chemistry	General and inorganic chemistry Organic chemistry Biochemistry
Biology	Modern biological principles Genetics Cell biology

The core biomedical engineering content is described in Table 2. Depending on the size of the program, some of the content may be delivered in courses outside of biomedical engineering (e.g., thermodynamics from mechanical engineering). It is not uncommon to find some variability between programs in the content of their core curriculums. This will likely always be the case as each program must provide the curriculum that best enables its graduates to achieve the program's unique educational objectives.

ABET Criterion 3 stipulates that engineering programs must demonstrate achievement of a minimum set of program outcomes. These outcomes are statements that describe skills that "students are expected to know or be able to do by the time of graduation from the program" (5). A closer examination of these skills suggests that they can be divided into two sets as illustrated in Table 3. The first set, "domain" skills, is one that engineering educators are typically adept in both teaching and quantitatively measuring achievement. Programs generally use courses, like those listed in Tables 1 and 2, to develop these domain

Table 2. Biomedical Engineering Core Curriculum Subjects

Subject	Sampling of Topical Coverage
Biomechanics	Principles of statics Mechanics of biomaterials Dynamics
Biotransport	Mass transfer Heat transfer Momentum transfer
Biothermodynamics	Thermodynamic principles Mass and energy balances
Biomaterials	Metals, polymers and composite materials Biocompatibility
Bioinstrumentation	Instrumentation concepts Amplifiers and filters Sensors and transducers
Biofluids	Blood vessel mechanics Hydrostatics and steady flow models Unsteady Flow and non-uniform geometric models
Systems Physiology	Cellular metabolism Membrane dynamics Homeostasis Endocrine, cardiovascular and nervous systems Muscles
Biosignal Analysis	Digital signal processing theory Filtering Frequency-domain characterization of signals

skills in their students. The second set, "professional" skills, is more difficult to teach and assess. However, these professional skills are often the ones most frequently cited by employers of engineers as the most important skills they value in their employees.

Humanities and social science courses are integral to the achievement of these professional skills. However, programs must avoid employing the "inoculation" model for teaching these skills to the students. In this model, it is assumed that students can learn these skills by simply taking isolated courses in ethics, technical communications, and so on. There are several problems with this model. It can decontextualize these skills, treating them as add-ons and not an integral part of everyday engineering practice. This is a false and even dangerous message to give the students—that written and oral communication and ethical behavior are peripheral to the real world of engineering. This message is further driven home because the faculty responsible for teaching these skills is humanities or social science faculty not engineering faculty. In addition, the complexity of these skills to be learned is too great for students to master within the framework of isolated courses. Research suggests, however, that students need quasirepetitive activity cycles and practice in multiple settings to develop proficiency in these professional skills (14–16).

Professional Skills

Before describing methods of developing these professional skills in students, it is necessary to establish operational

Table 3. Program Outcomes Specified in ABET Criterion 3

Domain Skills	Professional Skills
An ability to apply knowledge of mathematics, science, and engineering	An ability to function on multi-disciplinary teams
An ability to design and conduct experiments, as well as to analyze and interpret data	An understanding of professional and ethical responsibility
An ability to design a system, component, or process to meet desired needs	An ability to communicate effectively
An ability to identify, formulate, and solve engineering problems	The broad education necessary to understand the impact of engineering solutions in a global and societal context
A knowledge of contemporary issues	A recognition of the need for, and an ability to engage in lifelong learning
An ability to use the techniques, skills, and modern engineering tools necessary for engineering practice	

descriptions for these constructs. Such descriptions serve two functions. They reveal the complexity of the particular skills in terms of the subskills required to demonstrate the higher level skills specified in the ABET lists. Descriptions can also serve as articulations of learning outcomes, which can be designed toward and assessed. The following represents one interpretation of the variables that are indicators of these constructs (16).

Ability to communicate effectively.

Oral + written communication skills

- Convey information and ideas accurately and efficiently.
- Articulate relationships among ideas.
- Inform and persuade.
- Assemble and Organize evidence in support of an argument.
- Make communicative purpose clear.
- Provide sufficient background to anchor ideas—information.
- Be aware of and address multiple interlocutors.
- Clarify conclusions to be drawn from information.

Ability to function on multidisciplinary teams.

Team – collaboration skills + communication skills 3

- Help group develop and achieve team goals.
- Avoid contributing excessive or irrelevant information.
- Confront others directly when necessary.
- Demonstrate enthusiasm and involvement.
- Monitor group progress and complete tasks on time.
- Facilitate interaction with other members.

Understanding professional and ethical responsibilities.

- Recognize moral problems and issues in engineering.

- Comprehend, clarify, and critically assess opposing arguments.
- Form consistent and comprehensive viewpoints based on facts.
- Develop imaginative responses to problematic conflicts.
- Think clearly in the midst of uncertainty and ambiguity.
- Appreciate the role of rationale dialogue in resolving moral conflicts.
- Ability to maintain moral integrity in face of pressures to separate professional and personal convictions.

Broad education necessary to understand the impact of engineering solutions in a global and societal context.

- Identify human needs or goals technology will serve.
- Analyze and evaluate the impact of new technologies on economy, environment, physical and mental health of manufacturers, uses of power, equality, democracy, access to information and participation, civil liberties, privacy, crime and justice.
- Identify unintended consequences of technology development.
- Create safeguards to minimize problems.
- Apply lessons from earlier technologies and experiences of other countries.

Recognition of the need for, and an ability to engage in life-long learning.

- Identify learning needs and set specific learning objectives.
- Make a plan to address these objectives.
- Evaluate inquiry.
- Assess the reliability of sources.
- Evaluate how the sources contribute to knowledge.
- Question the adequacy and appropriateness of forms of evidence used to report back on learning needs.
- Apply knowledge discovered to the problem.

Table 4. Repetitive Activities in the Problem-Solving Cycle

Activity	Professional Skill				
	Communicate	Teams	Responsibilities	Impact	Learning
Identifying learning–knowledge needs as a team–individual					X
Acquiring knowledge needed to solve problem			X	X	X
Reporting back to team	X	X			X
Digging deeper and solving	X	X	X	X	X
Presenting solution to audience of experts	X				
Writing a report on problem solution	X				

There are a variety of methods programs can employ to foster the development of these professional skills in students. These include the use of team-based capstone design experiences, facilitating student participation in coop and internship experiences, encouraging involvement in undergraduate research projects, and incorporating oral and written communication exercises throughout the curriculum.

The creation of new undergraduate biomedical engineering programs has led to the development of some new approaches to professional skills development. For example, the Wallace H. Coulter Department of Biomedical Engineering at Georgia Tech and Emory University has implemented an integrative approach to the development of professional skills and adaptive expertise in its program. This approach anchors professional skills development in the context of team-based problem solving and design experiences over the four-year curriculum. This approach provides multiple opportunities for the students to work on and develop skills and knowledge in a variety of “real-world” engineering settings in which these professional skills are practiced. Within each experience, activities are identified within the problem-solving cycle that help students develop these professional skills. These activities are described in Table 4.

The need for real-world problems cannot be overstated. Authentic, open-ended problems are needed as contexts and catalysts for the development of these professional skills. Not only do they help prepare students for the professional practice of engineering, but they are also a significant motivator for the students to delve more deeply into the problem space. Moreover, the use of these skills in the context of a large problem makes them central not peripheral to biomedical engineering problem solving. They begin to understand the value of clear, thoughtful communication, and collaboration when confronting complex problems. They see how ethical issues can arise when seeking design solutions. If the problems are authentic, then the information needed to solve them must be found in multiple places, which helps students to develop inquiry and research skills for lifelong learning.

SUMMARY

The field of biomedical engineering had its foundations laid roughly 50 years ago. Undergraduate degree programs in the field followed shortly thereafter. Fueled in part by generous support from the Whitaker Foundation, there has been a significant increase in the number of new

undergraduate degree programs in the field. This has led to a significant increase in student interest in the field. This growth has increased the need for the biomedical engineering education community to work with industry to better define the skills that graduates need to obtain to lead productive careers in the field. There exists a movement, led by the NSF VaNTH ERC, to define a core undergraduate curriculum within the constraints imposed by ABET accreditation criteria. The VaNTHs vision to transform bioengineering education to produce adaptive experts has been adopted by new undergraduate degree programs and has produced demonstrated examples of pedagogical advances in the field of engineering education.

INTRODUCTION

One primary reason there is a tremendous amount of interest in cellular patterning techniques is that numerous examples in nature use these techniques to segregate cells into tissues, vessels, and organs. The idea of templates in nature abounds for the creation of organized biological systems using both inorganic (1), as well as organic template systems (2). There is also a certain allure to being able to integrate electrically active cells directly to electronic devices using standard electronic fabrication techniques. Researchers have attempted to use surface cues to pattern cells since as early as 1917, in which spider webs were used to pattern cells (3). Most of the early work on cellular patterning used topographical cues until 1988, when a landmark publication by Kleinfeld et al. (4) used lithographic templating to fabricate simple patterns of cortical neurons. This was an adaptation of standard technology developed by the electronics industry to create computer chips that was then applied to the creation of patterns to guide neuronal cell attachment. It was at this point that interest in this field mushroomed, as the idea of creating neuronal networks from living neurons has potential applications in understanding biological information processing, creating hybrid computer systems, as well as a whole host of biomedical applications. Some prominent

efforts to use cell patterning have been for spinal cord repair, creation of *in vitro* test bed systems to study diseases, as well as blood vessel formation from patterned endothelial cells (5). The initial lithography-based technique used by Kleinfeld et al. has been extended to include many other methods for the patterning of cells, including self-assembled monolayer (SAM) patterning, laser ablation, microcontact printing or stamping, ink jet printing, AFM printing, as well as patterning using microfluidic networks. Methods have also been extended in the area of topographical cues for 3D patterning, which has evolved from early work that used scratched grooves in glass surfaces. At this point, depending on the facilities that one has available, some form of mask making and pattern templating is available to just about any laboratory in the world. However, the biological interactions with these patterns that have been created are still not well developed, and this limits applications at this point.

There are many reasons for the lack of long-term applications of this technique, even after the large amount of work that has been done in this area. The first is that, in many instances, the patterns direct the initial attachment of cells, but as the extracellular matrix is deposited by the cells, long-term adherence to the patterns is not maintained. Another issue is that longer term cell survival is also dependent on factors besides the surface, such as media composition, cell–cell contact interactions, and the lack of growth factors that are normally present from other support cells and tissues. Defined systems are being developed in an attempt to control these other variables in addition to the surface (6,7), but these efforts have been limited to date. However, as progress is made in these areas, it will open up possible applications in tissue engineering, tissue repair, biosensors, and functional *in vitro* test beds.

PATTERNING METHODS

Many methods have been developed for creating templates to be used for cell patterning. These can be divided roughly into two categories: those that are derived from photolithography techniques and those that depend on physical segregation, although there is some crossover in the methods between the two. The photolithography-based systems typically use some sort of organic layer, from polymers to monolayers, which is illuminated, either directly with a pattern or through the template pattern to be created. This can involve many or a few steps depending on the particular method used. Generally, a second layer is deposited in the area where material was removed. Specific variations of this technique are discussed in this section.

The second major category, physical segregation, involves the actual placement of the molecules or cells in a pattern on a surface. Stamping is the most well-known method of creating a molecular-based template and of all the techniques is probably the most economical, but other techniques have been investigated for physical placement of cells in a desired pattern on the surface. Finally, both of these methods, which are 2D in nature, are now being extended into 3D patterning using many of the same

Figure 1. Protocol and images of the pattern. (a) Protocol of photolithography. A glass coverslip (continuous line) is coated with domains of fluorosilane molecule (dark) and with regions of polylysine (light gray) according to the pattern designed on the mask (dashed line), using ultraviolet (UV) exposure of a spin-coated photoresist (gray). (b) Images of neural networks of controlled architecture. Top: linear network. Bottom left: matrix 4×4 . Bottom right: star. Cell bodies of neurons are restricted to squares or disks of $80 \mu\text{m}$ and neurites to line ($80 \mu\text{m}$ length, $2\text{--}4 \mu\text{m}$ wide). Square and disk diameters are $80 \mu\text{m}$ for each figure. Scale bar is $50 \mu\text{m}$ (Ref. 9).

techniques, or combinations thereof, described therein. Below there is a brief description, along with the appropriate references, of the techniques that can be used to create these cellular templates.

Photolithography

A variety of photolithographic techniques has been employed to pattern proteins and cells on surfaces from the micrometer to the nanometer scale (8). The basic tools needed are a radiation source and a photomask. The photomask can be created using standard photolithography processes developed for the electronics industry. Irradiation of the surface through the photomask is used to create the patterns by ablation or by using a photosensitive material such as a photoresist as shown in Fig. 1.

Kleinfeld et al. (4) first demonstrated that dissociated neurons could be grown on 2D substrates consisting of lithographically defined patterned monolayers of diamines and triamines with alkylsilanes. The method used by Kleinfeld et al. started with a clean silicon or quartz surface that was spin coated with a layer of photoresist (an organic photosensitive polymer used in the electronics industry). The resist was exposed to UV light with a patterned photomask and then developed. The surface was refluxed in the presence of an alkylsilane, and the photoresist was then stripped off so that areas the photomask covered were reduced to bare silicon or quartz. These areas were then reacted with an aminosilane to form the patterned surface. The patterned cells developed electrical excitability and immunoreactivity for neuron-specific proteins. A further modification of this technique eliminated the photoresist from the pattern formation by direct ablation of the SAM layer (10).

Patterns of self-assembled monolayers formed from organosilanes on glass or silicon substrates and on gold

surfaces can be made by using a photoresist mask and deep UV radiation (10–18). Monolayers can also be directly ablated with various forms of radiation such as UV, X ray, ions, and electrons (8) depending on the resolution needed for the patterns. Organosilanes self-assemble and condense onto substrates that have surface $-\text{OH}$ functionalities (19). The $-\text{SH}$ functionality of the alkanethiol (20) is also highly reactive to ozone and other irradiation sources and has been used in patterning (21). Methods using X-ray or extreme UV (EUV) radiation give better resolution than the traditional photolithography using deep UV and photoresist masks. The ablated regions of the SAM can then be reacted with an organosilane or alkanethiol with different characteristics from the original layer to enable cell growth (22). Azides (23) and aromatic hydrocarbon silanes (24) have also been shown to be reactive for creating patterns.

A typical method to prepare a patterned glass silanated surface is illustrated next. The glass must first be acid cleaned or oxygen plasma cleaned to maximize the surface $-\text{OH}$ functional density. Next, the glass is reacted with a silane that contains $-\text{chloro}$, $-\text{methoxy}$, or $-\text{ethoxy}$ bonds in the presence of a small amount of water that acts as a catalyst. A mask is then used to protect certain areas of the surface while allowing the radiation source to ablate others in the desired pattern. The ablated regions of the surface can then be coated with a different silane with different properties than the original, thus forming the patterned surface; an example of this is shown in Fig. 2.

The photoreactivity of polymers, such as poly(ethylene glycol) and polystyrene, has also been used to pattern surfaces (25). Biologically based polymers, such as poly-L-lysine and extracellular matrix proteins, have been ablated to create patterns (26). Polymer photolithography followed by protein adsorption has been combined to create patterned cytophobic and cytophilic areas. Patterning of perfluoropolymers followed by adsorption of poly-L-lysine

Figure 2. Micrograph of circuit-patterned day 2 *in vitro* hippocampal neurons plated onto DETA/15F modified glass coverslips. Electrophysiology of day 12 *in vitro* hippocampal neurons displaying both spontaneous and evoked activity on a DETA/15F line-space patterned surface. Top trace: post-synaptic neuron. Bottom trace: stimulated presynaptic neuron.

and albumin has been one method used (27). Photosensitive polymers have been treated with UV radiation to create an $-COOH$ functional unit on the surface and then patterned via the linkage of proteins to form cytophilic and cytophobic regions (28). A bioactive photoresist (bioresist) has been developed that does not require the use of solvents that can denature the biomolecule that is patterned (29).

Photolithographic protein patterning requires the attachment of photosensitive groups to proteins on a substrate. Patterns can be made using a patterned mask and selective ablation. This method has been shown to be useful to produce micropatterned cultures (30). Various methods are used to covalently attach proteins in patterns to surfaces (31), to pattern using biomolecule photoimmobilization (32), and to create density gradients of photoreactive biomolecules (33). Heterobifunctional crosslinker molecules have been used to attach proteins to silanated surfaces both before and after the photolithographic patterning step (34). Protein patterning has been achieved using a micro-mirror array (MMA), which can transfer a pattern from the mirrors that are switched on, ablating a photolabile protecting group (35). Photolithography was also used to pattern thermosensitive copolymers through polymer grafting (36). The surface micropattern appeared and disappeared interchangeably, as observed under a phase-contrast microscope, by varying the temperature between 10 and 37 °C. The copolymer-grafted polystyrene surface was hydrophobic at 37 °C and hydrophilic at 10 °C.

Photolithography provides high resolution patterning and the ability to make complex patterns on surfaces. Unlike stamping techniques, the patterns are more permanent; however, the process can be relatively expensive as it generally requires the use of a laser and clean room facilities for the mask production. To attach proteins, such as ECM proteins, the use of a covalently attached crosslinker is necessary, and stamping techniques are generally preferred for this application.

Microcontact Printing (Stamping)

Microcontact printing was introduced by George Whiteside's group at Harvard in 1994 (37) to pattern self-assembled monolayers on gold substrates to control surface properties, cell adhesion, proliferation, and protein secre-

tion by patterned cells. The basic method to create surface patterns by microcontact printing has not changed much since then. Usually, a poly(dimethylsiloxane) (PDMS) stamp is created using a molding technique from a master pattern relief mold and then used to transfer chemical patterns to flat or curved surfaces. The master is usually prepared from silicon by standard photolithography and/or etching, but other substrates can also be used. The transferred chemical patterns can be created using a compound that binds covalently to the substrate (e.g., self-assembled monolayers or proteins immobilized by crosslinkers) (38) or a compound that binds noncovalently, such as absorbed extracellular matrix proteins (39). This methodology is illustrated in Fig. 3. Oliva et al. presented a novel method to couple proteins to patterned surfaces based on the strong interaction of protein A and the Fc fragment of immunoglobulins. This method involved the creation of a covalently coupled Fc fragment and the target protein (41). Methods have also been developed to transfer proteins from a fluid phase to a surface using hydrogels as the stamp (42). Moreover, recently introduced techniques are allowing the creation of protein gradients with microcontact printing (43). Although alignment of the stamp/patterns with surface features such as microelectrodes is more difficult than in the case of photolithographic patterning, several groups are beginning to address this issue (44). Microcontact printing is usually a favored method among biologists compared with photolithography, because (1) the equipment and controlled environment facilities required for photolithography are not routinely available to cell biologists and (2) the steps are simpler to pattern proteins, the molecules of greatest interest to biologists, using microcontact printing than with photolithography and crosslinkers. The refinement of the PDMS molding technique has directly led to the development of another important patterning method, microfluidics, which gained wider applications with the introduction of microelectromechanical systems (MEMS) and "lab-on-a-chip" systems. However, initial results using PDMS indicated some transfer of the PDMS to the surface during the stamping process. This can be troublesome in cell patterning applications as PDMS can be toxic to cells or mask the chemical functionality of interest. Methods of "curing" the stamps or presoaking to enable better release of the compound has been reported (45).

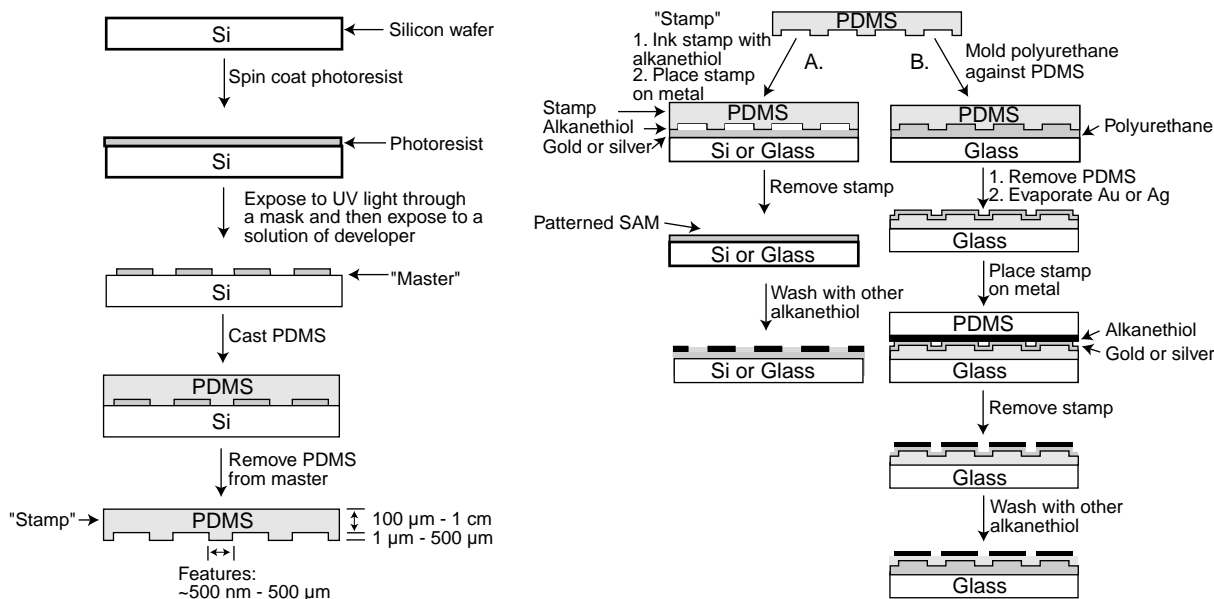

Figure 3. The creation of the master stamp is indicated on the left side of the figure, and its use to make patterns is indicated on the flow chart to the right (40).

Inkjet Printing

Inkjet technology used in desktop printers can be applied to the creation of viable cell patterns by printing proteins on to a surface (46). It is a fast and inexpensive method that does not require any contact (such as with stamping) to the surface. This method is desirable for high throughput printing of surfaces, and there is good control of the drop volume and of the alignment of the pattern. Printing occurs when small volumes of a protein solution or a solution containing cells is pumped through a nozzle in a continuous jet or small droplets of the solution are formed either by an acoustic or thermal pulse. The drop size is in the range of 10–20 pL (8). Inkjet printing and the use of computer-aided design (CAD) have impacted the biomaterials field greatly in the areas of biosensor development (47), immobilization of bacteria on biochips (48), DNA arrays and synthesis (49), microdeposition of proteins on cellulose (50), and free-form fabrication techniques to create acellular polymeric scaffolds. A drawback of this method is that the resolution, in the 20–50 μm range, is limited by the statistical variations in the drop direction and spreading on the surface (8). Other high throughput printing methods have also been adapted to pattern proteins on surfaces for biological application such as the already developed DNA spotter used to create DNA microchips (51).

Patterning via Microfluidic Networks

Synthetic surfaces may also be patterned using microfluidic networks (μFNs) to selectively generate regions with greater cytophilicity. This method involves the use of a microfluidic network fabricated in an elastomeric polymer, usually polydimethylsiloxane (PDMS), to direct a protein solution to the regions where cell-adhesion is desired. Gravity and pressure-driven flows are the most common methods for circulating the solution.

The most basic application of this method involves allowing a solution of the material to be patterned non-covalently to the substrate surface using the microchannels as guides. Some of the earliest work done with this method by Folch and Toner (52) involved patterning of various polymer surfaces with human plasma fibronectin (Fn) and collagen to create adhesion promoting domains for hepatocyte/fibroblast cocultures. Similar work by Chiu et al. (53) involved the patterning of glass coverslips with fibrinogen (Fb) and bovine serum albumin (BSA) for patterned cocultures with bovine adrenal capillary endothelial cells (BCEs) and human bladder cancer cells (ECVs). Further work by Takayama et al. (54) demonstrated an added degree of sophistication of this technique by using the laminar flow characteristics of microchannels to generate patterns using a single microchannel.

In addition to simple noncovalent binding of proteins to the substrate, it is possible to use a crosslinking agent to covalently link a molecule of interest. Delamarche et al. (55) used a hydroxylsuccinimidyl ester to chemically couple immunoglobulin G (IgG) to various substrates. Another more commonly used method involves functionalized silane SAMs on substrates, such as 3-aminopropyltriethoxysilane (APTES), and a crosslinking reagent, such glutaraldehyde (GA), to achieve crosslinking of protein molecules to a substrate. Romanova et al. (25) demonstrated the applicability of this method using microfluidic patterning to study controlled growth of *Aplysia* neurons on geometric patterns of poly-L-lysine and collagen IV. Yet another variation on this method was developed by Itoga et al. (56), who generated patterns by photopolymerization of acrylamide on 3-methacryloxypropyltrimethoxysilane modified glass coverslips. In this method, the acrylamide monomer was flowed through microchannels adhered to the derivatized coverslip and cross-linked via photopolymerization to generate cytophobic poly-acrylamide regions.

Perhaps the most sophisticated application of microfluidic patterning of substrates for cell adhesion was demonstrated by Tan and Desai (57,58), who demonstrated the fabrication of complex multilayer cocultures for biomimetic blood vessels. In this work, the 3D structure of blood vessels was recreated by differential deposition of protein and cell layers on a glass coverslip. By alternately layering proteins (Collagen I, collagen/chitosan, and matrigel) and cell types found in blood vessels (fibroblasts, smooth muscle, and endothelial cells), it was possible to recreate layers mimicking the adventitial, medial, and intimal layers observed in blood vessels.

Topographical (3D) Patterning Methods

Control of Cell Placement, Movement, and Process Growth Based on Topographical Clues. It has been known for many years that cells react to topographical clues in their environment (59). Originally, natural fibers were used to create topological clues. Later, fabrication methods developed for the microchip industry were adapted to micromachine silicon surfaces for cell culture applications (45). For the creation of micro- or nanotopography, sophisticated methods and equipment are necessary, which are available in most electronics laboratories, but are usually not available to cell biologists. In recent years, as a response to the increased need for high-throughput screening methods (planar patch clamp, lab-on-a-chip) and in response to the challenge of biological applications of nanoscience, several multidisciplinary team/centers have been established with microfabrication capabilities. The most commonly used fabrication methods are (1) silicon etching (60), (2) photoresist-based methods (61), (3) PDMS molding (62), and (4) polymer/hydrogel molding (63). Methods have also been developed for the creation of complex 3D structures by the rapid prototyping/layer-by-layer technique (58). Tan et al. (62) used 3D PDMS structures not only to control attachment and morphology of cells but also to measure attachment force through flexible microneedles as the culture substrate. Xi et al. used AFM cantilevers to demonstrate and measure the contracting force of cardiac muscle cells (64).

3D Patterning of Living Cells. Several hydrogel scaffold-based methods have also been developed to create 3D patterns from cells. For example, photo-polymerization of hydrogels can be used to create patterns of entrapped cells (65). These scaffolding methods offer possible intervention in spinal cord injury (66). Layer-by-layer methods have also been used to create complex “tissue analog” cellular structures, such as blood vessels (57).

Other Patterning Methods

Several other methods, based on microcontact printing and PDMS stamping, have been developed to create cellular patterns. Folch et al. used an inexpensive method to create microwells for coculture experiments based on a reusable elastomeric stencil (i.e., a membrane containing thru holes), which seals spontaneously against the surface (67,68). Gole and Sastry developed a novel method to pattern surfaces with lipids followed by selective protein

incorporation into the lipid patterns that result in complex protein patterns on the surface (69). A scanning electrochemical microscope has also been adapted to pattern self-assembled monolayers on surfaces with high spatial resolution by either chemical removal of SAMs (70) or by gold deposition (71). Amro et al. used an AFM tip to directly print nanoscale patterns using the so-called dip-pen technique (72–74). However, none of these methods has been proven beyond the demonstration step.

Applications

Many *potential* applications for cell patterning remain in the biomedical and biotechnology fields. However, there has been limited success to date, besides demonstrations in the literature, for any of the applications envisioned by the host of researchers in this area. However, the promise of the use of cellular patterning for real applications is bolstered by the success that has been achieved for patterning of DNA, RNA, and protein arrays (42,51) as well as for enzymatic biosensors, such as simple pregnancy tests. Much like with cellular patterning, there was a period of time during the development of molecular patterning techniques before the applications became relevant, and the authors believe this is the situation that exists for cell patterning at this time. One reason for this long development stage is that viable and reproducible cellular patterns have many other variables that are not a major issue with biomolecule patterning applications. The cellular media are very important for cell survival, especially long term, as well as cell preparation, which has a significant affect on an extracellular attachment. In addition, no universal combination will be good for every cell, as each cell type has a unique environment that it needs to survive and function, and some aspect of these factors needs to be reproduced for long-term applications. That said, many examples of tissues exhibit some segregation, including blood vessels, lung tissue, the lining of the stomach and intestines, as well as a host of other tissues, which could benefit from this methodology. However, one of the most studied cell tissues is that of the central nervous system (CNS), which exhibits a complicated network of structures that will be difficult to reproduce for reconstruction or repair of neuronal tissue or for other *in vivo* as well as *in vitro* applications. To date, there has been some success in manipulating cells in patterns and controlling certain variables that would be necessary for the creation of functional tissues, but a complete system, using this methodology, has not been reported in the literature. However, there has been some success in demonstrating the intermediate steps that will be necessary for the realization of applications of this method for biomedical and biotechnological applications. Cell attachment has been demonstrated by several researchers, and generally, pattern adherence is maintained for approximately 1 week although longer times have been demonstrated (75). Control of cell morphology and differentiation are two important factors that are necessary in creating functional systems, and these have also been demonstrated. For neuronal-based systems, the primary variable, that of axonal polarity, has also been demonstrated. Brief descriptions and progress in these areas are described below.

Controlling Cell Attachment, Morphology, and Differentiation. *In vivo*, cells are arranged in distinct patterns (76). This patterning effect is dictated during development, with cues provided by both physical contact with other cells and chemicals present in the extracellular matrix (77). Because the random arrangement of cells cultured *in vitro* does not represent the complex architecture seen in tissues, studies of many cell types lack a clear *in vivo* relationship. Consequently, techniques to create defined and reproducible functional patterns of cells on surfaces have been created.

Controlling Attachment and Morphology. Several methods have been developed to control the attachment of cells on surfaces creating patterns that more accurately mimic conditions found *in vivo*. Using photolithography, microcontact printing, and microstamping, groups have been able to create 2D patterns that guide cell attachment and alignment (37,78–81). Three-dimensional patterning techniques have also been employed to influence cell orientation and polarity of neurons and osteoblasts (82–84). Cells have also been attached to capillaries and microfluidic devices using SAMs and protein adsorption or microcontact printing (85,86). Additionally, cell attachment and proliferation has been enhanced using biomolecules attached covalently, by stamping, or microcontact printing to surfaces (37,78–82,84–87).

Controlling Morphology and Differentiation of Cell Types Other Than Neurons. Microfabrication and photolithography used to create microtextured membranes for cardiac myocyte culture showed greater levels of attachment and cell height relative to 2D culture techniques (88). Similar techniques applied to vascular smooth muscle also showed the ability to control shape and size of the cells (89). Furthermore, microtextured surfaces were shown to influence gene expression and protein localization in neonatal cardiomyocytes (90). Cues provided to cells by the topography of their extracellular environment are thought to play a role in differentiation. The generation of microtopographical surfaces in titanium has been used to regulate the differentiation of osteoblasts *in vitro* (91).

Study of Axon Guidance in Neurons. Using photolithographic techniques and SAMs, the 2D patterns created were shown to influence neuronal polarity (22). Photolithographically fabricated 3D surfaces demonstrated that topology also influenced the orientation of neurons and the polarity of axonal outgrowth (83). The ability to guide neurite outgrowth and axonal elongation has significant applications in the areas of spinal cord repair, synapse formation, and neural network formation. Initial studies using striped patterns on glass coverslips showed that neurons would adhere and preferentially extend axons along the length of the pattern (4,92). Growth of neurons on micropatterned 2D surfaces showed preferential axon extension along the length of the pattern as well as increased axon extension (92–96).

The use of 3D microchannels and microstructured surfaces has also been shown to increase the complexity of neuronal architecture, increase neurite growth, and enhance cell activity (61). Photolithography has also been

used to pattern neurons and control axon elongation for the formation of neuronal networks (25,97). The synapses formed by these hippocampal neurons showed strong electrophysiological activity up to 17 days in culture (10). These network formations show promise for use in screening pharmacological agents as well as for electronic connection.

INTRODUCTION

The ability to use wireless techniques for measurement and control of various physiological parameters inside human and animal bodies has been a long-term goal of physicians and biologists going back to the early days of wireless communication. From early on, it was recognized that this capability could provide effective diagnostic, therapeutic, and prosthetic tools in physiological research and pathological intervention. However, this goal eluded scientists prior to the invention of transistor in 1947. Vacuum tubes were too bulky and power hungry to be of any use in many wireless biomedical applications. During the late 1950s, MacKay performed his early pioneering work on what he called Endoradiosonde (1). This was a single-transistor blocking oscillator designed to be swallowed by a subject and was able to measure pressure and temperature in the digestive track. Following this early work, came a number of other simple discrete systems each designed to measure a specific parameter (temperature, pressure, force, flow, etc.) (2). By the late 1960s, progress in the design and fabrication of integrated circuits provided an opportunity to expand the functionality of these early systems. Various hybrid single and multichannel telemetry systems were developed during the 1970s and the 1980s (3). In addition, implantable therapeutic and prosthetic devices started to appear in the market. Cardiac pacemakers and cochlear prosthetics proved effective and reli-

able enough to be implanted in thousands of patients. We direct the interested readers to several excellent reviews published over the past several decades summarizing these advances in their perspective time periods. These include a review article by W. H. Ko and M. R. Neuman in the *Science* covering the technologies available in the 1960s (4) and another similar paper by Topich covering the 1970s period (5). Three subsequent reviews detailed the efforts in the 1980s (6–8) followed by the most recent article published in 1999 (9). An outdated, but classic reference book in biotelemetry, is by MacKay, which still can be used as a good starting point for some simple single channel systems and includes some ingenious techniques used by early investigators to gain remote physiological information (10).

The latter part of the 1990s witnessed impressive advances in microelectromechanical (MEMS) based transducer and packaging technology, new and compact power sources (high efficiency inductive powering and miniature batteries), and CMOS low power wireless integrated circuits that provided another major impetus to the development of biotelemetry systems (11–18). These advances have created new opportunities for increased reliability and functionality, which had been hard to achieve with previous technologies. The term biotelemetry itself has been for most part superseded by Microbiotelemetry or Wireless Microsystems to denote these recent changes in technology. Furthermore, the burgeoning area of nanotechnology is poised to further enhance these capabilities beyond what have been achievable using current miniaturization techniques. This is particularly true in the biochemical sensing and chemical delivery areas and will undoubtedly have a major impact on the future generations of implantable biotelemetry microsystems.

This review article is intended to complement and expand the earlier reviews by emphasizing newer developments in the area of biomedical telemetry in particular attention is paid to the opportunities created by recent advances in the area of microbiotelemetry (i.e., systems having volumes $\sim 1 \text{ cm}^3$ or less) by low power CMOS wireless integrated circuits, micromachined-MEMS transducers, biocompatible coatings, and advanced batch-scale packaging. We have both expanded and narrowed the traditional definition of biotelemetry by including therapeutic-rehabilitative microsystems and excluding wired devices that although fit under the strict definition of biotelemetry; do not constitute an emerging technology. In the following sections, after discussing several major components of such biotelemetry microsystems, such as transducers, interface electronics, wireless communication, power sources, and packaging, we will present some selected examples to demonstrate the state of the art. These include implantable systems for biochemical and physiological measurements, drug delivery microsystems, and neuromuscular and visual prosthetic devices. Although our primary definition of biotelemetry encompass devices with active electronics and signal processing capabilities, we will also discuss passive MEMS-based transponders that do not require on-board signal processing and can be interrogated using simple radio-frequency (rf) techniques. Finally, we should mention that although in a strict sense biotelemetry encompasses systems targeted for physiological measurements, this

narrow definition is no longer valid or desirable. A broader scope including neuromuscular stimulation and chemical delivery is currently understood to be more indicative of the term biotelemetry.

BIOTELEMETRY SYSTEMS

For the purpose of current discussion biotelemetry systems can be defined as a group of medical devices that (1) incorporate one or several miniature transducers (i.e., sensors and actuators), (2) have an on-board power supply (i.e., battery) or are powered from outside using inductive coupling, (3) can communicate with outside (bidirectional or unidirectional) through an rf interface, (4) have on-board signal processing capability, (5) are constructed using biocompatible materials, and (6) use advanced batch-scale packaging techniques. Although one microsystem might incorporate all of the above components, the demarcation line is rather fluid and can be more broadly interpreted. For example, passive MEMS-based microtransponders do not contain on-board signal processing capability, but use advanced MEMS packaging and transducer technology and are usually considered to be a telemetry device. We should also emphasize that the above components are interrelated and a good system designer must pay considerable attention from the onset to this fact. For example, one might have to choose a certain power source or packaging scheme to accommodate the desired transducer, interface electronics, and wireless communication. In the following sections, we will discuss various components of a typical biotelemetry system with more attention being paid to the wireless communication block. For other components, we provide a brief discussion highlighting major recent developments and refer the reader to some recent literature in these areas.

Transducers

Transducers are interfaces between biological tissue and readout electronics—signal processing. Their performance is critical to the success of the overall microsystem (19–24). Current trend in miniaturization of transducers and their integration with signal processing circuitry have considerably enhanced their performance. This is particularly true with respect to MEMS-based sensors and actuators, where the advantages of miniaturization have been prominent. Development in the area of microactuators has been lagging behind the microsensors due to the inherent difficulty in designing microdevices that efficiently and reliably generate motion. Although some transducing schemes, such as electrostatic force generation, has advantageous scaling properties in the microdomain, problems associated with packaging and reliability has prevented their successful application. The MEMS-based microsensors have been more successful and offer several advantages compared to the macrodomain counterparts. These include lower power consumption, increased sensitivity, higher reliability, and lower cost due to batch fabrication. However, they suffer from a poor signal/noise ratio, hence requiring a close by interface circuit. Among the many microsensors designed and fabricated over the past two decades, physical sensors have been by and large more successful. This is due to their

inherent robustness and isolation from any direct contact with biological tissue in sensors, such as accelerometers and gyroscopes. Issues related to packaging and long-term stability have plagued the implantable chemical sensors. Long-term baseline and sensitivity stability are major problems associated with implantable sensors. Depending on the type of the sensor, several different factors contribute to the drift. For example, in implantable pressure sensors, packaging generated stresses due to thermal mismatch and long-term material creep are the main sources of baseline drift. In chemical sensors, biofouling and fibrous capsule formation is the main culprit. Some of these can be mitigated through clever mechanical design and appropriate choice of material, however, some are more difficult to prevent (e.g., biofouling and fibrous capsule formation). Recent developments in the area of antifouling material and controlled release have provided new opportunities to solve some of these long standing problems (25–27).

Interface Electronics

As mentioned previously, most miniature and MEMS-based transducers suffer from poor signal/noise ratio and require on-board interface electronics. This, of course, is also more essential for implantable microsystems. The choice of integrating the signal processing with the MEMS transducer on the same substrate or having a separate signal processing chip in close proximity depends on many factors, such as process complexity, yield, fabrication costs, packaging, and general design philosophy. Except for post-CMOS MEMS processing methods, which rely on undercutting micromechanical structures subsequent to the fabrication of the circuitry (28), other integrated approaches require extensive modifications to the standard CMOS processes and have not been able to attract much attention. Post-CMOS processing is an attractive approach although packaging issues still can pose roadblocks to successful implementation. Hybrid approach has been typically more popular with the implantable biotelemetry microsystem designers providing flexibility at a lower cost. Power consumption is a major design consideration in implantable wireless microsystems that rely on batteries for an energy source. Low power and subthreshold CMOS design can reduce the power consumption to nanowatt levels (29–33). Important analogue and mixed-signal building blocks for implantable wireless microsystems include amplifiers, oscillators, multiplexers, A/D and D/A converters, and voltage references. In addition, many such systems require some digital signal processing and logic function in the form of finite-state machines. In order to reduce the power consumption, it is preferable to perform the DSP functions outside the body although small finite-state machines can be implemented at low power consumptions.

Wireless Communication

The choice of appropriate communication scheme for a biotelemetry system depends on several factors, such as (1) number of channels, (2) device lifetime, and (3) transmission range. For single (or two) channel systems, one can choose a variety of modulation schemes and techniques.

These systems are the oldest type of biotelemetry devices (1) and can range from simple blocking oscillators to single channel frequency modulation (FM) transmitters. They are attractive since one can design a prototype rather quickly using off-the-shelf components. Figure 1 shows a schematic of the famous blocking oscillator first used by MacKay to transmit pressure and temperature (10). It consists of a single bipolar transistor oscillator configured to periodically turn itself on and off. The oscillation frequency depends on the resonant frequency of the tank circuit that can be made to vary with parameters, such as pressure, by including a capacitive or inductive pressure sensor. The on-off repetition frequency can be made to depend on the temperature by incorporating a thermistor in the circuit. This is an interesting example of an ingenious design that can be accomplished with a minimum amount of effort and hardware. An example of a more recent attempt at single channel telemetry is a two-channel system designed by Mohseni et al. to transmit moth electromyograms (34). The circuit schematic and a picture of the fully assembled device are shown in Fig. 2. As can be seen, each channel

Figure 1. Schematic circuit of a blocking oscillator used to transmit pressure and temperature.

Figure 2. Schematic diagram and photograph of a biotelemetry system used to transmit flight muscle electromyograms in moths showing the polyimide flex circuit and various components (the Colpitts Oscillator inductor is used as the transmitting antenna).

consists of a biopotential amplifier followed by a Colpitts oscillator with operating frequency tunable in the 88–108 MHz commercial FM band. The substrate for the biotelemetry module was a polyimide flex circuit in order to reduce the weight such that the Moth can carry the system during flight. The overall system measures $10 \times 10 \times 3$ mm, weighs 0.74 g, uses two 1.5 V batteries, dissipates ~ 2 mW, and has a transmission range of 2 m.

Multichannel systems are of more scientific and clinical interest. These systems rely on different and more elaborate communication schemes. For the purpose of current discussion, we will divide these systems into the ones that operate with a battery and the ones that are powered from outside using an inductive link. Battery-operated biotelemetry microsystems rely on different communication schemes than the inductively powered ones. Figure 3 shows a schematic block diagram of a time-division multiplexed multichannel system. It consists of several transducers with their associated signal conditioning circuits. These might include operations, such as simple buffering, low level amplification, filtering, or all three. Subsequent to signal conditioning, different channels are multiplexed using an analogue MUX. Although recent advances in AD technology might allow each channel to be digitized prior to multiplexing, this is not an attractive option for biotelemetry systems (unless there are only a few channels), since it requires an increase in power consumption that most biotelemetry systems cannot afford. All the timing and framing information is also added to the outgoing multiplexed signal at this stage. After multiplexing, an AD converter is used to digitize the signal. This is followed by a rf transmitter and a miniature antenna. The transmitted signal is picked up by a remote receiver and the signal is demodulated and separated accordingly. The described architecture is the one used currently by

most investigators. Although over the years many different modulation scheme (pulse-width-modulation, pulse-position-modulation, pulse-amplitude-modulation, etc.) and system architectures have been tried; due to the proliferation of inexpensive integrated low power AD converters, the pulse-code-modulation (PCM) using an integrated AD is the dominant method these days.

The transmission of the digitized signal can be accomplished using any of the several digital modulation schemes (PAM, PFM, QPSK, etc.), which offer standard trade offs between transmitter and receiver circuit complexity, power consumption, and signal/noise ratio (35). Typical frequencies used in such systems are in the lower UHF range (100–500 MHz). Higher frequencies result in smaller transmitter antenna at the expense of increased tissue loss. Although tissue loss is a major concern in transmitting power to implantable microsystems, it is less of an issue in data transmission, since a sensitive receiver outside the body can easily demodulate the signal. Recent advances in low power CMOS rf circuit design has resulted in an explosive growth of custom made Application Specific Integrated Circuits (ASIC), and off-the-shelf rf circuits suitable for a variety of biotelemetry applications (36–38). In addition, explosive proliferation of wireless communication systems (cell phones, wireless PDAs, Wi-Fi systems, etc.) have provided a unique opportunity to piggyback major WLAN manufacturers and simplify the design of biotelemetry microdevices (39,40). This cannot only increase the performance of the system, but also creates a standard platform for many diverse applications. Although the commercially available wireless chips have large bandwidths and some superb functionality, their power consumption is higher than what is acceptable for many of the implantable microsystems. This, however, is going to change in the future by the aggressive move

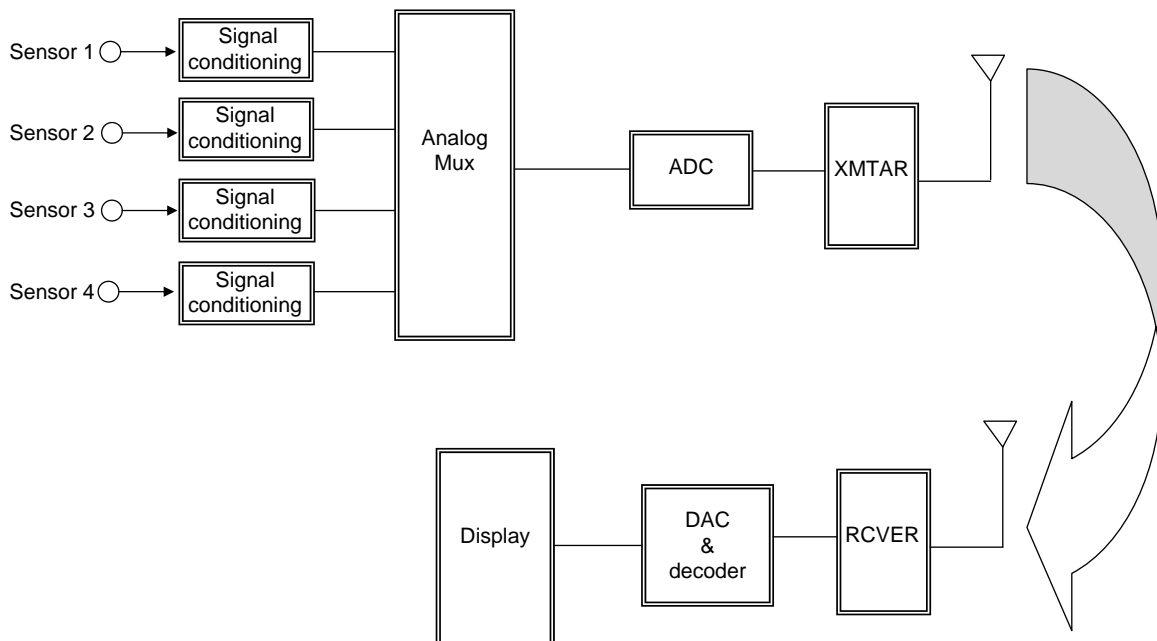

Figure 3. Block diagram of a multichannel biotelemetry system.

toward lower power handheld consumer electronics. A particularly attractive WLAN system suitable for biotelemetry is the Bluetooth system (41). This system, which was initially designed for wireless connection of multiple systems (computer, fax, printer, PDA, etc.) located in close proximity, has been adopted by many medical device manufacturer for their various biotelemetry applications. The advantage of Bluetooth compared to other Wi-Fi system, such as 902.11-b, is its lower power consumption at the expense of a smaller data rate (2.4 GHz carrier frequency, 1 Mbps data rate, and 10 m transmission range). This is not critical in most biotelemetry applications since the frequency bandwidth of most physiologically important signals are low (< 1 kHz). However, note that since the Bluetooth carrier frequency is rather high (2.4 GHz), the systems using Bluetooth or similar WLAN devices can not operate from inside the body and has to be worn by the subject on the outside.

Inductively powered telemetry systems differ from the battery operated ones in several important ways (42). First and foremost, the system has to be powered by an rf signal from outside; this puts several restrictions on frequency and physical range of operation. For implantable systems, the incoming signal frequency has to remain low in order for it to allow enough power to be coupled to the device (this means a frequency range of 1–10 MHz, see next section). In addition, if the device is small, due to a low coupling coefficient between the transmitter and receiver coil, the transmission range is usually limited to distances < 10 cm. Finally, in inductively powered systems, one has to devise a method to transmit the measured signal back to the outside unit. This can be done in several different ways with the load-modulation being the most popular method (43). In “load modulation”, the outgoing digital stream of data is used to load the receiver antenna by switching a resistor in parallel with the tank circuit. This can be picked up through the transmitter coil located outside the body. A second technique that is more complex requires an on-chip transmitter and a second coil to transmit the recorded data at a different frequency. The inward link can be easily implemented using amplitude modulation, that is, the incoming rf signal that powers the microsystem is modulated by digitally varying the amplitude. It is evident that the modulation index cannot be 100% since that would cut off the power supply to the device (unless a storage capacitor is used). The coding scheme is based on the pulse time duration, that is, “1” and “0” have the same amplitude, but different durations (42). This modulation technique requires a simple detection circuitry (envelope detector) and is immune to amplitude variations, which are inevitable in such systems.

In addition to the above mentioned differences between the battery operated and inductively powered biotelemetry systems, the implanted circuit in the latter case also includes several modules that are unique and require special attention. These have mostly to do with power reception (rectifier and voltage regulator), clock extraction, and data demodulation. Figure 4 shows a block diagram of the receiver circuit for an inductively powered microsystem currently being developed in the author’s laboratory for the measurement of intraocular pressure in glaucoma patients. It consists of a full-bridge rectifier, a voltage

Figure 4. Block diagram of an implantable biotelemetry system used in the measurement of intraocular pressure in glaucoma patients.

regulator, a piezoresistive pressure sensor, and voltage to frequency converter. The incoming rf signal is first rectified and used to generate a stable voltage reference being used by the rest of the circuit (amplifiers, filters, etc.). The clock is extracted from the incoming rf signal and is used wherever it is needed in the receiver circuit. The pressure sensor bridge voltage is first amplified and converted to a stream of pulses having a frequency proportional to the pressure. This signal is then used to load-modulate the tank circuit. The receiver circuitry for most of the reported inductively powered biotelemetry systems were fabricated through CMOS foundries, such as MOSIS. This is due to the fact that one can simply design a single chip performing all of the mentioned functions in a CMOS technology, and hence save valuable space. In the sections dealing with various applications, we will describe several other inductively powered telemetry systems.

There has not been much effort in the area of antenna design for biotelemetry applications. This is due to the basic fact that these systems are small and operate at low frequencies, hence, most antennas employed in such systems belong to the “small antenna” category, that is, the antenna size is much smaller than the wavelength. In such cases it is difficult to optimize the design and most investigators simply use a short electrical or magnetic dipole. For example, in many situations the inductor in the output stage can be used to transmit the information. Or alternatively, a short wire can be used in the transmitter as an electrical dipole. These antennas are usually low gain and have an omnidirectional pattern (44). Systems operating at higher frequencies, such as externally worn Wi-Fi modules, however, can benefit from an optimized design.

In addition to using an rf signal to transmit information that constitutes the majority of the work in the biotelemetry area, the use of ultrasound and infrared (IR) have also been explored by some investigators (45,46). The use of ultrasound is attractive in telemetering physiological information from aquatic animals and divers. This is due to the fact that rf signals are strongly absorbed by seawater while ultrasound is not affected to the same extent. The use of IR is also limited to some specific areas, such as systems that can be worn by the animal on the outside and are not

impeded by solid obstructions. This is due to the inability of IR to negotiate solid opaque objects (line of sight propagation) and its severe absorption by tissue. The advantage of free space IR transmission lies in its very wide bandwidth making it useful for transmitting neural signals. The rf, ultrasonic, and IR systems share many of the system components discussed so far, with the major difference between them having to do with the design and implementation of the output stage. The output transmitter for the ultrasonic biotelemetry systems is usually an ultrasonic transducer, such as PZT or PVDF, whereas for the IR systems it is usually a simple light-emitting diode (LED). The driver circuitry has to be able to accommodate the transducers, that is, a high voltage source for driving the ultrasonic element and a current.

Power Source

The choice of power source for implantable wireless microsystems depends on several factors, such as implant lifetime, system power consumption, temporal mode of operation (continuous or intermittent), and size. Progress in battery technology is incremental and usually several generations behind other electronic components (47). Although lithium batteries have been used in pacemakers for several years, they are usually large for microsystem applications. Other batteries used in hearing aids and calculators are smaller, but have limited capacity and can only be used for low power systems requiring limited lifespan or intermittent operation. Inductive powering is an attractive alternative for systems with large power requirements (e.g., neuromuscular stimulators) or long lifetime (e.g., prosthetic systems with > 5 years lifetime) (14,15). In such systems, a transmitter coil is used to power a microchip using magnetic coupling. The choice of the transmission frequency is a trade-off between adequate miniaturization and tissue loss. For implantable microsystems, the frequency range of 1–10 MHz is usually considered optimum for providing adequate miniaturization while still staying below the high tissue absorption region (>10 MHz) (48). Although the link analysis and optimization methods have been around for many years (49), recent integration techniques that allow the fabrication of microcoils on top of CMOS receiver chip has allowed a new level of miniaturization (50). For applications that require the patient to carry the transmitter around, a high efficiency transmitter is needed in order to increase the battery lifetime. This is particularly critical in implantable microsystem, where the magnetic coupling between the transmitter and the receiver is low (<1%). Class-E power amplifier/transmitters are popular among microsystem designers due to their high efficiency (>80%) and relatively easy design and construction (51,52). They can also be easily amplitude modulated through supply switching.

Although ideally one would like to be able to tap into the chemical reservoir (i.e., glucose) available in the body to generate enough power for implantable microsystems (glucose-based fuel cell), difficulty in packaging and low efficiencies associated with such fuel cells have prevented their practical application (53). Thin-film batteries are also attractive, however, there still remain numerous material

and integration difficulties that need to be resolved (54). Another alternative is nuclear batteries. Although they have been around for several decades and were used in some early pacemakers, safety and regulatory concerns forced medical device companies to abandon their efforts in this area. There has been a recent surge of interest in microsystem nuclear batteries for military applications (55). It is not hard to envision that due to the continuous decrease in chip power consumption and improve in batch scale MEMS packaging technology, one might be able to hermetically seal a small amount of radioactive source in order to power an implantable microsystem for a long period of time. Another possible power source is the mechanical movements associated with various organs. Several proposals dealing with parasitic power generation through tapping into this energy source have been suggested in the past few years (56). Although one can generate adequate power from activities, such as walking, to power an external electronic device, difficulty in efficient mechanical coupling to internal organ movements make an implantable device hard to design and utilize.

Packaging and Encapsulation

Proper packaging and encapsulation of biotelemetry microsystems is a challenging design aspect particularly if the device has to be implanted for a considerable period. The package must accomplish two tasks simultaneously: (1) protect the electronics from the harsh body environment while providing access windows for transducers to interact with the desired measurand, and (2) protect the body from possible hazardous material in the microsystem. The second task is easier to fulfill since there is a cornucopia of various biocompatible materials available to the implant designer (57). For example, silicon and glass, which are the material of choice in many MEMS applications, are both biocompatible. In addition, polydimethylsiloxane (PDMS) and several other polymers (e.g., polyimide, polycarbonate, parylene) commonly used in microsystem design are also accepted by the body. The first requirement is, however, more challenging. The degree of protection required for implantable microsystems depends on the required lifetime of the device. For short durations (several months), polymeric encapsulants might be adequate if one can conformally deposit them over the substrates (e.g., plasma deposited parylene) (58). These techniques are considered non-hermetic and have a limited lifetime. For long-term operation, hermetic sealing techniques are required (59). Although pacemaker and defibrillator industries have been very successful in sealing their systems in tight titanium enclosures; these techniques are not suitable for microsystem applications. For example a metallic enclosure prevents the transmission of power and data to the microsystem. In addition, these sealing methods are serial in nature (e.g., laser or electron beam welding) and are not compatible with integrated batch fabrication methods used in microsystem design. Silicon–glass electrostatic and silicon–silicon fusion bonding are attractive methods for packaging implantable microsystems (60). Both of these bonding methods are hermetic and can be performed at the wafer level. These are particularly attractive for

Figure 5. Schematic of the IOP measurement microsystem (61).

inductively powered wireless microsystems since most batteries cannot tolerate the high temperatures required in such substrate bondings. Other methods, such as metal electroplating, have also been used to seal integrated MEMS microsystems. However, their long-term performance is usually inferior to the anodic and fusion bondings. In addition to providing a hermetic seal, the package must allow feedthrough for transducers located outside the package (18). In macrodevices, such as pacemakers, where the feedthrough lines are large and not too many, traditional methods, such as glass-metal or ceramic-metal has been employed for many years. In microsystems, such methods are not applicable and batch scale techniques must be adopted.

DIAGNOSTIC APPLICATIONS

Diagnostic biotelemetry microsystems are used to gather physiological or histological information from within the body in order to identify pathology. Two recent examples are discussed in this category. The first is a microsystem designed to be implanted in the eye and to measure the intraocular pressure in order to diagnose low tension glaucoma. The second system, although not strictly implanted, is an endoscopic wireless camera-pill designed to be swallowed in order to capture images from the digestive track.

Figure 5 shows the schematic diagram of the intraocular pressure (IOP) measurement microsystem (61,62). This device is used to monitor the IOP in patients suffering from low tension glaucoma, that is, the pressure measured in the doctor's office is not elevated (normal IOP is $\sim 10\text{--}20$ mmHg, $1.33\text{--}2.66$ kPa) while the patient is showing optic nerve degeneration associated with glaucoma. There is great interest in measuring the IOP in such patients during their normal course of daily activity (exercising, sleeping, etc). This can only be achieved using a wireless microsystem. The system shown in Fig. 5 consists of an external transmitter mounted on a spectacle, which is used to power a microchip implanted in the eye. A surface micromachined capacitive pressure sensor integrated with CMOS interface circuit is connected to the receiving antenna. The receiver chip implemented in an n-well $1.2\ \mu\text{m}$ CMOS technology has overall dimensions of $2.5 \times 2.5\ \text{mm}^2$ and consumes $210\ \mu\text{W}$ (Fig. 6). The receiver polyimide-based antenna is, however, much

Figure 6. Micrograph of the IOP measurement microsystem receiver chip showing surface micromachined capacitive pressure sensors and other parts of the receiver circuitry (62).

larger (1 cm in diameter and connected to the receiver using flip chip bonding) requiring the device to be implanted along with an artificial lens. The incoming signal frequency is 6.78 MHz, while the IOP is transmitted at 13.56 MHz using load-modulation scheme. This example illustrates the levels of integration that can be achieved using low power CMOS technology, surface micromachining, and flip chip bonding.

The second example in the category of diagnostic microsystems is an endoscopic wireless pill shown in Fig. 7 (63,64). This pill is used to image small intestine, which is a particularly hard area to reach using current fiber optic technology. Although these days colonoscopy and gastroscopy are routinely performed, they cannot reach the small intestine and many disorders (e.g., frequent bleeding) in this organ have eluded direct examination. A wireless endoscopic pill cannot only image the small intestine, but also will reduce the pain and discomfort associated with regular gastrointestinal endoscopies. The endoscopic pill is a perfect example of what can be called *Reemerging Technology*, that is, the rebirth of an older technology based on new capabilities offered by advances in modern technology. Although the idea of a video pill is not new, before the development of low power microelectronics, white LED, CMOS image sensor, and wide-band wireless communication, fabrication of such a device was not feasible. The video pill currently marketed by Given Imaging Inc. is 11 mm in diameter and 30 mm in length (size of a large vitamin tablet) and incorporates: (1) a short focal length lens, (2) a CMOS image sensor (90,000 pixel), (3) four white LEDs, (4) a low power ASIC transmitter, and (5) two batteries (enough to allow the pill to go through the entire digestive track). The pill can capture and transmit

(a)

two images per second to an outside receiver capable of storing up to 5 h of data.

THERAPEUTIC APPLICATIONS

Therapeutic biotelemetry microsystems are designed to alleviate certain symptoms and help in the treatment of a disease. In this category, two such biotelemetry microsystems unit be described. The first is a drug delivery microchip designed to administer small quantities of potent drugs upon receiving a command signal from the outside. The second device is a passive micromachined glucose transponder, which can be used to remotely monitor glucose fluctuations allowing a tighter blood glucose control through frequent measurements and on-demand insulin delivery (pump therapy or multiple injections).

Figure 8 shows the central component of the drug delivery microchip (65,66). It consists of several microreservoirs (25 nL in volume) etched in a silicon substrate. Each microreservoir contains the targeted drug and is covered by a thin gold membrane (0.3 μm), which can be

dissolved through the application of a small voltage (1 V vs. Saturated Calomel Electrode). The company marketing this technology (MicroCHIPS Inc.) is in the process of designing a wireless transceiver that can be used to address individual wells and release the drug upon the reception of the appropriate signal (67). Another company (ChipRx Inc.) is also aiming to develop a similar microsystem (Smart Pill) (68). Their release approach, however, is different and is based on conductive polymer actuators acting similar to a sphincter, opening and closing a tiny reservoir. Due to the potency of many drugs, safety and regulatory issues are more stringent in implantable drug delivery microsystems and will undoubtedly delay their appearance in the clinical settings.

Figure 9 shows the basic concept behind the glucose-sensitive microtransponder (69). A miniature MEMS-based microdevice is implanted in the subcutaneous tissue and an interrogating unit remotely measures the glucose levels without any hardware connection. The microtransponder is a passive LC resonator, which is coupled to a glucose-sensitive hydrogel. The glucose-dependent swelling and deswelling of the hydrogel is coupled to the resonator causing a change the capacitor value. This change translates into variations of the resonant frequency, which can be detected by the interrogating unit. Figure 10 shows the schematic drawing of the microtransponder with a capacitive sensing mechanism. The glucose sensitive hydrogel is mechanically coupled to a glass membrane and is separated from body fluids (in this case interstitial fluid) by a porous stiff plate. The porous plate allows the unhindered flow of water and glucose while blocking the hydrogel from escaping the cavity. A change in the glucose concentration of the external environment will cause a swelling or deswelling of the hydrogel, which will deflect the glass membrane and change the capacitance. The coil is totally embedded inside the silicon and can achieve a high quality factor and hence increased sensitivity by utilizing the whole wafer thickness (reducing the series resistance). The coil-embedded silicon and the glass substrate are hermetically sealed using glass-silicon anodic bonding.

REHABILITATIVE MICROSYSTEMS

Rehabilitative biotelemetry microsystems are used to substitute a lost function, such as vision, hearing, or motor activity. In this category, two microsystems are described. The first one is a single-channel neuromuscular microstimulator used to stimulate paralyzed muscle groups in paraplegic and quadriplegic patients. The second microsystem is a visual prosthetic device designed to stimulate ganglion cells in retina in order to restore vision to people afflicted with macular degeneration or retinitis pigmentosa.

Figure 11 shows a schematic of the single channel microstimulator (13). This device is $10 \times 2 \times 2 \text{ mm}^3$ in dimensions and receives power and data through an inductively coupled link. It can be used to stimulate paralyzed muscle groups using thin-film microfabricated electrodes located at the ends of a silicon substrate. A hybrid capacitor

Figure 8. MicroCHIP drug delivery chip (a), a reservoir before and after dissolution of the gold membrane (b,c), the bar is 50 μm (65).

is used to store the charge in between the stimulation pulses and to deliver 10 mA of current to the muscle every 25 ms. A glass capsule hermetically seals a BiCMOS receiver circuitry along with various other passive components (receiver coil and charge storage capacitor) located

on top of the silicon substrate. Figure 12 shows a photograph of the microstimulator in the bore of a gauge 10 hypodermic needle. As can be seen, the device requires a complicated hybrid assembly process in order to attach a wire-wound coil and a charge storage capacitor to the

Figure 9. Basic concept behind the glucose-sensitive microtransponder.

Figure 10. Cross-section of glucose micro-transponder.

Figure 11. Schematic of a single-channel implantable neuromuscular microstimulator.

receiver chip. In a subsequent design targeted for direct peripheral nerve stimulation (requiring smaller stimulation current), the coil was integrated on top of the BiCMOS electronics and on-chip charge storage capacitors were used thus considerably simplifying the packaging process. Figure 13 shows a micrograph of the chip with the electroplated copper inductor (70). A similar microdevice (i.e., a

Figure 12. Photograph of the microstimulator in the bore of a gage 10 hypodermic needle.

single channel microstimulator) was also developed by another group of investigators with the differences mainly related to the packaging technique (laser welding of a glass capsule instead of silicon–glass anodic bonding), chip technology (CMOS instead of BiCMOS), and electrode material (tantalum and iridium instead of iridium oxide) (42). Figure 14 shows a photograph of the microstimulator developed by Troyk, Loeb, and their colleagues.

Figure 15 shows the schematic of the visual prosthetic microsystem (71,72). A spectacle mounted camera is used to capture the visual information followed by digital conversion and transmission of data to a receiver chip

Figure 14. Photograph of a single channel microstimulator developed by Troyk (42).

implanted in the eye. The receiver uses this information to stimulate the ganglion cells in the retina through a micro-electrode array in sub or epi-retinal location. This micro-system is designed for patients suffering from macular degeneration or retinitis pigmentosa. In both diseases, the light sensitive retinal cells (cones and rods) are destroyed while the more superficial retinal cells, that is, ganglion cells, are still viable and can be stimulated. Considering that macular degeneration is an age related pathology and will be afflicting more and more people as the average age of the population increases, such a micro-system will be of immense value in the coming decades. There are several groups pursuing such a device with different approaches to electrode placement (epi- or sub-retinal), chip design, and packaging. A German consortium that has also designed the IOP measurement microsystem is using a similar approach in antenna placement (receiver antenna in the lens), chip design, and packaging technology to implement a retinal prosthesis (61). Figure 16 shows photographs of the retinal stimulator receiver chip, stimulating electrodes, and polyimide antenna. The effort in the United States is moving along a similar approach (72,72).

CONCLUSIONS

In this article, several biotelemetry microsystems currently being developed in the academia and industry were reviewed. Recent advances in MEMS-based transducers, low power CMOS integrated circuit, wireless communication transceivers, and advanced batch scale packaging have provided a unique opportunity to develop implantable bio-

Figure 16. Retinal stimulator receiver chip, stimulating electrodes, and polyimide antenna (61). Chip size.

telemetry microsystems with advanced functionalities not achievable previously. These systems will be indispensable to the twenty-first century physician by providing assistance in diagnosis and treatment. Future research and development will probably be focused on three areas: (1) nanotransducers, (2) self-assembly, and (3) advanced biomaterials. Although MEMS-based sensors and actuators have been successful in certain areas (particularly physical sensors), their performance could be further improved by utilizing nanoscale fabrication technology. This is particularly true in the area of chemical sensors where future diagnostic depends on detecting very small amounts of chemicals (usually biomarkers) well in advance of any

Figure 15. Schematic of a visual prosthetic microsystem (61).

physical sign. Nanosensors capable of high sensitivity chemical detection will be part of the future biotelemetry systems. In the actuator-delivery area, drug delivery via nanoparticles is a burgeoning area that will undoubtedly be incorporated into future therapeutic microsystems. Future packaging technology will probably incorporate self-assembly techniques currently being pursued by many micro-nanoresearch groups. This will be particularly important in microsystems incorporating multitude of nanosensors. Finally, advanced nanobased biomaterials will be used in implantable microsystems in order to enhance biocompatibility and prevent biofouling. These will include biocompatible surface engineering and interactive interface design (e.g., surfaces that release anti-inflammatory drugs in order to reduce postimplant fibrous capsule formation).

INTRODUCTION

The discovery of electricity introduced enormous changes to human society: Electricity not only improved daily life, but also opened up new opportunities in scientific research. The effects of electrical stimulation on muscular and nervous tissue have been known for several centuries, but the underlying electrophysiological theory to explain these effects was first derived after the development of classical electrostatics and the development of nerve cell models (1).

Luigi Galvani first suggested that electricity could produce muscular contraction in his animal experiments (2). He found that a device constructed from dissimilar metals, when applied to the nerve or muscle of a frog's leg, would induce muscular contraction. His work formed the foundation for later discoveries of transmembrane potential and electrically mediated nerve impulses. Alessandro Volta, the inventor of the electrical battery (or voltaic pile) (3), was later able to induce a muscle contraction by producing a potential with his battery and conducting it to a muscle strip. The use of Volta's battery for stimulating nerves or muscles became known as galvanic stimulation.

Another basis for modern neural stimulators was the discovery of the connection between electricity and magnetism, demonstrated by Oersted in 1820; he described the effect of current passing through a wire on a magnetized needle. One year later, Faraday showed the converse—that a magnet could exert a force on a current-carrying wire. He continued to investigate magnetic induction by inducing current in a metal wire rotating in a magnetic field. This device was a forerunner of the electric motor and made it possible to build the magneto-electric and the induction coil stimulator. The latter, the first electric generator, was called the Faraday stimulator. Faradic stimulation could produce sustained titanic contractions of muscles, instead of a single muscle twitch as galvanic stimulation had done.

Duchenne used an induction coil stimulator to study the anatomy, physiology, and pathology of human muscles. Finally, he was able to study the functional anatomy of individual muscles (4,5). This work is still valid for the investigation of functional neuromuscular stimulation.

Another basis for modern stimulator devices lay in the work of Chaffee and Light (6). They examined the problem

of stimulating neural structures deep in the body, while avoiding the risk of infection from percutaneous leads: They implanted a secondary coil underneath the skin and placed a primary coil outside the body, using magnetic induction for energy transfer and modulation. Further improvement was achieved by radio frequency (rf) induction (7,8). The Glenn group developed a totally implanted heart pacemaker—one of the first commercially available stimulators. In the ensuing years, stimulators for different organ systems were developed, among them the above-mentioned heart pacemaker, a diaphragmatic pacemaker (7,8), and the cochlear implant (9).

BLADDER STIMULATION

Electrical stimulation of the bladder dates back to 1878. The Danish surgeon M.H. Saxtorph treated patients with urinary retention by inserting a special catheter with a metal electrode into the urinary bladder transurethrally and placing a neutral electrode suprapubically (10). Also, Katona et al. (11) described their technique of intraluminal electrotherapy, a method that was initially designed to treat a paralytic gastrointestinal tract, but was later used for neurogenic bladder dysfunction in patients with incomplete central or peripheral nerve lesions (11,12).

Further interest in the electrical control of bladder function began in the 1950s and 1960s. The most pressing question at that time was the appropriate location for stimulation. Several groups attempted to initiate or prevent voiding (in urinary retention and incontinence, respectively) by stimulation of the pelvic floor, the detrusor directly, the spinal cord, or the pelvic and sacral nerves or sacral roots. Even other parts of the body, such as the skin, were stimulated in an attempt to influence bladder function (13).

In 1954, McGuire performed extensive experiments of direct bladder stimulations in dogs (14) with a variety of electrodes, both single and multiple, in a variety of positions. Boyce and associates continued this research (15).

It was realized that with a single pair of electrodes, the maximal response was obtained when the electrodes were placed on both lateral bladder walls so that the points of stimulation encompassed a maximal amount of detrusor muscle. When this was performed in human studies, an induction coil for direct bladder stimulation was implanted in three paraplegic men with complete paralysis of the detrusor muscle. The secondary coil was implanted in the subcutaneous tissue of the lower abdominal wall. Of the three, only one was a success, with the other a failure and the third only partially successful (15).

In 1963, Bradley and associates published their experience with an implantable stimulator (16). They were able to achieve complete bladder evacuation in the chronic dog model over 14 months. However, when the stimulator was implanted in seven patients, detrusor contraction was produced, but bladder evacuation resulted in only two. Further experiments were performed in the sheep, calf, and monkey in an attempt to resolve species discrepancies. These animals were chosen because, in the sheep and calf,

the bladder is approximately the same size as in the human, and this similarity could determine whether more power is needed for a bladder larger than that of the dog. In addition, the pelvis of monkeys and humans is similarly deep; thus, the influence (if any) of pelvic structure could be investigated. The results showed that a larger bladder needs more power and wider contact between the electrodes and that differences in structure do not necessitate different stimulation techniques (13,16).

PELVIC FLOOR STIMULATION

In 1963, Caldwell described his clinical experience with the first implantable pelvic floor stimulator (17). The electrodes were placed into the sphincter, with the secondary coil placed subcutaneously near the iliac spine. Though this device was primarily designed for the treatment of fecal incontinence; Caldwell also treated urinary incontinence successfully.

Another approach to pelvic floor stimulation for females is intravaginal electrical stimulation, reported initially by Magnus Fall's group (1977) (18). They published numerous studies dealing with this subject in the ensuing years and found that intravaginal electrical stimulation also induces bladder inhibition in patients with detrusor instability. Lindstram, a member of the same group, demonstrated that bladder inhibition is accomplished by reflexogenic activation of sympathetic hypogastric inhibitory neurons and by central inhibition of pelvic parasympathetic excitatory neurons to the bladder (13,19). The afferent pathways for these effects could be shown to originate from the pudendal nerves.

POSTERIOR TIBIAL OR COMMON PERONEAL

Another interesting application of electrical stimulation for inhibition of detrusor activity is the transcutaneous stimulation of the posterior tibial or common peroneal nerve. This technique, drawn from traditional Chinese medicine, is based on the acupuncture points for inhibition of bladder activity and was reported by McGuire et al. in 1983 (20).

A percutaneous tibial nerve stimulation (PTNS) (Urgent PC, CystoMedix, Anoka, MN) was approved by the Food and Drug Administration in 2000. A needle is inserted ~5 cm cephalad from the medial malleolus and just posterior to the margin of the tibia. Stimulation is done using a self-adhesive surface stimulation electrode without an implanted needle electrode (21). Current data describe results after an initial treatment period of 10–12 weeks. If patients get a good response, they are offered tapered chronic treatment. As in sacral root neuromodulation, PTNS seems less effective for treating chronic pelvic pain (22).

More substantial data, in particular on objective parameters and long-term follow up, are needed, as are studies looking into the underlying neurophysiological mechanisms of this treatment modality. Although minimally invasive, easily applicable, and well tolerated, the main disadvantage of PTNS seems to be the necessity of chronic treatment. The development of an implantable subcutaneous stimulation device might ameliorate this problem (23). It has never found widespread acceptance.

PELVIC NERVE STIMULATION

Pelvic nerves do not tolerate chronic stimulation and the pudendal nerves are activated, increasing outflow resistance. Also, in humans the fibers of the parasympathetic nervous system innervating the bladder split early in the pelvis, forming a broad plexus unsuitable for electrode application (24).

DETRUSOR STIMULATION

Direct detrusor stimulation offers high specificity to the target organ (25), but its disadvantages are electrode displacement and malfunction due to bladder movement during voiding, and fibrosis (even erosion) of the bladder wall. In 1967, Hald et al. (26) reported their experience of direct detrusor stimulation with a radio-linked stimulator in four patients, three with upper motor-neuron lesions and one with a lower motor-neuron lesion. The receiver was placed in a paraumbilical subcutaneous pocket. Two wires from the receiver were passed subcutaneously to the ventral bladder wall, where they were implanted. A small portable external transmitter generated the necessary energy. The procedure worked in three patients; in one it failed because of technical problems (13).

SPINAL CORD STIMULATION

The first attempt to achieve micturition via spinal cord stimulation was through the exploration of the possibility of direct electrical activation of the micturition center in the sacral segments of the conus medullaris. This was conducted by Nashold, Friedman, and associates, and had reported that the region for optimal stimulation was S1–S3.

Effectiveness was determined not only by location, but also by frequency. In two subsequent experiments, the same group compared the stimulation of the dorsal surface of the spinal cord at LS, S1, and S2 with depth stimulation (2–3 mm) at S1 and S2 in acute and chronic settings (27). It was only through the latter, the depth stimulation, that voiding was produced: High bladder pressures were achieved by surface stimulation, but external sphincter relaxation did not occur, and was noted only after direct application of the stimulus to the micturition center in the spinal cord. Stimulation between L5 and S1 produced pressure without voiding, even with depth stimulation (13).

Jonas et al. continued the investigation of direct spinal cord stimulation to achieve voiding (28–30). They compared 12 different types of electrodes: three surface (bipolar surface electrode, dorsal column electrode, and wrap-around electrode) and nine depth electrodes. These differed in many parameters (e.g., bipolar–tripolar, horizontal–vertical–transverse). Regardless of the type of electrode, the detrusor response to stimulation was similar. Interestingly, the wrap-around surface electrode with the most extended current spread provoked the same results as the coaxial depth electrode with the least current spread, prompting those authors to theorize that current does not

cross the midline of the spinal cord. Unfortunately, no real voiding was achieved. It was found that the stimulation of the spinal cord motor centers stimulates the urethral smooth and striated sphincteric elements simultaneously: The expected detrusor contraction resulted, but sphincteric contraction was associated. The sphincteric resistance was too high to allow voiding: It allowed only minimal voiding at the end of the stimulation, so-called poststimulus voiding (13). These results contrasted with the earlier work of Nashold and Friedman (27,31).

Thurhoff et al. (32) determined the existence of two nuclei, a parasympathetic and a pudendal nucleus. The parasympathetic nucleus could be shown within the pudendal nucleus; thus, at the level of the spinal cord, stimulation of the bladder separate to that of the sphincter is difficult.

SACRAL ROOT STIMULATION

Based on the hypothesis that different roots would carry different neuronal axons to different locations. The culmination of these studies led to the feasibility of sacral rootlet stimulation.

It appears that sacral nerve-root stimulation is the most attractive method since the space within the spinal column facilitates mechanically stable electrode positioning and the application of electrodes is relatively simple due to the long intraspinal course of the sacral roots.

The University of California, San Francisco (UCSF) group performed numerous experiments on a canine model (33), as the anatomy of bladder innervation of the dog is similar to that of the human. After laminectomy, the spinal roots were explored and stimulated, either intradurally or extradurally, but within the spinal canal, in the following modes:

1. Unilateral stimulation of the intact sacral root at various levels.
2. Simultaneous bilateral stimulation of the intact sacral root at various levels.
3. Stimulation of the intact ventral and dorsal root separately.
4. Stimulation of the proximal and distal ends of the divided sacral root.
5. Stimulation of the proximal and distal ends of the divided dorsal and ventral roots (13).

From these studies, it became clear that stimulating the intact root is least effective and stimulating the ventral component is most effective and that no difference exists between right- and left-root stimulation (33).

However, this stimulation also causes some sphincteric contraction, owing to the presence of both autonomic and somatic fibers in the ventral root, and the studies were continued with the addition of neurotomy to eliminate the afferent fibers. These experiments showed that, to achieve maximally specific detrusor stimulation, the dorsal component must be separated from the ventral component and the somatic fibers of the root must be isolated and selectively cut (34).

The experiments also demonstrated that stimulation with low frequency and low voltage can maintain adequate sphincteric activity, but that stimulation with high frequency and low voltage will fatigue the external sphincter and block its activity. When high frequency/low voltage stimulation is followed by high voltage stimulation, bladder contraction will be induced and voiding achieved.

The finding that detrusor contraction can be activated separately from sphincteric activity and that adequate sphincteric contraction can be sustained without exciting a detrusor reaction made it seem possible that a true bladder pacemaker could be achieved. In addition, in histological and electron microscopic examination of the stimulated sacral roots, no damage was found when they were compared with the contralateral nonstimulated roots. Neither the operation nor the chronic stimulation damaged the ventral root, and the responses remained reliable and stable (13).

Tanagho's group later performed detailed anatomical studies on human cadavers. The aim was to establish the exact anatomical distribution of the entire sacral plexus, following it from the sacral roots in the spinal cord through the sacral foramen inside the pelvic cavity. Emphasis was placed on the autonomic pelvic plexus as well as the somatic fibers. With this anatomical knowledge, the stimulation of human sacral roots in neurogenic bladder dysfunction was developed and made clinically applicable as a long-term treatment (35). Direct electrical stimulation was performed through a permanently implanted electrode, placed mostly in contact with S3 nerve roots in the sacral foramen, after deafferentation.

The stimulation of sacral rootlet bundles isolated from the rest of the sacral root gave the same increase of bladder pressure when stimulated close to the exit from the dura, in the mid-segment, or close to the origin in the spinal cord. This could make the stimulation more selective, eliminating detrusor-sphincter dyssynergia.

In additional work, taking advantage of the knowledge that high frequency current can block large somatic fibers, electrical blockade of undesired responses was tested to replace selective somatic neurotomies. High frequency sinusoidal stimulation was effective in blocking external sphincter activity. However, the sinusoidal waveform is not efficient. Alternate-phase, rectangular wave is more efficient and induces the same blockade: alternating pulses of high frequency and low amplitude followed by pulses of low frequency and high amplitude were effective in inducing low pressure voiding without the need for somatic neurotomies. This approach has not yet been tried clinically, but it might prove to be the answer to the problem of detrusor-sphincter dyssynergia in electrically stimulated voiding (13).

The three main devices used for sacral neuromodulation is the Medtronic InterStim, the Finetech-Brindley (VOCARE) bladder system, and the rf BION systems. Each is explained in detail below.

MEDTRONIC INTERSTIM

Indications for use: urge incontinence, retention and urgency frequency, male and female dysfunctional voiding

syndromes and postprostatectomy incontinence. There are also benefits beyond voiding disorders, including re-establishment of pelvic floor awareness, resolution of pelvic floor muscle tension and pain, reduction in bladder pain (interstitial cystitis) and normalization of bowel function.

The basic concept behind the implantable pulse generator (IPG) that provides stimulation to the sacral nerve is not far removed from the concepts behind cardiac pacing. A long-lived battery encased in biocompatible material is programmed to deliver pulses of electricity to a specific region of the body through an electrode at the end of an encapsulated wire.

Medtronic is the manufacturer of the InterStim neurostimulator. Earl Bakken, the founder of the company, first created a wearable, battery-operated pacemaker at the request of Dr. C. Walton Lillehei, a pioneer in open-heart surgery at the University of Minnesota Medical School Hospital, who was treating young patients for heart block.

The Itrel I, the first-generation neurostimulator, was introduced in 1983. Current versions are used for the treatment of incontinence, pain, and movement disorders.

System Overview

There are two established methods for sacral root neuromodulation using the Medtronic InterStim system.

1. An initial test phase, then the more permanent hardware is implanted.
2. An alternative method uses a staged testing-implant procedure, where a chronic lead is implanted and connected to a percutaneous extension and test stimulator.

Testing Phase (See Fig. 1). The testing hardware consists of a needle, test lead, test stimulator, interconnect cabling and a ground pad (Fig. 1).

- Needle (see Figs. 2 and 3).

A 20-gauge foramen needle with a bevelled tip is used to gain access to the sacral nerve for placing the test stimulation lead. The stainless steel needle is depth-marked along its length and electrically insulated along its center length. The portion near the hub is exposed to allow connection to

Figure 1. Test stimulation system.

Figure 2. Model 041828 (20 gauge) 3.5 in. (88.9 mm) foramen needles.

Figure 3. Model 041829 (20 gauge) 5 in. (127 mm) foramen needles.

the test stimulator. By stimulating through the uninsulated tip of the needle, the physician can determine the correct SNS site for the test stimulation lead.

- Test lead (see Fig. 4).

The initial test lead is a peripheral nerve evaluation (PNE) test lead with a coiled, seven-stranded stainless steel wire coated with fluoropolymer. Its electrode is extended to 10 mm (0.4 in.) to increase the length of coverage and reduce the effects of minor migration. Depth indicators help to align the lead electrode with the needle tip. The lead contains its own stylet, which is removed once the correct position has been found, leaving the lead flexible and stretchable, to mitigate migration.

- Test stimulator (see Fig. 5).

The most current version of test stimulators is the model 3625. The model 3625 test stimulator can be used both for patient screening, where the patient is sent home with the device, and for intraoperative usage in determining lead placement thresholds. It provides output characteristics that are similar to those of the implantable neurostimulator and can be operated in either monopolar or bipolar modes. It is battery operated by a regular, 9 V battery. The physician sets the maximum and minimum amplitude settings, allowing the patient to control the amplitude (within those maximum and minimum settings) to whatever level is comfortable.

The safety features of the stimulator include; an automatic output shut-off occurs when the amplitude is turned up too rapidly (as when the control is inadvertently bumped), a loose device battery will cause output shut-off also to prevent intermittent stimulation and shock to the patient, and sensors, which detect when electrocautery is being used, shut the output off. Turning the test stimulator off for a minimum of 3 s can reset the protection circuitry.

- Interconnect cables (see Fig. 6).

Single-use electrical cables are used to hook the test stimulation lead to the model 3625 test stimulator during the test stimulation procedure in the physician's office

Figure 4. Model 3057 test stimulation lead.

Figure 5. Model 3625 sacral nerve test stimulator.

and when the patient goes home for the evaluation period.

The patient cable is used to deliver acute stimulation during the test procedure. The insulated tin-plated copper cable has a 2 mm socket at one end and a spring-activated minihook at the other end. The minihook makes a sterile connection to the foramen needle, test stimulation lead, or implant lead. The socket end is connected to the test stimulator by a long screener cable, the latter being a two-wire cable with a single connector to the model 3625 test stimulator at one end; one of the wires is connected to the patient cable and the other to the ground pad. After the test stimulation, the patient cable is removed and a short screener cable is substituted for at-home use. This cable is connected to the ground pad and directly to the test lead. It is designed to withstand the rigours of home use and can be disconnected, to facilitate changing clothes (13).

- Ground pad.

The ground pad provides the positive polarity in the electrical circuit during the test stimulation and the at-home trial. It is made of silicone rubber and is adhered to the patient's skin. As described above, for the at-home trial a short screener cable is substituted for the long screener cable and connected directly to the lead.

Surgical Technique Used for Acute Testing Phase: The aims of percutaneous neurostimulation testing (PNE) are to check the neural and functional integrity of the sacral nerves, to determine whether neurostimulation is beneficial for each particular patient, and to clarify which sacral spinal nerves must be stimulated to achieve the optimum therapeutic effect in each individual case.

Local anesthetic is injected into the subcutaneous fatty tissue and the muscles, but not into the sacral foramen itself. The S3 foramen is localized on one side with a 20-gauge foramen needle. By stimulating through the uninsulated tip of the needle, the physician can find the correct sacral nerve stimulation site for placement of the test stimulation lead. Once the location of the S3 foramen is established, tracing of the other foramina is done. The

Figure 6. Model 041831 patient cable.

portion near the hub is exposed to allow connection to the test stimulator.

Keeping the needle at a 60° angle to the skin surface with a rostrocaudal and slightly lateral pointing tip of the needle will ensure that the needle is inserted into the targeted foramen. The puncture should progress parallel to the course of the sacral nerve, which normally enters at the upper medial margin of the foramen. This method achieves optimal positioning of the needle for stimulation and avoids injuring the spinal nerve. The insulated needle (cathode) is then connected to an external, portable pulse generator (Medtronic model 3625 test stimulator) via a connection cable. The pulse generator itself is connected to a neutral electrode (anode) attached to the shoulder.

Because patient sensitivity varies, the voltage used is between 1–6 V, which starts at 1 and is increased in 20 Hz increments. Stimulation of the S3 evokes the “bellows” effect (contraction of the levator ani and the sphincter urethra). Also, there is plantar flexion of the foot on the ipsilateral side. If plantar flexion of the entire foot is observed, the gastrocnemius muscle should be palpated, because a strong contraction usually indicates stimulation of S2 fibers and should be avoided.

Stimulation of S3 generally produces the most beneficial effect. Furthermore, most patients will not tolerate the permanent external rotation of the leg caused by stimulation of S2. Occasionally, stimulating S4 also causes clinical improvement. Stimulation of S4 provokes a strong contraction of the levator ani muscle, accompanied by a dragging sensation in the rectal region. If stimulating one side produces an inadequate response, the contralateral side should be tested; the aim is to obtain a typical painless stimulatory response.

Once the optimal stimulation site has been identified, the obturator is removed from the foramen needle, and a temporary wire test lead (Medtronic model 3057 test lead) is inserted through the lumen of the needle. Once the test lead has been inserted into the needle, the latter must not be advanced any further in order to avoid severing the lead. The needle is then carefully removed from the sacral foramen, leaving the test lead in place. The stimulation is then repeated to check the correct position of the test electrode. To mitigate migration the lead contains its own stylet, which is removed once the correct position has been found, leaving the lead flexible and stretchable.

A repetition of the test stimulation, confirming the correct position of the test lead, is therefore mandatory at this stage; otherwise the test lead cannot be reinserted.

After correct positioning, the test lead is coiled on the skin and fixed with adhesive transparent film. Finally, the correct position of the wire is radiologically confirmed and the portable external impulse generator is connected.

Percutaneous Extension Hardware (see Fig. 7). If acute testing is inconclusive, or when there is a need for positive fixation of the test lead, percutaneous extension hardware is the best method used. Also called the staged implant, it is an alternative method for patient screening.

The chronic lead is implanted in the normal manner and is connected to a percutaneous extension (model 3550-05). The extension is designed to provide a connection between

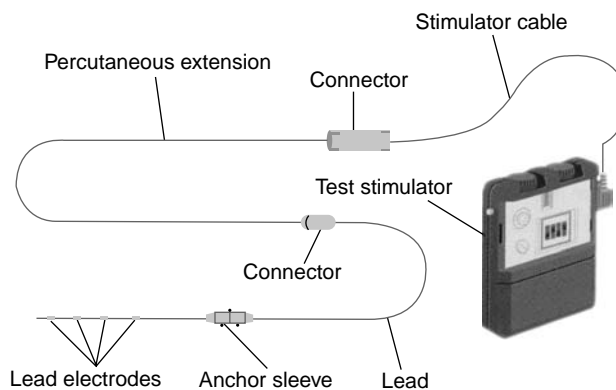

Figure 7. Percutaneous extension system.

the chronic lead and the external test stimulator. Positive contact is made using four set screws; the connection is sealed with a silicone boot that covers the set screws. The percutaneous extension, which is intended for temporary use, features four insulated wires, wound together and sized for a small incision, so that they can be brought through the skin. The percutaneous extension is then connected to the screener cable, as described above (13).

Chronic System. The chronic system consists of an implantable neurostimulator, a lead, an extension, a physician programmer and a patient programmer.

- Neurostimulator (see Fig. 8).

The implantable neurostimulator (Medtronic model 3023) weighs ~42 g and has a volume of 22 cm³. It comprises ~70% battery and 30% electronics. The physician has unlimited access to programmable parameters such as amplitude, frequency, and pulse width. Each parameter can be changed by means of an external, physician programmer that establishes a rf link with the implanted device. A patient programmer provides limited access to allow the patient to turn the neurostimulator on and off, or to change amplitude within a range established by the physician (via the physician programmer) (13).

The external titanium container of the neurostimulator may be used in either a monopolar configuration (lead negative, can positive) or a bipolar configuration, which will result in marginally better longevity. The life of the neurostimulators is usually ~7–10 years. Factors that affect this are the mode, programming of the amplitude, pulse width and frequency, and the use of more than one active electrode.

- Implantable lead system (see Fig. 9–14).

Figure 8. Model 3023 implantable neurostimulator.

Figure 9. Model 3080 lead.

Figure 10. Model 3092 lead.

Figure 11. Model 3093 lead.

Figure 12. Model 3886 lead.

Figure 13. Model 3889 lead.

Figure 14. Model 3966 lead.

The lead is a quadripolar design, with four separate electrodes that can be individually programmed to plus, minus, or off. This allows the physician to optimize the electrode configuration for each patient and to change programming, without additional surgery, at a later date, to adapt to minor lead migration or changing disease states. The electrode sizes, spacing, and configurations have been designed specifically for SNS.

The lead is supplied with multiple stylets and anchors, to accommodate physician preferences. A stylet (straight or bent) is inserted into the lumen of the lead to provide extra stiffness during implant. Two different degrees of stiffness provide the physician with options to tailor the handling and steering properties of the lead, as preferred. The stylet must be removed before connection with the mating component.

The physician also has a choice of anchors, which allow fixation of the lead to stable tissue to prevent dislodging of the lead after implantation. Three anchor configurations are available: a silicone rubber anchor fixed in place on the lead has wings, holes and grooves to facilitate suturing; a second type, also made of silicone, slides into place anywhere along the lead body, and must be sutured to the lead to hold it in place; a new plastic anchor is also available, which can be locked in place anywhere along the lead body without a suture to the lead.

- Quadripolar extension (see Fig. 15).

Figure 15. Series 3095 extension.

Figure 16. Physician programmer.

The quadripolar extension, which is available in varying lengths to facilitate flexibility in IPG placement, is designed to provide a sealed connection to the lead. This extension provides the interface with the neurostimulator. Positive contact is made with four set screws, and the connection is sealed with a silicone boot covering the screws.

- Physician programmer (Fig. 16).

The console programmer (Medtronic model 8840 N'Vision) is a microprocessor-based system that the physician uses to program the implanted neurostimulator noninvasively. The programmer uses an application-specific memory module, installed by means of a plug-in software module.

- Patient programmer (Fig. 17).

The patient programmer also communicates with the implanted neurostimulator by an rf link. The patient can adjust stimulation parameters within the range set by the physician. This range is intended to allow the patient to turn the device on or off, and to change amplitude for comfort (as during postural changes), without returning to the physician's office.

Surgical Technique Used for Chronic Implantable System. The sacral foramen electrode and impulse generator are implanted under general anesthesia. Long-acting muscle relaxants must not be used, as these would impair the intraoperative electrostimulation.

The patient is placed in the prone position with a 45° flexion of the hip and knee joints. An 8 cm long midline

Figure 17. Patient programmer.

incision is made above the sacrum, reaching one-third caudal and two-thirds cranial from the S3 foramen. After transection of the subcutaneous fat, the muscle fascia (thoracolumbar fascia) is incised approximately 1 cm lateral of the midline in a longitudinal direction.

Usually, the Gluteus maximus has to be incised over a length of 1–2 cm for good exposure of the S3 foramen and a little further caudal if implantation of the S4 foramen is intended. The paraspinal muscles are then divided longitudinally and the dorsal aspect of the sacrum is exposed.

Intraoperative test stimulation, using the same equipment as for the acute testing phase, will confirm the precise location of the foramen selected. The foramen needle is left in place to avoid relocation of the foramen while preparing the permanent electrode for implantation. Proximal to the four contact points of the permanent electrode, a silicon rubber cuff is glued to the electrode body. The cuff is fitted with three eyelets to accommodate nonabsorbable atraumatic needle-armed sutures.

After removal of the foramen needle, the permanent electrode (Medtronic quadripolar lead, model 3080) is gently inserted into the foramen. Renewed test stimulation will determine the most effective contact point between the electrode and spinal nerve; the most distal contact point is termed “0”, with the subsequent three being numbered 1–3 sequentially. An identical motor response at all four contact points is ideal. If only one contact gives a satisfactory response, the electrode should be repositioned at a different angle to the foramen and the test stimulation repeated. The preattached sutures are then used to secure the electrode to the ligaments overlying the periosteum of the sacral bone. Test stimulation should be repeated at this stage to confirm an appropriate position of the electrode after fixation.

A small skin incision is now made in the flank between the iliac crest and the 12th rib on the side where the electrode has been placed. A subcutaneous tunnel is formed between the two wounds, starting from the flank incision and running toward the sacral incision.

The obturator of the tunneling device is removed and the silicone sheath, which is open at both ends, left in place. The free end of the electrode is guided through the sheath to the flank incision, after the stylet has been removed from the electrode.

The silicone sheath is now removed from the flank incision, the proximal end of the electrode is marked with a suture, and the electrode is buried in a subcutaneous pocket that has been created at the site of the flank incision. The flank incision is temporarily closed, leaving the marking suture exposed between the skin sutures. The sacral incision is then closed in layers and covered with a sterile dressing.

The patient is now positioned on the contralateral flank. The flank and abdomen on the side chosen previously for placement of the Medtronic InterStim model 3023 implantable pulse generator are disinfected and the surgical field is draped with a sterile cover. The flank incision is now reopened, and a subcutaneous tunnel is again created between the flank incision and the subcutaneous pocket in the lower abdomen through which a connecting extension cable (Medtronic quadripolar extension, model 3095) between electrode and impulse generator is guided.

Once the electrode has been connected to the extension cable in the area of the flank incision, the contact point is sealed with a silicone cover, fixed with two sutures and placed subcutaneously. The flank incision is closed in layers and covered with a sterile dressing.

Finally, the other end of the connecting cable is attached to the impulse generator. The generator is attached to the rectus fascia using two nonabsorbable sutures. The abdominal incision is closed in two layers and covered with sterile dressings.

On the first postoperative day, anterior–posterior and lateral radiographs of the implant are obtained to verify that all components are correctly positioned and will act as a control for comparison in case of subsequent problems.

Modifications of the surgical procedure include placement of the pulse generator in the gluteal area thus avoiding repositioning of the patient during the procedure and implantation of bilateral electrodes, which should be powered by a two-channel pulse generator (Medtronic Synergy, model 7427) for adequate synchronous independent stimulation of each side. The implant remains deactivated at least until the day following surgery and will be activated by a telemetric programming unit (Medtronic Console Programmer, model 7432) allowing programming of all features of the implant by the physician during the initial activation and follow-up stages.

NEW MEDTRONIC TINED LEAD PERCUTANEOUS IMPLANT (SEE FIGS. 18 AND 19)

Tined leads offer sacral nerve stimulation through a minimally invasive implant procedure. The use of local anesthesia allows for patient sensory response during the implant procedure. This response helps ensure optimal lead placement and may result in better patient outcomes. With previous lead designs, many physicians used general anesthesia, which did not allow for patient sensory response.

Figure 18. Tined lead percutaneous implant.

Among the advantages of the minimally invasive implant procedure are the radiopaque markers to identify where tines are deployed, helping physicians in identifying the exact lead location relative to the sacrum and nerves. Tactile markers indicate lead deployment, and a white marker bands on the lead and tactile markers aid in proper lead placement and to notify the physician when the tines are ready to be deployed.

Percutaneous lead placement allows use of local anesthesia. This reduces the risks of general anesthesia and surgical incision and may facilitate faster patient recovery time as a result of less muscle trauma and a minimized surgical incision. Also, it may reduce surgical time as a result of a sutureless anchoring procedure and reduced number of surgical steps.

To date, a positive response to the PNE test has been the only predictive factor for the long-term efficacy of sacral nerve stimulation therapy. Current studies show that up to 40% of patients who experience improvement in symptoms during PNE test stimulation with a temporary lead do not have this improvement carried through after neurostimulator implantation (36). A study by Spinelli et al. looked at patients who underwent tined lead implant without PNE testing, and reported a positive outcome of 80% during the screening phase, which was maintained at an average follow up of 11 months, resulting in a higher success rate than that currently reported in the literature (37).

The development of the new tined lead allows fully percutaneous implantation of the permanent lead and offers the possibility of a longer and more reliable screening period than that possible with the PNE test. The advantage for patient screening are that the permanent tined lead is less prone to migration, hence if the results of screening are

Figure 19. Tined lead percutaneous implant.

Figure 20. The foramen needle stylet and directional guide.

positive, the lead is already in the precise place where positive results were obtained, and there is a decrease in false-positive and false-negative results after screening (37). However, use (or lack thereof) of PNE testing in conjunction with the tined lead differs from center to center, depending on fiscal and/or other reasons.

The tined lead models 3093 and 3889 are designed to work with the current lead introducer model 355018 or 042294.

Surgical Technique for Tined Lead Implant. The foramen needle is inserted and tested for nerve response. The foramen needle stylet is then removed and replaced with the directional guide (see Fig. 20). The foramen needle itself is then removed.

A small incision is made on either side of the directional guide, which is followed by fitting the dilator and the introducer sheath over the directional guide and advanced into the foramen (see Fig. 21). The guide and the dilator are then removed, leaving the introducer sheath in place.

The lead is then inserted into the introducer sheath and advanced until visual marker band C on the lead lines up with the top of the introducer sheath handle. Using fluoroscopy, electrode 0 of the lead is confirmed to be proximal to the radiopaque marker band at the distal tip of the sheath (see Fig. 22).

While holding the lead in place, the introducer sheath is retracted until visual marker band D on the lead lines up with the introducer sheath handle. Using fluoroscopy, radiopaque marker band at the tip of the sheath is

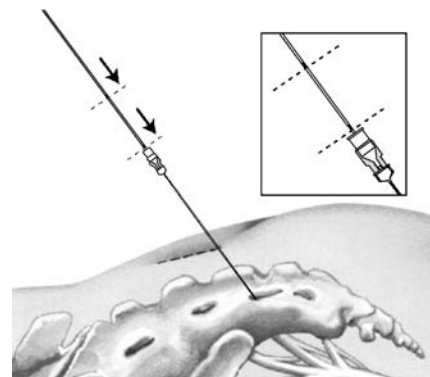

Figure 21. Fitting the dilator and introducer sheath.

Figure 22. Confirming lead proximal to radiopaque marker band.

confirmed to be proximal to electrode 3 and adjacent to radiopaque marker band A on the lead (see Fig. 23).

Test stimulation of the various electrodes (0, 1, 2, 3) is done and the responses are observed. If necessary, the lead is repositioned within the foramen. When the lead is in the proper position, the lead is held in place and the introducer sheath and lead stylet are carefully withdrawn, thereby deploying the tines and anchoring the lead.

FINETECH-BRINDLEY (VOCARE) BLADDER SYSTEM

Introduction (see Fig. 24)

Indications for use: The VOCARE bladder system is indicated for the treatment of patients who have clinically complete spinal cord lesions with intact parasympathetic innervation of the bladder and are skeletally mature and neurologically stable. However, patients with other neurological disorders, including multiple sclerosis, spinal cord tumours, transverse myelitis, cerebral palsy and meningo-myelocoele, have also benefited from the implant (38). A secondary use of the device is to aid in bowel evacuation and promote penile erection.

The sacral anterior root stimulation (SARS) system was developed by Brindley with the support of the Medical Research Council (Welwyn Garden City, Herts, UK), is manufactured by Finetech Medical Ltd. in England, and is

Figure 23. Confirming marker band proximal to electrode 3.

marketed as the Vocare system by NeuroControl Corporation (Cleveland, OH) (1).

Beginning in 1969, Brindley developed a new device to stimulate sacral roots at the level of the cauda equina. This technique, first tested in baboons, led to the development of a stimulator that was first successfully implanted in a patient in 1978 (39).

Hardware

The Finetech-Brindley bladder controller is composed of external and internal equipment.

1. External (see Fig. 25):

One analog and three digital versions of the external controller are available in different countries (1). This device has no batteries but is powered and controlled by rf transmission from a portable external controller operated by the user and programmed by the clinician. It consists of a transmitter block connected to the control box via a transmitter lead. The patient holds the transmitter over the implanted receiver to apply stimulation. A new, smaller control box that is more powerful will be available in the coming months (39).

2. Internal (see Fig. 26):

The internal equipment consists of three main parts: (1) the electrodes, (2) the cables, (3) and the receiver block.

Two types of electrodes are used, depending on the approach (intra- or extradural).

For intradural implantation the electrode mounts in which the anterior sacral roots are trapped are called "books" because of their shape.

The two-channel implant has an upper book with only 1 slot. Trapping of S3 and S4 roots is often sufficient to obtain bladder contractions. In males, S2 roots were trapped in the upper book and S3 and S4 roots, in the lower book.

The three-channel implant is composed of two electrode books. The upper book contains three parallel slots for S3 and S2 roots and the lower contains one slot for S4 roots. There are three electrodes in each slot (one cathode in the center and two anodes at the two ends) to avoid stimulation of unwanted structures.

The four-channel implant has two books like those of the three-channel implant, and the four slots allow independent stimulation of four sets of nerve fibers. It is used in patients who retained sacral-segment pain sensitivity.

The special eight-channel implant allowed the stimulation of four anterior roots and the destruction of any of the four posterior roots, if necessary, after implantation. It is no longer used.

For extradural implantation the cables end with three helical electrodes (a cathode between two anodes) and are attached to the roots with a strip of Dacron-reinforced silicone rubber. The cables used

Figure 26. Internal equipment.

Figure 27. Finetech-Brindley system.

are encapsulated in silicone rubber, and the wires are made of 90% platinum and 10% iridium and connect the electrodes to the radio receiver block. The radio receiver block, which contains two, three, or four radioreceivers imbedded in silicone rubber, is activated by pulse-modulated rf waves (39).

Surgical Technique for Finetech-Brindley System (see Fig. 27):. The surgical technique for *intrathecal* implantation developed by Brindley et al. (40) involves laminectomy of the fourth and fifth lumbar vertebrae and the first two pieces of the sacrum, exposing 10–12 cm of dura. The dura and arachnoid are opened at the midline to expose the roots. The roots are identified by their size and situation and by perioperative stimulation during the recording of bladder pressure and observation of skeletal muscle responses with the naked eye.

The S2 anterior roots contract the triceps surae, the glutei, and the biceps femoris. The S3 anterior roots innervate the pelvic floor and the toe flexors. The S4 anterior roots innervate the pelvic floor. The sphincters (anorectal and urethral) are innervated predominantly by S4 and also by S3 and S2. The detrusor response is always obtainable by stimulation of S3 and S4 and sometimes achievable by stimulation of S2.

The roots are split into the anterior and posterior components. The identity of the posterior root is confirmed by electrical stimulation and then a segment measuring ~20–40 mm in length is removed. When the S5 root has been identified, it is resected if no bladder response is obtained (39).

If a posterior rhizotomy is performed, stimulation can be applied to mixed sacral nerves in the sacral spinal canal extradurally, since the action potentials generated on the afferent axons do not reach the spinal cord. This has the advantage that the electrodes can be placed extradurally, reducing the risk of leakage of cerebrospinal fluid along the cables, and reducing the risk of breakage of the cables where they cross the dura. In addition, the extradural

nerves are more robust than the intradural roots, being covered with epineurium derived from the dura, and require less dissection than the intradural roots; therefore, there is less risk of neuropraxia of the axons, which could otherwise lead to a delay in usage of the stimulator but not usually in permanent loss of function (1,41).

The benefits of a posterior rhizotomy include abolition of the neurogenic detrusor over activity, resulting in increased bladder capacity and compliance, reduced incontinence, and protection of the kidneys from ureteric reflux and hydronephrosis. The rhizotomy also reduces detrusor-sphincter dyssynergia, which improves urine flow, and prevents autonomic dysreflexia arising from distension or contraction of the bladder or bowel. In addition, a posterior rhizotomy improves implant-driven micturition. However, there are also drawbacks with a rhizotomy. They include abolition of reflex erection, reflex ejaculation, reflex defecation and sacral sensation, if present. Still, in many subjects with spinal lesions, these reflexes are not adequately functional, and function can be restored by other techniques (42).

The surgical technique for *extradural* implantation involves laminectomy of the first three pieces of the sacrum. It may also involve laminectomy of the L5 vertebra, depending on whether it is decided to implant electrodes on S2 roots (39). Extradural electrodes are used for patients in whom arachnoiditis makes separation of the sacral roots impossible. In some centers, however, extradural electrodes are used for all or nearly all patients.

After electrode implantation, the operation proceeded with closure of the dura, tunneling of the leads to a subcutaneous pocket in the flank, and closure of the skin. The patient is turned over and the leads are prepared for connection to the implantable stimulator.

At this time the leads are connected via an aseptic cable to an experimental stimulator. Prior to stimulation the bladder is filled with 200 mL saline using a transurethral filling catheter. The experimental stimulator consisted of two synchronized current sources with a common cathode. Pressure responses are elicited using pulse trains of 3–5 s duration; containing identical monophasic rectangular pulses delivered at a rate of 25 pulses \cdot s⁻¹. Stimulation is usually limited to the S3 and S4 ventral roots since they contain most of the motoneurons innervating the lower urinary tract.

After 15–20 min of experimental stimulation the leads are disconnected from the stimulator and the normal procedure is resumed with implantation stimulator.

A two-channel transurethral pressure catheter is used to measure intravesical and intraurethral pressure. The urethral pressure sensor is positioned at the level of the external sphincter such that in response to suprathreshold stimulation a maximal pressure response is measured. Pressures are sampled at 8 Hz, displayed on a monitor, and stored in a portable data logger (43).

All patients are followed up according to a fixed protocol. Urodynamic measurements are taken at 2 days, 15 days, 4 months, and 1 year after surgery and every 2–3 years thereafter. Renal ultrasound examination is performed every year. Stimulation is performed for the first time

Figure 28. BION microstimulator.

between days 8 and 14, depending on the level of the spinal cord lesion (33).

PUDENDAL NERVE STIMULATION FOR THE TREATMENT OF THE OVERACTIVE BLADDER (rf BION) (SEE FIGS. 28 AND 29)

Indications for use: The rf Bion system is still relatively new, and though no clear, established indications have been set so far, its activity on the pudendal nerve and inhibition of the detrusor muscle makes it ideal for overactive bladder disorders.

Electrical stimulation of the pudendal nerve has been demonstrated to inhibit detrusor activity and chronic electrical stimulation may provide effective treatment for overactive bladder disorders (44). The hurdle to date has been the technical challenge of placing and maintaining an electrode near the pudendal nerve in humans; however, recent development of the BION has made chronic implantation feasible.

The BION is a small, self-contained microstimulator that can be injected directly adjacent to the pudendal nerve (see Fig. 28). The ischial spine is an excellent marker for the pudendal nerve as it re-enters the pelvis through Alcock's canal. This is a very consistent anatomical landmark in both men and women. Also, the implanted electrode is protected in this area by both the sacral tuberosus and sacrospinous ligaments. Stimulation in this area activates afferent innervation over up to three sacral segments. Efferent stimulation also provides direct activation of the external urethral sphincter, the external anal sphincter, and the levator ani muscles, which may be of some benefit in bladder control. The external components of this neural prosthesis include a coil that is worn around the subject's hips and a controller that is worn around the shoulder or waist.

The technique chosen to implant the device is that of the transperineal pudendal block. This approach is minimally invasive and is well established. A special implant tool was

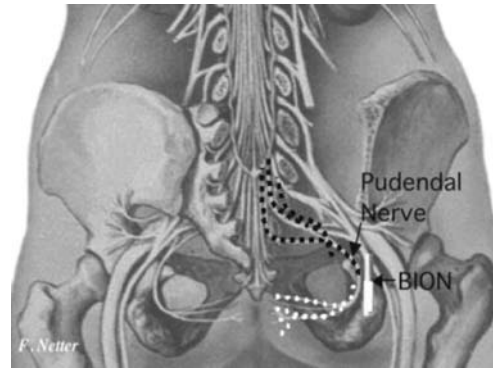

Figure 29. Placement of BION system near pudendal nerve.

devised to facilitate placement. The BION implantation technique was developed in cadavers. The optimum insertion location is 1.5 cm medial to the ischial tuberosity using a vaginal finger to guide the implant toward the ischial spine where electrical stimulation of the pudendal nerve may be confirmed (see Fig. 29).

A percutaneous stimulation test (PST) was developed and proved to be a very effective way to assess acute changes in bladder volumes while stimulating the pudendal nerve. A baseline cystometrogram (CMG) was obtained followed by percutaneous pudendal nerve stimulation for 10 min with a repeat CMG.

The first implant was done on August 29, 2000. The BION was implanted under local anesthesia with intravenous sedation. Proper placement was verified by palpation and EMG activity. An intermittent stimulation mode of 5 s on 5 s off was used. Subjects returned 5–7 days later for activation, to distinguish between postoperative pain and potential stimulation pain. Subjects were followed up at 15, 30, and 45 days after activation. At each follow-up visit they underwent another cystometrogram and brought in a 72 h voiding diary. The results indicated a favorable response to maximum cystometric capacity throughout the study period. Diary entries verified improvement— incontinent episodes decreased by 65%, and both daytime and nighttime voids were decreased, as was pad use per day.

FUTURE DIRECTION OF THE THERAPY HARDWARE

The ongoing development of tools and hardware is driven by the desire to reduce the invasiveness of the implant and the likelihood of adverse events. Development efforts are concentrated on system components and tools that will allow implantation of the lead system through small incisions or percutaneous approaches. It is inevitable that the size of the neurostimulator will be reduced as future generations of the device are developed; more efficient power batteries and packaging will drive this aspect of development.

A rechargeable power battery may allow a smaller device. Although a smaller device would be welcomed, attaining this goal with a rechargeable battery is not seen as the best approach. A rechargeable neurostimulator would

require the patient frequently to recharge the unit; this would inconvenience the patient and could reduce patient compliance. Additionally, a rechargeable battery would be more expensive than a nonrechargeable one owing to the technology required and the additional equipment necessary for recharging. Furthermore, this would not eliminate the need for periodic replacement of the neurostimulator every 5–10 years. System components will be optimized for the therapy, to reduce the time needed for management of both implant and patient. The incorporation of microprocessors and implementation of features such as a battery gauge will provide additional operational information while decreasing the time needed to manage the patient.

Physicians will be able to analyze system use, lead status, and other parameters. The addition of sensing technology may provide an opportunity to create a closed-loop system that captures data to optimize both diagnosis and functioning.

Bilateral stimulation may provide more efficacious therapy. There is considerable interest in this approach, and it seems to be a probable avenue of research in the near future. However, any use of bilateral stimulation would have to justify the larger neurostimulator, the extra lead system, and the additional costs associated with this approach; at present, there is no scientific experience to support this approach.

Apart from a reduction in the size of the implanted device, enhanced physician control is the most likely development to occur in the foreseeable future. Graphics-based programming and control will simplify device programming; it will allow more complex features to be incorporated in the neurostimulator without adding undue complexity to the physician programmer. Management of patient data files will become easier as additional data-management features are added to the programmer; the physician will be able to obtain a patient-programming history and other patient-management data. It is conceivable that, in the not-so-distant future, the physician may be able to access patient-device data over the Internet, thus making unnecessary some clinic visits and allowing for remote follow-up of patients who are on holiday or have moved house.

Future devices may allow software loading in a non-invasive manner, to upgrade the device long after implantation. Such capability could be used to provide new therapy algorithms as well as new therapy waveforms.

The future will also bring enhanced test stimulation devices, which will provide improved fixation during the test stimulation period. The development of new leads is one such focus with the aim of allowing a longer test stimulation period without lead migration.

The future application of SNS is dependent on new clinical research. Pelvic disorders, such as pelvic pain and sexual dysfunction, appear likely to be the first areas of investigation; sacral anterior root stimulation for spinal cord injury may also provide a worthwhile avenue of enquiry. The development of these applications—or of any other, for that matter—will potentially require new waveforms and the development of new therapy algorithms. The future is as open as the availability of resources and the application of science allow (45).

BLIND AND VISUALLY IMPAIRED, ASSISTIVE TECHNOLOGY FOR

ANDREW Y. J. SZETO
San Diego State University
San Diego, California

INTRODUCTION

Severe visual impairment represents one of the most serious sensory deficits that a human being can have. When this sensory input channel is so impaired that little useful information can pass through it, assistive devices that utilize alternative sensory input channels are often necessary. Familiar examples include the use of Braille and the white cane, respectively, for reading and obstacle avoidance by persons who are blind. Both of these assistive devices provide environmental information to the user via the sense of touch. Other assistive devices provide environmental feedback via the sense of hearing.

In the material that follows, examples of available assistive technology and promising new assistive technology under development for persons who are blind or severely visually impaired are presented. This article begins with an overview of the prevalence and impairments associated with blindness impairments and follows with an examination of reading aids, independent living aids, and mobility aids. The article concludes with a brief look at kinds of assistive technology likely to be available in the near future for persons with severe visual impairments.

The term blindness has many connotations and is difficult to define precisely. To many people, blindness refers to the complete loss of vision with no perception of light. The U.S. government, however, defines blindness as the best corrected visual acuity of 20/200 or worse in the better seeing eye. The acuity designation 20/200 means that a vision impaired person is able to see at a distance of 20 ft (6.09 m) what a person with normal visual acuity is able to see at 200 ft (60.96 m). Low vision is defined as the

Table 1. Prevalence of Blindness and Low Vision Among Adults 40 Years and Older in the United States^a

Age, Years	Blindness		Low Vision		All Vision Impaired	
	Persons	%	Persons	%	Persons	%
40–49	51,000	0.1	80,000	0.2	131,000	0.3
50–59	45,000	0.1	102,000	0.3	147,000	0.4
60–69	59,000	0.3	176,000	0.9	235,000	1.2

> 80	648,000	7.0	1,532,000	16.7	2,180,000	23.7
<i>Total</i>	<i>937,000</i>	<i>0.8</i>	<i>2,361,000</i>	<i>2.0</i>	<i>3,298,000</i>	<i>2.7</i>

^aAbstracted from Ref. 3 Arch. Ophthalmol. Vol. 122, April 2004.

best corrected visual acuity that is worse than 20/40 in the better seeing eye. People with extreme tunnel vision (a visual field that subtends an angle $> 20^\circ$ regardless of the acuity within that visual angle) also are classified as being legally blind and thus qualify for certain disability benefits.

It is important to realize that a great majority (~ 70 – 80%) of people with severe impairments has some degree of usable vision (1,2). The severity of vision loss can vary widely and result in equally varying degrees of functional impairment. Although the degree of impairment may differ from one person to another, people who are blind or have low vision experience the common frustration of not being to see well enough to perform common everyday tasks.

The prevalence of blindness and low vision among adults 40 years and older is given in Table 1. According to the National Eye Institute (2), a component of the National Institutes of Health in the United States Department of Health and Human Services, the leading causes of vision impairment and blindness are primarily age-related eye diseases. These include age-related macular degeneration, cataract, diabetic retinopathy, and glaucoma. The 2000 census data revealed > 5 million people of all ages in America have visual impairments severe enough to significantly interfere with their daily activities.

CONSEQUENCES OF SEVERE VISUAL IMPAIRMENTS

The two major difficulties faced by persons who are blind or severely visually impaired are access to reading material and independent travel or mobility. Simple-to-sophisticated technology has been used in a variety of assistive devices to help overcome these problems. The term reading is used in this context to include access to all material printed on paper or electronically. Reading material can include text, pictures, drawing, tables, maps, food labels, signs, mathematical equations, and graphical symbols. Safe and independent mobility is used to encompass both obstacle avoidance and navigation. For safe and independent mobility, the first concern is avoiding obstacles, such as curbs, chairs, low hanging branches, and platform drop-offs. After the sight impaired traveler has gained an awareness of the basic spatial relationships between objects within the travel environment, their needs wayfinding or navigational assistance, which involves knowing one's position, one's heading with respect to the intended destination, and a suitable path to reach it.

LOW VISION READING AIDS

People with low vision significantly outnumber those who are totally without sight (Table 1). Hence, the consumer market for low vision aids is much larger than the one dedicated to people with zero vision. The technology used in low vision aids is rather straightforward and the technologically used is relatively mature. Hence, only a brief overview of such assistive devices will be presented before discussing the more challenging issues faced by persons with zero useful vision. For readers desiring detailed product information about low vision aids, a search of the Internet using the term low vision aids will yield a bounty of pictures, product specifications, and purchasing information.

All low vision aids aim to maximize an individual's residual vision to its fullest. Low vision aids can be categorized as optical, nonoptical, and electronic. Optical aids include handheld magnifying glasses, telescopes mounted on eyeglass frames, and even microscope lenses. Nonoptical aids include enlarged high contrast print and high intensity lamps.

Electronic low vision aids represent the highest level in terms of cost, complexity, and performance. They include electronic video magnifiers that project printed material on a closed circuit monitor, regular television, or computer screen. Electronic video magnifiers can maximize readability of the written material by providing a wide range of magnification, brightness, contrast, type of fonts, and foreground and background colors. A good example of a modern closed circuit TV type of electronic low vision aid is the Optelec Traveller (Fig. 1). This portable video

Figure 1. This portable video magnifier has a built-in 6 in. (15.24 cm) color screen and can magnify text and pictures up to 16 times. (Courtesy of Optelec International, New York.)

Figure 2. Closed-circuit television with computer based text-to-speech output, a talking computer.

magnifier has a built-in 6 in. (15.24 cm) color screen and can magnify text and pictures up to 16 times and more if its video signal is sent to a television set.

People with tunnel vision or central blind spots due to macular degeneration often find it difficult and tiring to read an entire computer screen. For such individuals, the advent of the talking computer (Fig. 2) represented a major technological breakthrough. The capability and flexibility of such a computer or reading machine addressed many of their needs as well as the needs of persons without any useful vision.

READINGS AIDS FOR THE BLIND

For persons with essentially zero useful vision, the tactile sense has been utilized as an alternative sensory input channel for reading. One of the oldest reading substitutes for the blind is Braille, a six dot matrix code that Louise Braille adapted in 1824 for use by blind persons to read written text. The standard Braille cell consists of two columns and three rows of dots separated by 2.3 mm with 4.1 mm separating adjacent cells. Each Braille cell occupies a rectangular area of 4.3×8.6 mm and can represent $2^6 - 1$ (or 63) possible symbols within that areas. Grade I Braille maps each cell a one-to-one basis to each letter of the alphabet, basic punctuation marks, and simple abbreviations so that Grade I Braille has an informational density of approximately 1 bit per 6 mm^2 of surface area. For greater informational compactness and faster reading rates, Grade II Braille uses combinations of dots to represent contractions, frequently used words, prefixes, and suffices. Grade III Braille is even more compact and affords the highest reading rates, but very few people ever master it. The largest proportion of Braille literature is produced at the Grade II level, which can be read at up to 200 words per minute (4) by those proficient in Braille. Braille is a unique reading aid that not only gives blind persons access to printed material but also provides them with a writing medium.

Despite Braille's unique place as a complete writing system that is spatially distributed and retains many advantages of a printed page, Braille is a specialized code that only a small percentage of blind individuals learn to use. This is especially true for persons who become blind

Figure 3. Portable refreshable Braille reader that can playback or store messages using a cassette recorder. The reader has a single-line tactile display, a Braille keyboard, and a tape cassette for data storage and recall. (Picture taken from Fig. 2.8 of Ref. 5.)

after the age of 15 years. Given the difficulty of mastering Braille, the lack of up-to-date Braille printed material, and advances in alternate technologies such as electronic reading machines, many blind individuals choose to not bother with Braille.

Other disadvantages of Braille printed material include the cost to produce it, store it, and maintain it. Embossable Braille paper is not only bulky, heavy, and expensive, the pattern of raised dots (laboriously and noisily impressed into the paper) is fragile and short lived. Assistive technologies such as portable Braille readers (Fig. 3) have mitigated some of the inconveniences associated with Braille (5), but these electronic Braille readers-recorders often do not display the two-dimensional (2D) information embedded in graphs, tables, and mathematical formulas. The single and dual line tactile displays found in most portable readers also makes the rapid search for content via headings very difficult.

Refreshable Braille readers can be used as a computer interface for accessing information on the computer screen. Some full-sized electronic Braille displays are 80 cells long and cost upward of \$10,000. The dots in these transient Braille displays are produced by pins raised and lowered (refreshed) to form Braille characters. Refreshable Braille readers allow users to access any portion of the screen information via specialized control buttons and status Braille cells. Tactually distinguishable arrow keys offer screen cursor control while extra status cells provide additional information about text-attributes or line and colon positions.

Refreshable Braille displays are especially useful for deaf blind individuals and users working with computer programming languages. For example, the Braille Voyager 44 (Fig. 4), made by F.J. Tieman BV, has a 44 cell Braille display, and 5 thumb keys for screen navigation. Using its built-in macro program, USB connection, and any screen reader, the Voyager enables a user to access many features of the Windows operating system.

Figure 4. The Braille Voyager 44 made by Manufacturer: F.J. Tieman BV. It has a 44 cell Braille display and 5 navigation keys.

Despite Braille’s many drawbacks and limited popularity, its long history, status as the only complete writing and reading system for the blind, and tenacity of advocates like the American Federation for the Blind combine to keep Braille viable as an informational medium. Nonprofit groups like the Braille Institute produce millions of pages of Braille each year for business, schools, government agencies and individuals across the nation. They sell recreational reading material in Braille to both children and adults and provide low cost transcription, embossing, and tactile graphic services.

For the majority of blind persons who do not know Braille, reading material converted into the audio format (aka talking books) and played back on variable speed tape recorders have proven to be popular and convenient to use. To overcome spoken speech’s inherently slower reading rate, variable speed tape recorders with special electronic circuits that compensate for the pitch change during high speed playback (1.5–3 times normal speed) can be used. Obtaining reading material in audio form for playback on such recorders also has become more convenient as vendors

make downloading of electronic text and audio files available to their subscribers (6).

Although audio books are popular for persons with severe visual impairments, this approach does not work for reading the newspaper, daily mail, memoranda, cook-books, technical reports, handwritten notes, and common everyday correspondence, such as utility bills and bank statements. Before the advent of a reading machine, which has now become part of a general purpose talking computer, persons with no useful vision relied on human readers with its attendant inconvenience, loss of independence, and lack of privacy.

For severely sight impaired individuals and even those who know Braille, the power, convenience, and versatility of a reading machine, also known as a talking computer, have made it the preferred method of accessing most reading material. First marketed in the early 1980s, reading machines of today are affordable, compact, and can reliably and rapidly convert alphanumeric text into synthetic speech. In addition to a synthetic voice that reads aloud the actual text, the talking computer or reading machine also provides auditory feedback of cursor location and navigational commands.

A talking computer or dedicated reading machine contains artificial intelligence that converts alphanumeric text into spoken speech. The multistep process begins with an optical device that scans the text of a printed document or web page and, using optical character recognition, converts that alphanumeric text string into prefixes, suffixes, and root words (Fig. 5).

The process through which the text string is converted into speech output is somewhat complex and undergoing refinement. The clarity and naturalness of the voice output depend on the text-to-speech technique employed. In general, clearer and more natural costlier sounding speech requires more memory and greater processing power and is thus more expensive.

After the written material has been converted into a text string by optical character recognition software, one of

Figure 5. Functional components of a reading machine. (Taken from Fig. 2.18 of Ref. 5.)

three basic methods can be employed to convert the string into speech sounds. The first method is called whole word look-up. It produces the most intelligible, life-like speech, but it is the most memory intensive even for modest sized vocabularies. Despite steady advances in low cost, high density memory chips, whole-word-look-up tends to be prohibitively expensive or the vocabulary is limited (7).

A less memory intensive approach is the letter-to-sound conversion in which a synthetic sound processor divides the text string into basic letter groups and then follows certain pronunciation rules for the creation of speech. Many languages (especially American English) are replete with numerous exceptions to the usual rules of pronunciation. Hence, the quality of the speech output using letter-to-sound conversion depends on the sophistication of the rules and the number of exceptions employed (7,8).

The third method of converting text into speech is called morphonemic text-to-speech conversion. This approach relies on prestored combination of morphemes (basic units of language such as prefixes, suffixes, and roots) and their corresponding speech sounds. Some 8000 morphemes can generate ~95% of the English words (8,9) so this approach avoids the memory demands of the whole word look-up approach. Morphonemic based speech generation generally yields synthetic speech output that is more intelligible than the letter to speech approach, but is more demanding computationally. Continuing advances in technology have now made single chip text to speech converters powerful, capable, and affordable in consumer electronics (10).

A blind individual using a computer running a text-to-speech program can now hear what is on the screen and use cursor keys to select a specific part of the screen to read. Equipped with such a computer, high speed connection to the Internet, and a modern reading machine, sight impaired individuals now have wide access to news, e-mail, voice messaging, and Internet's vast repository of information. These powerful information technologies have reduced the social isolation formerly felt by blind persons while also broadening their employment opportunities.

One example of how recent technological advances are improving access to reading materials is the Spoken Interface that Apple Computer unveiled at the 2005 Annual Technology & Persons with Disabilities Conference held in Los Angeles. Because Spoken Interface is a screen reader that is fully integrated into Apple's operating system, assistive technology developers should be able to set up easy inter-operability between their software and the operating platform with little additional modifications.

Another example of a low cost, user friendly, and powerful text-to-speech software is the TextAloud MP3 by Nextup Technologies (<http://www.nextuptech.com/about.html>). This software converts any text into natural sounding speech or into MP3 files for downloading and later playback on portable electronic devices (e.g., MP3 players, pocket PCs, and portable data assistants).

MANDATED WEB ACCESSIBILITY

With so much information available on the Internet and the blind people's increasing dependence on it, the

United States government included web accessibility in its 1998 amendment of the Rehabilitation Act (11). Section 508 of this law requires that when Federal agencies develop, procure, maintain, or use electronic information technology, they must ensure that this technology offers comparable access to Federal employees who have disabilities. Although the scope of Section 508 is limited to the Federal sector, these requirements have gradually spread to the private sector, especially to large corporations that deal frequently with the Federal government.

The accessibility requirements of Section 508 are reflected in several guidelines, including as the Web Content Accessibility Guidelines (WCAG) from the World Wide Web Consortium (W3C). The WCAG recommendations, which are updated periodically, include implementing standardized style sheets instead of custom HTML tags and offering closed-captioning and transcripts of multimedia presentations. Other recommendations for making a web site compliant (12) include the following: provide text alternates to images; make meaning independent of color; identify language changes; make pages style sheet independent; update equivalents for dynamic content; include redundant text links for server-side image maps; use client-side image maps when possible; put row and column headers in data tables; associate all data cells with header cells; title all frames; make the site script independent.

An assortment of adaptive hardware and software can be effectively utilized once a web site satisfies the WCAG recommendations (13). Persons with low vision can change their browser settings or use screen magnifiers. Internet users who are blind or have very limited vision can use text-based Web browsers with voice-synthesized screen readers, audio browsers, or refreshable Braille displays to read and interact with the Web.

Recent efforts to increase internet's compatibility with assistive technologies used by sight impaired persons include the development and implementation of search engines that read aloud their results using male and female voices. Some websites offer speech-synthesized renditions of articles from news organizations like BBC, Reuters, and the New York Times (14).

While internet accessibility by persons with severe visual impairments is improving, a number of problems and challenges remain. Screen readers or Braille keyboards that blind people use to navigate the Internet cannot scan or render graphical elements into a readable format. Spam, security checks, popup ads, and other things that slow down a sighted person's Web searches are even worse impediments for those with severe visual impairments using assistive technology.

INDEPENDENT LIVING AIDS

Because blindness and severe visual impairments are so pervasive in their impact, numerous and relatively low cost assistive devices have been developed to make non-reading activities of daily living (ADL) easier. In general, these ADL devices rely on the users' auditory or tactile sense for their operation.

Figure 6. A talking calculator with a female voice speaks the individual digits or whole integers. Its large 8 digit LCD readout is ~0.6 in. (1.52 cm) high. The calculator can add, subtract, divide, multiply and calculate percentages. (Reproduced from Ref. 5.)

A quick check of electronic catalogs on the Internet shows that many types of independent living aids are available. For example, special clocks and timers that give both voice and vibratory alarms are available in various sizes and features. Other assistive devices for ADL include talking wrist watches, push-button padlocks, special money holders, Braille embossed large push button phones, and jumbo sized playing cards embossed with Braille. Personal care items for the blind include talking bathroom scales, thermometers, glucose monitors, blood pressure gauges, and prescription medicine organizers. Educational aids that facilitate note taking, calculating, searching, printing, and organizing information include talking calculators (Fig. 6), pen-like handheld scanner for storing text, letter writing guides with raised lines, Braille metal guides and styluses, and signature guides.

MOBILITY AIDS

For persons with severe visual impairments, the advent of powerful and affordable reading machines and the vast amount information (already in electronic form) on the internet, the problem of access to reading materials has been significantly ameliorated. In contrast, their other major problem (the ability to travel safely, comfortably, gracefully, and independently through the environment) has only been partially solved.

Despite years of effort and some major advances in technology, there is no widely accepted electronic travel aid (ETA). Most blind individuals rely on the sighted human guide, a guide dog, and the familiar white cane. The human sighted guide offers companionship, intelligence, wayfinding capability, route recall, and adaptability. Unfortunately, human guides are not always available, and their very presence constitutes a lack of independence. A guide dog or animal guide has been popular, but not every blind person can independently care for a living animal nor afford the cost of its care. In

some social situations, a guide dog can be awkward or unacceptable. The white cane, which is both a tool and a symbol for the blind, can alert sight-impaired travelers to obstacles in their path, but only those at ground level and < 5 ft. (1.5 m) away. Above ground obstacles and especially those at head height remain a source of apprehension and danger for travelers depending on just the white cane.

To understand why decades of research and development efforts have not yielded an efficacious and widely accepted electronic travel aid, one needs to realize that mobility aids must deal with a very different set of constraints and inputs than do reading aids. An identification error made by reading aids results only in misinformation, mispronunciation, or inconvenience. In contrast, a failed detection of an obstacle or step-down or a missed landmark can lead to confusion, frustration, apprehension, and physical injury.

Another major difference between a mobility aid and a reading aid lies in their operating milieu. Mobility aids must detect and analyze unconstrained, long range, and highly variable environmental inputs, that is, obstacles of differing sizes, textures, and shapes distributed over a 180° wide area. In contrast reading machines must identify and convert into intelligible speech inputs that are often well defined and short ranged, for example, high contrast printed alphanumeric symbols and punctuation marks (15).

To further complicate matters, users of reading aids often have the luxury of focusing all or most of their attention on the task at hand: interpreting the output of the reading aid. Users of mobility aids, however, must divide their attention among several demanding tasks associated with traveling, such as avoiding obstacles, listening to environmental cues, monitoring their physical location, recalling the memorized route, and interpreting the auditory or tactile cues from their mobility aid. Given these challenges, today's mobility aids represent a much less satisfactory solution (in comparison to available reading aids) to the problem of independent and safe mobility for persons with severe visual impairments.

THE IDEAL MOBILITY AID

Before examining the capabilities of currently available mobility aids, it is desirable to enumerate the fundamental features of an ideal electronic travel or mobility aid (Table 2) (16–18). The first three items of an ideal mobility aid can be categorized as nearby obstacle avoidance; features 4–7 fall under the category of navigational guidance or wayfinding; and features 8–10 represent good ergonomic design or user friendliness.

CONVENTIONAL ELECTRONIC TRAVEL AIDS

Standard or conventional electronic travel aids detect nearby obstacles, but provide no wayfinding assistance. Obstacle detection entails the transmission of some sort of energy into the surrounding space and the detection of the reflections. After analyzing the reflected signals, the ETA warns the traveler of possible obstacles using either auditory feedback or tactile feedback.

Table 2. The Ideal Mobility Aid

	Capabilities and Features	Description
Feature No. 1	Obstacle detection	Detect nearby obstacles that are ahead, at head level, and at ground level and indicate their approximate locations and distances without causing sensory overload.
Feature No. 2	Warn of impending Obstacles	Reliably locate and warn of impending potholes, low obstacles, step-downs and step-ups.
Feature No. 3	Guidance around obstacles	Guide the traveler around impending obstacles.
Feature No. 4	Ergonomically designed	Offer voice and/or tactile feedback of traveler's present location. Capable of voice input operation and/or have tactually distinct push buttons
Feature No. 5	Wayfinding	Able to monitor the traveler's present location and indicate the direction toward the destination
Feature No. 6	Route recall	Be able to remember a previous route and warn of changes in the environment due to construction or other blockages
Feature No. 7	Operational flexibility	Reliably function in a variety of settings, that is, outdoors, indoors, stairways, elevators, and cluttered open spaces
Feature No. 8	User friendliness	Be portable, rugged, fail-safe, and affordable for a blind user
Feature No. 9	Cosmesis	Be perceived by potential users as cosmetically acceptable and comfortable to use in terms of size, styling, obtrusiveness, and attractiveness
Feature No. 10	Good battery life	Have rechargeable batteries that can last for at least 6 h per charge

The LASER CANE (Fig. 7) is one of the few conventional ETAs that can serve as a stand-alone, primary travel aid because it has obstacle detection (features 1–3 of Table 2) and is reasonably user friendly and cosmetic (features 8–10). The laser cane's shaft houses three narrow-beam lasers; the lasers scan upward, forward, and downward. Reflections from objects in these zones are detected by three optical receivers also housed in the shaft. The UP channel monitors head level obstacles and causes high pitched beeps to be emitted. The FORWARD channel monitors objects located 4–10 ft. (1.21–3.01 m) ahead of the cane's tip and produces warning signals in the form of either vibrations in the handle of the cane or a medium (1600 Hz) audio tone. Obstacles encountered by the DOWN channel produce a low frequency (200 Hz) warning tone (19). Because the laser cane is swept through an arc ~ 3 –4 ft. (0.91–1.21 m) wide in the direction of the intended path (in a manner similar to standard long cane usage), the laser cane augments the auditory and tactile feedback of an ordinary white cane by detecting objects at greater distances and, most importantly, head level obstructions.

The laser cane's main drawbacks include it being somewhat costly and fragile. It also cannot monitor the traveler's geographic location nor guide the traveler toward the intended destination (features 5 and 6). Field tests and consumer feedback revealed that laser obstacle detection can be highly variable because certain surfaces and objects reflect laser light better than others. For example, the laser beam mostly passes through glass so that the laser cane may miss glass doors or large glass windows ahead.

Although the laser cane is imperfect, it has one major advantage as an ETA; It is failsafe. Should its batteries run down or its electronics malfunction, the laser cane can still serve as a standard long cane (20) and thus still be useful to the traveler.

Another commercially available electronic travel aid is the Sonic Guide, an eyeglass frame equipped with one ultrasonic transmitter and two receivers embedded in

Figure 7. The laser cane projects three narrow beams of laser light. If any of the beams (up, forward, and downward) encounter an object and is reflected back to the receivers in the cane's shaft, a tactile or auditory warning is generated. (Reproduced from Ref. 19.)

the nose piece (21). The pulsed ultrasonic beam radiates through a forward solid angle of $\sim 100^\circ$. Objects in the environment reflect ultrasound back to the two receivers with time delays proportional to their distance and angle with respect to the wearer's head. The wearer is given awareness of his surroundings via binaural auditory feedback of the reflected signals, recreating the experience of echolocation as found in bats or dolphins. An object's distance is displayed in terms of frequencies proportional to the object's distance from the user. The azimuth of an object relative to the user's head is displayed via the relative intensity of tones sent to the ears (stereoscopic aural imaging). As a result, the binaural sounds heard by the user changes as he moves or turns his head.

To circumvent Sonic Guide's tendency to interfere with normal hearing, Kuc (22) investigated the utility of using vibrotactile feedback via a pair of sonar transceivers and vibrators worn on the wrists. Being on opposite sides of the body, the dual sonar transceivers offered better left-right obstacle discrimination than could a single sonar unit embedded in the nose piece of the eyeglasses. The wrist mounted pager-like device vibrated at a frequency inversely related to the reflecting object's distance from that side of the body.

Unfortunately, neither the original eyeglass frame based Sonic Guide nor the wrist worn sonar guide can serve as a stand-alone travel aid because neither can detect impending step-ups, step-downs, or other tripping hazards in the pathway. Other user comments about the Sonic Guide include interference with normal hearing, sensory overload, and difficulty in combining the aid's feedback with other important environmental cues such as the sound of traffic at street intersections, tactile feedback from a white cane, or the subtle pull of a guide dog.

In contrast to Sonic Guide's rich auditory feedback, the Mowat Sensor implements the design philosophy that simpler is better. The Mowat Sensor is a handheld ultrasonic flash light that acts like a clear path detector. It measures $6 \times 2 \times 1$ in. ($15 \times 5 \times 2.5$ cm), weighs 6.5 oz (184.2 g), can be easily carried in a pocket or purse, and is manufactured by Pulse Data International Ltd. of New Zealand and Australia.

The Mowat device emits a pulsed elliptical ultrasonic beam $\sim 15^\circ$ wide by 30° high, a beam pattern that should detect doorway sized openings located some 6 ft. (1.8 m) away. Reflections from objects in the beam pattern cause the Mowat to produce vibrations that are inversely proportional to the object's distance from the detector. As the traveler points at and gets closer to the object, the Mowat vibrates faster and faster. As the traveler aims moves away from that object, the vibrations slow and then cease. Objects outside of Mowat's beam pattern produce no vibrations.

The Sonic Guide, Mowat Sensor, and their various derivatives share similarities while representing two divergent design philosophies. They all employ ultrasound instead of laser light to detect nearby obstacles. None of them can detect tripping hazards, such as impending step-ups, step-downs, uneven concrete walkways, or small low obstacles in the path of travel so they cannot serve as a stand-alone travel aid. The Mowat sensor scans a small

portion of the environment, displays limited data from that region, and offers easily interpreted vibratory information to the user. Alternatively, the Binaural Sonic Guide sends a broad sonic beam into much of the traveler's forward environment, displays large amounts of environmental information, and leaves it up to the user to select which portion of the auditory feedback to monitor and which to ignore.

While similar in concept, obstacle detection via ultrasound and obstacle detection via laser light interact with the environment differently. For example, hard vertical surfaces and glossy painted surfaces reflect sound and light very well so they tend to be detected by both methods at greater distances than oblique surfaces or dark cloth covered soft furnishings. Transparent glass, however, reflects sound very well, but laser light very poorly. Hence an ultrasonic beam would readily note the presence of a glass door whereas laser light could miss it entirely. Sonar based ETAs, however, are susceptible to spurious sources of ultrasound such as squealing air breaks on buses. Such sources and even heavy precipitation can cause the sonar sensor to signal the presence of a phantom obstacle or produce unreliable feedback. Furthermore, because all ETAs display environmental information via the sense of touch or hearing, severe environmental noise and wearing gloves or ear muffs can reduce a user's ability to monitor an ETAs feedback signals.

Other drawbacks of conventional electronic travel aids include the lack of navigational guidance (features 5 and 6 of Table 2), thus limiting the blind traveler to familiar places or necessitating directional guidance from a sighted guide until they have memorized the route. Furthermore, conventional ETAs often require the user to actively scan the environment and interpret the auditory and tactile feedback from the aids. These somewhat burdensome tasks require conscious effort and can slow walking speed.

INTELLIGENT ELECTRONIC TRAVEL AIDS

Recent advances in technology have sparked renewed efforts to develop mobility aids that address some of the aforementioned drawbacks. One promising intelligent electronic travel aid, under development at the University of Michigan Mobile Robotics Laboratory, is the GuideCane (23). The GuideCane (Fig. 8) is a semiautonomous robotic guide that improves user friendliness by obviating the burden of constant scanning while also guiding the traveler around obstacles, not merely detecting them. It consists of a self-propelled and servocontrolled mobile platform connected to a cane. An array of 10 ultrasonic sensors is mounted on the small platform. The sensors emit slightly overlapping signals to detect ground-level obstacles over a 120° arc ahead of the platform. The sonar units, made by Polaroid Corporation, emit short bursts of ultrasound and then uses the time of flight of the reflections to gauge the distance to the object. The sonar has a maximum range of 30 ft. (10 m) and an accuracy of $\sim 0.5\%$ (24).

When walking with the GuideCane, the user indicates his intended direction of travel via a thumb-operated mini-joystick mounted at the end of a cane attached to the

Figure 8. The GuideCane functions somewhat like a robotic guide dog. It is able to scan the environment and steer around obstacles by using its ultrasonic sensors, steering servomotors, and on-board computer to keep track of nearby obstacles and the intended path of travel. (Reprinted from figure on p. 435 of Ref. 23.)

platform. The mobile platform maintains a map of its immediate surroundings and self-propels along the indicated direction of travel until it detects an obstacle at which time the robotic guide steers itself around it. The blind traveler senses the GuideCane's change of direction and follows it accordingly.

Like the Laser cane, the GuideCane can function as a stand-alone travel aid because it gives advance warning of impending step-downs and tripping hazards. Its bank of 10 ultrasonic detectors and ability to navigate around detected obstacles make the GuideCane easier and less mentally taxing to use than the Laser Cane. To address the wayfinding needs of the blind traveler, efforts are underway to add GPS capability, routing software and area maps to the GuideCane. The drawbacks of the wheel mounted GuideCane, however, include its size and weight and its inability to detect head height objects.

NAVIGATIONAL NEEDS

Electronic travel aids like those described above are becoming proficient at detecting and enabling the traveler to avoid obstacles and other potential hazards. Avoiding obstacles, however, represents only a partial solution to a blind person's mobility problem. Many visually impaired or blind travelers hesitate to visit unfamiliar places because they fear encountering an emergency or possibly getting lost. Their freedom of travel is hampered by having to pre-plan their initial trip to a new place or needing to enlist the help of a sighted person.

Furthermore, blind pedestrians, even those with training in orientation and mobility, often experience difficulty in unfamiliar areas and areas with free flowing traffic, such as parking lots, open spaces, shopping malls, bus

terminals, school campuses, and roadways or sidewalks under construction. They also have difficulty crossing nonorthogonal, multiway traffic intersections (25). Conventional traffic signals combined with audible pedestrian traffic signals have proven somewhat helpful in reducing the pedestrian accident rates at intersections (26–28), but audible traffic signals offer guidance only at traffic intersections and not other important landmarks.

One proposed solution for meeting the wayfinding needs of blind travelers is the Talking Sign, a remote infrared signage technology that has been under development and testing at The Smith-Kettlewell Eye Research Institute in San Francisco, CA (29,30). The Talking Signs system consists of strategically located modules that transmit environmental speech messages to small, hand held receivers carried by blind travelers (Fig. 9). The repeating and directionally selective voice messages are transmitted to the receiver by infrared (IR) light (940 nm, 25 kHz). Guided by these orientation aids, blind travelers can know their present location and move in the direction from which the desired message, for example, Corner of Front Street and Main Street, is being broadcasted, thus finding their way without having to remember the precise route.

The Talking Sign and other permanently mounted voice output devices, however, require standardization, costly retrofitting of existing buildings, and the possession of a suitable transceiver to detect or activate the installed devices. Retrofitting buildings with such devices is not cost effective due to their inherent inflexibility and the need for many users to justify the implementation costs. What's especially frustrating for persons with severe visual impairments is that talking signs may not reflect their travel patterns or be available at unfamiliar locations and wide open spaces. To be truly useful, talking signs would have to be almost ubiquitous and universally adopted.

GPS NAVIGATIONAL AIDS

In addition to obstacle avoidance, the ideal navigational aid also must address two other key aspects of independent travel: orientation (the ability to monitor one's position in relationship to the environment) and route guidance (the ability to determine a safe and appropriate route for reaching one's destination). As an orientation aid, the Global Positioning System (GPS) seems promising. For route guidance, a notebook computer or personal data assistant (PDA) equipped with speech input/output software, route planning software (artificial intelligence), and digital maps have been proposed (18,31,32). A voice operable, handheld GPS unit used in combination with obstacle detecting ETAs like the Laser Cane might constitute the ideal navigational aid for blind persons.

Several GPS equipped PDAs have recently become available. For example, the iQue 3600 (\$600 from Garmin International Inc., Olathe, Kansas) is a handheld device that combines a PDA and mapping software with a built-in GPS receiver. The iQue 3600 uses the Palm operating system and offers a color screen and voice output turn-by-turn navigational guidance. For someone who already possesses a PDA (e.g., Palm Pilot or Microsoft's Pocket

Figure 9. Talking Signs not only gives location information, but also tells the pedestrian the current status of the pedestrian cycle, aids in finding the cross-walk, and indicates the direction of the destination corner. (Reproduced from Ref. 29.)

PC), various third party software and GPS add-on units can be used.

While promising as a navigational aid for persons with severe visual impairments, GPS equipped portable PDAs (or notebook computers) have significant limitations. To fully appreciate these limitations, a brief review of how the Global Positioning System works (Fig. 10) would be apropos.

Global Positioning System (GPS) began some 30 years ago when Aerospace Corporation in Southern California studied ways to improve radio navigation systems for the military (33). Although GPS was not fully operational at the outbreak of the Persian Gulf War in January 1991, its exceptional performance in accurately locating fighting units evoked a strong demand from the military for its immediate completion.

Currently, 24 satellites of the GPS circle the earth every 12h at a height of 20,200 km. Each satellite continuously transmits pseudorandom codes at 1575.42 and 1227.6 MHz. The orbital paths of the satellites and their altitude enable an unobstructed observer to see between five and eight satellites from any point on the earth. Signals from different visible satellites arrive at the GPS receiver with different time delays. The time delay needed to achieve coherence between the satellites' pseudorandom codes and the receiver's internally generated code equals the time-of-flight delay from a given satellite. GPS signals from at least four satellites are analyzed to determine the receiver's

longitude, latitude, altitude (as measured from earth's center) and the user's clock error with respect to system time (33).

For civilian applications, position accuracy of a single channel receiver is about 100 m and its time accuracy is ~ 340 ns. Greater accuracy, usually within 1 m, can be achieved using differential GPS wherein signals from additional satellites are analyzed and/or the satellite signals are compared with and corrected by a GPS transceiver at a known fixed location (33).

At first glance, GPS signals seem fully able to meet the orientation needs of persons with severe visual impairments. The GPS signals are sufficiently accurate if combined with differential GPS and signals are immune to weather and are available at any time of the day, anywhere there's a line of sight to at least four GPS satellites. Lastly, a GPS receiver is relatively inexpensive, < \$200.

Unfortunately, just equipping blind persons with a voice-output GPS receiver for wayfinding outdoors is insufficient. The GPS signals are often unavailable or highly attenuated under bridges, inside natural canyons, and between tall buildings in urban areas. The altitude GPS information is generally not useful, and its longitudinal and latitudinal coordinates are useless when unaccompanied by local area maps (17). For college campuses or even major metropolitan areas, the location of major buildings and their entrances in terms of longitude and latitude coordinates are rarely available. Without these key pieces

Figure 10. Synchronized signals from four satellites are analyzed by the mobile receiver to determine its precise position in three dimensions. The distances for the four satellites include an unknown error due to the inaccuracy of the receiver's clock and Doppler effects. (Reprinted from Ref. 33.)

of information, the GPS navigational aid is unable to offer directional guidance to the blind traveler.

INDOOR NAVIGATIONAL AIDS

One of the key characteristics of an ideal mobility aid is that the device reliably function indoors, outdoors, and within changing environments (Table 2). When used in combination with detailed local area maps, the GPS receiver and voice output could form the basis for a navigational aid. However, GPS signals may not be available at all times and are totally absent indoors. To function indoors, an electronic navigational aid will need to rely on some other set of electronic beacons as signposts.

For wayfinding within a large building, several investigators have borrowed the idea found in the Hansel and Gretel fairy tale about two children leaving a trail of bread crumbs to find their way home again. Instead of bread crumbs, Szeto (18) proposed placing small, low cost electronic beacons along corridors or at strategic locations (e.g., elevators, bathrooms, stairs) of buildings visited. Acting like personal pathmarkers, these radio frequency (RF) emitting electronic beacons would be detected by the associated navigational aid and guide the traveler back to a previous location or exit. To avoid confusion with other users, the electronic beacons could be keyed to work with one navigational aid.

Kulyukin et al. (34) recently studied the efficacy of using Radio Frequency Identification (RFID) tags in robot-assisted indoor navigational for the visually impaired. They described how strategically located, passive (nonpowered) RFID tags could be detected and identified by a RFID reader employing a square 200×200 mm antenna and linked to a laptop computer. In field tests, wall-mounted RFID tags responded to the spherical electromagnetic field from an RFID antenna at a distance of ~ 1.5 m. Since each tag is given a unique identifier, its location inside a building can be easily recalled and used to locate one's position inside a building.

In comparison to wall-mounted Talking Signs, the approach of Szeto (18) and Kulyukin et al. (34) seems to be less costly and more flexible. Placing disposable electronic beacons in the hands of individual travelers does not require permanent retrofits of buildings, can be cost effective even for single users, and easily changes with the travel patterns of the user.

The electronic beacons and handheld electronic transceivers also should be economically feasible because they utilize a technology that's being developed for the mass market. World's largest retailer, Wal-Mart, has mandated 2008 as the year when all its suppliers must implement an RFID tracking system for their deliveries. It is likely that RFID tags, antenna, and handheld interrogators developed for inventory tracking can be adapted for use in an indoor navigational aid.

Although not yet a reality, a low cost, portable, handheld, indoor-outdoor mobility aid that embodies many of the features listed in Table 2 is clearly feasible. The needed technological infrastructure will soon be in place. For obstacle avoidance, the Laser Cane, Guide Cane, or their variants can be used. For indoor wayfinding and route guidance, the

blind traveler could augment the cane or guide dog with a handheld voice output electronic navigational aid linked to strategically placed electronic beacons. For outdoor wayfinding, the blind traveler could augment the Laser Cane with a handheld mobility aid equipped with a GPS receiver, compass, local area maps, and wireless internet link.

The intelligent navigational aid just described would address the mobility needs of the blind by responding to voice commands; automatically detecting GPS signals or searching for the presence of electronic beacons; wirelessly linking to the local area network to obtain directory information; converting the GPS coordinates or the signals from electronic beacons into a specific location on a digital map; and, with the help of routing finding software, generating step-by-step directions to the desired destination.

FUTURE POSSIBILITIES

Of course, the ultimate assistive technology for overcoming the many problems of severe visual impairment would be an artificial eye. Since the mid-1990s, research by engineers, ophthalmologists, and biologists to develop a bionic eye have grown and artificial retina prototypes are nearing animal testing. An artificial eye would incorporate a small video camera to capture light from objects and transmit the image to a wallet-sized computer processor that in turn sends the image to an implant that would stimulate either the retina (35) or visual cortex (36).

Researchers at Stanford University recently announced progress toward an artificial vision system that can stimulate a retina with enough resolution to enable a visually impaired person to orient themselves toward objects, identify faces, watch television, read large fonts, and live independently (37). Their optoelectronic retinal prosthesis system is expected to stimulate the retina with resolution corresponding to a visual acuity of 20/80 by employing 2500 pixels per square millimeter. The researchers see the device as being particularly helpful for people left blind by retinal degeneration. Although such developments are exciting, tests with human subjects on practical but experimental prototypes won't likely occur for another 6–8 years (38).

What else does the future hold in terms of assistive technology in general and mobility aids in particular? In an address to the CSUN 18th Annual Conference on Technology and Persons with Disabilities in 2003, futurist and U.S. National Medal of Technology recipient, Ray Kurzweil, presented his vision of the sweeping technological changes that he expected to take place over the next few decades (39). His comments are worthy of reflection and give cause for optimism.

With scientific and technological progress doubling every decade, Kurzweil envisions ubiquitous computers with always-on Internet connections, systems that would allow people to fully immerse themselves in virtual environments, and artificial intelligence embedded into Web sites by 2010. Kurzweil (39) expects the human brain to be fully reverse-engineered by 2020, which would result in computers with enough power to equal human intelligence. He forecasted the emergence of systems that provide subtitles for deaf people around the world, as well as listening systems geared

toward hearing-impaired users. Blind people would be able to take advantage of pocket-sized reading devices within a decade or have retinal implants that restore useful vision in 10–20 years. Kurzweil believed that people with spinal cord injuries would be able to resume fully functional lives by 2020, either through the development of exoskeletal robotic systems or techniques that bridged severed neural pathways, possibly by wirelessly transmitting nerve impulses to muscles. Even if one-half of what Kurzweil predicted became reality, the future of assistive technology for the blind is bright and an efficacious intelligent mobility aid for such persons will soon be commercially available.

Reading List

- Cook AM, Hussey SM. *Assistive Technologies: Principles and Practice*. 2nd ed., St. Louis (MO): Mosby, Inc.; 2002. A thorough text on assistive technologies that is especially suited for the rehabilitation practitioner or those in allied health.
- Smith RV, Leslie JH Jr., editors. *Rehabilitation Engineering*. Boca Rotan (FL): CRC Press; 1990. Contains diverse articles that should be of particular interest to practitioners in the rehabilitation field although several of the articles present definitive state-of-the-art information on rehabilitation engineering.
- Webster JG, Cook AM, Tompkins WJ, Vanderheiden GC, editors. *Electronic Devices for Rehabilitation*. New York: John Wiley & Sons Inc. Medical; 1985. Though somewhat dated, this book offers a comprehensive overview of rehabilitation engineering and describes many of the design issues that underlie various types of assistive devices. A useful introductory text for undergraduate engineering students interested in rehabilitation.
- Golledge RG. *Wayfinding Behavior: Cognitive Mapping and Other Spatial Processes*. Baltimore: John Hopkins University Press; 1999. A good reference that covers the cognitive issues of wayfinding behavior in blind and sighted humans.
- Teodorescu HNL, Jain LC, editors. *Intelligent Systems and Technologies in Rehabilitation Engineering*. Boca Rotan (FL): CRC Press; 2000. A compendium of technical review articles covering intelligent technologies applied to retinal prosthesis, auditory & cochlear prostheses, upper and lower limb orthoses/prostheses, neural prostheses, pacemakers, and robotics for rehabilitation.
- Yonaitis RB. *Understanding Accessibility-A Guide to Achieving Compliance on Websites and Intranets*, ISBN: 1-930616-03-1, HiSoftware, 2002. This is a free booklet in electronic form for complying with the Federal government's "Section 508" of the Workplace Rehabilitation Act (amendments of 1998). The book gives a brief and clear discussion of accessibility testing and how to integrate this activity into web design and related tasks.
- Blasch B, Weiner W, Welsh R. *Foundations of Orientation and Mobility*. 2nd ed., New York: American Foundation for the Blind; 1997. A useful book for general background regarding the issues of orientation and mobility.
- IEEE Spectrum*, Vol. 33(5), May 1996, carries six special reports on the development of an artificial eye. Articles in this issue examine physiology of the retina, neural network signal processing, electrode array design, and sensor technology.
- Journal of Visual Impairment and Blindness*, Vol. 97(10), Oct. 2003, is a special issue that focused on the impact of technology on blindness.
- Speech Technology*, a magazine published bimonthly by AmCom Publications, 2628 Wilhite Court, Suite 100, Lexington, KY 450503. This magazine regularly covers the development and implementation of technologies that underlie speech recognition and speech generation. For example, its March/April 2005 issue contained articles on the following topics: guide to speech standards; applications of transcription; role of speech in healthcare, embedding speech into mobile devices, technology trends, new products, and speech recognition software.

INTRODUCTION

Phlebotomy may date back to the Stone Age when crude tools were used to puncture vessels to allow excess blood to drain out of the body (1). This purging of blood, subsequently known as blood letting, was used for therapeutic rather than diagnostic purposes and was practiced through to modern times. Phlebotomy started to be practiced in a more regulated and dependable fashion after the Keidel vacuum tube for the collection of blood was manufactured by Hynson, Wescott, and Dunning. The system consisted of a sealed ampoule with or without culture medium connected to a short rubber tube with a needle at the end. After insertion onto the vein, the stem of the ampoule was crushed and the blood entered the ampoule by vacuum. Although effective, the system did not become popular until evacuated blood collection systems started to be used in the mid-twentieth century. With evacuated blood collection systems came a new interest in phlebotomy and blood drawing techniques and systems. A lot of technical improvements have been made, not only are needles smaller, sharper, and sterile, they are also less painful. The improved techniques of obtaining blood samples assure more accurate diagnostic results and less permanent damage to the patient. Today, the main purpose of phlebotomy synonymous with venipuncture is to obtain blood for diagnostic testing.

Venipuncture Standards and Recent Standard Changes

The Clinical and Laboratory Standards Institute (CLSI, formerly the National Committee for Clinical Laboratory Standards, NCCLS) develops guidelines and sets standards for all areas of the laboratory (www.CLSI.org). Phlebotomy program approval as well as certification examination questions are based on these important national standards. Another agency that affects the standards of phlebotomy is the College of American Pathologists (CAP; www.CAP.org). This national organization is an outgrowth of the American Society of Clinical Pathologists (ASCP). The membership in this specialty organization is made up of board-certified pathologists only and offers, among other services, a continuous form of laboratory inspection by pathologists. The CAP Inspection and Accreditation Program do not compete with the Joint Commission on Accreditation of Health Care Organizations

(JCAHO) accreditation for health care facilities, because it was designed for pathology services only.

The CLSI has published the most current research and industry regulations on standards and guidelines for clinical laboratory procedures (2,3). The most significant changes to specimen collection are (1) collectors are now advised to discard the collection device without disassembling it, this reflects the Occupational Safety and Health Administration's (OSHA) mandate against removing needles from tube holders; (2) the standard now permits gloves to be applied just prior to site preparation instead of prior to surveying the veins; (3) collectors are advised to inquire if the patient has a latex sensitivity; (4) sharp containers should be easily accessible and positioned at the point of use; (5) there is a caution recommended against the use of ammonia inhalants on fainting patients in case the patient is asthmatic; (6) collectors must attempt to locate the median cubital vein on either arm before considering alternative veins due to the proximity of the basilica vein to the brachial artery and the median nerve; (7) forbids lateral needle relocation in an effort to access the basilica vein to avoid perforating or lacerating the brachial artery; (8) immediate release of tourniquet "if possible" upon venous access to prevent the effects of hemoconcentration from altering test results.

The Role of the Phlebotomist Today

Professionalism. Phlebotomists are healthcare workers and must practice professionalism and abide by state and federal requirements. A number of agencies have evolved offering the phlebotomist options for professional recognition (1). Certification is a process that indicates the completion of defined academic and training requirements and the attainment of a satisfactory score on a national examination. Agencies that certify phlebotomists and the title each awards include the following: American Society of Clinical Pathologists (ASCP): Phlebotomy Technician, PBT (ASCP); American Society for Phlebotomy Technology (ASPT): Certified Phlebotomy Technician, CPT (ASPT); National Certification Agency for Medical Laboratory Personnel (NCA): Clinical Laboratory Phlebotomist (CLP) (NCA); National Phlebotomy Association (NPA); Certified Phlebotomy Technician, CPT (NPA). Licensure is defined as a process similar to certification, but at the state or local level. A license to practice a specific trade is granted through examination to a person who can meet the requirements for education and experience in that field. Accreditation and approval of healthcare training programs provides an individual with an indication of the quality of the program or institution. The accreditation process involves external peer review of the educational program, including an on-site survey to determine if the program meets certain established qualification or educational standards referred to as 'essentials'. The approval process is similar to accreditation; however, programs must meet educational—standards and competencies—rather than essentials, and an on-site survey is not required.

Public Relations and Legal Considerations. The Patient's Bill of Rights was originally published in 1975 by the

American Hospital Association. The document, while not legally binding, is an accepted statement of principles that guides healthcare workers in their dealings with patients. It states that all healthcare professionals, including phlebotomists, have a primary responsibility for quality patient care, while at the same time maintaining the patient's personal rights and dignity. Two rights especially pertinent to the phlebotomist are the right of the patient to refuse to have blood drawn and the right to have results of lab work remain confidential. Right of Privacy: "An individual's right to be let alone, recognized in all United States jurisdictions, includes the right to be free of intrusion upon physical and mental solitude or seclusion and the right to be free of public disclosure of private facts. Every healthcare institution and worker has a duty to respect a patient's or client's right of privacy, which includes the privacy and confidentiality of information obtained from the patient—client for purposes of diagnosis, medical records, and public health reporting requirements. If a healthcare worker conducts tests on or publishes information about a patient—client without that person's consent, the healthcare worker could be sued for wrongful invasion of privacy, defamation, or a variety of other actionable torts." In 1996, the Health Insurance Portability and Accountability Act (HIPAA) law was signed. It is a set of rules to be followed by health plans, doctors, hospitals, and other healthcare providers. Patients must be able to access their record and correct errors and must be informed of how their personal information will be used. Other provisions involve confidentiality of patient information and documentation of privacy procedures.

SAFETY

Universal Precautions

An approach to infection control that is mandated by federal and state laws is the so-called Universal Precautions. The guidelines for Universal Precautions are outlined by OSHA (www.OSHA.gov). According to the concept of Universal Precautions, all human blood and certain human body fluids are treated as if known to be infectious for human immunodeficiency virus (HIV), hepatitis B virus (HBV), and other blood borne pathogens. For blood collections, the use of needles with a safety device or a needle integrated into a safety device and the use of gloves is now mandatory in most institutions. Biohazard material should be disposed of in an appropriately labeled biohazard container. Needles and other sharp instruments should be disposed of in rigid puncture-resistant biohazard containers.

First Aid Procedures

Most phlebotomy programs require cardio pulmonary resuscitation (CPR) certification as a prerequisite or include it as part of the course and in the event of an emergency situation: basic First Aid Procedures should be performed by the phlebotomist. These procedures are not in the scope of this article and training needs to be performed by qualified experts.

*A butterfly with luer adapter is shown as well as a standard needle

Figure 1. Basic components of the Evacuated Blood Collection System.

BLOOD COLLECTION SYSTEM AND EQUIPMENT

Blood Collection System

The components of the Evacuated Blood Collection System are shown in Fig. 1. The system consists of the following;

Plastic evacuated collection tube: The tubes are designed to fill with a predetermined volume of blood by vacuum. The rubber stoppers are color coded according to the additive that the tube contains (see Table 1). Evacuated collection devices are supplied by many vendors worldwide. These evacuated collection devices use similar color coding systems, proprietary additives, and recommended uses. Various sizes are available.

Tube holder (single use): For use with the evacuated collection system.

Needles (also available with safety device): The gauge number indicates the bore size: the larger the gauge number, the smaller the needle bore. Needles are available for evacuated systems and for use with a syringe, single draw, or butterfly system.

Additional Materials

Tourniquet: Wipe off with alcohol and replace frequently. Nonlatex tourniquets are recommended.

Table 1. Tube Guide^a

Tube Top Color	Additive	Inversions at Blood Collection ^a	Laboratory Use
Gold or Red/Black	Clot activator	5	Tube for serum determinations in chemistry.
	Gel for serum separation		Blood clotting time: 30 min
Light Green or Green/Gray	Lithium heparin	8	Tube for plasma determinations in chemistry
Red	Gel for plasma separation		
	Clot activator	5	Tube for serum determination in chemistry, serology, and immunohematology testing
Orange or Gray/Yellow	Thrombin	8	Tube for stat serum determinations in chemistry. Blood clotting occurs in < 5 min
Royal Blue	Clot activator	5	Tube for trace-element, toxicology and nutritional chemistry determinations.
	K ₂ EDTA, where EDTA = ethylenediaminetetraacetic acid	8	
Green	Sodium heparin	8	Tube for plasma determination in chemistry
	Lithium heparin	8	
Gray	Potassium oxalate/sodium fluoride	8	Tube for glucose determination. Oxalate and EDTA anticoagulants will give plasma samples. Sodium fluoride is the antiglycolytic agent
	Sodium fluoride/Na ₂ EDTA	8	
	Sodium fluoride (serum tube)	8	
Tan	K ₂ EDTA	8	Tube for lead determination. This tube is certified to contain < 0.01 μg·mL ⁻¹ lead
Lavender	Spray-coated K ₂ EDTA	8	Tube for whole blood hematology determination and immunohematology testing
White	K ₂ EDTA with gel	8	Tube for molecular diagnostic test methods such as polymerase chain reaction (PCR) and/or DNA amplification techniques.
Pink	Spray-coated K ₂ EDTA	8	Tube for whole blood hematology determination and immunohematology test. Designed with special cross-match label for required patient information by the AABB ^b
Light Blue	Buffered sodium citrate (3.2%) Citrate, theophylline, adenosine, dipyridamole (CTAD)	3	Tube for coagulation determinations. The CTAD for selected platelet function assays and routine coagulation determination

^aReproduced from Becton Dickinson www.bd.com/vacutainer. Evacuated collection devices made by other manufacturers use similar color coding systems and additives. Recommended inversion times and directions for use are provided by each supplier.

^bAABB = American Association of Blood Banks.

Gloves: Worn to protect the patient and the phlebotomist. Nonlatex gloves are recommended.

Antiseptics–Disinfectants: 70% isopropyl alcohol or iodine wipes (used if blood culture is to be drawn).

Sterile gauze pads: For application on the site from which the needle is withdrawn.

Bandages: Protects the venipuncture site after collection.

Disposal containers: Needles should never be broken, bent, or recapped. Needles should be placed in a proper disposal unit immediately after use.

Syringe: May be used in place of evacuated collection system in special circumstances.

Permanent marker or pen: To put phlebotomist initials, time, and date of collection on tube as well as any patient identification information not provided by test order label.

BEST SITES FOR VENIPUNCTURE

The most common sites for venipuncture are located in the antecubital (inside elbow) area of the arm (see Fig. 2). The primary vein used is the median cubital vein. The basilica and cephalic veins can be used as a second choice. Although the larger and fuller median cubital and cephalic veins of the arm are used most frequently, wrist and hand veins are also acceptable for venipuncture. Certain areas are to be avoided when choosing site such as; (1) Skin areas with extensive scars from burns and surgery (it is difficult to puncture the scar tissue and obtain a specimen); (2) the upper extremity on the side of a previous mastectomy (test results may be affected because of lymphedema); (3) site of a hematoma (may cause erroneous test results). If another site is not available, collect the specimen distal to the hematoma; (4) Intravenous therapy (IV)/blood transfusions (fluid may dilute the specimen, so

Figure 2. Venipuncture sites.

collect from the opposite arm if possible); (5) cannula/fistula/heparin lock (hospitals have special safety and handling policies regarding these devices). In general, blood should not be drawn from an arm with a fistula or cannula without consulting the attending physician; (6) edematous extremities (tissue fluid accumulation alters test results).

ROUTINE PHLEBOTOMY PROCEDURE

Venipuncture is often referred to as “drawing blood”. Most tests require collection of a blood specimen by venipuncture and a routine venipuncture involves the following steps *Note:* The following steps were written using guidelines established by the CLSI/NCCLS (3).

1. **Prepare Order.** The test collection process begins when the physician orders or requests a test to be performed on a patient. All laboratory testing must be requested by a physician and results reported to a physician. The form on which the test is ordered and sent to the lab is called the test requisition. The requisition may be a computer-generated form or a manual form.
2. **Greet and Identify Patient.** Approach the patient in a friendly, calm manner. Identify yourself to the patient by stating your name. Provide for their comfort as much as possible. The most important step in specimen collection is patient identification. When identifying a patient, ask the patient to state their name and date of birth. Outpatients can use an identification card as verification of identity. Even if the patient has been properly identified by the receptionist, the phlebotomist must verify the patient's ID once the patient is actually called into the blood drawing area. The phlebotomist should ask for two identifiers that match the test requisition form (e.g., name and social security or name and date of birth).
3. **Verify Diet Restrictions and Latex Sensitivity.** Once a patient has been identified, the phlebotomist should verify that the patient has followed any special diet instructions or restrictions. The phlebotomist should also inquire about the patient's sensitivity to latex.

Assemble Supplies: See the section on Blood Collection System and Equipment

Position Patient

A patient should be either seated or lying down while having blood drawn. The patient's arm that will be used for the venipuncture should be supported firmly and extended downward in a straight line.

4. **Apply Tourniquet.** A tourniquet is applied to increase pressure in the veins and aid in vein selection. The tourniquet is applied 3–4 in. (7.62–10.16 cm) above the intended venipuncture site. Never leave the tourniquet in place longer than 1 min.

5. **Select a Vein.** Palpate and trace the path of veins in the antecubital (inside elbow) area of the arm with the index finger. Having a patient make a fist will help make the veins more prominent. Palpating will help to determine the size, depth, and direction of the vein. The main veins in the antecubital area are the median cubital, basilica, and cephalic (see the section; Best Sites for Venipuncture). Select a vein that is large and well anchored.
6. **Put on Gloves.** Properly wash hands followed by glove application.
7. **Cleanse Venipuncture Site.** Clean the site using a circular motion, starting at the center of the site and moving outward in widening concentric circles. Allow the area to air dry.
8. **Perform Venipuncture.** Grasp patients arm firmly to anchor the vein. Line the needle up with the vein. The needle should be inserted at a 15–30° angle BEVEL UP. When the needle enters the vein, a slight “give” or decrease in resistance should be felt. At this point, using a vacuum tube, slightly, with firm pressure, push the tube into the needle holder. Allow tube to fill until the vacuum is exhausted and blood ceases to flow to assure proper ratio of additive to blood. Remove the tube, using a twisting and pulling motion while bracing the holder with the thumb. If the tube contains an additive, mix it immediately by inverting it 5–10 times before putting it down.
9. **Order of Draw.** Blood tubes are drawn in a particular order to ensure integrity of each sample by lessening the chances of anticoagulants interference and mixing. The order of draw also provide a standardized method for all laboratories (3,4).

Blood Cultures: With sodium polyanethol sulfonate anticoagulant and other supplements for bacterial growth.

Light Blue: Citrate Tube (*Note:* When a citrate tube is the first specimen tube to be drawn, a discard tube should be drawn first). The discard tube should be a nonadditive or coagulation tube.

Gold or Red/Black: Gel Serum Separator Tube, no additive.

Red: Serum Tube, no additive.

Green: Heparin Tube.

Light Green or Green/Gray: Gel Plasma Separator Tube with Heparin.

Lavender: EDTA Tube.

Gray: Fluoride (glucose) Tube.

10. **Release the Tourniquet.** Once blood begins to flow the tourniquet may be released to prevent hemoconcentration.
11. **Place the Gauze Pad.** Fold clean gauze square in half or in fourths and place it directly over the needle without pressing down. Withdraw the needle in one smooth motion, and immediately apply pressure to the site with a gauze pad for 3–5 min, or until the bleeding has stopped. Failure to apply pressure

will result in leakage of blood and hematoma formation. Do not bend the arm up, keep it extended or raised.

12. **Remove and Dispose of the Needle.** Needle should be disposed of immediately by placing it and the tube holder in the proper biohazard sharps container. Dispose of all other contaminated materials in proper biohazard containers.
13. **Bandage the Arm.** Examine the patients arm to assure that bleeding has stopped. If bleeding has stopped, apply an adhesive bandage over the site.
14. **Label Blood Collection Tubes.** Specimen tube labels should contain the following information: patient’s full name, patient’s ID number, date, time, and initials of the phlebotomist must be on each label of each tube.
15. **Send Blood Collection Tube to be Processed.** Specimens should be transported to the laboratory processing department in a timely fashion. Some tests may be compromised if blood cells are not separated from serum or plasma within a limited time.

SPECIMEN PROCESSING

Processing of blood is required in order to separate out the components for screening, diagnostic testing, or for therapeutic use. This section will concentrate primarily on processing of blood for screening purposes and diagnostic testing. An overview of the main blood processing procedures, specimen storage, and common uses for each of the components is provided in Table 2. Because there are many different blood components and many different end uses for these components, the list is not comprehensive and the reader should refer to other specialized literature for further details. The OSHA regulations require laboratory technicians to wear protective equipment (e.g., gloves, labcoat, and protective face gear) when processing specimens. Many laboratories mandate that such procedures are carried out in biosafety cabinets.

Whole Blood Processing

Because whole blood contains all but the active clotting components, it has the ability to rapidly deteriorate and all blood components are subject to chemical, biological, and physical changes. For this reason, whole blood has to be carefully handled and any testing using whole blood has to be performed as soon as possible after collection to ensure maximum stability. Whole blood is typically used for the complete blood count (CBC). The test is used as a broad screening test to check for such disorders as anemia, infection, and many other diseases (www.labtestsonline.org). The CBC panel typically includes measurement of the following: white blood, platelet and red blood cell count, white blood cell differential and evaluation of the red cell compartment by analysis of hemoglobin and hematocrit, red cell distribution width and mean corpuscular volume, and mean corpuscular hemoglobin. The CBC assays are now routinely performed with automated

Table 2. Blood Processing Procedures and Specimen Storage

Component	Processing	Short-Term Storage	Long-Term Storage	Uses
Red blood cells	Gravity and/or centrifugation	~ 1 month at 4 °C	Frozen up to 10 years	Transfusion
Plasma	Gravity and/or centrifugation	Use immediately	Frozen up to 7 years	Serology, diagnostics, immune monitoring source of biologics
Serum	Clotting and centrifugation	Use immediately	Frozen up to 7 years	Serology, diagnostics, immune monitoring source of biologics
Platelets	Plasma is centrifuged to enrich for platelet fraction	Five days at room temperature	Cannot be cryopreserved	Transfusion
Granulocytes	Centrifugation and separation from red blood cells	Use within 24 h	Cryopreserved in liquid nitrogen ^a	Transfusion
Peripheral blood mononuclear cells	Ficoll-hypaque separation	Use immediately	Cryopreserved in liquid nitrogen ^a	Immune monitoring, specialized expansion and reinfusion
Albumin, immune globulin, specific immune globulins, and clotting factor concentrates	Specialized processing, fractionation and separation	Not applicable	Variable	Multiple therapeutic uses

^aAlthough it has been shown that cells can be stored indefinitely in liquid nitrogen, the functionality of the cells would have to be assessed and storage lengths determined for each type of use proposed.

analyzers in which capped evacuated collection devices are mixed and pierced through the rubber cap. Whole blood drawn in EDTA (lavender) tubes are usually used, although citrate (blue top) vacutainers will also work (although the result must be corrected because of dilution). Blood is sampled and diluted, and moves through a tube thin enough that cells pass by one at a time. Characteristics about the cell are measured using lasers or electrical impedance. The blood is separated into a number of different channels for different tests.

The CBC technology has expanded in scope to encompass a whole new field of diagnostics, namely, analytical cytometry. Analytical cytometry is a laser-based technology that permits rapid and precise multiparameter analysis of individual cells and particles from within a heterogeneous population of blood or tissues. Analytical cytometry is now routinely used for diagnosis of different pathological states. This technique can be used to examine cell deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) content, cell-cycle distribution, cellular apoptosis, tumor ploidy, cell function measurements (i.e., oxidative metabolism, phagocytosis), cellular biochemistry (i.e., intracellular pH, calcium mobilization, membrane potential, microviscosity, glutathione content), and fluorescence image analysis of individual blood cells. Since the blood is truly a window on what happens in the body, it is possible to use blood samples for a wide array of diagnostic and research purposes.

A second important use for whole blood is in the setting of HIV infection and treatment as a way to monitor CD4 T cell counts and percentages. These single or multiplatform tests use fresh whole blood with EDTA as anticoagulant (< 18 h after collection) samples are run with or without lysis of red cells and fixation of the lymphocytes. There are several different companies that make specialized equipment for enumeration of CD4 cell counts, the basic principle of which is to use a fluores-

cently tagged anti CD4 cell surface marker. The results for the CD4 or other subset are expressed as a percentage of total gated lymphocytes. In order to determine the absolute CD4 cell counts, the percent CD4 must be multiplied by an absolute lymphocyte count derived from a hematology analyzer or by an integrated volumetric analysis method (5–7).

Another common use for whole blood is for the detection of secretion of cytokines from antigen or mitogen stimulated lymphocytes. This assay can provide information on a patient's T cell response to pathogens [e.g., cytomegalovirus (CMV) and Epstein Ban virus (EBV), HIV, and tuberculosis (TB)]. The technique can also be used to monitor vaccine induced responses or responses to immunotherapy. Whole blood is drawn into heparin, 0.5–1 mL of blood is stimulated with antigen of interest and costimulatory antibodies in the presence of Brefeldin-A. The latter inhibits transport of proteins from the Golgi so that secreted cytokines accumulate inside the cell. The samples are incubated at 37 °C for 6 h, after which they can be placed at 4 °C overnight or processed immediately. The samples are treated with EDTA to reduce clumping, red cells are lysed, and the sample is fixed by addition of paraformaldehyde. At this stage, the samples can be stored frozen for up to 4 months prior to detection of cell surface markers and intracellular cytokines by flow cytometry (8).

Serum Processing

Because of the ease of performing serum separation and the fact that so many tests rely on the use of serum, the technique has become routine in clinical and diagnostic laboratories. Specimens are drawn into tubes that contain no additives or anticoagulants (Table 1). Two commonly used tubes are the red serum collection tubes or commercially available serum separation tubes. Serum is obtained

by drawing the blood into a red top or the serum separator tube, allowing it to clot, and centrifuging to separate the serum. The time allowed for clotting depends on the ambient temperature and the patient sample. The typical recommendation is to allow the tube to clot for 20–30 min in a vertical position. A maximum of 1 h should suffice for all samples except those from patients with clotting disorders. Once the clot has formed, the sample is centrifuged for a recommended time of 10 min at 3000 revolutions per minute (rpm). The serum is transferred into a plastic transport tube or for storage purposes into a cryovial. Many tests collected in the serum separator tubes do not require transferring the supernatant serum unless the serum is to be stored frozen. Specimens transported by mail or stored > 4 h should be separated from the clot and placed into a transport tube. Polypropylene plastic test tubes or cryovials are more resistant to breakage than most glass or plastic containers, especially when specimens are frozen. Caution needs to be observed with serum separator tubes for some tests since the analyte of interest may absorb to the gel barrier. Erroneous results may be obtained if the serum or plasma is hemolyzed, lipemic, or icteric. As eloquently described by Terry Kotrla, phlebotomist at Austin Community College these conditions cause specimen problems. (www.austin.cc.tx.us/kotrla/PHBLab15SpecimenProcessingSum03.pdf).

1. **Hemolysis** is a red or reddish color in the serum or plasma that will appear as a result of red blood cells rupturing and releasing the hemoglobin molecules. Hemolysis is usually due to a traumatic venipuncture (i.e., vein collapses due to excessive pressure exerted with a syringe, “digging” for veins, or negative pressure damages innately fragile cells. Gross hemolysis (serum or plasma is bright red) affects most lab tests performed and the specimen should be recollected. Slight hemolysis (serum or plasma is lightly red) affects some tests, especially serum potassium and LDH (lactate dehydrogenase). Red blood cells contain large amounts of both of these substances and hemolysis will falsely elevate their measurements to a great extent. In addition to hemolysis caused during blood draw procedures, blood collection tubes (for serum and or whole blood) that are not transported correctly or in a timely fashion to the processing laboratory may be subject to hemolysis. Extremes of heat and cold in particular can cause red blood cells to lyse and sheering stresses caused by shaking of the specimens during transport may cause lysis. Finally, incorrect centrifugation temperatures and speeds may cause hemolysis of red blood cells.
2. **Icterus**. Serum or plasma can be bright yellow or even brownish due to either liver disease or damage or excessive red cell breakdown inside the body. Icterus can, like hemolysis, affect many lab tests, but unfortunately, recollection is not an option since the coloration of the serum or plasma is due to the patient’s disease state.

3. **Lipemia**. Occasionally, serum or plasma may appear milky. Slight milkiness may be caused when the specimen is drawn from a nonfasting patient who has eaten a heavy meal. A thick milky appearance occurs in rare cases of hereditary lipemia.

Both for serum and plasma there are documented guidelines for specimen handling dependent on which analyte, is being examined. The kinds of tests that can be done on blood samples is ever expanding and includes allergy evaluations, cytogenetics, cytopathology, histopathology, molecular diagnostics, tests for analytes, viruses, bacteria, parasites, and fungi. Incorrect preparation, shipment, and storage of specimens may lead to erroneous results. The guidelines for preparing samples can be obtained from the CLSI (9). Diagnostic testing laboratories (e.g., Quest diagnostics) provide comprehensive lists of the preferred specimen type, transport temperature, and rejection criteria (www.questest.com).

Plasma Processing

Specimens are drawn into tubes that contain anticoagulant (Table 1.). The plasma is obtained by drawing a whole blood specimen with subsequent centrifugation to separate the plasma. Plasma can be obtained from standard blood tubes containing the appropriate anticoagulant or from commercially available plasma separation tubes. The plasma separation tubes combine spray-dried anticoagulants and a polyester material that separates most of the erythrocytes and granulocytes, and some of the lymphocytes and monocytes away from the supernatant. The result is a convenient, safe, single-tube system for the collection of whole blood and the separation of plasma. Samples can be collected, processed, and transported *in situ* thereby reducing the possibility of exposure to bloodborne pathogens at the collection and sample processing sites. One drawback is that plasma prepared in a plasma separation tube may contain a higher concentration of platelets than that found in whole blood. For plasma processing, after drawing the blood, the tube for plasma separation must be inverted five to six times to ensure adequate mixing and prevent coagulation. The recommended centrifugation time is at least 10 min at 3000 rpm. Depending on the tests required, plasma specimens may be used immediately, shipped at ambient or cooled temperatures, or may require freezing. The plasma is transferred into a plastic transport tube or for storage purposes into a cryovial. Some tests require platelet poor plasma, in which case the plasma is centrifuged at least two times.

Processing and Collection of Peripheral Blood Mononuclear Cells (PBMC) from Whole Blood

Peripheral blood mononuclear cells are a convenient source of white blood cells, T cells comprise ~ 70% of the white cell compartment and are the work-horses of the immune system. These T cells play a crucial role in protection from or amelioration of many human diseases and can keep tumors in check. The most readily accessible source of T

cells is the peripheral blood. Thus collection, processing, cryopreservation, storage, and manipulation of human PBMC are all key steps for assessment of vaccine and disease induced immune responses. The assessment of T cell function in assays may be affected by procedures beginning with the blood draw through cell separation, cryopreservation, storage, and thawing of the cells prior to the assays. Additionally, the time of blood collection to actual processing for lymphocyte separation is critical. Procedures for PBMC collection and separation are shown in Table 3 along with potential advantages and disadvantages.

When conducting cellular immunology assays, the integrity of the PBMC, especially the cellular membranes, is critical for success. A correct cellular separation process yields a pure, highly viable population of mononuclear cells consisting of lymphocytes and monocytes, minimal red blood cell and platelet contamination, and optimum functional capacity. The standard method for separation of PBMC is the use of Ficoll-hypaque gradients as originally described by Boyum in 1968 (10). A high degree of technical expertise is required to execute the procedure from accurate centrifuge rpm and careful removal of the cellular interface to avoid red cell contamination. Within the last 10 years, simplified separation ficoll procedures have largely replaced the standard ficoll method, two such procedures are outlined below (Adapted from Ref. 11) and in Fig. 3. The simplicity of these methods, superior technical reliability, reduced interperson variability, faster turnaround, and higher cell yields makes these the methods of choice.

The Cell Preparation Tube (CPT) method is described below and in greater detail in literature provided by Becton Dickinson (<http://www.bd.com/vacutainer/products/molecular/citrate/procedures.asp>). Vacutainer cell preparation tubes (VACUTAINER CPT tubes, Becton Dickinson) provide a convenient, single-tube system for the collection and separation of mononuclear cells from whole blood. The CPT tube is convenient to use and results in high viability of the cells after transportation. The blood specimens in the tubes can be transported at ambient temperature, as the gel

forms a stable barrier between the anticoagulated blood and ficoll after a single centrifuge step. Cell separation is performed at the processing-storage laboratory using a single centrifugation step. This reduces the risk of sample contamination and eliminates the need for additional tubes and processing reagents. In many instances, and in particular when biosafety level 2 (BL2) cabinets are not available on site, the CPT method is useful because the centrifugation step can be done on site and the remaining processing steps can be performed after shipment to a central laboratory within the shortest time possible, optimally within 8 h. The central laboratory can complete cell processing in a BL2 cabinet and set up functional assays or cryopreserve the samples as needed.

Centrifuge speed is critical for PBMC processing. The centrifugal force is dependent on the radius of the rotation of the rotor, the speed at which it rotates, and the design of the rotor itself. Centrifugation procedures are given as xg measures, since rpm and other parameters will vary with the particular instrument and rotor used. The rpms may be calculated using the following formula where r = radius of rotor g = gravity; $g = 1.12 r (\text{rpm}/1000)^2$. This conversion can be read-off a nomogram chart available readily online or in centrifuge maintenance manuals. Typically laboratory centrifuges can be programmed to provide the correct rpm.

Protocol 1. Separation of PBMC Using CPT Tubes

- 1. Materials and Reagents:** Vacutainer CPT tubes (Becton Dickinson); Sterile Phosphate Buffered Saline (PBS) without Ca^+ and Mg^+ , supplemented with antibiotics (Penicillin and Streptomycin); Sterile RPMI media containing 2% fetal bovine serum (FBS) and supplemented with antibiotics.

The CPT tubes are sensitive to excessive temperature fluctuations, resulting in deterioration of the gel and impacting successful cellular separation. This problem is particularly serious in tropical countries where ambient storage temperatures may be $> 25^\circ\text{C}$. Following PBMC separation, one

Table 3. Stages and Variables in the Separation of PBMC from Whole Blood

Procedure/Technology	Alternatives	Advantages	Disadvantages
PBMC collection	Heparin	Greater cellular stability than EDTA	Impacts DNA isolation. Plasma from whole blood cannot be used for PCR based assays ^a
	EDTA		Time dependent negative impact on T cell responses
PBMC separation	Sodium Citrate Standard Ficoll	Greater cellular stability than EDTA	Technically challenging Time consuming
	CPT	Rapid Technically easy and less inter-person variability Blood is drawn into same tube that is used for separation	Subject to temperature fluctuations manifested by gel deterioration and contamination in PBMC fraction.
	Accuspin/Leucosep	Rapid Technically easy and less inter-person variability	

^aThe inhibitory effects of heparin on DNA isolation can be removed by incubation of plasma or other specimens with silicon glass beads or by heparinase treatment prior to DNA extraction.

(Graphic courtesy of Greg Khoury and Clive Gray, National Institute for Communicable Diseases, Johannesburg, South Africa.)

may macroscopically observe the presence of gel spheres in the cellular layer, which are very difficult to distinguish from the actual PBMC. This has been observed after storage at temperatures $> 25^{\circ}\text{C}$. Where possible, the tubes should be stored at no $> 25^{\circ}\text{C}$. Once the tubes have blood drawn into them, an attempt should be made to keep them at temperatures of between 18 and 25°C . Blood filled CPT should under no circumstances be stored on ice or next to an ice pack. It is recommended that they are separated from any ice-packs by bubble wrap or other type of insulation within a cooler so that the temperature fluctuations are kept to a minimum.

- Method:** (a) Specimens should be transported to the laboratory as soon as possible after collection. The manufacturer recommends the initial centrifugation to separate the lymphocytes be within 2 h. The samples may then be mixed by inversion and the processing completed preferably within 8 h after centrifugation. If there is a significant time delay, the specimens should be put into a cooler box and transported at room temperature ($18\text{--}25^{\circ}\text{C}$). (b) Spin tubes at room temperature ($18\text{--}25^{\circ}\text{C}$) in a horizontal rotor (swinging bucket head) for a mini-

imum of 20 min and maximum of 30 min at $\sim 400g$. The brake is left off to assure that the PBMC layer is not jarred or disturbed while the centrifuge rotors are being mechanically halted. (c) Remove the tubes from the centrifuge and pipette the entire contents of the tube above the gel into a 50 mL tube. This tube will now contain both PBMC and undiluted plasma. An additional centrifugation step will allow removal of undiluted plasma if desired. Wash each CPT tube with 5 mL of PBS/1% Penicillin/Streptomycin (Pen/Strep). This wash step will remove cells from the top of the gel plug. Combine with cells removed from tube. This wash increases yield of cells by as much as 30–40%. (d) Spin down this tube at $300g$ for 15–20 min at room temperature with the brake on. (e) The PBMC pellet is resuspended in RPMI, 2% FBS and washed one more time to remove contaminating platelets. The PBMC are counted and cryopreserved or used as required.

- Separation of PBMC Using Accuspin or Leucosep Tubes.** More recently, the Leucosep and Accuspin tube have become available. Further information on the Leucosep is available at www.gbo.com and for the Accuspin at www.sigmaaldrich.com. The principle of these tubes is the

same. The tube is separated into two chambers by a porous barrier made of highly transparent polypropylene (the frit). This biologically inert barrier allows elimination of the laborious overlaying of the sample material over Ficoll. The barrier allows separation of the sample material added to the top from the separation medium (ficoll added to the bottom). Figure 3 shows a comparison of the standard ficoll method and the Accuspin or Leucosep method. The tubes are available in two sizes and may be purchased with or without Ficoll. There is an advantage of buying the tubes without Ficoll because they can be stored at room temperature rather than refrigerated. This may be an important problem if cold space is limiting or cold chain is difficult. The expiration date of the Ficoll will not affect the tube expiration. The following procedure describes the separation procedure for Leucosep tubes that are not prefilled with Ficoll-hypaque. The Accuspin procedure is virtually identical. Note that whole blood can be diluted 1:2 with balanced salt solution. While this dilution step is not necessary, it can improve the separation of PBMC and enhance PBMC yield. The procedure is carried out using aseptic technique.

Protocol 2: Separation of PBMC Using Accuspin or Leucosep Tubes

1. Warm-up the separation medium (Ficoll-hypaque) to room temperature protected from light.
2. Fill the Leucosep tube with separation medium: 3 mL for the 14 mL tube and 15 mL for the 40 mL tube.
3. Close the tubes and centrifuge at 1000 *g* for 30 s at room temperature.
4. Pour the whole blood or diluted blood into the tube: 3–8 mL for the 14 mL tube and 15–30 mL for the 50 mL tube.
5. Centrifuge for 10 min at 1000 *g* or 15 min at 800 *g* in a swinging bucket rotor, with the centrifuge brake off. The brake is left off to assure that the PBMC layer is not jarred or disturbed while the centrifuge rotors are being mechanically halted.
6. After centrifugation, the sequence of layers from top to bottom should be plasma and platelets; enriched PBMC fraction; Separation medium; porous barrier; Separation medium; Pellet (erythrocytes and granulocytes).
7. Plasma can be collected to within 5–10 mm of the enriched PBMC fraction and further processed or stored for additional assays.
8. Harvest the enriched PBMC and wash with 10 mL of PBS containing 1% Pen/Strep and centrifuge at 250 *g* for 10 min.
9. The PBMC pellet is resuspended in RPMI, 2% FBS and washed one more time to remove contaminating platelets. The PBMC are counted and cryopreserved or used as required.

1. Specimen Rejection Criteria

- Incomplete or inaccurate specimen identification.
- Inadequate volume of blood in additive tubes (i.e., partially filled coagulation tube) can lead to inappropriate dilution of addition and blood.
- Hemolysis (i.e., potassium determinations)
- Specimen collected in the wrong tube (i.e., end product is serum and test requires plasma).
- Improper handling (i.e., specimen was centrifuged and test requires whole blood).
- Insufficient specimen or quantity not sufficient (QNS). For PBMC, the rejection criteria are not usually evaluated at the time of draw due to the complexity of the tests performed. However, a minimum of 95% viability would be expected after PBMC separation unless the specimens have been subjected to heat or other adverse conditions (see note below).

The optimal time frame between collection of blood sample to processing, separation and cryopreservation of PBMC should be < 8 h or on the same day as collection. It is not always feasible to process, separate and cryopreserve PBMC within 8 h when samples are being shipped to distant processing centers. Under these conditions, PBMC left too long in the presence of anticoagulants or at noncompatible temperatures, adversely affect PBMC function and causes changes which affect the PBMC separation process (11).

There have been significant revisions to the procedures for the handling and processing of blood specimens; specimens for potassium analysis should not be recentrifuged because centrifugation may cause results to be falsely increased; the guidelines recommend that serum or plasma exposed to cells in a blood-collection tube prior to centrifugation should not exceed 2 h; storage recommendations for serum-plasma may be kept at room temperature up to 8 h, but for assays not completed within 8 h, refrigeration is recommended (2–8 °C), if the assay is not completed within 48 h serum-plasma should be frozen at or below –20 °C.

BLOOD GAS MEASUREMENTS

AHMAD ELSHARYDAH
 RANDALL C. CORK
 Louisiana State University
 Shreveport, Louisiana

INTRODUCTION

Blood gas measurement–monitoring is essential to monitor gas exchange in critically ill patients in the intensive care units (1,2), and “standard of care” monitoring to deliver general anesthesia (3). It is a cornerstone in the diagnosis and management of the patient’s oxygenation and acid–base disorders (4). Moreover, it may indicate the onset or culmination of cardiopulmonary problems, and may help in evaluating the effectiveness of the applied therapy. Numerous studies and reports have shown the significance of utilizing blood gas analyses in preventing serious oxygenation and acid–base problems. This article gives a summarized explanation of the common methods and instruments used nowadays in blood gas measurements in clinical medicine. This explanation includes a brief history of the development of these methods and instruments, the principles of their operation, a general descrip-

tion of their designs, and some of their clinical uses, hazards, risks, limitations, and finally the direction in the future to improve these instruments or to invent new ones. Blood gas measurement in clinical medicine can be classified into two major groups: (1) Noninvasive blood gas measurement, which includes blood oxygen–carbon dioxide measurement–monitoring by using different types of pulse oximeters (including portable pulse oximeters), transcutaneous oxygen partial pressure–carbon dioxide partial pressure (PO_2/PCO_2) monitors, intrapartum fetal pulse oximetry, cerebral oximetry, capnometry, capnography, sublingual capnometry, and so on; (2) invasive blood gas measurement, which involves obtaining a blood sample to measure blood gases by utilizing blood gas analyzers (in a laboratory or by using a bedside instrument), or access to the vascular system to measure/monitor blood gases. Examples include, but not limited to, mixed venous oximetry (SvO_2) monitoring by utilizing pulmonary artery catheter or jugular vein (SvO_2) measurement (5); continuous fibroptic arterial blood gas monitoring, and so on. In this article, we will talk about some of these methods; others have been mentioned in other parts of this encyclopedia.

BASIC CONCEPTS IN INVASIVE AND NONINVASIVE BLOOD GAS MEASUREMENTS

The Gas Partial Pressure

Gases consist of multiple molecules in rapid, continuous, random motion. The kinetic energy of these molecules generate a force as the molecules collide with each other and bounce from one surface to another. The force per unit area of a gas is called pressure, and can be measured by a device called a manometer. In a mixture of gases (e.g., a mixture of O_2 , CO_2 , and water vapor), several types of gas molecules are present within this mixture, and each individual gas (e.g., O_2 or CO_2) in the mixture is responsible for a portion of the total pressure. This portion of pressure is called partial pressure (P). According to Dalton’s law, the total pressure is equal to the sum of partial pressures in a mixture of gases. Gases dissolve freely in liquids, and may or may not react with the liquid, depending on the nature of the gas and the liquid. However, all gases remain in a free gaseous phase to some extent within the liquid. Gas dissolution in liquids is a physical, not chemical, process. Therefore, gases (e.g., CO_2 , O_2) dissolved in liquid (blood) exist in two phases: liquid and gaseous phase. Henry’s law states that the partial pressure of a gas in the liquid phase equilibrates with the partial pressure of that gas in the gaseous phase (6,7).

BLOOD GAS ELECTRODES

Basic Electricity Terms

Electricity is a form of energy resulting from the flow of electrons through a substance (conductor). Those electrons flow from a negatively charged pole called Cathode, which has an excess of stored electrons, to a positively charged pole called Anode, which has a relative shortage

of electrons. The potential is the force responsible for pumping these electrons between the two poles. The greater the difference in electron concentration between these two poles, the greater is the potential. Volt is the potential measurement unit. The electrical current is the actual flow of electrons through a conductor. Ampere (amp) is the unit of measurement for the electrical current. Conductors display different degree of electrical resistance to the flow of the electrical current. The unit of the electrical resistance is ohm (Ω). Ohm's law states: voltage = current \times resistance.

The Principles of Blood Gas Electrodes

Blood gas electrodes are electrochemical devices used to measure directly pH and blood gases. These blood gas electrodes use electrochemical cells. The electrochemical cell is an apparatus that consists of two electrodes placed in an electrolyte solution. These cells usually incorporated together (one or more cells) to form an electrochemical cell system. These systems are used to measure specific chemical materials (e.g., PO_2 , PCO_2 and pH). The basic generic blood gas electrode consists of two electrode terminals, which are also called half-cells: one is called the working half-cell where the actual chemical analysis occurs, or electrochemical change is taken place; and the other one is called the reference half-cell. The electrochemical change occurring on the working terminal is compared to the reference terminal, and the difference is proportional to the amount of blood gas in the blood sample (6,7).

PO_2 Electrode

The PO_2 electrode basically consists of two terminals (1). The cathode, which usually made of platinum (negatively charged) and (2) the anode, which usually made of silver-silver chloride (positively charged). How does this unit measure PO_2 in the blood sample? As shown in Fig. 1,

the electricity source (battery or wall electricity) supplies the platinum cathode with energy (voltage of ~ 700 mV). This voltage attracts oxygen molecules to the cathode surface, where they react with water. This reaction consumes four electrons for every oxygen molecule reacts with water and produces four hydroxyl ions. The consumed four electrons, in turn, are replaced rapidly in the electrolyte solution as silver and chloride react at the anode. This continuous reaction leads to continuous flow of electrons from the anode to the cathode (electrical current). This electrical current is measured by using an ammeter (electrical current flow meter). The current generated is in direct proportion to the amount of dissolved oxygen in the blood sample, which in direct proportion to PO_2 in that sample.

Oxygen Polarography

The electrical current and PO_2 have a direct (linear) relationship when a specific voltage is applied to the cathode. Therefore, a specific voltage must be identified, to be used in PO_2 analysis. The polarogram is a graph that shows the relationship between voltage and current at a constant PO_2 . As shown in Fig. 2, when the negative voltage applied to the cathode is increased, the current increases initially, but soon it becomes saturated. In this plateau region of the polarogram, the reaction of oxygen at the cathode is so fast that the rate of reaction is limited by the diffusion of oxygen to the cathode surface. When the negative voltage is further increased, the current output of the electrode increases rapidly due to other reactions, mainly, the reduction of water to hydrogen. If a fixed voltage in the plateau region (e.g., -0.7 V) is applied to the cathode, the current output of the electrode can be linearly calibrated to the dissolved oxygen. Note that the current is proportional not to the actual concentration, but to the activity or equivalent partial pressure of dissolved oxygen. A fixed voltage between -0.6 and -0.8 V is usually selected as the

Figure 1. PO_2 electrode.

Figure 2. Polarogram.

polarization voltage when using Ag/AgCl as the reference electrode.

pH Electrode

The pH electrode uses voltage to measure pH, rather than actual current as in PO_2 electrode. It compares a voltage created through the blood sample (with unknown pH) to known reference voltage (in a solution with known pH). To make this possible, the pH electrode basically needs four electrode terminals (Fig. 3), rather than two terminals (as in the PO_2 electrode). Practically, one common pH-sensitive glass electrode terminal between the two solutions is adequate. This glass terminal allows the hydrogen ions to diffuse into it from each side. The difference in the hydrogen ions concentration across this glass terminal creates a net electrical potential (voltage). A specific equation is used to calculate the blood sample pH, using the reference fluid pH, the created voltage, and the fluid temperature.

PCO₂ Electrode

The PCO_2 electrode is a modified pH electrode. There are two major differences between this electrode and the pH

electrode. The first difference is that in this electrode, the blood sample comes in contact with a CO_2 permeable membrane (such as Teflon, Silicone rubber), rather than a pH-sensitive glass (in the pH electrode), as shown in Fig. 4. The CO_2 from the blood sample diffuses via the CO_2 permeable (silicone) membrane into a bicarbonate solution. The amount of the hydrogen ions produced by the hydrolysis process in the bicarbonate solution is proportional to the amount of the CO_2 diffused through the silicone membrane. The difference in the hydrogen ions concentration across the pH-sensitive glass terminal creates a voltage. The measured voltage (by voltmeter) can be converted to PCO_2 units. The other difference is that the CO_2 electrode has two similar electrode terminals (silver–silver chloride). However, the pH electrode has two different electrode terminals (silver–silver chloride and mercury–mercurous chloride).

BLOOD GAS PHYSIOLOGY (8,9)

Oxygen Transport

Oxygen is carried in the blood in two forms: A dissolved small amount and a much bigger, more important component combined with hemoglobin. Dissolved oxygen plays a small role in oxygen transport because its solubility is so low, 0.003 mL O_2 /100 mL blood per mmHg (133.32 Pa). Thus, normal arterial blood with a PO_2 of ~100 mmHg (13332.2 Pa) contains only 0.3 mL of dissolved oxygen per 100 mL of blood, whereas ~20 mL is combined with hemoglobin. Hemoglobin consists of heme, an iron-porphyrin compound, and globin, a protein that has four polypeptide chains. There are two types of chains, alpha and beta, and differences in their amino acid sequences give rise to different types of normal and abnormal human hemoglobin, such as, hemoglobin F (fetal) in the newborn, and hemoglobin S in the sickle cell anemia patient. The combination of oxygen (O_2) with hemoglobin (Hb) (to form oxyhemoglobin– HbO_2) is an easily reversible. Therefore, blood is able to transport large amounts of oxygen.

The relationship between the partial pressure of oxygen and the number of binding sites of the hemoglobin that have oxygen attached to it, is known as the oxygen dis-

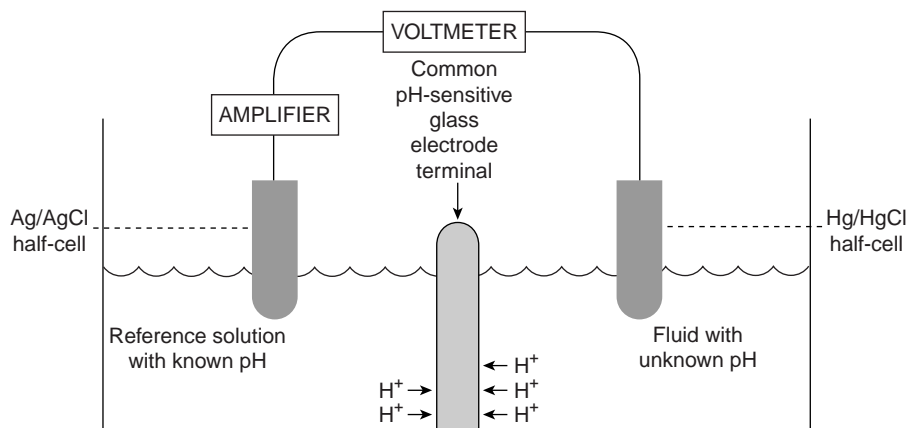

Figure 3. pH electrode.

Figure 4. PCO_2 electrode.

sociation curve (Fig. 5). Each gram of pure hemoglobin can combine with 1.39 mL of oxygen, and because normal blood has ~ 15 g Hb/100 mL, the oxygen capacity (when all the binding sites are full) is ~ 20.8 mL O_2 /100 mL blood. The total oxygen concentration of a sample of blood, which includes the oxygen combined with Hb and the dissolved oxygen, is given by $(Hb \times 1.36 \times SaO_2) + (0.003 \times PaO_2)$ Hb is the hemoglobin concentration.

The characteristic shape of the oxygen dissociation curve has several advantages. The fact that the upper portion is almost flat means that a fall of 20–30 mmHg in arterial PO_2 in a healthy subject with an initially normal value (e.g., ~ 100 mmHg or 13332.2 Pa) causes only a minor reduction in arterial oxygen saturation. Another consequence of the flat upper part of the curve is that loading of oxygen in the pulmonary capillary is hastened. This results from the large partial pressure difference between alveolar gas and capillary blood that continues to exist even when most of the oxygen has been loaded. The steep lower part of the oxygen dissociation curve means that considerable amounts of oxygen can be unloaded to the peripheral tissues with only a relatively small drop in capillary PO_2 . This maintains a large partial pressure difference between the blood and the tissues, which assists in the diffusion process. Various factors affect the position of the oxygen dissociation curve, as shown in Fig. 5. It is shifted to the right by an increase of temperature, hydrogen ion concentration, PCO_2 , and concentration of 2,3-diphosphoglycerate in the red cell. A rightward shift indicates that the affinity of oxygen for hemoglobin is reduced. Most of the effect of the increased PCO_2 in reducing the oxygen affinity is due to the increased hydrogen concentration. This is called the Bohr effect, and it means that as peripheral blood loads carbon dioxide, the unloading of oxygen is assisted. A useful measure of the position of the dissociation curve is the PO_2 for 50% oxygen saturation; this is known as the P_{50} . The normal value for human blood is ~ 27 mmHg (3599.6 Pa).

Carbon Dioxide Transport

Carbon dioxide is transported in the blood in three forms: dissolved, as bicarbonate, and in combination with proteins

such as carbamino compounds (Fig. 6). Dissolved carbon dioxide obeys Henry’s law (as mentioned above). Because carbon dioxide is some 24 times more soluble than oxygen in blood, dissolved carbon dioxide plays a much more significant role in its carriage compared to oxygen. For example, $\sim 10\%$ of the carbon dioxide that evolves into the alveolar gas from the mixed venous blood comes from the dissolved form. Bicarbonate is formed in blood by the following hydration reaction:

The hydration of carbon dioxide to carbonic acid (and vice versa) is catalyzed by the enzyme carbonic anhydrase (CA), which is present in high concentrations in the red cells, but is absent from the plasma. However, some carbonic anhydrase is apparently located on the surface of the endothelial cells of the pulmonary capillaries. Because of the presence of carbonic anhydrase in the red cell, most of the hydration of

Figure 5. Oxygen dissociation curve and the effects of different factors on it.

Figure 6. Carbon dioxide transport in blood.

carbon dioxide occurs there, and bicarbonate ion moves out of the red cell to be replaced by chloride ions to maintain electrical neutrality (chloride shift). Some of the hydrogen ions formed in the red cell are bound to Hb, and because reduced Hb is a better proton acceptor than the oxygenated form, deoxygenated blood can carry more carbon dioxide for a given PCO_2 than oxygenated blood can. This is known as the Haldane effect. Carbamino compounds are formed when carbon dioxide combines with the terminal amine groups of blood proteins. The most important protein is the globin of hemoglobin. Again, reduced hemoglobin can bind more carbon dioxide than oxygenated hemoglobin, so the unloading of oxygen in peripheral capillaries facilitates the loading of carbon dioxide, whereas oxygenation has the opposite effect. The carbon dioxide dissociation curve, as shown in Fig. 7, is the relationship between PCO_2 and total carbon dioxide concentration. Note that the curve is much more linear in its working range than the oxygen dissociation curve, and also that, as we have seen, the lower the saturation of hemoglobin with oxygen, the larger the carbon dioxide concentration for a given PCO_2 .

Figure 7. The carbon dioxide dissociation curve showing the effect of PO_2 variations.

OXIMETRY

Historical Development

Oximetry has its origins in the early 1860s (10), when Felix Hoppe-Seyler described the hemoglobin absorption of light using the spectroscope. He demonstrated that the light absorption was changed when blood was mixed with oxygen, and that hemoglobin and oxygen formed a compound called oxyhemoglobin. Soon after, George Gabriel Stokes reported that hemoglobin was in fact the carrier of oxygen in the blood. In 1929, Glen Allan Millikan (11), an American physiologist, began construction of a photoelectric blood oxygen saturation meter, which, used to measure color changes over time when desaturated hemoglobin solutions were mixed with oxygen solutions in an experimental setting. The use of photoelectric cells later proved to be crucial to the development of oximeters. In 1935, Kurt Kramer demonstrated, for the first time, *in vivo* measurement of blood oxygen saturation in animals. The same year, Karl Matthes introduced the ear oxygen saturation meter. This was the first instrument able to continuously monitor blood oxygen saturation in humans. In 1940, J.R. Squire introduced a two-channel oximeter that transmitted red and infrared (IR) light through the web of the hand. In 1940, Millikan and colleagues developed a functioning oximeter, and introduced the term "oximeter" to describe it. The instrument used an incandescent, battery-operated light and red and green filter. In 1948, Earl Wood of the Mayo Clinic made several improvements to Millikan's oximeter, including the addition of a pressure capsule. Then, in the 1950s, Brinkman and Zijlstra of the Netherlands developed the reflectance oximetry. However, oximetry did not fully achieve clinical applicability until the 1970s.

Principles of Operation

It is important to understand some of the basic physics principles that led to the development of oximetry and pulse oximetry. This is a summary of these different physics principles and methods (7,12).

Spectrophotometry. The spectroscope is a device which was used initially to measure the exact wavelengths of light emitted from a light generator (bunsen burner) (10). Each substance studied with the spectroscope has its unique light emission spectrum, in other words, each substance absorbed and then emitted light of different wavelengths. The graph of the particular pattern of light absorption-emission of sequential light wavelengths called the absorption spectrum. Figure 8 reveals the absorption spectra of common forms of hemoglobin.

Colorimetry. Colorimetry is another method of qualitative analysis (10). In this method, the color of known substance is compared of that of unknown one. This method is not highly exact, because it depends on visual acuity and perception.

Photoelectric Effect. The photoelectric effect is the principle behind spectrophotometry. It is defined as the ability of light to release electrons from metals in proportion to the

Figure 8. Absorption spectra of common forms of hemoglobin. Absorption spectra of oxyhemoglobin, deoxyhemoglobin, methemoglobin, carboxyhemoglobin.

intensity of the light. In spectrophotometry, light passes via a filter that converts the light into a specific wavelength. This light then passes through a container that contains the substance being analyzed. This substance absorbs part of this light and emits the remaining part, which goes through a special cell. This cell is connected to a photodetector, which detects and measures the emitting light (spectrophotometry). This method can be used for quantitative as well as qualitative analyses.

Lambert–Beer Law. This law combines the different factors that affect the light absorption of a substance:

$$\log_{10} I_o/I_x = kcd$$

I_o = intensity of light incident on the specimen
 I_x = intensity of the transmitted light
 I_o/I_x = optical density

As shown in the above formula, the concentration of absorbing substance, the path length of the absorbing medium (d) and the characteristics of the substance and the light wavelength ($k = \text{constant}$) all affect light absorption (12).

Transmission Versus Reflection Oximetry. When the light at a particular wavelength passes through a blood sample, which contains Hb, this light would be absorbed, transmitted, or reflected. The amount of the absorbed, transmitted, or reflected light at those particular wavelengths is determined by various factors, including the concentration (Lambert–Beer law) and the type of the Hb present in the blood sample. The amount of light transmitted through the blood sample at a given wavelength is related inversely to the amount of light absorbed or reflected. The transmission oximetry is a method to determine the arterial oxygen saturation (S_aO_2) value by measuring the amount of light transmitted at certain wavelengths. On the other side, in the reflection oximetry, measuring the amount of light reflected is used to determine the S_aO_2 value. The significant difference between these two methods is the location of the photodetector (Fig. 9). In the reflection method, the

Figure 9. Major components of transmission and reflection oximeters.

photodetector is on the same side of the light source. However, in the transmission oximetry, it is on the opposite side of the light source (7,12).

Oximetry Versus Cooximetry. Each form of hemoglobin (e.g., oxyhemoglobin, deoxygenated hemoglobin, carboxyhemoglobin, methemoglobin) has its own unique absorption–transmission–reflection spectrum. By plotting the relative absorbance to different light wavelengths for both oxyhemoglobin and deoxygenated Hb as shown in Fig. 10. It is clear that these two hemoglobins absorb light differently at different light wavelengths. This difference is big in some light wavelengths (e.g., 650 nm in the red region), and small or not existing in other light wavelengths. The isosbestic point (13) is the light wavelength at which there is no difference between these two hemoglobins in absorbing light (~ 805 nm near the IR region). The difference in these two wavelengths can be used to calculate the S_aO_2 .

Figure 10. Light absorption spectra of oxygenated and deoxygenated hemoglobin.

However, these two hemoglobins are not only the hemoglobins exist in the patient's blood. There are other abnormal hemoglobins (dys-hemoglobins) that can join these two hemoglobins in some abnormal conditions (such as carboxyhemoglobin and methemoglobin). Each one of these dys-hemoglobins has its unique transmission–reflection–absorption spectrum. Some of these spectra are very close to the oxyhemoglobin spectrum at the routinely used two light wavelengths (see above). This makes these two wavelengths are incapable in detecting those dys-hemoglobins. Therefore, the use of regular oximeters in these conditions may lead to erroneous and false readings, which may lead to detrimental effects on the patient's care. To overcome this significant problem a special oximeter (cooximeter, i.e., cuvette oximeter) is needed when there is a suspicion of presence of high level of dys-hemoglobins in the patient's blood. Functional S_aO_2 is the percentage of oxyhemoglobin compared to sum of oxy- and deoxyhemoglobins. Therefore, the abnormal hemoglobins are not directly considered in the measurement of functional S_aO_2 by using regular oximetry. Cooximetry uses four or more light wavelengths, and has the ability to measure carboxyhemoglobin and methemoglobin as well as normal hemoglobins. The fractional S_aO_2 measures the percentage of oxyhemoglobin to all hemoglobins (normal and abnormal) present in the blood sample (14,15).

EAR OXIMETRY

Historical Development

In 1935, Matthes (16,17) showed that transmission oximetry could be applied to the external ear. However, a major problem with noninvasive oximetry applied to the ear was the inability to differentiate light absorption due to arterial blood from that due to other ear tissue and blood. In the following years, two methods were tried to solve this problem. The first was increasing local perfusion by heating the ear, applying vasodilator, or rubbing the ear. The second was comparing the optical properties of a "bloodless" earlobe (by compressing it using a special device) to the optical properties of the perfused ear lobe. Arterial S_aO_2 was then determined from the difference in these different measurements. This step was a significant step toward an accurate noninvasive measurement of S_aO_2 . In 1976, Hewlett-Packard (18) used the collected knowledge about ear oximetry to that date to develop the model 47201A ear oximeter, Fig. 11.

HEWLETT-PACKARD EAR OXIMETER

This oximeter (18) is based on the measured light transmission at eight different wavelengths, which made this sensor less accurate and more complex than pulse oximeters. It used a high intensity tungsten lamp that generated a broad spectrum of light wave lengths. This light passes through light filters, then enters a fiberoptic cable, which carries the filtered light to the ear. A second fibroptic cable carries the light pulses transmitted through the ear to the device for detection and analysis. The ear probe is relatively bulky ($\sim 10 \times 10$ cm) equipped with a tempera-

Figure 11. The Hewlett-Packard Model 47201A ear oximeter.

ture-controlled heater (to keep temperature of 41°C). It is attached to the antihelix after the ear has been rubbed briskly. This monitor is no longer manufactured because of its bulkiness and cost, and because of the development widely of a more accurate, smaller, and cost-effective monitor, the pulse oximeter.

PULSE OXIMETRY

Historical Development

In the early 1970s, Takuo Aoyagi (16,19,20), a Japanese physiological bioengineer, introduced pulse oximetry, the underlying concept of which had occurred to him while trying to cancel out the pulsatile signal of an earpiece densitometer with IR light. In early 1973, Dr. Susumu Nakajima, a Japanese surgeon, learned of the idea and ordered oximeter instruments from Nihon Kohden. After several prototypes were tested, Aoyagi and others delivered the first commercial pulse oximeter in 1974. This instrument was the OLV-5100 ear pulse oximeter, (Fig. 12). In 1977, the Minolta Camera Company

Figure 12. The OLV-5100 ear pulse oximeter, the first commercial pulse oximeter, it was introduced by Nihon Kohden in 1974.

Figure 13. The basic components of a pulse oximeter sensor. Two LEDs with different wavelengths as light sources and a photodiode as receiver.

introduced the Oximet MET-1471 pulse oximeter with a fingertip probe and fiberoptic cables. Nakajima and others tested the Oximet MET-1471 and reported on it in 1979. In the years since, pulse oximetry has become widely used in a number of fields, including Anesthesia, intensive care, and neonatal care.

Principles of Operation

Pulse oximetry differs from the previously described oximetry in that it does not rely on absolute measurements, but rather on the pulsations of arterial blood. Oxygen saturation is determined by monitoring pulsations at two wavelengths and then comparing the absorption spectra of oxyhemoglobin and deoxygenated hemoglobin (20,21). Pulse oximetry uses a light emitter with red and infrared LEDs (light-emitting diodes) that shine through a reasonably translucent site with good blood flow (Fig. 13). Typical adult-pediatric sites are the finger, toe, pinna (top), or lobe of the ear. Infant sites are the foot or palm of the hand and the big toe or thumb. On the opposite side of the emitter is a photodetector that receives the light that passes through the measuring site. There are two methods of sending light through the measuring site (see above) (Fig. 9). The transmission method is the most common type used, and for this discussion the transmission method will be implied. After the transmitted red (R) and IR signals pass through the measuring site and are received at the photodetector, the R/IR ratio is calculated. The R/IR is compared to a “look-up” table (made up of empirical formulas) that converts the ratio to pulse oxygen saturation (S_pO_2) value. Most manufacturers have their own tables based on calibration curves derived from healthy subjects at various S_pO_2 levels. Typically, an R/IR ratio of 0.5 equates to approximately 100% S_pO_2 , a ratio of 1.0 to ~82% S_pO_2 , while a ratio of 2.0 equates to 0% S_pO_2 . The major change that occurred from the eight-wavelength Hewlett-Packard oximeters (see above) of the 1970s to the oximeters of today was the inclusion of arterial pulsation to differentiate the light absorption in the measuring site due

Figure 14. Schematic Representation of light absorption in adequately perfused tissue.

to skin, tissue, and venous blood from that of arterial blood. At the measuring site there are several light absorbers (some of them are constant) such as skin, tissue, venous blood, and the arterial blood (Fig. 14). However, with each heart beat the heart contracts and there is a surge of arterial blood, which momentarily increases arterial blood volume across the measuring site. This results in more light absorption during the surge. Light signals received at the photodetector are looked at as a waveform (peaks with each heartbeat and troughs between heartbeats). If the light absorption at the trough, which should include all the constant absorbers, is subtracted from the light absorption at the peak, then the resultants are the absorption characteristics due to added volume of blood only, which is arterial blood. Since peaks occur with each heartbeat or pulse, the term “pulse oximetry” was applied.

New Technologies

Conventional pulse oximetry accuracy degrades during motion and low perfusion. This makes it difficult to depend on these measurements when making medical decisions. Arterial blood gas tests have been and continue to be commonly used to supplement or validate pulse oximeter readings. Pulse oximetry has gone through many advances and developments since the Hewlett-Packard Model 47201A ear oximeter invention in 1976. There are several types of pulse oximeters manufactured by different companies available in the market nowadays. Different technologies have been used to improve pulse oximetry quality and decrease its limitations, which would lead eventually to better patient care. Figure 15 shows a modern pulse oximeter (Masimo Rad-9) designed by Masimo using the Signal Extraction Technology (Masimo SET) (22,23), is a software system composed of five parallel algorithms designed to eliminate nonarterial “noise” in a patient’s blood flow. This monitor display includes: S_pO_2 , pulse rate, alarm, trend, perfusion index (PI) (24), signal IQ, and plethysmographic waveform. Moreover, Masimo manufactures a handheld pulse oximeter by utilizing the same technology (Masimo SET) as shown in Fig. 16. Its small size (~15.7 × 7.6 × 3.5 cm) and broad catalog of features make it suited for hospital, transport, and home use. Nellcor (25) uses the OxiMax technology to produce a list of pulse oximetry monitors and sensors. These sensors have a small digital memory chip that transmits

Figure 15. Masimo Rad-9 pulse oximeter.

sensor-specific data to the monitor. These chips contain all the calibration and operating characteristics for that sensor design. This gives the monitor the flexibility to operate accurately with a diverse range of sensor designs without the need for calibrating each sensor to the specific monitors. This opens a new area of pulse oximetry innovations. Figure 17 reveals some of the Nellcor monitors and sensors available. Furthermore, Nellcor has designed a handheld pulse oximeter, as shown in Fig. 18, compatible with its line of OxiMax pulse oximetry sensors. Nellcor combines two advanced technologies in measuring blood gases: the OxiMax technology and Microstream CO₂ technology (see the section Capnography) to produce a S_pO₂ and end-tidal CO₂ partial pressure (PetCO₂) handheld capnograph–pulse oximeter to monitor both S_pO₂ and PetCO₂. Several additional parameters are now available on the modern oximeter, and they add additional functionality for these monitors and decrease their limitations. One of these parameters is called the “perfusion index” (PI) (24,26). This is a simple

Figure 16. Masimo Rad-5 handheld pulse oximeter.

Figure 17. Nellcor N-595 pulse oximeter.

measure of the change that has occurred in the tissue-under-test (e.g., the finger) over the cardiac cycle. When this parameter was first recognized as being something that a pulse oximeter could measure, it was difficult to imagine a value to the measurement because it is affected by so many different physiological and environmental variables, including systemic vascular resistance, volume status, blood pressure, and ambient temperature. But as time continues to pass since its introduction, more applications for PI have been found. The most obvious use for perfusion index is as an aid in sensor placement. It provides a means to quantify the validity of a given sensor site and, where desired, to maximize measurement accuracy. Perfusion index has also provided a simple and easy way test for sufficient collateral blood flow in the ulnar artery to allow for harvest of the radial artery for coronary artery bypass graft (CABG) surgery and for monitoring peripheral perfusion in critically ill patients.

Clinical Uses

Pulse oximeters are widely used in clinical practice (27–30). They are used extensively in the intensive care units to monitor oxygen saturation, and to detect and prevent hypoxemia. Monitoring oxygen saturation during anesthesia is a standard of care, which is almost always done by pulse oximeters. Pulse oximeters are very helpful in monitoring patients during procedures like bronchoscopy, endoscopy, cardiac catheterization, exercise testing,

Figure 18. Nellcor N-45 handheld pulse oximeter.

Figure 19. Portable Nonin Onyx 9500 pulse oximeter.

and sleep studies. Also, they are commonly used during labor and delivery for both the mother and infant. These sensors have no significant complications related to their use. There are several types of portable pulse oximeters on the market. These oximeters are small in size, useful for patients transport, and can be used at home. Figure 19 shows one of these pulse oximeters.

Accuracy and Limitations

The accuracy of pulse oximeters in measuring exact saturation has been shown to be $\sim \pm 4\%$ as compared to blood oximetry measurements. Several studies have shown that with low numbers of S_aO_2 , there is a decreased correlation between S_pO_2 and S_aO_2 , especially when $S_aO_2 < 70\%$ and in unsteady conditions (31). However, newer technologies have improved accuracy during these conditions substantially. Another factor that influences the accuracy of pulse-oximetry is the response time. There is a delay between a change in S_pO_2 and the display of this change. This delay ranges from 10 to 35 s. Pulse-oximeters have several limitations that may lead to inaccurate readings. One of its most significant limitations is that it estimates the S_aO_2 , not the arterial oxygen tension (P_aO_2). Another limitation is the difficulty these sensors have in detecting arterial pulsation in low perfusion states (low cardiac output, hypothermia etc.) (32). Furthermore, the presence of dyshemoglobins (e.g., methemoglobin, carboxyhemoglobin) (15) and diagnostic dyes (e.g., methylene blue, indocyanine green, and indigo carmine) (33) affects the accuracy of these monitors, leading to false readings. High carboxyhemoglobin levels will falsely elevate S_pO_2 readings, which may lead to a false sense of security regarding the patient's

oxygenation, and possible disastrous outcome. CO-oximetry should be used to measure S_aO_2 in every patient who is suspect for elevated carboxyhemoglobin (such as fire victims). Methemoglobinemia may lead to false $\sim 85\%$ saturation reading. The clinician should be alert to the potential causes and possibility of methemoglobinemia (e.g., nitrites, dapsone, and benzocaine). The CO-oximetry is also indicated in these patients. Vascular dyes may also affect the S_pO_2 readings significantly, especially methylene blue, which is also used in the treatment of methemoglobinemia. Brown, blue, and green nail polish may affect S_pO_2 too. Therefore, routine removal of this polish is recommended. The issue of skin pigmentations effect on S_pO_2 reading is still controversial. Motion artifacts are a common problem in using pulse oximeters, especially in the intensive care units.

Future Directions for Pulse Oximeters

As mentioned above, there are several limitations with the recent commercially available pulse oximeters. Pulse oximeters technology is working on decreasing those limitations and improving pulse oximeters function (34). In the future, techniques to filter out the noise component common to both R and IR signals, such as Masimo signal extraction, will significantly decrease false alarm frequency. Pulse oximeters employing more than two wavelengths of light and more sophisticated algorithms will be able to detect dyshemoglobins. Improvements in reflection oximetry, which detects backscatter of light from light-emitting diodes placed adjacent to detectors, will allow the probes to be placed on any body site. Scanning of the retinal blood using reflection oximetry can be used as an index of cerebral oxygenation. Combinations of reflectance oximetry and laser Doppler flowmetry may be used to measure microcirculatory oxygenation and flow.

Continuous Intravascular Blood Gas Monitoring (CIBM)

The current standard for blood gas analysis is intermittent blood gas sampling, with measurements performed *in vitro* in the laboratory or by using bedside blood gas analyzer. Recently, miniaturized fiberoptic devices have been developed that can be placed intravascularly to continuously measure changes in PO_2 , PCO_2 , and pH. These devices utilize two different technologies: Electrochemical sensors technology, based on a modified Clark electrode, and optode (photochemical/optical) technology (35,36).

Optode (Photochemical–Optical) Technology. An optode unit consists of optical fibers with fluorescent dyes encased in a semipermeable membrane. Each analyte, such as hydrogen ion, oxygen, or carbon dioxide, crosses the membrane and equilibrates with a specific chemical fluorescent dye to form a complex. As the degree of fluorescence changes with the concentration of the analyte, the absorbance of a light signal sent through the fiberoptic bundles changes, and a different intensity light signal is returned to the microprocessor. Optode technology has accuracy comparable to that of a standard laboratory blood gas analyzer. However, several reasons and problems, including the cost (see below) still limit the use of this monitor routinely.

At present, the Paratrend 7+ (PT7+; Diametric Medical Inc., High Wycombe, U.K.; distributed by Philips Medical Systems), and Neotrend (NT) are the only commercially available multiparameter CIBM systems. The original probe of Paratrend 7 (PT7) was introduced in 1992. It consists of a hybrid probe incorporating four different sensors: miniaturized Clark electrode to measure PO_2 , optode to determine PCO_2 , and pH (absorbance sensors, phenol red in bicarbonate solution), and a thermocouple (copper, constantan) to measure temperature and allow temperature correction of the blood gas values. All these sensors were encased in a heparin-coated microporous polyethylene tube that was permeable to the analytes to be measured. This sensor was modified in 1999. In the new sensor (PT7+) (Fig. 20), the Clark electrode was replaced by an optical PO_2 sensor. According to the manufacturer, this new PO_2 sensor is more accurate and has a faster response time.

Clinical Uses

Continuous intravascular blood gas monitoring has been applied in various clinical settings (36,37) in the operating room and the intensive care unit. In the operating room, especially in adults undergoing one lung ventilation for major surgery (e.g., one lung ventilation for thoracoscopic surgery or lung transplantation, major cardiac or vascular surgery). The most common site for CIBM measurement is the radial artery in adults and the femoral artery in children. The umbilical artery is used for probe insertion in neonates. Reports and studies showed that performance and accuracy of CIBM devices appear to be sufficient for clinical use.

Figure 20. The Paratrend 7+ (PT7+; Diametric Medical Inc.) sensor.

Limitations and Complications

Reliable intravascular blood gas measurement depends on a number of mechanical, electrical, and physicochemical properties of the CIBM probe as well as the conditions of the vessel into which the probe is inserted (36,37). Therefore, several factors can affect the performance of CIBM, including mechanical factors related to the intraarterial probe (e.g., not advanced adequately in the artery, the sensor becomes attached to the wall of the vessel), factors related to the artery itself (e.g., vasospasm), interference from electrocautery and ambient or endoscopic light, or related to the “flush” solution used to flush the intraarterial catheter, which may lead to false measurements. Complications may include thrombosis, ischemia, vasospasm, and failure. Although CIBM appears to be advantageous, there are no prospective, randomized, double-blind studies of its impact on morbidity and mortality. Future outcome studies should focus on well-defined groups of selected patients who might benefit from CIBM (e.g., critically ill patients with potentially rapid and unexpected changes in blood gas values). Furthermore, no data is available on the cost/benefit ratio of CIBM, and more studies are still needed to know if this monitor is cost-effective.

Intrapartum Fetal Pulse Oximetry

Intrapartum fetal pulse oximetry is a direct continuous noninvasive method of monitoring fetal oxygenation (38). Persistent fetal hypoxemia may lead to acidosis and neurological injury, and current methods to confirm fetal compromise are indirect and nonspecific. Therefore, intrapartum fetal pulse oximetry may improve intrapartum fetal assessment and, most important, improve the specificity of detecting fetal compromise (39,40). Intrapartum fetal pulse oximetry may monitor, not only the fetal heart rate (FHR), but also the arterial oxygen saturation and peripheral perfusion may be assessed.

Principle of Operation and Placement

The fetus *in utero* does not have an exposed area that would allow placement of a transmission sensor (38). Thus, reflectance sensors have been designed where the light-emitting diodes are located adjacent to the photodetector (Fig. 9). During labor, the sensor is placed transvaginally between the uterine wall and the fetus, with contact on the fetal presenting part, usually the soft tissue of the fetal cheek. Monitoring of fetal oxygen saturation has been encumbered by multiple technical obstacles (38). For example, reflectance sensors not directly attached to the fetus, work only when in contact with fetal skin and may not produce an adequate S_pO_2 signal when contact is suboptimal during intense uterine contractions or during episodes of fetal movement. In this situation, sensor position may require adjustment. Improved reflectance sensor contact has been attempted via a variety of sensor modifications, including suction devices, application with glue, and direct attachment to the fetal skin with a special clip. The Nellcor (Fig. 21) sensors have been developed with a “fulcrum” modification, which mechanically places the sensor surface into better contact with the fetal skin. Other technical

Figure 21. Nellcor OxiFirst fetal pulse oximeter.

advances, such as modification of the red light-emitting diode from a 660 to a 735 nm wavelength, have resulted in improved registration times.

Future Direction of Intrapartum Fetal Pulse Oximetry.

Ideally, calibration of these monitors in human fetuses should be done by simultaneous measurement of S_pO_2 and preductal S_aO_2 . Because the access to fetal circulation during labor is not feasible, calibration of these monitors is still a major problem (38). It appears that well-designed animal laboratory studies and human infant and neonatal studies will have to suffice for calibration and validation of these monitors. To make this monitor more valuable and accurate as a guide for obstetric and neonatal management during labor, prospective studies with a larger number of abnormal fetuses will be necessary to determine duration and level of hypoxia leading to metabolic acidosis in humans. Also, more studies are needed to answer questions about its safety and efficacy. Finally, further refinements in equipment design should improve the accuracy of S_pO_2 determination and the ability to obtain an adequate signal. Decreased signal-to-noise ratios, motion artifacts (e.g., contractions, fetal movement, maternal movement), impediments to light transmission (e.g., vernix, fetal hair, meconium), and calibration difficulties are unique obstacles in accurately assessing the fetus by this monitor. Technical development goals of fetal pulse oximetry should include improvement of sensor optical design, hardware, and software modification to obtain high signal quality and precise calibration. Major advantages of fetal oxygen saturation monitoring include its ease of interpretation for clinicians of varying skills, being noninvasive method, and the ability to monitor fetal oxygenation continuously during labor. However, more studies are needed to evaluate its safety, efficacy, and cost issues (41). When these issues are resolved, intrapartum fetal oxygen saturation monitoring could perhaps be one of the major advances in obstetrics during the twenty-first century.

TRANSCUTANEOUS BLOOD GAS MONITORING (TCM)

Historical Development

The possibility of continuously monitoring arterial blood oxygen and carbon dioxide using a heated surface electrode on human skin was discovered in the early 1970s and made commercially available by 1976 (42). In 1951, Baumberger and Goodfriend published an article showing a method to determine the arterial oxygen tension in man by equilibration through intact skin. By immersing a finger in a phosphate buffer solution heated to 45°C, they found that

the PO_2 of the buffer approached that of the alveolar air. They showed that if skin blood flow increased by the highest tolerable heat (45°C), the surface PO_2 rises to arterial blood PO_2 . A few years later (in 1956), Clark invented the membrane covered platinum polarographic electrode to measure O_2 tissue tensions. By 1977, at least three commercial transcutaneous PO_2 ($tcPO_2$) electrodes were available (Hellige, Roche, RADIOMETER). These devices were applied initially to premature infants in an effort to reduce the incidence of blindness due to excessive oxygen administration. Throughout more than three decades, the TCM technology has been closely linked to the care of neonates; however, recent studies suggest that TCM technology may work just as well for older children and adults (29). The TCM offers continuous noninvasive measurement of blood gases, which is especially advantageous in critically ill patients in whom rapid and frequently life-threatening cardiopulmonary changes can occur during short periods of time. However, with the widespread use of pulse oximetry, the use of transcutaneous blood gas monitors has decreased.

Blood Gas Diffusion Through the Skin

The human skin consists of three main layers: the stratum corneum, epidermis, and dermis (Fig. 22). The thickness of the human skin varies with age, sex, and region of the body. The thickness of the stratum corneum varies from 0.1 to 0.2 mm depending on the part of the body. This is nonliving layer composed mainly of dehydrated cells (dead layer), which do not consume oxygen or produce carbon dioxide. The next layer is the epidermis layer, which consists of proteins, lipids, and melanin-forming cells. The epidermis is living, but is blood-free. The thickness of this layer ~0.05–1 mm. Underneath the epidermis is the dermis, which consists of dense connective tissue, hair follicles, sweat glands, fat cells, and capillaries. These capillaries receive blood from arterioles and drain in venules. Arteriovenous anastomoses innervated by nerve fibers are commonly found in the dermis of the palms, face, and ears. These shunting blood vessels regulate blood flow

Figure 22. Human skin.

through the skin. Heat increases blood flow through these channels almost 30-fold. Gas diffusion through the skin occurs due to a partial pressure difference between the blood and the outermost surface of the skin. Diffusion of blood gases through the skin normally is very low, however, the heated skin ($\sim 43^\circ\text{C}$) becomes considerably more permeable to these gases.

Principle of Transcutaneous PO_2 Measurement ($tcPO_2$)

The probe used to measure the $tcPO_2$ is based on the idea of oxygen polarography (see above). This probe (7,12) consists of a platinum cathode and a silver reference anode encased in an electrolyte solution and separated from the skin by a membrane permeable to oxygen (usually made of Teflon, polypropylene, or polyethylene). The electrode is heated, thereby melting the crystalline structure of the stratum corneum, which otherwise makes this skin layer an effective barrier to oxygen diffusion. The heating of the skin also increases the blood flow in the capillaries underneath the electrodes. Oxygen diffuses from the capillary bed through the epidermis and the membrane into the probe, where it is reduced at the cathode, thereby generating an electric current that is converted into partial pressure measurements and displayed by the monitor. Because of an *in vitro* drift inevitably occurring inside the probe, where several chemical reactions are going on, the $tcPO_2$ sensor must be calibrated before using, and be repeated every 4–8 h. Since the O_2 -dependent current flow exhibits a linear relationship at a fixed voltage, only two known gas mixtures are required for the calibration. Two *in vitro* calibration techniques can be employed: by using two precision gas mixtures (e.g., nitrogen and oxygen), and by using a “zero O_2 solution” (e.g., sodium sulfite) and room air.

The Transcutaneous PO_2 Sensor. The modern transcutaneous PO_2 sensors still use the principles used by Clark decades ago (7,12). Figure 23 illustrates a cross-sectional diagram of a typical Clark-type sensor. This particular sensor consists of three glass-sealed platinum cathodes that are separately connected via current amplifiers to a surrounding Ag–AgCl cylindrical ring. A buffered KCl electrolyte, which has a low water content to reduce drying of the sensor, is used. The following basic reactions happen between the two electrodes:

At the anode (+ electrode):

(the electrons complete the circuit)

At the cathode (– electrode):

(the electrons are boiled off of the platinum electrode)

Overall:

The two electrodes are covered with a thin layer of electrolytic solution that is maintained in place by a membrane that allows slow diffusion of O_2 from the skin into the sensor. The diffusion of O_2 through the skin is normally very low. Under normal physiological conditions, the PO_2

Figure 23. A cross-sectional diagram of a typical Clark-type sensor.

measured at the surface of the skin using a nonheated transcutaneous PO_2 electrode is near zero, regardless of the underlying blood PO_2 . In order to facilitate O_2 diffusion through the skin, abrasion of the skin and drug-induced hyperemia through the application of nicotinic acid cream were initially used. However, since direct skin heating gives a more prolonged and consistent effect, a heating element is now used in all commercial transcutaneous PO_2 sensors. Generally, temperatures between 43 and 44° yield adequate vasodilatation of the cutaneous blood vessels with minimal skin damage. Heating the skin speeds up O_2 diffusion through the stratum corneum. In addition, it also causes vasodilatation of the dermal capillaries, which increases blood flow to the region of skin in contact with the sensor. With increased blood flow, more O_2 is available to the tissues surrounding the capillaries in the skin, and consequently the PO_2 of the blood in these capillary loops approximate more closely that of the arterial blood. Heating the blood also shifts the oxygen dissociation curve to the right. Therefore, the binding of hemoglobin with O_2 is reduced and the release of O_2 to the cells is increased. Simultaneously, skin heating also increases local tissue O_2 consumption. Fortunately, however, these two factors tend to cancel each other.

Transcutaneous PCO_2 Monitoring

Continuous PCO_2 monitoring is helpful in monitoring lung ventilation during spontaneous breathing or artificial ventilation. It makes it easier to adjust the parameters of the ventilator and prevent respiratory acidosis or alkalosis.

The Transcutaneous PCO_2 Sensor

The typical sensor is similar the O_2 sensor that was described above, as shown in Fig. 24. This sensor (7,12) consists of glass pH electrode with a concentric Ag–AgCl reference electrode that also serves as a temperature-

Figure 24. The transcutaneous PCO_2 sensor.

controlled heater. A buffer electrolyte (e.g., HCO_3^-) is placed on the surface of the electrode and a thin CO_2 permeable membrane (e.g., Teflon) stretched over the electrode separates the sensor from its surroundings. As CO_2 molecules diffuse via the CO_2 -permeable membrane into the HCO_3^- containing solution, the following chemical reaction occurs:

A potential between the pH and the reference electrodes is generated as a result of this reaction. This potential is proportional to the CO_2 concentration. Measurement of pH with a pH electrode can lead to estimation of the skin PCO_2 , which correlates with the $PaCO_2$. According to the Henderson–Haselbach relationship, pH is proportional to the negative logarithm of PCO_2 .

Skin temperature must be considered when analyzing PCO_2 measurements, because the skin heating can affect the transcutaneous PCO_2 sensor reading. This effect is due to the high temperature coefficient of the PCO_2 sensor. Heating the sensor results in an increase in PCO_2 , since CO_2 solubility decreases, increase in local tissue metabolism, and increase in the rate of CO_2 diffusion through the stratum corneum. Therefore, the transcutaneous PCO_2 values are usually higher than the corresponding arterial PCO_2 . Calibration of the PCO_2 sensor is different from the PO_2 sensor calibration. In the CO_2 sensor case, the voltage signal generated in the PCO_2 sensor is proportional to the logarithm of the CO_2 concentration (not to CO_2 concentration directly, as the case in PO_2). Therefore, there is no “zero point” calibration in transcutaneous PCO_2 sensor as there is with a transcutaneous PO_2 sensor. For this reason, one needs two different precisely analyzed gas mixtures for calibration. Usually, gas mixtures containing 5 and 10% CO_2 are used for calibrating the PCO_2 sensor. On the other side, PCO_2 sensor calibration must be done at the temperature at which it will be operated.

Clinical Applications of Transcutaneous PO_2 and PCO_2 Monitoring

Transcutaneous PO_2 and PCO_2 monitoring have found numerous applications in clinical medicine and research (42,43) during the past two decades: (1) neonatology: $tcPO_2$ monitoring remains the most commonly used technique to guide oxygen therapy in premature infants. In low birth weight infants, $tcPO_2$ is one of the best available

Figure 25. Radiometer TCM 4 transcutaneous blood gas monitor.

monitor of ventilation. (2) Fetal monitoring: specially designed electrodes attached to the fetal scalp have been used. Changes in $tcPO_2$ rapidly reflected changing maternal and fetal conditions. Some studies showed that fetal $tcPO_2$ is considerably affected by local scalp blood flow, therefore repeated episodes of asphyxia, which may lead to increase in catecholamines, can reduce fetal scalp blood flow and lead to misleading reduction in $tcPO_2$. (3) Sleep studies: pulse oximetry and combined $tcPO_2$ – $tcPCO_2$ electrode are used in sleep studies. This combination made it possible to study the ventilator response of hypoxia in sleeping infants. (4) Peripheral circulation: $tcPO_2$ electrodes are extensively used in evaluation peripheral vascular disease (44). Furthermore, transcutaneous oximetry has been used in several clinical situations such as prediction of healing potential for skin ulcers or amputation sites, assessment of microvascular disease (45), and determination of cutaneous vasomotor status. Figure 25 shows one of the commercially available transcutaneous blood gas monitor.

CAPNOMETRY AND CAPNOGRAPHY

Introduction

Capnometry is the measurement of carbon dioxide (CO_2) in the exhaled gas. Capnography is the method of displaying CO_2 measurements as waveforms (capnograms) during the respiratory cycle. The end-tidal PCO_2 ($P_{et}CO_2$) is the maximum partial pressure of the exhaled CO_2 during tidal breathing (just before the beginning of inspiration). The measurement of CO_2 in respiratory gases was first accomplished in 1865, using the principle of Infrared (IR) absorption. Capnography was developed in 1943 and introduced to clinical practice in the 1950s (27). Since then, capnometry–capnography has gone through significant advances. Now capnography is a “standard of care” for general anesthesia (3), as described by the American Society of Anesthesiologists (ASA).

Measurement Techniques

Capnometry most commonly utilizes IR light absorption or mass spectrometry. Other technologies include Raman spectra analysis and a photoacoustic spectra technology (46,47)

Infrared Light Absorption Technique. This is the most common technique used to measure CO_2 in capnometers.

Figure 26. Single-beam infrared CO₂ analyzer, used in some mainstream sampling systems.

This method is cheaper and simpler than mass spectrometry. However, it is less accurate and has a slower response time (~ 0.25 vs. 0.1 s for mass spectrometry). There are two types of IR analyzers, a double and a single beam. The double-beam positive-filter model consists of an IR radiation source, which radiates to two mirrors. The two beams pass via a filter to two different chambers (sample chamber and reference chamber), and then to a photodetector. Consequently, it is possible to process the detector output electronically to indicate the concentration of CO₂ present. The single-beam negative-filter (Fig. 26), utilizes only one beam without using a reference. The principle behind this technique is that gases generally absorb electromagnetic IR radiation, and gas molecules with two or more atoms, provided these atoms are dissimilar (e.g., CO₂, but not O₂) absorb IR radiation in the range 1000–15000 nm. By filtering particular wavelengths, carbon dioxide and other gases can be measured. Carbon dioxide absorbs IR radiation strongly between 4200 and 4400 nm. Nitrous oxide and water have absorption peaks close to this area. Thus, there is a potential for the introduction of error with these substances in this method.

Raman Spectrography. Raman spectrography uses the principle of “Raman Scattering” for CO₂ measurement. The gas sample is aspirated into an analyzing chamber, where the sample is illuminated by a high intensity monochromatic argon laser beam. The light is absorbed by molecules, which are then excited to unstable vibrational or rotational energy states (Raman scattering). The Raman scattering signals (Raman light) are of low intensity and are measured at right angles to the laser beam. The spectrum of Raman scattering lines can be used to identify all types of molecules in the gas phase. Raman scattering technology has been incorporated into many newer anesthetic monitors (RASCAL monitors) to identify and quantify instantly CO₂ and inhalational agents used in anesthesia practice (48).

Mass Spectrography. The mass spectrograph separates molecules on the basis of mass to charge ratios. A gas sample is aspirated into a high vacuum chamber, where an electron beam ionizes and fragments the components of the sample. The ions are accelerated by an electric field into a final chamber, which has a magnetic field, perpendicular to the path of the ionized gas stream. In the magnetic field, the particles follow a path wherein the radius of curvature

is proportional to the charge: mass ratio. A detector plate allows for determination of the components of the gas and for the concentration of each component. Mass spectrometers are quite expensive and too bulky to use at the bedside and are rarely used presently. They are either “stand alone”, to monitor a single patient continuously, or “shared”, to monitor gas samples sequentially from several patients in different locations (multiplexed). Up to 31 patients may be connected to a multiplexed system, and the gas is simultaneously sampled from all locations by a large vacuum pump. A rotary valve (multiplexer) is used to direct the gas samples sequentially to the mass spectrometer. In a typical 16-station system, with an average breathing rate of $10 \text{ breaths} \cdot \text{min}^{-1}$, each patient will be monitored about every 3.2 min. The user can interrupt the normal sequence of the multiplexer and call the mass spectrometer to his patient for a brief period of time (46–48).

Photoacoustic Spectrography. Photoacoustic gas measurement is based on the same principles as conventional IR-based gas analyzers: the ability of CO₂, N₂O and anesthetic agents to absorb IR light (46,49). However, they differ in measurement techniques. While IR spectrography uses optical methods, photoacoustic spectrography (PAS) uses an acoustic technique. When an IR energy is applied to a gas, the gas will expand and lead to an increase in pressure. If the applied energy is delivered in pulses, the gas expansion would be also pulsatile, resulting in pressure fluctuations. If the pulsation frequency lies within the audible range, an acoustic signal is produced and is detected by a microphone. Potential advantages of PAS over IR spectrometry are higher accuracy, better reliability, less need of preventive maintenance, and less frequent need for calibration. Furthermore, as PAS directly measures the amount of IR light absorbed, no reference cell is needed and zero drift is nonexistent in PAS. The zero is reached when there is no gas present in the chamber. If no gas is present there can be no acoustic signal (49).

CO₂ Sampling Techniques

Sidestream versus Mainstream. Capnometers that are used in clinical practice use two different sampling techniques (50) (Fig. 27): sidestream or mainstream. A mainstream (flow-through) capnometer has an airway adaptor cuvette attached in-line and close to the endotracheal tube. The cuvette incorporates an IR light source and sensor that

Figure 27. Sidestream vs. mainstream CO_2 sampling techniques. (a) Mainstream CO_2 sampling. (b) Sidestream sampling.

senses carbon dioxide absorption to measure PetCO_2 . A sidestream capnometer uses a sampling line that attaches to a T-piece adapter at the airway opening, through which the instrument continually aspirates tidal airway gas for analysis of carbon dioxide. The main advantage of the mainstream analyzer is its rapid response, because the measurement chamber is part of the breathing circuit. The sample cuvette lumen, through which inspired and expired gases pass, is large in order to minimize the work of breathing, and pulmonary secretions generally do not interfere with carbon dioxide analysis. Compared with sidestream (aspiration) sampling, the airway cuvette is relatively bulky and can add dead space. However, within the past few years lighter and smaller airway cuvettes have been developed to allow its use in neonates. The sidestream PCO_2 analyzer adds only a light T-adapter to the breathing circuit, and can be easily adapted to non-intubation forms of airway control. Because the sampling tubing is small bore, it can be blocked by secretions. During sidestream capnography, the dynamic response, the steepness of the expiratory upstroke and aspiratory downslope, tends to be blunted because of the dispersive mixing of gases through the sampling line, where gas of high PCO_2 mixes with gas of low PCO_2 . In addition, a washout time is required for the incoming sampled gas to flush out the volume of the measuring chamber. The overall effect is an averaging of the capnogram, resulting in a lowering of the alveolar plateau and an elevation of the inspiratory baseline. Thus, PetCO_2 may be underestimated and rebreathing can be simulated. These problems are exacerbated by high ventilatory rates and by the use of long sampling catheters. In addition, the capnogram is delayed in time by transport delay, the time required to aspirate gas from the airway opening adapter through the sampling tubing to the sampling chamber.

Micro-Stream Technology. Micro-stream technology (51) is a new CO_2 sampling technique that uses a low aspiration rate (as low as $50 \text{ mL} \cdot \text{min}^{-1}$), such as NBP-75, Nellcor Puritan Bennett, as shown in Fig. 28. In addition, this

technology uses a highly CO_2 -specific IR source, where the IR emission exactly matches the absorption spectrum of the CO_2 molecules. The advantages of this technology, compared to the traditional high flow side-stream capnometer ($150 \text{ mL} \cdot \text{min}^{-1}$), is that it gives more accurate PetCO_2 measurements and better waveforms in neonates and infants with small tidal volumes and high respiratory rates. Furthermore, these low flow capnometers are less likely to aspirate water and secretions into the sampling tubes, resulting in either erroneous PetCO_2 values or in total occlusion of sampling tube.

Phases of Capnography

A normal single breath capnogram (time capnogram) is shown in Fig. 29. Time capnogram is the partial pressure of expired CO_2 plotted against time on the horizontal axis. This capnogram can be divided into inspiratory (phase 0) and expiratory segments. The expiratory segment, similar to a single breath nitrogen curve or single breath CO_2 curve, is divided into phases I, II, and III, and occasionally, phase IV, which represents the terminal rise in CO_2 concentration. The angle between phase II and III is the alpha angle. The nearly 90° angle between phase III and the descending limb is the beta angle. Changes in time

Figure 28. Nellcor Microstream ETCO_2 breath sampling unit.

Figure 29. Normal single breath capnogram.

capnogram help to diagnose some of the breathing and ventilation problems, especially during anesthetic management of patients undergoing surgery (e.g., bronchospasm, esophageal intubation, CO₂ rebreathing, and even cardiac arrest).

Clinical Uses of Capnography

Capnography and capnometry (52) are safe, noninvasive test, and have few hazards. They are widely used in clinical medicine. Their uses include, but are not limited to (1) evaluating the exhaled CO₂, especially end-tidal CO₂ in mechanically ventilated patients during anesthesia. (2) Monitoring the severity of pulmonary disease and evaluating response to therapy, especially therapy intended to improve the ratio of dead space to tidal volume (V_D/V_T) and the matching of ventilation to perfusion (V/Q). (3) Determining that tracheal rather than esophageal intubation has taken place (low or absent cardiac output may negate its use for this indication) (53). Colorimetric CO₂ detectors are adequate devices for this purpose. (4) Evaluating the efficiency of mechanical ventilatory support by determination of the difference between the arterial partial pressure for CO₂ (PCO_2) and the $PetCO_2$. Figure 30 shows a combined handheld capnograph/pulse oximeter.

Limitations

Note that although the capnograph provides valuable information (52) about the efficiency of ventilation, it is not a replacement or substitute for assessing the PCO_2 . The difference between PCO_2 and $PetCO_2$ increases as dead-space volume increases. In fact, the difference between the PCO_2 and $PetCO_2$ has been shown to vary within the same patient over time. Alterations in breathing pattern and tidal volume may introduce error into measurements designed to be made during stable, steady-state conditions. Interpretation of results must take into account the stability of physiologic parameters, such as minute ventilation, tidal volume, cardiac output, ventilation/perfusion ratios, and CO₂ body stores. Certain situations may affect the reliability of the capnogram. The extent to which the reliability is affected varies somewhat among types of devices (IR, photoacoustic, mass spectrometry, and Raman spectrometry). Furthermore, the composition of the respiratory gas mixture may affect the capnogram (depending on

Figure 30. Nellcor OxiMax NBP-75 handheld capnograph/pulse oximeter.

the measurement technology incorporated). The IR spectrum of CO₂ has some similarities to the spectra for both oxygen and nitrous oxide. High concentrations of either or both oxygen or nitrous oxide may affect the capnogram, and, therefore, a correction factor should be incorporated into the calibration of any capnograph used in such a setting. The reporting algorithm of some devices (primarily mass spectrometers) assumes that the only gases present in the sample are those that the device is capable of measuring. When a gas that the mass spectrometer cannot detect (such as helium) is present, the reported values of CO₂ are incorrectly elevated in proportion to the concentration of helium in the gas mixture. Moreover, the breathing frequency may affect the capnograph. High breathing frequencies may exceed the response capabilities of the capnograph. In addition, the breathing frequency, > 10 breaths · min⁻¹, has been shown to affect devices differently. Contamination of the monitor or sampling system by secretions or condensate, a sample tube of excessive length, a sampling rate that is too high, or obstruction of the sampling chamber, can lead to unreliable results. Use of filters between the patient airway and the sampling line of the capnograph may lead to lowered $PetCO_2$ readings. Inaccurate measurement of expired CO₂ may be caused by leaks of gas from the patient-ventilator system preventing collection of expired gases, including, leaks in the ventilator circuit, leaks around tracheal tube cuffs, or uncuffed tracheal tubes.

Sublingual Capnometry

Sublingual capnometry is a method to measure the partial pressure of carbon dioxide under the tongue ($PSLCO_2$). This method is being used mainly in the critical care units to evaluate patients with poor tissue perfusion and multiple organ dysfunction syndrome.

Pathophysiologic Basis. Significant increases in the partial pressure of carbon dioxide (PCO_2) in tissue have

Figure 31. Nellcor CapnoProbe Sublingual capnometer.

been associated with hypoperfusion, tissue hypoxia, and multiple organ dysfunction syndrome (54). When perfusion of the intestinal mucosa is compromised, CO_2 accumulates in the gut. The high diffusability of CO_2 allows for rapid equilibration of PCO_2 throughout the entire gastrointestinal (GI) tract. The vasculature of the tongue and the GI tract are controlled by similar neuronal pathways. Thus, the vasculatures of both respond similarly during vasoconstriction (55). Because the tongue is the most proximal part of the GI tract, measurement of PCO_2 can be conveniently and noninvasively obtained by placing a sensor under the tongue. Clinical studies have demonstrated that PSLCO_2 can be used in the assessment of systemic tissue hypoperfusion and hypercapnia (56).

Capnometer Components and Principle of Operation.

Figure 31 shows a commercially available sublingual capnometer (Nellcor CapnoProbe Sublingual System). This system (25) consists of two components: (1) SLS-I Sublingual Sensor: This sensor contains an optrode (a sensitive analyte detector) consists of an optical fiber capped with a small silicone membrane containing a pH-sensitive solution (Fig. 32). When the optrode is brought into contact with sublingual tissue, CO_2 present in the tissue freely diffuses across the silicone membrane into the fluorescent dye solution. No other commonly encountered gases or liquids can pass across the membrane. The CO_2 dissolves and forms carbonic acid, which in turn lowers the pH of the solution. The fluorescence intensity of the dye in the solution is directly proportional to pH.

This single use sensor is packaged in a sealed metal canister. Inside the canister, the sensor tip is enclosed in a gas permeable reservoir that contains a buffer solution. The solution prevents the optrode from drying out. The solution also allows calibration just prior to use, as it is in equilibrium with a known concentration of CO_2 within the canister. To begin use, the clinician opens the canister and inserts the cable handle into the SLS-I Sublingual Sensor. This action initiates a calibration cycle that allows the

Figure 32. Diagram of Nellcor CapnoProbe sublingual capnometer basic components.

instrument to observe the sensor signal at the known PCO_2 of the calibrant (2). The N-80 instrument contains a precision optical component that emits light at two wavelengths in the violet and blue portions of the visible spectrum. The fluorescence intensity generated by the violet wavelength is insensitive to pH, whereas that generated by the blue wavelength is strongly sensitive to pH. The light is launched into an optical fiber and delivered to the tip of the disposable sensor. The green fluorescent light generated in the optrode is directed back to the N-80 instrument through an optical fiber. The light is then ratio metrically quantitated and directly correlated to PSLCO_2 . When the fluorescence intensity of the optrode has stabilized (within 60–90 s), the N-80 instrument reports the measured value of PSLCO_2 on its LCD screen.

Chemical Colorimetric Airway Detector

This is a device (57,58) that uses a pH-sensitive indicator to detect breath-by-breath exhaled carbon dioxide (Fig. 33).

Figure 33. Nellcor Easy Cap II Pedi-Cap chemical colorimetric CO_2 detector.

The colorimetric airway detector is interposed between the endotracheal tube (ETT) and the ventilation device. Both adult and pediatric adaptors exist, but they cannot be used in infants who weigh < 1 kg. Because of excessive flow resistance, they are not suited for patients who are able to breathe spontaneously. Excessive humidity will render them inoperative in 15–20 min. The devices can be damaged by mucous, edematous, or gastric contents, and by administration of intratracheal epinephrine. Despite these drawbacks, colorimetric sensors have been found to be useful in guiding prehospital CPR (cardiopulmonary resuscitation) both in intubated patients and those with a laryngeal mask airway.

Role of Capnometry–Capnography in CPR. The relationship between cardiac output and $P_{et}CO_2$ is logarithmic (59). Decreased presentation of CO_2 to the lungs is the major rate-limiting determinant of the $P_{et}CO_2$ during low pulmonary blood flow. Capnography can detect the presence of pulmonary blood flow even in the absence of major pulses (pseudoelectromechanical dissociation, EMD) and also can rapidly indicate changes in pulmonary blood flow (cardiac output) caused by alterations in cardiac rhythm. Data suggests that $P_{et}CO_2$ correlates with coronary perfusion pressure, cerebral perfusion pressure, and blood flow during CPR. This correlation between perfusion pressure and $P_{et}CO_2$ is likely to be secondary to the relationship of $P_{et}CO_2$ and cardiac output (60).

SUMMARY

Blood gas measurement methods and instruments have gone through significant improvements and advances in the last few decades. Invasive techniques have moved steadily toward using smaller instruments and closer to the patient's bed (bedside), which requires smaller blood sample. These improvements have made these devices more convenient, need less personnel to operate them, and more cost-effective. These bedside devices have comparable accuracy and reliability to the traditional central laboratory instruments. Continuous intravascular blood gas monitoring is a new invasive technique that uses miniaturized fiberoptic devices. This method has been used in different clinical settings with good results. However, several limitations and complications still exist. More studies and improvements are needed to know its cost-effectiveness in clinical medicine and to minimize its complications (such as ischemia and thrombosis). Other invasive instruments and methods were discussed in other parts of this encyclopedia. On the other hand, noninvasive blood gas measurement methods and devices improved greatly since its introduction to clinical medicine. These devices have been used extensively during anesthesia administration and in critical care units. Using pulse oximetry is "standard of care" in anesthesia practice. The use of pulse oximeter decreased the risk of hypoxia and its deleterious effect significantly. However, several limitations to its use still exist, especially in low perfusion states, during the presence of dyshemoglobins and motion artifacts. New technologies, such as the Oxi-Max and the Signal Extraction technologies, have been developed to overcome some of these limitations,

and to add more features for these instruments (such as scanning the retina as an index of cerebral oxygenation and using Laser Doppler flowmetry–reflection oximetry to measure microcirculatory oxygenation and flow). Other types of pulse oximetry have been introduced to clinical medicine. Intrapartum fetal pulse oximetry is an example of these new pulse oximeters. This device provides a continuous, noninvasive method of monitoring fetal oxygenation, which may help in detecting persistent fetal hypoxemia and improve intrapartum fetal assessment. However, more studies are needed to evaluate its safety, efficacy, and cost issues. Transcutaneous blood gas monitoring is another noninvasive method to measure blood gases. This method is losing ground and popularity against the newer pulse oximeters, which have replaced this method in several situations. Capnometry–capnography has been used extensively in anesthesia practice in the last two decades. New CO_2 sampling technique such as microstream technology has been introduced. This method uses a low aspiration rate, making it more accurate than the previous techniques. Moreover, this technique can detect very small amount of CO_2 . Photoacoustic spectroscopy is a new technique has been developed to measure $P_{et}CO_2$. This method is more reliable, accurate, and needs less calibration than the traditional methods. Studies showed an encouraging result and an important role for capnometry–capnography in cardiopulmonary resuscitation, which may lead to widespread use of these devices in CPR, in prehospital and in-hospital settings.

BLOOD PRESSURE MEASUREMENT

CAN ISIK
 Electrical Engineering and
 Computer Science Department,
 Syracuse University Syracuse,
 New York

INTRODUCTION

Blood pressure is an important signal in determining the functional integrity of the cardiovascular system. Scientists and physicians have been interested in blood pressure measurement for a long time. The first blood pressure measurement is attributed to Reverend Stephen Hales, who in the early eighteenth century connected water-filled glass tubes in the arteries of animals and correlated their blood pressures to the height of the column of fluid in the tubes. It was not until the early twentieth century that the blood pressure measurement was introduced into clinical medicine, albeit with many limitations.

Blood pressure measurement techniques are generally put into two broad classes: direct and indirect. Direct techniques of blood pressure measurement, which are also known as invasive techniques, involve a catheter to be inserted into the vascular system. The indirect techniques are noninvasive, with improved patient comfort and safety, but at the expense of accuracy. The accuracy gap between the invasive and the noninvasive methods, however, has been narrowing with the increasing computational power available in portable units, which can crunch elaborate signal processing algorithms in a fraction of a second.

During a cardiac cycle, blood pressure goes through changes, which correspond to the contraction and relaxation of the cardiac muscle, with terminology that identifies different aspects of the cycle. The maximum and minimum pressures over a cardiac cycle are called the systolic and diastolic pressures, respectively. The time average of the cardiac pressure over a cycle is called the mean pressure, and the difference between the systolic and diastolic pressures is called the pulse pressure.

Normal blood pressure varies with age, state of health, and other individual conditions. An infant’s typical blood

Table 1. Classification of Blood Pressure for Adults

Category	Systolic—mmHg		Diastolic—mmHg
Normal	<120	and	<80
Prehypertension	120–139	or	80–89
Stage 1 Hypertension	140–159	or	90–99
Stage 2 Hypertension	160 or higher	or	100 or higher

pressure is 80/50 mmHg (10.66/6.66 kPa) (systolic/diastolic). The normal blood pressure increases gradually and reaches 120/80 (15.99/10.66 kPa) for a young adult. Blood pressure is lower during sleep and during pregnancy. Many people experience higher blood pressures in the medical clinic, a phenomenon called the “white coat effect.” Therefore, the ranges given in Table 1 are used as guidelines rather than as diagnostic facts.

DIRECT TECHNIQUES

The operation of direct measurement techniques can be summarized in very simple terms: They all use a pressure transducer that is coupled to the vascular system through a catheter or cannula that is inserted to a blood vessel, followed by a microcontroller unit with electronics and algorithms for signal conditioning, signal processing, and decision making. There are many advantages of this set of techniques, including:

- The pressure is measured very rapidly, usually within one cardiac cycle.
- The measurement is done to a very high level of accuracy and repeatability.
- The measurement is continuous, resulting in a graph of pressure against time.
- The measurement is motion tolerant.

Therefore, the direct techniques are used when it is necessary to accurately monitor patients’ vital signs, for example, during critical care and in the operating room. Although direct techniques have a lot in common, there are differences in the details of various approaches.

Extravascular Transducers

The catheter in this type of device is filled with a saline solution, which transmits the pressure to a chamber that houses the transducer assembly. As a minor disadvantage, this structure affects the measured pressure through the dynamic behavior of the catheter. As the catheter has a known behavior, this effect can be minimized to insignificant levels through computational compensation (1).

Intravascular Transducers

The transducer is at the tip of the catheter in this type of device. Then the measured signal is not affected by the hydraulics of the fluid in the catheter. The catheter diameter is larger in this class of transducers.

Transducer Technology

A wide spectrum of transducer technologies is available to build either kind of transducer. They include metallic or semiconductor strain gauges, piezoelectric, variable capacitance, variable inductance, and optical fibers. Appropriate driver and interface circuitry accompanies each technology (2).

Other Applications of Direct Pressure Measurement

Another advantage of direct measurement techniques is that they are not limited to measuring the simple arterial pressure. They can be used to obtain central venous, pulmonary arterial, left atrial, right atrial, femoral arterial, umbilical venous, umbilical arterial, and intracranial pressures by inserting the catheter in the desired site (3).

Sources of Errors

Direct blood pressure measurement systems have the flexibility of working with a variety of transducers/probes. It is important that the probes are matched with the appropriate compensation algorithm. Most modern equipment does this matching automatically, eliminating the possibility of operator error. An additional source of error occurs when air bubbles get trapped in the catheter. This changes the fluid dynamics of the catheter, causing an unintended mismatch between the catheter and its signal processing algorithm. This may cause distortions in the waveforms and errors in the numeric pressure values extracted from them. It is difficult to recognize this artifact from the waveforms, so it is best to avoid air bubbles in the catheter.

NONINVASIVE (INDIRECT) TECHNIQUES

An overwhelming majority of blood pressure measurements do not require continuous monitoring or extreme accuracy. Therefore, noninvasive techniques are used in most cases, maximizing patient comfort and safety. Currently available devices for noninvasive measurement are

- Manual devices: These devices use the auscultatory technique.
- Semiautomatic devices: These devices use oscillatory techniques.
- Automatic devices: Although most of these devices use oscillatory techniques, some use pulse-wave velocity or plethysmographic methods.

The Auscultatory Technique

In the traditional, manual, indirect measurement system, an occluding cuff is inflated and a stethoscope is used to listen to the sounds made by the blood flow in the arteries, called Korotkov sounds. When the cuff pressure is above the systolic pressure, blood cannot flow, and no sound is heard. When the cuff pressure is below the diastolic pressure, again, no sound is heard. A manometer connected to the cuff is used to identify the pressures where the transi-

Figure 1. Blood pressure waveform, and systolic, diastolic, and mean pressures, from an invasive monitor screen (4).

tions from silence to sound to silence are made. This combination of a cuff, an inflating bulb with a release valve, and a manometer is called a sphygmomanometer and the method an auscultatory technique. Usually, the cuff is placed right above the elbow, elevated to the approximate height of the heart, and the stethoscope is placed over the brachial artery. It is possible to palpate the presence of pulse under the cuff, rather than to use a stethoscope to listen to the sounds. The latter approach works especially well in noisy places where it is hard to hear the heart sounds.

This method has various sources of potential error. Most of these sources are due to misplacement of the cuff, problems with hearing soft sounds, and using the wrong cuff size. Using a small cuff on a large size arm would result in overestimating the blood pressure, and vice versa. Nevertheless, an auscultatory measurement performed by an expert healthcare professional using a clinical grade sphygmomanometer is considered to be the gold standard in noninvasive measurements.

Oscillatory Techniques

Most automatic devices base their blood pressure estimations on the variations in the pressure of the occluding cuff, as the cuff is inflated or deflated. These variations are due to the combination of two effects: the controlled inflation or deflation of the cuff and the effect of the arterial pressure changes under the cuff. The Korotkov sounds are not used in the oscillatory techniques.

The cuff pressure variation data may be collected while the cuff is being inflated or deflated. Furthermore, the inflation or deflation during the data collection may be controlled in a continuous fashion or in a step-wise fashion. This variability gives four different strategies in data collection. Their differences may seem insignificant at first, but they have significant effects on the way a variety of algorithms are designed.

Data in Fig. 2 were collected using an experimental system. The cuff is first rapidly inflated to a value higher than the anticipated systolic pressure, an approximate pressure of 170 mmHg (22.66 kPa) in this case. Then it is deflated in small steps until the cuff pressure is below the anticipated diastolic pressure, ~50 mmHg (6.66 kPa). Please note that when the cuff pressure is very high or very low, the arterial blood pressure variations contribute very little to the cuff pressure trajectory. As a matter of fact, the height of those pulses above the cuff pressure baseline is at their maximum when the baseline pressure is equal to the mean arterial pressure (MAP). We demonstrate this in Fig. 3, with a plot of pulses relative to their baseline pressure (pulse-wave amplitude), against their respective baseline cuff pressures. Please note that only

Figure 2. Cuff pressure trajectory when data are collected during step-wise deflation of the cuff (5).

a few of the pulses observed in Fig. 2 are transferred to Fig. 3 to maintain clarity.

Figure 4 shows a cycle of data collected during the continuous inflation of the cuff as well as the pulse-wave amplitude. The pulse-wave amplitude is obtained by subtracting the baseline cuff pressure from the raw pressure data. Next, we will return to the example developed in Figs. 2 and 3 and continue with the estimation of blood pressure values.

It seems trivial to pick the pulse with the tallest height above baseline and to select its baseline pressure to be the MAP. So, for the example at hand, MAP would be just under 100 mmHg (13.33 kPa), as shown in Fig. 5. The systolic and diastolic pressures are then estimated from the MAP using a variety of heuristic rules. A common class of these heuristic rules works as follows. First, the peak values (heights) of the pulse-wave amplitudes are connected to form an envelope. Again, the baseline pressure at the peak of this envelope is the MAP value. Then, the height of the MAP pulse is reduced by a predetermined systolic ratio, and the intersection of this “systolic height” with the envelope to the right of the MAP pulse is selected as the systolic location. The baseline pressure at this location is assigned as the estimate of the systolic pressure, as depicted in Fig. 5. The diastolic pressure is estimated in a similar fashion by using a ratio of its own to arrive at the

Figure 3. Pulse-wave amplitude profile (6).

Figure 4. Cuff pressure trajectory and pulse-wave amplitude when data are collected during continuous inflation of the cuff.

diastolic height and then by finding the corresponding intersection with the envelope to the left of the MAP pulse.

In the example shown in Fig. 5, the systolic ratio and diastolic ratio were arbitrarily selected as 0.5 and 0.7, respectively. In a realistic system, those ratios would be found statistically (using methods such as regression, fuzzy rule-based systems, neural networks, or evolutionary algorithms) to minimize deviations between estimated and actual blood pressure values.

Algorithmic Components of Blood Pressure Measurement

In the earlier measurement units, it was a combination of hardware and software that controlled the various aspects of the automated measurement (or estimation) of blood pressure. With the ever increasing computational power of microcontrollers, all decision making and control are now implemented in software and with more elaborate algorithms. Here are some functions that are included in a measurement system. Please refer to Fig. 6 for a typical organization of such algorithms in a blood pressure measurement system.

- **Inflation/deflation control:** Whether data collection is done during inflation or deflation, continuously

Figure 5. Blood pressure estimation from pulse-wave amplitude profile.

Figure 6. A typical organization of algorithmic components of (oscillatory) blood pressure measurement.

or in steps, there are many challenges to appropriately controlling the air pump. They include maintaining a smooth baseline cuff pressure without filtering out the arterial variations; adjusting the pump speed to variations arising from different cuff sizes, arm sizes, and cuff tightness; and selecting the range of cuff pressures for which data will be collected.

- **Pulse detection:** This is a fundamental part of extracting features from raw cuff pressure data. It becomes especially challenging when conditions such as arrhythmia, or tremors, affect the regularity of pulses. Pattern recognition techniques with features found in time, frequency, or wavelet domains are used to deal with difficult situations.
- **Blood pressure estimation:** The indirect method of measurement is a process of estimating pressures with the use of features extracted from cuff pressures or other transducer data. This algorithm used to be limited to linear interpolation, as described in the example of Fig. 5. Recently, more elaborate decision-making and modeling tools such as nonlinear regression, neural networks, and fuzzy logic also are being used for this purpose.

Sources of Inaccuracy

Many factors contribute to the inaccuracies in the automated measurement of blood pressure. The following are some of the more significant sources of error:

- **Sparseness of data:** An important design criterion of a blood pressure monitor is to go through a cycle as quickly as possible. However, the faster a device functions, the fewer pulses it will have in a cycle. A cycle time of 1 min would yield about 60–70 pulses, whereas a 20-min cycle would have only 20–23 pulses. The oscillatory techniques are based on collecting cuff pressure due to pulses at baseline pressures that change from above systolic to below diastolic. If we divide a cuff pressure range of about 150–180 mmHg (10.99–23.99 kPa) by the number of pulses in a cycle, we can see that the baseline increment between successive pulses varies from 2 to 3 mmHg (0.26 to 0.39 kPa) in a 1 min cycle to 6 to 9 mmHg (0.79 to 1.19 kPa) in a 20 s cycle. This quantization error affects the accuracy in the estimate of the mean arterial pressure as well as

the shape of the pulse envelope, hence, the accuracy of the systolic and diastolic values. Various curve-fitting and interpolation techniques are used to remedy this problem.

- **Pulse extraction uncertainty:** Whether the baseline cuff pressure is varied continuously or in steps, figuring out where one pulse ends and another one starts is not a trivial matter. An inspection of Fig. 2 will show that many artifacts in the data stream may confuse a pulse extraction algorithm and cause errors in the pulse-wave amplitude profile in Fig. 3. In addition, common factors such as an irregularity in the pulses as in arrhythmia, small wrinkles, or folds in the cuff changing its volume suddenly during data collection, or small movements of the patient may amplify those artifacts. A variety of pattern recognition techniques are employed to improve the accuracy of pulse detection (7).
- **Motion artifacts:** The performance of the oscillatory techniques depends on all measurements during a cycle. Therefore, any error caused by a motion of the patient may affect the accuracy of the blood pressure estimations. A comparative study of six noninvasive devices has found that average percent errors due to motion artifacts may be as high as 39% (8). Remedies to this source of error may be a combination of three strategies: (1) to identify and compensate for minor artifacts, (2) to identify and discard data that include significant artifacts or to repeat the entire cycle if the estimates are deemed unreliable, and (3) to incorporate features from additional sensors or monitors such as electrocardiogram (EKG) to help identify motion artifacts (8,9).

Other Blood Pressure Measurement Techniques

Oscillometry is by far the most common technique in automatic noninvasive blood pressure measurement. However, other methods are found in commercial units or in units that are being developed. In this section, a few of these methods are summarized and references are given for further information. It should be noted that algorithmic components and sources of inaccuracy presented within the context of oscillatory technique may apply to other automated measurement methods.

Arterial Tonometry. This relatively new technique in blood pressure measurement is inspired by the tonometry devices that were made in the mid-1950s to measure intraocular pressure. The arterial tonometry device is based on a pressure sensor and pneumatic actuator combination, which is placed on the wrist, above the radial artery. When the pressure applied on the artery is adjusted to the appropriate level (called the hold-down pressure), the portion of the artery wall that is facing the actuator is partially flattened. This configuration maximizes the energy transfer between the artery and the sensor, yielding pulses with the highest amplitude. The relative amplitudes of the tonometry pulses are calibrated to the systolic and the diastolic pressures. Tonometry is suitable for continuous monitoring applications. Sensor placement sensi-

vity, calibration difficulties, and motion sensitivity are problems that need improvement (10,11).

Pulse-Wave Velocity. A pulse wave is generated by the heart as it pumps blood, and it travels ahead of the pumped blood. By solving analytical equations of fluid dynamics, it has been shown that changes in blood pressure heavily depend on changes in pulse-wave velocity. Blood pressure can be continuously calculated from pulse wave velocity, which in turn is calculated from EKG parameters and peripheral pulse wave measured by an SpO₂ probe on the finger or toe. This method is suitable for continuous monitoring as well as for detecting sudden changes in blood pressure to trigger an oscillometric cycle (12).

Plethysmographic Methods. In this method, changes in the blood volume during a cardiac cycle are sensed using a light emitter and receiver at the finger. Tissue and blood have different infrared light absorbance characteristics. That is, the tissue is practically transparent to the infrared light, whereas blood is opaque to it. A prototype of a ring-like sensor/signal processor/transmitter combination has been reported (13,14)

DIFFERENT FORMS OF BLOOD PRESSURE MEASUREMENT DEVICES

The techniques, algorithms, and transducers discussed in the previous sections have led to a variety of forms of devices, differentiated by where in the body the measurements are taken, or for what purpose the device is used.

Ambulatory Blood Pressure Monitoring

These portable and wearable devices monitor the patient's blood pressure over a long period, say for 24 h. While the patient is following her daily routine, the device periodically takes measurements and saves the results. These measurements are later downloaded for analysis by a physician. The first ambulatory devices, introduced in the early 1960s, were rudimentary and used tape recorders to capture the Korotkoff sounds with an occluding cuff. Most current ambulatory devices use the oscillatory technique. As the patient is subjected to repeated blood pressure measurements with an ambulatory device, it is essential to improve motion tolerance, patient comfort, measurement time, and of course overall accuracy of measurement algorithms that are employed in ambulatory monitors (15).

Ambulatory devices have been instrumental in clinical research and practice. Through their use, there have been significant improvements in our understanding of blood pressure dynamics in a variety of physiological and psychological conditions, and concepts such as "white-coat hypertension," "episodic hypertension," and "circadian rhythm of blood pressure" (e.g., daytime/nighttime variations of blood pressure) have been investigated and added to the medical lexicon (16).

Wrist Blood Pressure Monitoring

These monitors have smaller cuffs than their upperarm-attached counterparts. Hence, they are more compact and

more conducive to self-measurement. It is important that the monitors are held at the heart level for correct measurement. They are popular with the home users but typically less accurate than the full-size arm monitors.

Finger Blood Pressure Monitoring

Finger monitors are not nearly as common as the arm or wrist monitors. The approaches used are auscultatory and plethysmographic.

Semiautomatic Blood Pressure Monitoring

The semiautomatic devices have cuffs that are inflated manually by an attached bulb, like a sphygmomanometer. Once the cuff is inflated, the monitor functions in the same manner as an automatic device, taking cuff-pressure measurements while releasing the pressure in a controlled way. These devices are more economical and have longer battery lives than their fully automated counterparts.

ACCURACY OF BLOOD PRESSURE MEASUREMENT DEVICES

Blood pressure measurement devices play an important role in medicine, as they measure one fundamental vital sign. In addition to this traditional use, noninvasive blood pressure devices, especially the automated ones, have become ubiquitous in the home, regularly used by lay people. Two widely used protocols for testing the accuracy of these devices are those set by the Association for the Advancement of Medical Instrumentation (AAMI), a pass/fail system published in 1987 and revised in 1993, and the protocols of the British Hypertension Society (BHS), an A–D graded system, established in 1990 and revised in 1993. These protocols describe in detail the process manufacturers should follow in validating the accuracy of their devices. Their numeric accuracy thresholds can be summarized as follows. A device would pass the AAMI protocols if its measurement error has a mean of no >5 mmHg (0.66 kPa) and a standard deviation of no >8 mmHg (1.06 kPa). The BHS protocol would grant a grade of A to a device if in its measurements 60% of the errors are within 5 mmHg, 85% of the errors are within 10 mmHg (1.33 kPa), and 95% within 15 mmHg (1.99 kPa). BHS has progressively less stringent criteria for the grades of B and C, and it assigns a grade D if a device performs worse than C.

The European Society of Hypertension introduced in 2002 the International Protocol for validation of blood pressure measuring devices in adults (17). The working group that developed this protocol had the benefit of analyzing many studies performed according to the AAMI and BHS standards. One of their motivations was to make the validation process simpler, without compromising its ability to assess the quality of a device. They achieved it by simplifying the rules for selecting subjects for the study. Another change was to devise a multistage process that recognized devices with poor accuracy early on. This is a pass/fail process, using performance requirements with multiple error bands.

Whether blood pressure measurement devices are used by professionals or lay people, their accuracy is important.

Table 2. Summary of Accuracy of Blood Pressure Measurement Devices

Device Type	Number Surveyed	Recommended?		
		Yes	Questionable	No
Manual, clinical	4	1	1	2
Auto, clinical	6	3	2	1
Auto, home, arm	20	4	4	12
Auto, home, wrist	4	0	2	2
Ambulatory	50	26	5	19
Total	84	34	14	36

Yet, most devices in the market have not been evaluated for accuracy independently, using the established protocols (18). In their study, O'Brien et al. surveyed published independent evaluations of manual sphygmomanometers, automated devices for clinical use, and automated devices for personal use. If a device was found acceptable by AAMI standards, and received a grade of A or B by BHS standards, for both systolic and diastolic measurements, then it was "recommended". Otherwise it was not recommended. Few studies they surveyed had issues such as specificity, so devices reported in those studies were "questionably recommended."

Table 2 summarizes the result of their survey. It is interesting to note that of the four clinical grade sphygmomanometers, a kind that is highly regarded by health-care providers, only one was "recommended". Overall, the number of devices "not recommended" is more than the number of "recommended" devices. What one should take away from this analysis is that at every level of quality, price, and target market, it is essential to research the accuracy of a device before investing in it and relying on it.

BLOOD PRESSURE, AUTOMATIC CONTROL OF

YIH-CHOUNG YU
Lafayette College
Easton, Pennsylvania

INTRODUCTION

Arterial pressure is one of the vital indexes of organ perfusion in human bodies. Generally speaking, blood pressure is determined by the amount of blood the heart pumps and the diameter of the arteries receiving blood from the heart. Several factors influence blood pressure. The

nervous system helps to maintain blood pressure by adjusting the size of the blood vessels, and by influencing the heart's pumping action. The heart pumps blood to make sure a sufficient amount of blood circulates to all the body tissues for organ perfusion. The more blood the heart pumps and the smaller the arteries, the higher the blood pressure is. The kidneys also play a major role in the regulation of blood pressure. Kidneys secrete the hormone rennin, which causes arteries to contract, thereby raising blood pressure. The kidneys also control the fluid volume of blood, either by retaining salt or excreting salt into urine. When kidneys retain salt in the bloodstream, the salt attracts water, increasing the fluid volume of blood. As a higher volume of blood passes through arteries, it increases blood pressure.

Hypertension is defined as abnormal high systemic arterial blood pressure, systolic and diastolic arterial pressures > 140 and 95 mmHg (18.662 and 12.664 kPa). The causes of hypertension might be due to acute myocardial infarction, congestive heart failure, and malignant hypertension. Postoperative cardiac patients may experience hypertension because of pain, hypothermia, reflex vasoconstriction from cardiopulmonary bypass, derangement of the rennin-angiotension system, and ventilation difficulties. A prolonged postoperative hypertension could lead to complications, including myocardial ischemia, myocardial infarction, suture line rupture, excessive bleeding, and arrhythmia. As a result, clinical treatment to postoperative hypertension is needed to reduce the potential risk of complications.

Postoperative hypertension is usually treated pharmacologically in the intensive care unit (ICU). Sodium nitroprusside (SNP) is one of the most frequently used pharmaceutical agents to treat hypertensive patients and is a vasodilating drug that can reduce the peripheral resistance of the blood vessel, and thus causes the reduction of arterial blood pressure. A desired mean arterial pressure (MAP) can be achieved by monitoring MAP and regulating the rate of SNP infusion. The mean arterial pressure can be measured from a patient by using an arterial pressure transducer with appropriate signal amplification. Low pass filtering is used to remove high frequency noise in the pressure signal and provide MAP for monitoring purpose. Administration of SNP infusion could be performed by manual operation. The drug infusion rate should be adjusted frequently in response to the spontaneous pressure variation and patient's condition changes. In addition, blood pressure response to the drug infusion changes over time and varies from patient to patient. Therefore, this manual approach is extremely difficult and time consuming for the ICU personnel. As the result, the use of control techniques to regulate the infusion of the pharmaceutical agents and maintain MAP within a desired level automatically has been developed in the last 30 years.

IVAC Corporation developed an automatic device, TITRATOR, to infuse SNP and regulate MAP in postoperative cardiac patients in early 1990s. Clinical evaluation for the clinical impact of this device in multiple centers was reported by Chitwood et al. (1). Patients who participate in this trial were treated by either automatic or

manual control. The automated group showed a significant reduction in the number of hypertensive episodes per patient. Chest tube drainage, percentage of patients receiving transfusion, and total amount transfused were all reduced significantly by the use of an automated titration system. Although TITRATOR was not commercialized successfully due to economic reasons, the promising clinical experiences encouraged future development of automatic blood pressure regulation devices.

An automatic blood pressure control system usually includes three components: sensors, a controller, and a drug delivery pump. This article provides an overview of automatic control schemes, including proportional-integral-derivative (PID) controllers, adaptive-controllers, rule-based controllers, and artificial neural network controllers that regulate mean arterial blood pressure using SNP. A brief description of each control strategy is provided, followed by examples from literature. Testing of the control performance in computer simulations, animal studies, and clinical trials, is also discussed.

CONTROL SCHEMES

PID Controller

The PID control of MAP determines the SNP infusion rate, $u(t)$, based on the difference between the desired output and the actual output,

$$u(t) = K_P e(t) + K_I \int_{t_0}^{t_1} e(t) dt + K_D \frac{d}{dt} e(t) \quad (1)$$

where $e(t) = P_d(t) - P_m(t)$, $P_d(t)$ is the desired MAP, and $P_m(t)$ is the actual mean arterial pressure. The parameters K_P , K_I , and K_D are the proportional, integral, and differentiation gain respectively. The design of this type of controller involves the selection of appropriate control gains, K_P , K_I , and K_D , such that the actual blood pressure, $P_m(t)$, can be stabilized and maintained close to the desired level, $P_d(t)$. Typical components of the automatic blood pressure control system, including the PID controller, the infusion pump, the patient, as well as the patient monitor along with physiologic sensors are illustrated in Fig. 1.

Sheppard and co-worker (2-4) developed a PI-type controller, by setting $K_D = 0$ in (1), to regulate SNP, which has been tested over thousands of postcardiac-surgery patients in the ICU. The control gains were tuned to satisfy an acceptable settling time with minimal overshoot. The discrete-time PI controller updates the infusion rate as

$$u(k) = u(k-1) + \Delta u(k) \quad (2)$$

where $u(k-1)$ is the previous infusion rate a minute ago and $\Delta u(k)$ is the infusion rate increment defined by,

$$\Delta u(k) = K \{0.4512 e(k) + 0.4512 [e(k) - e(k-1)]\} \quad (3)$$

where $e(k)$ and $e(k-1)$ are the current and previous error, respectively. The gain K in Eq. 3 as well as the further correction of $\Delta u(k)$ were determined by the region of current MAP $P_m(k)$ as described in the following:

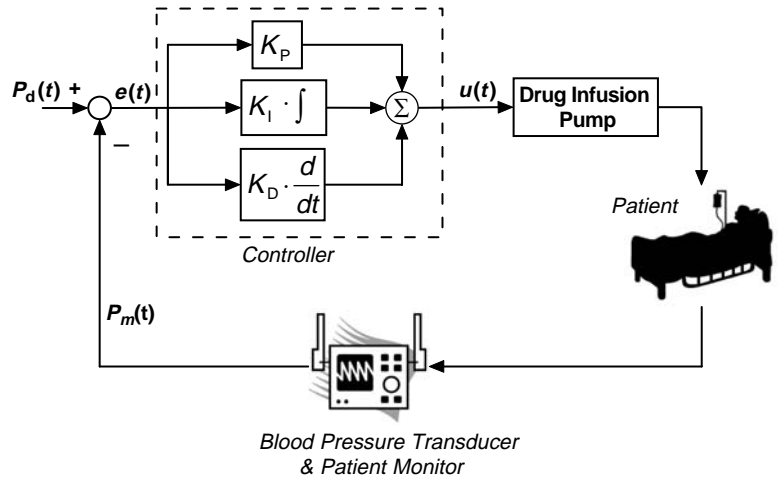

Figure 1. Proportional-integral-derivative control scheme of blood pressure control.

- Rule 1 If $P_m(k) \geq P_d + 5$, then $K = -1$ and $\Delta u(k) = \Delta u(k)$ from Eqs. 3–2
- Rule 2 If $P_d \leq P_m(k) < P_d + 5$, then $K = -0.5$ and $\Delta u(k) = \Delta u(k)$ from Eq. 3
- Rule 3 If $P_d - 5 \leq P_m(k) < P_d$, then $K = -1$ and $\Delta u(k) = \Delta u(k)$ from Eq. 3
- Rule 4 If $P_m(k) \leq P_d - 5$, then $K = -2$ and $\Delta u(k) = \Delta u(k)$ from Eq. 3
- Rule 5 If $P_m(k) < P_d - 5$ and $\Delta u(k) > 0$, then $\Delta u(k) = 0$
- Rule 6 If $P_m(k) \geq P_d$ and $\Delta u(k) > 7$, then $\Delta u(k) = 7$

These rules were designed to provide a boundary for the controller and achieve the optimal performance with the minimal pharmacological intervention. As a result, the controller is a nonlinear PI-type controller.

The automatic blood pressure controller described herein performed better than human operation in a comparison study (5). Automatic blood pressure regulation exhibits approximately one-half of the variation observed during manual control; MAP are more tightly distributed about the set-point, as shown in Fig. 2 (2). Forty-nine postcardiac surgery patients in ICU were managed by the automatic controller. The patients' MAPs were maintained within ± 5 mmHg (± 0.667 kPa) of the desired MAP 94% of the total operation time (103 out of the 110 operation hours). A group of 37 patients were managed with manual operation provided by experienced personals, with which only 52% of the time the patients' MAPs were within the prescribed range.

Adaptive Controller

The PID controller considered previously was with the control gains determined prior to their implementation. The control gains were usually tuned to satisfy the performance criterion in simulation or animal studies where the parameters characterizing the system dynamics were fixed variables. In clinical applications, the cardiovascular vascular dynamics change over time as well as from patient to patient. In addition, the sensitivity to drugs varies from one patient to another and even with the same patient at different instant. Therefore, it would be beneficial if the

control gains can be adjusted automatically during operation to adapt the differences between patients as well as physiologic condition changes in a patient over time. This type of controllers is called adaptive controller.

An adaptive control system usually requires a model, representing plant (the patient and the drug infusion system) dynamics. Linear black box models, expressed by

$$y(k) = \frac{B(q^{-1})}{A(q^{-1})} u(k) + \frac{C(q^{-1})}{A(q^{-1})} n(k)$$

$$A(q^{-1}) = 1 + a_1q^{-1} + a_2q^{-2} + \dots + a_nq^{-n} \quad (4)$$

$$B(q^{-1}) = 1 + b_1q^{-1} + b_2q^{-2} + \dots + b_lq^{-l}$$

$$C(q^{-1}) = 1 + c_1q^{-1} + c_2q^{-2} + \dots + c_mq^{-m}$$

are typically used to represent the plant dynamics. A , B , and C are polynomials in the discrete shift operator q , where a_i , b_i , and c_i are coefficients in the polynomials; $y(k)$, $u(k)$, and $n(k)$ are the model input, output, and noise, respectively. Depending on the polynomials B and C , the model in Eq. 4 can be classified as autoregressive [AR, $B(q^{-1}) = 0$, $C(q^{-1}) = 1$], autoregressive with inputs [ARX, $C(q^{-1}) = 1$], autoregressive moving average [ARMA, $B(q^{-1}) = 0$], and autoregressive moving average with inputs (ARMAX). The coefficients of the polynomials are time-varying, much slower than the plant dynamic changes. The controller updates the control input, $u(k)$, by taking the model parameter changes into consideration. General reviews and descriptions on adaptive control theory can be found in literature (6–8). Three types of adaptive control schemes are frequently used in blood pressure controller design: self-tuning regulator, model reference adaptive control, and multiple model adaptive control.

Self-Tuning Regulator. The self-tuning regulator (STR) is based on the idea of separating the estimation of unknown parameters from the design of the controller. It is assumed that a priori knowledge of the model structure, that is, l , m , and n in Eq. 4. In choosing l , m , and n , one must compromise between obtaining an accurate representation of the system dynamics while keeping the system representation simple. The parameters of the regulator are adjusted by using a recursive parameter estimator and a

Figure 2. Comparison of manually controlled SNP infusion with computer control in the same patient. (Redrawn with permission from L.C. Sheppard, Computer control of the infusion of vasoactive drugs, *Ann. of Biomed. Eng.*, Vol. 8: 431–444, 1980. Pergamon Press, Ltd.)

regulator design calculation as shown in Fig. 3. The parameter estimates are treated as if they are true or at least asymptotically the true parameters. Several algorithms are available for parameter estimation, including recursive least-squares, generalized least-squares, stochastic approximation, maximum likelihood, instrumental variables, and Kalman filter. Every technique has its advantages and disadvantages. Descriptions of parameter estimation algorithms can be found in (9). Various approaches are available for regulator design calculation, such as minimum variance, gain and phase margin analysis, pole placement, and linear quadratic Gaussian (LQG). More detailed information of STR can be found in literature (6–8).

Various STR-type blood pressure controllers have been developed and tested in computer simulations, animal experiments, as well as clinical studies. Arnsparger et al. (10) used a second-order ARMA model to design the STR. A recursive least-mean-squares estimator was used to estimate the model parameters. The parameter estimates were then used to calculate the control signal, the drug infusion rate, based upon a minimum variance or a one-step-ahead control law. Both algorithms were implemented in microprocessor and tested in dog experiments for comparison. Both controllers were able to maintain the

MAP at the desired level. However, the one-step-ahead controller performed better in the test with less variation in the infusion rate.

A combination of proportional derivative with minimum variance adaptive controller was designed by Meline et al. (11) to regulate MAP using SNP. The plant dynamics was represented by a fifth-order ARMAX model, while the model parameters were estimated through a recursive least-squares algorithm. The controller was tested on ten dog experiments as well as human subjects (12). Twenty patients with postsurgical hypertension were randomly assigned to either the manual group, where SNP was administered by experience nurse, or the automatic group. Statistical analysis showed that MAP was maintained within $\pm 10\%$ from the desired MAP for 83.3% of the total operation time in the “automatic” group versus 66.1% of the total operation time in the “manual” group. This implies the automatic control performed better than the manual operation.

A pole-assignment STR was designed by Mansour and Linkens (13) to regulate blood pressure using a fifth-order ARMAX model. The model parameters were identified through a recursive weighted least-squares estimator. These parameters were then used to determine appropriate feedback gains for the controller. Pole-placement algorithm was used because of its robustness to a system with nonminimum phase behavior or unknown time delay. Effectiveness of the controller was evaluated extensively in computer simulation, using a clinically validated model developed by Slate (3) as shown in Fig. 4(2). The controller demonstrated a robust performance even with the inclusion of the recirculation term or a variable time delay.

Voss et al. (14) developed a control advance moving average controller (CAMAC) to simultaneously regulate arterial pressure and cardiac output (CO) using SNP and dobutamine. CAMAC is a multivariable STR, which has the advantage of controlling nonminimum phase plants with unknown or varying dead times. The controller determines the drug infusion rates based on the desired MAP and CO, past inputs, past outputs, and a on-line recursive least-squares estimator with an exponential forgetting factor identifying the subject’s response to the drugs.

Figure 3. Configuration of self-tuning regulator for blood pressure control.

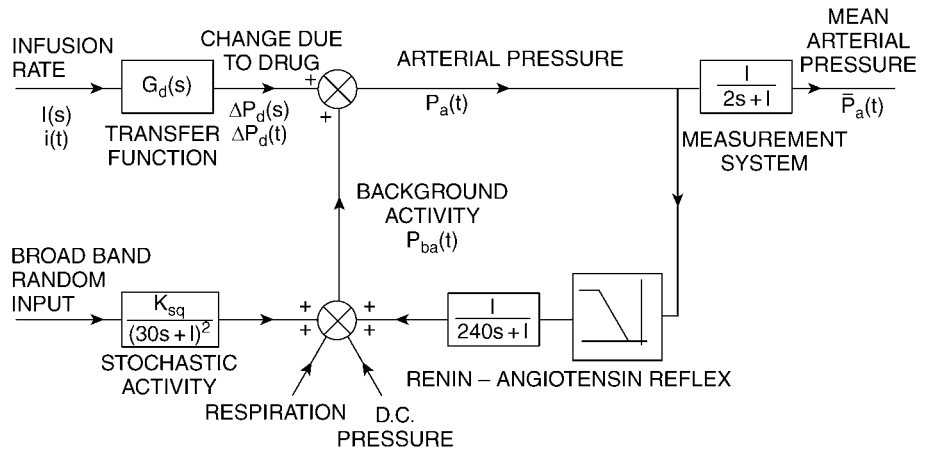

Figure 4. Model of MAP in response to SNP infusion. (Redrawn with permission from L.C. Sheppard, Computer control of the infusion of vasoactive drugs, *Ann. Biomed. Eng.* 1980; 8: 431–444. Pergamon Press, Ltd.)

The plant model for designing the controller and estimator was a second-order ARMAX model. The control algorithm was designed and tested in simulations prior to dog experiments. Although animal studies demonstrated that the controller was capable to maintain MAP and CO at their desired level, changing vasomotor tone and the lack of high frequency excitation signals could lead to inaccuracy in the parameter estimation, causing poor performance in transient response.

Model Reference Adaptive Control. The basic principle of the model reference adaptive control is illustrated in Fig. 5). The desired input–output response is specified by the reference model. The parameters of the regulator are adjusted by the error signal, the difference between the reference model output and the system output, such that the system output follows the reference output. More detailed information about MRAC can be found in Ref. 7.

The use of MRAC to regulate blood pressure was introduced by Kaufmann et al. (15). The format of the reference model was adopted from that developed by Slate (3). Controller design and evaluation were carried out in computer simulation. The controller with adaptation gains showed lower steady-state error than that with nonadaptive gains in simulations, particularly when a process disturbance was introduced. Animal studies were conducted to compare the performance of the MRAC with that of a well-tuned PI controller. Neosynephrine was introduced to change the transfer function characteristics of the subjects during experiments. The MRAC was superior to the PI controller

and maintained MAP closed to the reference with an error within ± 5 mmHg (± 0.667 kPa) regardless of the plant characteristic changes due to drug intervention.

Pajunen et al. (16) designed a MRAC to regulate blood pressure using SNP with the ability to adjust the reference model by learning the patient’s characteristics, represented by the model parameters, coefficients and time delays, of the transfer function. These model parameters were assumed to be unknown and exponentially time-varying. The time-varying reference model was automatically tuned to achieve the optimal performance while meeting the physical and clinical constraints imposed on the drug infusion rate and MAP. Extensive computer simulation was used to evaluate the robustness of the controller. The MAP was maintained within ± 15 mmHg (± 2 kPa) around the set-point regardless of changes in patient’s characteristics and the presence of high level noises.

Polycarpou and Conway (17) designed a MRAC to regulate MAP by adjusting SNP infusion rate. The plant model was a second-order model discretized from the Slate’s model (3). Time delay terms in the model were assumed to be known while the model parameters were constant with nonlinear terms. The constant terms were assumed to be known and the nonlinear terms were estimated by a radial basis function (RBF) neural network. The resulting parameter estimates were then used to update the control law such that the system output follows the reference model. Although the RBF was able to model the unknown nonlinearity and thus improve the closed-loop characteristics in computer simulation, the

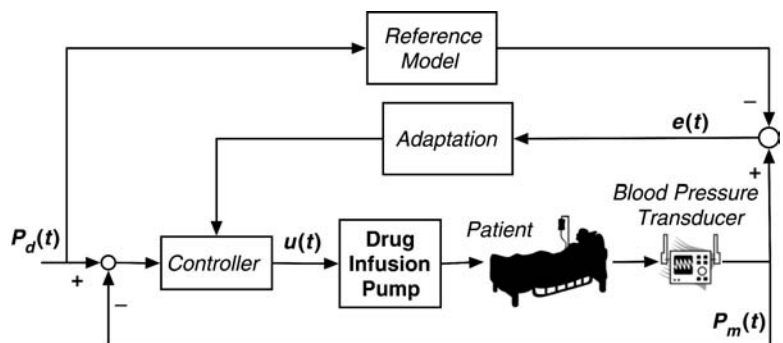

Figure 5. Configuration of MRAC for blood pressure regulation.

assumption that the model parameters and time delays were known would need further justification in practical applications.

Multiple Model Adaptive Control. The concept of multiple model adaptive control (MMAC) was first introduced by Lainiotis (18). This technique assumes that the plant response to the input can be represented by a bank of models. A controller is designed *a priori* to give a specified performance for each particular model. A probability, $P(q_i | t)$, describing the accuracy of each model, q_i , to represent the actual system, is calculated and used as the weighting factor to update the control input,

$$u = \sum_{i=1}^N u_i \cdot P(q_i | t) \quad (5)$$

where u_i is the control input based on the model q_i . As the response of the system changes, the probability, $P(q_i | t)$, will also be adjusted accordingly such that the model closest represents current dynamics gets the greatest probability. As a result, the contribution of the control input, obtained from the model with the greatest probability, to the updated control input in equation 5 is more significant than the inputs from other models with lower probabilities. Configuration of the MMAC is illustrated in Fig. 6.

He et al. (19) introduced the first blood pressure controller using the MMAC technique. There were eight plant models derived from Slate’s model (3) for controller design. Each plant model contains a constant model gain between 0.32 and 6.8, representing the plant gain of 0.25–9 in Slate’s model (3), along with the same time constants and delays at their nominal values. A proportional-plus-integral (PI) type controller was designed for each plant model. These controllers were with the same time constant but different gains. Computer simulation was used to test the controller performance in response to the variations of model parameters and the presence of background noise. The controller was able to settle MAP within 10 min with the error within ± 10 mmHg (± 1.333 kPa) from the set-

point. The control algorithm was further tested in animal experiments. The controller stabilized MAP in < 10 min with ± 5 mmHg (± 0.667 kPa) error from its set-point, regardless of the plant characteristic changes due to neosynephrine injection, the sensitivity of the subject to the SNP infusion, and the background noise. The mean error was < 3 mmHg (0.4 kPa) over the entire studies.

Martin et al. (20) developed a MMAC blood pressure controller with seven models modified from Slate’s model (3). The model gains in the seven models were from 0.33 to 9.03 to cover the variation of the plant gain between 0.25 and 10.86. The other model parameters were held constant at their nominal values. A pole-placement compensator was designed for each model. A Smith predictor was used to remove the effects of infusion delay, and thus simplify the control analysis and design. A PI unit was included to achieve zero steady-state error. Two constrains were used to limit the infusion rate when the patient’s blood pressure is too low or the resulting SNP infusion rate from the controller is beyond the preset threshold. The controller was able to maintain MAP with the settling time < 10 min, the maximum overshoot < 10 mmHg (1.333 kPa), and the steady-state error within ± 5 mmHg (± 0.667 kPa) around the pressure set-point in computer simulations. The controller was also tested on 5 dogs as well as 19 patients during cardiac surgery with the aid of a supervisor module, which oversees the overall environment and thus improves the safety (21,22).

Yu et al. (23) designed a MMAC to control MAP and CO by adjusting the infusion rates of SNP and dopamine for congested heart failure subjects. There were 36 linear multiinput and multioutput (MIMO) models, represented by first-order transfer functions with time delays, to cover the entire range of possible dynamics. A model predictive controller [MPC, (24)] was designed for each individual model to find a sequence of control signals such that a quadratic cost function can be minimized. In order to save computation time, only the control signals corresponding to the six models with the highest probability weights were used to determine the drug infusion rates. The control

Figure 6. Block diagram of multiple model predictive control. [Redrawn with permission from Rao et al., Automated regulation of hemodynamic variables, *IEEE Eng. Med. Biol.* 2001; 20 (1): 24–38. (© Copyright 2004 IEEE).]

Figure 7. Modified multiple model predictive control strategy. [Redrawn with permission from Rao et al., Automated regulation of hemodynamic variables, *IEEE Eng. Med. Biol.* 2001; 20 (1): 24–38. (© Copyright 2004 IEEE).]

algorithm was tested in six dogs, including some cases with induced heart failure. It took 3–10.5 min to settle MAP within ± 5 mmHg (± 0.667 kPa) of the steady-state set-point with the mean of 5.8 min in all cases. The overshoot was between 0 and 12 mmHg (1.6 kPa) with the average of 5.92 mmHg (0.79 kPa). The standard deviation of MAP about its set-point was 4 mmHg (0.533 kPa).

The major challenge of implementing MPC in MMAC is the computation time, especially for a large model bank. Rao et al. (25) designed a MMAC with a single constrained MPC as shown in Fig. 7. The model bank, constituted first-order-plus-time-delay MIMO models spanning sufficient spectrum of model gains, time constants, and time delays, was run in parallel to obtain the possible input–output characteristics of a patient’s response to drug dosages. A Bayesian weight was generated for each model based on the patient’s response to drugs. The MPC used the combination of model weights to determine the optimal drug infusion rates. This control scheme combines the advantages of model adaptation according to patient variations, as well as the ability to handle explicit input and output constraint specifications. The controller effectively maintained MAP and cardiac output in seven canine experiments (26). Figure 8 illustrates the results of control MAP and CO using SNP and dopamine in on study. High levels of fluothane were introduced to reduce CO, mimicking congestive heart failure. The controller achieved both set-points of MAP = 60 mmHg (8 kPa) and CO = 2.3 L·min⁻¹ in ~ 12 min. In average over the entire studies, MAP was maintained within ± 5 mmHg (± 0.667 kPa) of its set-point 89% of the time with a standard deviation of 3.9 mmHg (0.52 kPa). Cardiac output was held within ± 1 L·min⁻¹ of the set-point 96% of the time with a standard deviation of 0.5 L·min⁻¹. Manual regulation was performed in the experiments for comparison. The MAP was kept within ± 5 mmHg (± 0.667 kPa) of its set-point 82% of the time with a standard deviation of 5.0 mmHg (0.667 kPa) while CO stayed in the ± 1 L·min⁻¹ band of the set-point 92% of the time with a standard deviation of 0.6 L·min⁻¹. Clearly, the automatic control performed better than the manual approach.

Rule-Based Controller

The blood pressure controllers discussed previously rely on mathematical models that can characterize plant dynamics, including the drug infusion system, human cardiovascular dynamics, and pharmacological agents. Identifying such mathematical forms could be a challenge due to the complexity of human body. Despite this, there exist experienced personnel, whose ability to interpret linguistic statements about the process and to reason in a qualitative fashion prompts the question: “can we make comparable use of this information in automatic controllers?”

In rule-based or intelligent control, the control law is generated from linguistic rules. This model-free controller usually consists of an inference engine and a set of rules for reasoning and decision making. A typical control rules are represented by *if <condition> then <action>* statements. Rule-based approaches have been proposed as a way of dealing with the complex natural of drug delivery systems and, more importantly, as a way of incorporating the extensive knowledge of clinical personnel into the automatic controller design.

One of the most popular rule-based control approaches is fuzzy control. Fuzzy control approach is based on fuzzy set theory and is a rule-based control scheme where scaling functions of physical variables are used to cope with uncertainty in the plant dynamics. A typical fuzzy controller, shown in Fig. 9, usually includes three components: (1) membership functions to fuzzify the physical input, (2) an inference engine with a decision rule base, and (3) a defuzzifier that converts fuzzy control decisions into physical control signals. More details on fuzzy set theory and its control applications are available in (27–29).

Isaka et al. (30) applied an optimization algorithm to determine the membership functions of a fuzzy blood pressure controller using SNP. This method reduced the time and efforts to determine appropriate values for a large number of membership functions. In addition, it also provided the knowledge of the effect of membership functions to the fuzzy controller performance, as well as the effect of

Figure 8. Multiple model adaptive control of MAP and CO using SNP and dopamine in canine experiment. (© Copyright 2004 IEEE).

plant parameter variations to the changes in membership functions. Efficacy of using this controller to regulate MAP by infusing SNP was evaluated in computer simulation model proposed by Slate (3). The MAP was initialized at 120 mmHg (16 kPa) at the beginning of simulation. The target MAP value was first set at 80 mmHg (10.665 kPa) and then changed to 110 mmHg (14.665 kPa). The target MAP values were achieved in < 3 min with overshoots < 10 mmHg (1.333 kPa).

Ying et al. (31) designed an expert-system-shell-based fuzzy controller to regulate MAP using SNP. The controller was a nonlinear PI-type control while the control gains were predetermined by analytically converting the fuzzy control algorithm. This converting process provided the advantage of execution time reduction. The controller was further fine-tuned to be more responsive to the rapid and large changes of MAP. It was successfully tested in 12 postsurgical patients for the total of 95 hs and 13 min. MAP was maintained within $\pm 10\%$ of its target value, 80 mmHg (10.665 kPa), 89.3% of the time over the entire test.

Neural-Network Based Controller

Artificial neural networks (ANN) are computation models that have learning and adaptation capabilities. An ANN-based controller is usually more robust than the traditional

controllers in the presence of plant nonlinearity and uncertainty if the controller is trained properly. A survey article about the use of ANN in control by Hunt et al. (32) provides more detailed information.

The use of ANN-type controller in arterial blood pressure regulation was investigated in feasibility studies in either computer simulation or animal experiments. Chen et al. (33) designed an ANN-type adaptive controller to control MAP using SNP. The controller was tested in computer simulation with various gains and different levels of noise. The controller was able to maintain MAP close to the set point, 100 mmHg (13.33 kPa) with error within ± 15 mmHg (± 2 kPa) in an acceptable tolerance settling time < 20 min.

Kashihara et al. (34) compared various controllers, including PID, adaptive predictive control using ANN (APP_{NN}), a combined control of PID with APP_{NN}, a fuzzy controller, and a model predictive controller, to maintain MAP for acute hypotension using norepinephrine. The controllers were tested in computer simulation and animal studies. The controllers based on neural network approach were more robust in the presence of unexpected hypotension and unknown drug sensitivity. Adding an ANN or a fuzzy logic scheme to the PID or adaptive controller improved the ability of the controller to handle unexpected conditions more effectively.

DISCUSSION

Numerous controllers have been developed since 1970s to regulate SNP and control MAP for hypertension patients. The control strategies can generally be classified as PID control, adaptive control (including STR, MRAC, and MMAC), rule-based control, as well as neural network control. Most controllers were developed and tested in computer simulation and animal experiments successfully. A few controllers were tested clinically with satisfactory results. Table 1 summarizes the control algorithms reviewed in this article.

Controller performance is influenced by several factors, including the fit of the process model to the plant, signal conditioning of the sensors under various clinical environments, as well as the diagnosis ability of the devices. Model selection is crucial for the stability and robustness of a controller. In blood pressure regulation, variable time

delay, patient’s sensitivity to SNP, and rennin regulatory mechanism are important factors. These factors could cause parameter variations in the plant model that might reduce the performance of a fixed-gain controller. Adaptive controllers that can adjust the control signal based on the estimation of model parameters or the probability of model errors could overcome the limit of the fixed-gain control. Some controllers have been tested in the laboratory with promising results. However, clinical applications of this type of controllers were very few. Rule-based and ANN controllers do not need a specific plant model for control design. The training signals or information must provide a broad coverage of possible events in the clinical environment to assure the reliability of the control algorithm.

Patient care practices and other aspects of the clinical environment must be considered in the design of a clinical useful system. A supervisory algorithm that can detect potential risks, determine appropriate control signals to

stably maintain a patient's blood pressure near the set point, and identify excessive noise or artifact in sensor measurements would be beneficial (21,22,31). The supervisor oversees the entire conditions of the control environment and directs the controller to take control actions efficiently and safely. Control decision is based upon sensor measurements. It is very important that the supervisor is able to process measurements and detect the nonphysiological signals, such as the noisy signals due to suction the airway and flushing the arterial catheter, and thus avoid acting on unreliable information. In addition, the supervisor must have the ability to assure the proper operation of the infusion system for drug delivery. This monitoring system should be able to detect the potential faults that could prevent abnormal operation of the device (e.g., blood clotting, infusion kinking, leakage, and infusion pump stoppage).

CONCLUSION

Because of the quick action of SNP in blood pressure reduction, frequent monitoring of MAP followed by infusion rate adjustment is necessary. The use of manual control to achieve desired MAP would be burdensome to ICU personnel, who are already loaded with many duties. Successful development of a blood pressure controller that could automatically maintain patient's MAP within a preset range with self-monitoring capability would reduce the workload of the patient care providers and improve the patient's quality of life in the clinical environment.

Blood pressure control systems designed previously provide valuable experiences for further development. The future controller should be able to adapt the characteristic changes (represented by gains, time delays, and time constants) from patient to patient as well as the variations within a patient over time. In order to improve the reliability and safety of the controller, incorporating a supervisory scheme that can monitor system operation as well as identify and manage unexpected mechanical errors and clinical environment changes with the control system would be essential.

BLOOD RHEOLOGY

ROGER TRAN-SON-TAY

INTRODUCTION

Blood rheology has had broad impact in our understanding of diseases and in the development of medical technology. Rheology is the science dealing with the flow and deformation of matter. Therefore, it encompasses work in mechanical, chemical, and biomedical engineering. It plays a vital role not only in the design, manufacture, and testing of materials, but also in the health of the human body. Biorheology is therefore concerned with the description of the flow and deformation of biological substances. More specifically, hemorrheology, or blood rheology, deals with the rheological behavior of blood, including plasma and cellular constituents.

Blood flow is known to be responsible for the delivery of oxygen to tissue and the removal of carbon dioxide. However, it also plays a pivotal role in the transport of substances (nutrients, metabolites, hormones, cells, etc.) involved not only in the maintenance of the body and its immune response, but also in diseases. For example, cancer cells are transported through blood as they spread from one tissue to another in a process known as metastasis.

The rheology of blood is altered in a number of pathological conditions. Sick cell disease is a genetic disease producing abnormal hemoglobin causing red blood cells (RBCs) to become crescent shaped when they unload oxygen molecules or when the oxygen content of the blood is lower than normal. Under these conditions, the sickle hemoglobin aggregates and the RBCs become rigid, and consequently obstruct and/or damage the capillaries. Sick cell disease is also known as sickle cell anemia because of the abnormally low oxygen-carrying capacity of the blood due to an insufficient number of RBCs and an

abnormal hemoglobin. During a heart attack or stroke, there is a partial or complete occlusion of blood vessels due to the formation of a blood clot that alters blood flow. It is clear that many diseases and factors (atherosclerosis, hypertension, vasodilator agents, etc.) can compromise blood flow by occluding vessels or modifying their rheological properties. However, the study presented here will focus mainly on the rheology of blood.

It is important to recognize that the rheological properties of blood and its components, that is, blood cells, are important in the aptitude of blood to perform its functions correctly. The ability of a blood cell to flow into capillaries or migrate through tissues is governed, but its rheological properties. In addition, flow is expected to affect cells in two ways: (1) the fluid moving over or around the cell will exert mechanical stress on the cell, and (2) the motion of fluid will alter the concentration of chemical species in the immediate surrounding of the cell, leading to the mass transport of nutrients, waste products, drugs, hormones, and so on, to and from the cell. Finally, blood rheology can also have an indirect but critical role in our immune system and in diseases since a given applied stress, such as fluid shear, can generate a signal that can induce or modify cellular response.

Blood rheology is an extremely broad subject that cannot be covered in a single review. Therefore, the scope of the present article is to provide an understanding of blood rheology, and an appreciation of its contributions to the improvement of our understanding and assessment of diseases. The article also provides a review of the most common methods used to measure the rheological properties of blood and blood cells.

RHEOLOGICAL PROPERTIES OF BLOOD

Is blood a Newtonian fluid? A Newtonian fluid is a fluid that has a viscosity that is constant and independent of the properties of the flow. This simple question is not easily answered because blood is a complex fluid. It is a non-Newtonian fluid that behaves as a Newtonian fluid under certain conditions. For example, for a shear rate $> 100 \text{ s}^{-1}$ and a vessel/tube diameter $> 500 \mu\text{m}$, blood behaves as a Newtonian fluid. Blood is composed of formed elements (red cells, white cells, platelets, etc.) suspended in plasma. Blood cells are viscoelastic particles (possess both viscous and elastic properties), whereas plasma is Newtonian. Therefore, depending on the characteristics of the flow and size of the vessel (extent of deformation), the size and properties of the blood cells may not play a major role in the flow characteristics of blood. The behavior of blood needs to be described as a function of the size of the vessel and the rate of flow. Because of that behavior, the concept of apparent and relative viscosities is introduced. The viscosity value of a non-Newtonian fluid depends on the experimental conditions and instrument used to perform the measurement. Therefore, that measured viscosity is called the apparent viscosity, μ_{app} . The relative apparent viscosity, μ_{rel} , is defined as

$$\mu_{\text{rel}} = \frac{\mu_{\text{app}}}{\mu_{\text{p}}} \quad (1)$$

Figure 1. Effect of hematocrit on blood viscosity. Plasma has a relative viscosity of ~ 1.8 at 37°C , that is a viscosity of $\sim 1.2\text{ mPa}\cdot\text{s}$. Human blood at 40% hematocrit has a viscosity of $\sim 3\text{--}4\text{ mPa}\cdot\text{s}$. However, it is a function of both hematocrit and shear rate.

where μ_p is the viscosity of plasma or other suspending medium.

In general, the viscosity of plasma is ~ 1.8 times the viscosity of water (termed relative viscosity) at 37°C and is related to the protein composition of the plasma. Whole blood has a relative viscosity of ~ 4 depending on hematocrit (RBC concentration), temperature, and flow rate. The average hematocrit for a man and a woman is 42 and 38%, respectively. Hematocrit is an important determinant of the viscosity of blood. As hematocrit increases, there is a disproportionate (exponential) increase in viscosity (Fig. 1). For example, at a hematocrit of 40%, the relative viscosity is 4. At a hematocrit of 60%, the relative viscosity is ~ 8 . Therefore, a 50% increase in hematocrit from a normal value increases blood viscosity by $\sim 100\%$. Such changes in hematocrit and blood viscosity occur in patients with polycythemia.

Because blood is non-Newtonian, the effect of shear rate is important. Figure 2 illustrates the shear thinning characteristic (decrease in viscosity as the shear rate increases) of blood at two different temperatures. On the other hand, it is clearly seen that plasma is Newtonian. It has a viscosity of $\sim 1.2\text{ cP}$ or $1.2\text{ mPa}\cdot\text{s}$ at 37°C . The poise, P, is a unit of viscosity. The different viscosity units are related as follows: $1\text{ P} = 1\text{ dyn}\cdot\text{s}\cdot\text{cm}^{-2} = 0.1\text{ N}\cdot\text{s}\cdot\text{m}^{-2} = 0.1\text{ Pa}\cdot\text{s}$; therefore, $1\text{ cP} = 1\text{ mPa}\cdot\text{s}$. The fact that blood viscosity increases at low shear is one of the key factors for the initiation of atherosclerosis at specific sites in the arterial system. Increases in the viscosity of blood and plasma reflect clinical manifestations of atherothrombotic (formation of fibrinous clot) vascular disease. High blood viscosity invariably accompanies degenerative diseases. It is therefore not surprising that many treatments involve lowering blood viscosity to treat or prevent heart attacks, strokes, atherosclerosis, and so on.

Temperature also has a significant effect on viscosity. This can be seen in Figs. 3 and 4 where the effect of temperature on the viscosity of plasma and human blood is shown. Temperature has a similar effect on plasma and water. As temperature decreases, viscosity increases. Viscosity increases $\sim 2\%$ for each degree celcius decrease

Figure 2. Effect of shear rate on blood viscosity. The Newtonian behavior of plasma and non Newtonian behavior of blood are clearly demonstrated. Plasma has a constant viscosity of $\sim 1.2\text{ mPa}\cdot\text{s}$ at 37°C . The effect of temperature on blood viscosity is also shown.

in temperature. This effect has several implications. For example, when whole-body hypothermia is used during certain surgical procedures, it increases blood viscosity and therefore augments resistance to blood flow.

The viscoelastic profile of normal human blood can be divided into three regions depending on the shear rate levels. In the low shear rate region ($\dot{\gamma} \leq 20\text{ s}^{-1}$), red cells are in large aggregates and as the shear rate increases, the size of the aggregates diminishes. Blood viscoelasticity is dominated by the aggregation properties of the red blood cells. In this region, human blood behaves like a Casson fluid with a small but finite yield stress (i.e., blood will not flow or deform unless the applied stress exceeds that critical stress),

$$\sqrt{\tau} = a + b\sqrt{\dot{\gamma}} \tag{2}$$

where a and b are constant (Fig. 5). The magnitude of the rheological parameters like yield stress and viscosity depends on various factors such as plasma protein concentration,

Figure 3. Effect of temperature on plasma viscosity. Temperature has similar effects on the viscosity of plasma and water. Viscosity increases $\sim 2\%$ for each degree celcius decrease in temperature.

Figure 4. Effects of shear rate and hematocrit on blood viscosity. The shear thinning characteristics of blood is well illustrated in this figure. The solid and dashed lines represent, respectively, whole blood and washed red blood cells in a saline solution at 45 and 90% red cell volume concentrations. (Adapted from Ref. 1.)

hematocrit, and properties of the blood cells. At low flow rates, there are increased cell-to-cell and protein-to-cell adhesive interactions that can cause erythrocytes (RBC) to adhere to one another and increase the blood viscosity. However, at shear rates $> 100 \text{ s}^{-1}$, cell aggregation and rouleaux formation break up and blood behaves as a Newtonian fluid with a viscosity of $\sim 3\text{--}4 \text{ mPa}\cdot\text{s}$ depending on the hematocrit and other factors (Fig. 6). In the mid-shear rate range ($20 \leq \dot{\gamma} \leq 100 \text{ s}^{-1}$), the cells are progressively disaggregated with increasing shear rate. Increasing shear rate causes the cells to deform and orient in the direction of flow, and the viscoelasticity of the blood is dominated by the deformability of the RBC. Figure 6 also demonstrates the effect of cell deformability on blood viscosity. It is seen that deformable cells lower the blood viscosity as compared to rigid ones.

However, when the dimensions of the cells are not negligible in comparison with the diameter of the vessel

Figure 5. Blood behavior at low shear—casson behavior. These plots were generated from blood data obtained at 25°C . They show that blood has a yield stress that depends on hematocrit. (Adapted from Ref. 2.)

Figure 6. Effects of cell aggregation and deformability on blood viscosity. The logarithmic relation between the apparent viscosity and shear rate in three types of suspensions, each containing 45% human RBCs by volume is shown. Suspending plasma viscosity = $1.2 \text{ mPa}\cdot\text{s}$; NP = normal RBCs in plasma; NA = normal RBCs in 11% albumin; HA = hardened RBCs in 11% albumin solution. (Adapted from Ref. 3.)

through which flow is occurring, the two phase nature of blood has to be recognized. Thus blood flow through vessels narrower than $500 \mu\text{m}$ in diameter is accompanied by several anomalous effects which can be directly traced to the two phase nature of blood. The important artifacts are the Fahraeus (a decrease in the hematocrit of the vessel-tube as compared to the larger feeding vessel-reservoir hematocrit) and Fahraeus-Lindqvist (a decrease in the vessel-tube apparent viscosity as compared to the larger feeding vessel-reservoir viscosity) effects. The effects are more pronounced as the vessel-tube diameter decreases. For vessel diameters $< 10 \mu\text{m}$ (capillaries), blood cells must travel in single file and the flow must be analyzed as creeping (low Reynolds number) flow of a Newtonian fluid with particles embedded in it. The transition from a single file to suspension flow occurs in the diameter range of $10\text{--}25 \mu\text{m}$ and this domain is difficult to analyze.

To add to the complexity of blood behavior, vessels also affect blood flow characteristics. For example, the most noticeable feature of blood flow in the arteries is the pulsatile nature of the flow. However, this feature is lost in the microcirculation because its effect has been dampened by the viscoelastic blood vessels. The flow in the microcirculation occurs at very low Reynolds number (i.e., inertial forces due to transient and convective accelerations are negligible) and is determined by a balance of viscous stress and pressure gradient. Individual cells must be recognized. In the capillaries, $3\text{--}10 \mu\text{m}$ diameter vessels, cells flow in single line and their flow-deformation must be analyzed. Finally, in the veins, where $\sim 80\%$ of the total volume of blood is located, the most noticeable feature is that vessels can collapse and that their mechanical properties cannot be neglected.

The above descriptions represent just some of the rheological characteristics of blood, but many more factors can affect its behavior. However, they prove the point that blood is an extremely complex fluid with many facets and that only a few have been unveiled so far.

CORRELATION BETWEEN BLOOD RHEOLOGICAL PROPERTIES AND CLINICAL CONDITIONS

Blood is a complex fluid whose flow (rheological) properties are significantly affected by the arrangement, orientation, and deformability of red blood cells. Variations in blood rheology among healthy individuals are very small. Thus, changes due to disease or surgical intervention can be readily identified, making blood rheology a useful clinical marker. Variations in blood rheology are observed in such conditions as cardiovascular disease, peripheral vascular disease, sickle cell anemia, diabetes, and stroke.

Although studies of blood rheology date from at least the early studies of Poiseuille (4), the discipline of clinical hemorheology is relatively new. It underwent a rapid growth in 1970–1980, in large part due to support by pharmaceutical companies and equipment manufacturers. Various instruments and devices were developed specifically for studying blood rheology.

Some of the early clinical tests dealing with blood rheology were on blood coagulation and the formation of blood clots. Most people think of blood in its liquid state, but its ability to thicken into a blood clot is a vital part of the body's natural defense. This process of forming a clot is referred to as coagulation. Blood coagulation, or blood clotting, is a complex process involving platelets, coagulation factors present in the blood and blood vessels. If blood becomes too thin, it loses the ability to form the blood clots that stop bleeding. When blood becomes too thick, the risk of blood clots developing within the blood vessels rises creating a potentially life-threatening condition. Blood disorders occur when hemostasis falls out of balance. Hemostasis is achieved when blood chemicals, hormones and proteins are correctly balanced. Hemostasis refers to the complicated chemical interplay that maintains blood fluidity (e.g., viscosity, elasticity, and other rheological properties).

Coagulation, or the lack thereof, is a key factor in various diseases. Sometimes thrombi (large clots) can completely occlude vessels. This can lead to ischemia, and ultimately death in any part of the body. Myocardial infarction and stroke are among the major life-threatening conditions caused by vessel occlusion due to clots. Conversely, there are various coagulatory disorders in which thrombus formation does not occur when it should. These bleeding disorders include various forms of hemophilia [e.g., (5,6)].

A great deal of research has focused on the effects of rheology on thrombus formation. Various *ex vivo* and *in vitro* systems have been designed to mimic *in vivo* blood flow in order to study thrombus formation within the circulatory system (7), and on various devices. For example, these systems have been used to model blood flow in order to study thrombus formation on stents (8) and mechanical heart valve prostheses (9). In addition, some research has focused on the effect of shear on thrombus dissolution. These studies suggest that thrombi lysis is accelerated with increasing shear rates (10,11).

It is impossible to cite all the contributions of blood rheology to our understanding of diseases in this review, but it is clear that viscosity was and still is clinically the

most commonly used rheological property. The principal factors determining blood viscosity are hematocrit, plasma viscosity, cell aggregation, and cell deformability. Earlier rheological work was mainly performed on whole blood and on RBCs because the latter are by far the most numerous cells in our body (99% of the blood cells are RBCs). However, in the last two decades, the focus has shifted toward understanding the rheology of leukocytes or white blood cells (WBC) because they have been found to be bigger and more rigid than RBC. The major motivation behind all these blood cell studies is that the ability of a cell to deform and flow through the capillaries and/or to migrate in the tissue is determined by its rheological properties, and this ability is vital in its response to disease/infection. These properties, in turn, are a manifestation of the underlying structure of the cell and the organization of the structural components (microfilaments (F-actin), microtubules, intermediate filaments, lipid bilayer) in the cellular cytoplasm and cortex.

Because blood rheology is a very broad subject, this article focuses on the role of RBC deformability in clinical studies. The role of other blood cell types, cytoskeleton, proteins, adhesion molecules, and so on., although important and of interest, is beyond the scope of this article and will not be addressed.

RBC Deformability

Deformability is a term used to describe the ability of a body (cell in the present context) to change its shape in response to an applied force. A very important characteristic of a normal RBC is that it has a surface area ~30%–40% greater than that of a sphere of equal volume. Other major determinants of RBC deformability include rheological properties of the cell membrane, and intracellular fluid.

Cell deformability can be determined by direct microscopic measurement (micropipette) or indirect estimation (filtration). By using micropipettes with diameters $\geq 3 \mu\text{m}$, the entire RBC can be aspirated. The deformability of the cell can be estimated from the pressure required for its total aspiration.

The importance of cell deformability is well established in the studies of the rheological behavior of RBCs in the capillary network. It was clearly demonstrated that reductions in RBC deformability may adversely affect capillary perfusion (12) and that many diseases manifest reductions in RBC deformability (13–15). Of the many determinants of capillary perfusion, the size of the undeformed RBC relative to the capillary diameter may play the greatest role in affecting capillary perfusion. For example, studies of the passage of RBCs through capillary-sized pores of polycarbonate sieves (16) reveal that the flow resistance may increase 30–40 times as the ratio of pore to cell diameter is reduced from 1 to 0.1. Furthermore, after entry into a capillary, the ability of RBCs to deform may play an equally important role as RBCs negotiate irregularities in the capillary lumen, as manifested by encroachment of endothelial cell nuclei on the capillary lumen (17). It was also demonstrated that the microvascular network may passively compensate for increased RBC stiffness by

shunting RBCs within the capillary network through pathways of lesser resistance (18).

There are many methods for assessing the erythrocyte deformability but only two (filtration of RBCs through pores of 3–5 μm diameter and the measurement of RBC elongation using laser diffractometry) have been widely applied clinically. A brief description of these two methods is provided below.

Erythrocyte Filtration. Filtration method has been commonly used to study the deformability of RBC. The basic idea is to force the RBC suspension to flow through 3–5 μm pores (by using a negative or positive pressure or gravity), and obtain the relationship between pressure and flow rate to estimate the deformability of the cells. Either the flow rate is measured under a constant pressure or the pressure is measured under a constant flow rate. Contaminants, such as WBC, which is poorly deformable affect the experiment by plugging the pores.

The techniques for whole-blood filtration are almost all derived from that described by Reid et al. in 1976 (19). The results of these methods are expressed as volume of blood cells (VBCs) in the time unit. However, this technique is susceptible to aggregation of RBCs and contamination with leukocytes. A modified version of the apparatus was developed to reduce these problems (20). Nevertheless, WBC contamination remains an issue with whole-blood filtration techniques.

A common drawback among all these filtrometry-based instruments is the lack of any measure of individual cell volume, thereby making it difficult to distinguish changes in RBC filtration due to the volume distribution (or aggregates) within the RBC sample from those due to intrinsically less deformable cells.

Another filtration technique that is commonly used is the Bowden assay (21,22). However, this assay involves the migration of cells (WBCs) through a filter membrane with pores of defined diameter and is beyond the scope of this article.

Erythrocyte Elongation. The Ektacytometer (23) combines viscosity with laser diffractometry. It consists of a transparent cylindrical Couette or a cone-plate viscometer, which allows a helium–neon laser beam to pass through the erythrocyte test suspension during rotational shear. The laser diffracted image becomes elliptical as the RBCs are sheared, and the ratio of the major over minor axes of the image is called the elongation index. This dynamic measurement of RBC elongation has been used for the rheological studies of congenital defects of RBC membrane protein (24), and many blood disorders (25–27).

It is important to remember that the two methods described above provide information on the bulk deformability of the RBC only, and are not suited for characterizing the deformability of subpopulations. Alternative methods need to be used for these studies. Some of the methods that have been developed for specifically characterizing the rheological properties of individual cells are provided in the next section.

RHEOLOGICAL PROPERTIES MEASUREMENTS

The goal of this section is to provide an overview of the most commonly used techniques for characterizing the rheological properties of blood. Therefore, devices will be divided into two groups: one for characterizing fluids, the other for individual cells.

Techniques for Measuring the Rheological Properties of a Fluid

Cylindrical Tube. The first studies of blood rheology have been done in cylindrical tubes. In his quest toward developing a better method for measuring blood pressure, French physician and physiologist Jean Louis (or sometimes called Leonard) Marie Poiseuille (1799–1869) studied the flow of liquid through tubes. (There is some confusion about Poiseuille's precise name and year of birth, sometimes quoted as 1797.) In 1838, he established a series of meticulously executed experiments: At a given temperature the rate of water flow through tubes of very fine bore is inversely proportional to the length of the tube and directly proportional to the pressure gradient and to the fourth power of the tube diameter. In 1840 and 1846, he formulated and published an equation known as Poiseuille's law (or Hagen-Poiseuille law, named also after the German hydraulic engineer Gotthilf Heinrich Ludwig Hagen who independently carried out friction experiments in low speed pipe flow in 1840) based on his experimental pipe flow observation. Little is known of the life of Jean Leonard Marie Poiseuille. However, he made important contributions to the experimental study of circulatory dynamics. His law can be successfully applied to blood flow in capillaries and veins, and to air flow in lung alveoli, as well as for the flow through hypodermic needle or tubes, in general (28,29).

The derivation of Poiseuille's law for a Newtonian fluid, that is, the viscosity of the fluid is constant and independent of the properties of the flow. (Viscosity is a property of fluid related to the internal friction of adjacent fluid layers sliding past one another, as well as the friction generated between the fluid and the wall of the vessel. This internal friction contributes to the resistance to flow.) For example, water and plasma are Newtonian fluids. For a Newtonian, laminar (nonturbulent) case, the flow through a cylindrical tube is one-dimensional (1D) (Fig. 7) reaching the fully

Figure 7. Flow in a cylindrical tube. Fully developed, laminar, viscous flow in tubes produces a parabolic velocity profile. The shear stress varies linearly with the radial distance r . Parameters are as follows: velocity field, $V_x = V_x(r)$, $V_r = 0$, $V_\theta = 0$; shear rate, $\dot{\gamma} = -(\partial V_x / \partial r)$; lines of shear, straight lines parallel to the tube axis; shearing surfaces, concentric cylinders.

developed state, that is, exhibiting no variation in velocity profiles in the streamwise, x direction, and the streamwise velocity, V_x , has the following distribution on any cross-section

$$V_x = \frac{R^2 \Delta P}{4 \mu L} \left[1 - \left(\frac{r}{R} \right)^2 \right] \quad (3)$$

where ΔP is the pressure drop between two points located at a distance L apart, R is the tube radius, r is the radial distance from the tube axis, and μ is the fluid viscosity.

For 1D laminar flows in pipe, the pressure gradient, ΔP , necessary to produce a given flow rate, Q , is proportional to the viscosity and, as shown from the above equation, inversely proportional to the fourth power of the tube radius,

$$\frac{\Delta P}{L} = \frac{8 \mu Q}{\pi R^4} \quad (4)$$

This equation has important clinical implications. It tells us that for a given pressure drop, a 10% change in vessel radius will cause $\sim 50\%$ change in blood flow. Conversely, for a fixed flow, a 10% decrease in vessel radius will cause $\sim 50\%$ increase in the required pressure difference. Poiseuille law tells us the consequences of having a reduced vessel lumen like in arteriosclerosis.

Thus, the average fluid velocity can be expressed in terms of the volumetric flow rate Q or pressure ΔP

$$\bar{V} = \frac{Q}{\pi R^2} = \frac{R^2 \Delta P}{8 \mu L} \quad (5)$$

For a Newtonian fluid, the shear stress distribution in the tube is linear with r ,

$$\tau = \mu \dot{\gamma} = -\mu \frac{dV_z}{dr} = \frac{r \Delta P}{2L} \quad (6)$$

The shear stress is the frictional force per unit area as one layer of fluid slides past an adjacent layer. Therefore, the maximum shear stress occurs along the tube wall and is equal to

$$\tau_z = \frac{R \Delta P}{2L} = \frac{4 \mu Q}{\pi R^3} = \frac{4 \mu \bar{V}}{R} \quad (7)$$

The viscosity of blood and other fluids have been characterized with cylindrical tube devices. For example, Cannon–Fenske viscometers are cylindrical tubes used to measure the viscosity of fluids. However, they are not commonly used for measuring non-Newtonian fluids because the shear rate generated in these devices is not constant so its effect on viscosity cannot be easily characterized.

Viscometers. Viscometers are designed to measure the viscosity of fluids. They come in many forms (e.g., concentric cylinders, parallel disks) (30), but the review will focus only on instruments that have been used to characterize biological fluids (31,32). The most common is the cone-plate arrangement (Fig. 8) because it produces a linear velocity profile and, consequently, a constant shear rate throughout the gap for small cone angles.

For a cone-plate viscometer of radius R and cone angle α_0 , the relevant parameters, such as viscosity and shear rate, can be found by setting the angular speed of rotation

Figure 8. Cone-plate viscometer. For small cone angles, the flow between the cone and the plate is linear. Parameters are as follows: velocity field, $V_\phi = V_\phi(r, \theta)$, $V_\theta = 0$, $V_r = 0$; shear rate, $\dot{\gamma} = -\left(\frac{1}{r}\right)\left(\frac{\partial V_\phi}{\partial \theta}\right)$; lines of shear, circles of constant r and z ; shearing surfaces, cones of constant θ .

of the cone, ω , and observing the resultant torque, T . These relationships are provided through the expressions of the shear stress, τ , and shear rate, $\dot{\gamma}$.

$$\tau = \frac{3T}{2\pi R^3} = \frac{\mu \omega}{\alpha_0} \quad (8)$$

$$\dot{\gamma} = -\frac{\sin \theta}{r} \frac{d}{d\theta} \left(\frac{V_\phi}{\sin \theta} \right) \cong -\frac{1}{r} \frac{dV_\phi}{d\theta} = \frac{r\omega}{d} = \frac{\omega}{\alpha_0} \quad (9)$$

In Eq. 9, d represents the gap width at a radial distance, r .

In order to measure the elastic properties, dynamic testing needs to be performed. These viscometers have to be run in an oscillatory mode so that elastic effects can be detected. In general, the rheological properties of the fluid can be described in terms of the complex viscosity η^* , or complex modulus G^* . These complex parameters are composed of a viscous and an elastic components, and are related to each other by the angular frequency of the oscillation ω ($G^* = \omega \eta^*$). It is common to mix the notation and use the viscous component, η' , of η^* , and the elastic component or storage modulus, G' , of G^* , to characterize the viscoelastic properties of the fluid. The viscous and elastic components represent, respectively, energy lost irreversibly and stored reversibly by the sample during an oscillatory cycle.

Microrheometers. As opposed to viscometers, rheometers are devices that measure not only viscosity, but also other rheological properties, like elasticity and yield stress. However, that characterization is very casual since many viscometers have been modified, as described above, to measure the viscoelastic properties of fluids.

As their names indicate, microrheometers have been developed to measure the rheological properties of small volume biological fluids. Typically, these machines require one drop of fluid or less. The design of the magneto-acoustic ball microrheometer for measuring the rheological properties of a liquid is shown in Fig. 2 (33). This instrument requires a much smaller sample size (20 μL , i.e., about a drop) than traditional rheometers, and opaque suspensions

can be studied with it. The small-volume rheometer permits accurate temperature control and rapid temperature changes for kinetics studies, if needed (34).

The instrument itself consists of a magnetically driven 0.8 or 1.3 mm stainless steel ball that is tracked by ultrasonic echo location as it moves within the sample fluid. Using a system consisting of a time-to-voltage Converter (TVC), a pulse generator, a differential amplifier, and an oscilloscope (150 MHz), ball displacements as small as $3\ \mu\text{m}$ are measured. The improved microrheometer (34) is capable of accurately measuring the viscosity of water in the very short chamber. Two measurements can be made (1) a falling-ball viscosity and (2) an oscillating-ball frequency dependent viscoelastic measurement. Parameters measured are η , the falling ball or steady-state viscosity; η' , the viscous or loss modulus; and G' , the elastic or storage modulus.

An experiment with the falling ball consists of dropping the ball along the centerline of a 10 mm long tube with a radius of 1.6 mm. The tube is surrounded by a large flow-through chamber for accurate temperature control (Fig. 9). The terminal velocity of the ball, V , is inversely proportional to the viscosity, η . In rheology, it is common to denote the viscosity as η for a viscoelastic fluid. This velocity-viscosity relationship is readily derived from the Stokes drag equation:

$$\eta = 2[(\rho_s - \rho)R^2g]/9VK \quad (10)$$

where ρ_s and ρ are the ball and fluid density, respectively, R is the ball radius, g is the acceleration due to gravity, and K is the wall correction factor to account for the tube wall effect.

Oscillating ball experiments are operated over a frequency range of 1–20 Hz, whereby the sinusoidal driving force and the resulting sinusoidal sphere displacement are recorded. The magnitude of the displacement sinusoid and its phase shift relative to the driving force provide a measure for η' and G' . The system is calibrated with a series of Newtonian silicone oils from 0.1 to 100 P (1 P = 0.1 Pa·s). For a ball oscillating in a viscoelastic medium, the viscous and elastic moduli, when inertia is negligible, are defined as

$$\eta' = \frac{F_0 \sin\phi}{6\pi KR\omega X_0} \quad (11)$$

and

$$G' = \frac{F_0 \cos\phi}{6\pi KRX_0} \quad (12)$$

where F_0 is the magnitude of the oscillating magnetic force, ω is the angular frequency of oscillation ($\omega = 2\pi f$), and X_0 is the amplitude of the ball displacement.

The viscoelastic properties of blood have been characterized using the instruments described above in an oscillatory mode. However, these viscoelastic data, although useful as a tool for comparing different blood types and diseases, are not widely used because they are difficult to relate to the mechanical properties of the blood cells. For a non-Newtonian fluid, the apparent viscosity (i.e., the slope of the curve of shear stress vs. shear rate at a particular

Figure 9. The magneto-acoustic ball microrheometer. (a) sample chamber, (b) stainless steel ball, (c) ultrasound crystal, (d) ultrasound transducer, (e) water jacket, (f) electromagnet, (g) electromagnetic bath cap, (h) water flow outlet, (i) water flow inlet.

value of shear rate) is used instead of viscosity since the latter is no longer a constant value and will depend on the rate and extent of deformation.

Techniques for Measuring the Rheological Properties of Blood Cells

Micropipette. The most popular technique for measuring the mechanical properties of blood cells is the micropipette technique (35). The micropipette manipulation technique has been used for studying liquid drops, cells, and aggregates. It has been used to investigate the effects of diseases (36,37) as well as treatments (38,39).

Micropipettes are made from 1mm capillary-glass tubing pulled to a fine point by quick fracture to give an orifice of desired diameter with a square end. The micropipette technique has been extensively used to characterize the mechanical properties of the RBC, but its use is limited in

Figure 10. Schematic of the micropipette technique. Two micropipette experiments for determining cell viscosity and surface tension are depicted. (a) Aspiration experiment; for a given aspiration pressure, the length of the aspirated cell, L_p , is tracked as a function of time. (b) Recovery experiment; a cell fully aspirated inside a pipette is expelled from it. The length of the cell, L , is recorded as a function of time.

practice by the complexity of the theory associated with the biconcave shape of the cell. As an example of the micropipette technique, work on the characterization of WBCs will be presented below. The theoretical work is simplified because the shape of a WBC can be treated as a sphere. An equivalent simulation for a RBC will require extensive numerical work. Two typical types of experiment, aspiration and recovery (Fig. 10), are usually performed to determine the mechanical properties of individual WBCs (40–43).

Aspiration. Passive leukocytes (WBCs) are aspirated at a constant pressure into a micropipette. The length of the aspirated cell, L_p , is measured over time to generate an aspiration curve (Fig. 10a). Viscosity values, μ , can be derived from the slope, dL_p/dt , of the aspiration curves (42):

$$\mu = \frac{(\Delta P)R_p}{(dL_p/dt)m(1 - \frac{1}{\bar{R}})} \quad (13)$$

where ΔP is the aspiration pressure, R_p is the pipet radius, $\bar{R} = R/R_p$, R is the radius of the cell outside the pipette, and $m = 6$. Figure 11 shows the aspiration of a white blood cell (lymphocyte) into a $4 \mu\text{m}$ diameter pipette. Fluorescence is used to better see the deformation of the cell nucleus.

Recovery. White blood cells are drawn by a small suction pressure into a micropipette, held there for ~ 15 s, and quickly expelled out. The changing length of the cell, L , as it recovers its spherical shape (Fig. 10b), is recorded as a function of time, t , and is described by a polynomial (43):

$$\frac{L}{D_0} = \frac{L_i}{D_0} + A\bar{t} + B(\bar{t})^2 + C(\bar{t})^3 \quad (14)$$

Figure 11. Flow of a lymphocyte inside a $4 \mu\text{m}$ pipette. The flow of an $8 \mu\text{m}$ lymphocyte (a WBC) inside a $4 \mu\text{m}$ diameter micropipette as a function of time is shown. Fluorescent technique was used to track the cell nucleus as well as the cellular membrane.

where A , B , C are known functions of (L_i/D_0) . The parameters L_i and D_0 are the initial deformed length and resting diameter of the cell, respectively. The variable $\bar{t} = 2t/[(\mu/T_0)D_0]$ represents a dimensionless time, where μ is the cell viscosity, and T_0 is the surface tension of the membrane.

Figure 12 shows a lymphocyte (about $8 \mu\text{m}$ in diameter) aspirated inside a $4 \mu\text{m}$ diameter pipette (top picture). The cell is then expelled from the pipette and recovers its initial shape (bottom, left-hand side pictures). Pictures generated on the right hand side are from numerical simulation (44). In addition to the experimental techniques, significant progress has been made in the computational capabilities to simulate the dynamic behavior of blood at both large vessel and cellular scales (45).

Rheoscope

To allow direct observation of suspended cells during shear stress application, a modified cone-plate viscometer, called a rheoscope (Fig. 13), has been developed (46). In which the cone and plate counterrotate. This gives the advantage that a particle midway between the cone and plate is subjected to a well-defined shear stress field and remains nearly stationary in the laboratory frame of reference so that it can be studied without the help of high speed cinematography. It is important to note that, for an identical speed of rotation, that the shear rate generated in the rheoscope is twice that in the

Figure 12. Pictures of a lymphocyte inside a pipette and its recovery. The top left frame is a picture of a lymphocyte (a type of leukocyte) aspirated inside a micropipette, the frames below it show the cell recovering its initial shape. Pictures on the right hand side are those generated by a theoretical compound drop model (44).

Figure 13. The Rheoscope. The main feature of this instrument is the counterrotation of the cone and plate. This gives the advantage that a particle midway between the cone and plate, subjected to a well-defined shear stress can be studied without the help of high speed cinematography. At a distance r from the axis of rotation, the shear rate is equal to $\dot{\gamma} = 2r\omega/d$, where d is the local gap width and ω is the angular velocity of the cone and plate

Figure 14. Parallel-Plate Flow Channel. The velocity profile is parabolic, and the shear rate is linear with y . Parameters are as follows: velocity field, $V_x = V_x(y)$, $V_y = 0$, $V_z = 0$; shear rate, $\dot{\gamma} = (\partial V_x / \partial y)$; lines of shear, straight lines parallel to the channel axis; shearing surfaces, plane surfaces parallel to the channel axis.

conventional cone-plate viscometer because of the counter rotation of the cone and plate. Effects of shear and mechanical properties of individual cells and anchorage dependent cells have been determined with the rheoscope (e.g., 1,36,47-49). The rheoscope is popular for studying RBC under shear because the analysis of the behavior of RBC is simplified since its shape is an ellipsoid.

Parallel Plate Flow Channel. Another popular technique for characterizing the rheological properties of blood cells under flow or for studying the effects of shear stress on anchorage dependent cells is the parallel plate flow system (Fig. 14).

The flow between infinite parallel plates is often referred to as plane Poiseuille flow. The velocity field reduces to one component in the direction of flow, V_x ,

$$V_x = \frac{h^2 \Delta P}{8 \mu L} \left[1 - \left(\frac{2y}{h} \right)^2 \right] \quad (15)$$

where h is the distance between the plates, μ is the fluid viscosity, ΔP is the pressure drop between the inlet and outlet located at a distance L apart, and y is the vertical distance from the origin taken at the centerline of the channel.

The relationship between the pressure drop and volumetric flow rate Q is

$$\Delta P = \frac{12 \mu Q L}{w h^3} \quad (16)$$

where w is the channel width.

From the velocity field, Eq. 5, the shear rate across the channel gap is readily derived:

$$\dot{\gamma} = -\frac{dV_x}{dy} = \frac{12 Q}{w h^3} y \quad (17)$$

For a Newtonian fluid, the relationship between shear rate and shear stress, τ , is linear, and the shear stress across the flow channel gap is

$$\tau = \mu \dot{\gamma} = \frac{12 \mu Q}{w h^3} y \quad (18)$$

From the above equation, the shear stress is zero along the channel centerline, and the maximum shear stress, τ_s , is at the surface of the plate

$$\tau_s = \frac{h \Delta P}{2L} = \frac{6 \mu Q}{w h^2} \quad (19)$$

Vote stressed that, although they allow direct observation of individual particles, these devices do not provide a direct measurement of the particle viscosity. It is necessary to know the material constitutive properties of the particles, that is, expressions that relate stresses to strains, or to develop a mathematical model in order to determine the mechanical properties of the particles. Existing models can describe fairly accurately the rheological behavior of blood cells, but the exact rheological property values of these cells, with the exemption of red blood cells, are not known. That topic will not be covered here. For a review on the mechanical properties of blood cells, the reader is referred to Waugh and Hochmuth (35), and for a discussion on the discrepancy between the rheological data on white blood cells reported in the literature to Kan et al. (44).

CONCLUSION

Some of the major advances in blood rheology are now being linked to the development and application of microfabrication to medicine. As reviewed by Voldman et al. (50) and Shyy et al. (51), these new tools will be used to better characterize the rheological properties of blood and blood cells, as well as to detect and diagnose cardiovascular and blood related diseases. Microfabrication is a process used to construct objects with dimensions in the micrometer to millimeter range. These objects are composed of miniature structures that can include moving parts such as cantilevers.

Soft lithography is a tool for micro/nanofabrication. It provides a convenient and effective method for the formation and manufacturing of micro- and nanostructures. Soft

lithography is the collective name for a set of techniques that include replica molding, microcontact printing, micro-transfer molding (52). The major advantages of soft lithography are that it is very fast as compared to conventional methods, relatively inexpensive, and applicable to almost all polymers. It is possible to go from design to production of replicated structures in < 24 h. In soft lithography, a master mold is first made by a lithographic technique, and an elastomeric stamp is then cast using the master mold. The elastomeric stamp with patterned relief structures on its surface is used to generate patterns and structures with feature sizes as small as 30 nm (53). Polydimethylsiloxane (PDMS) is the polymer of choice for many biological applications because it is optically transparent, isotropic, homogeneous, durable, and has interfacial properties that are easy to modify (53,54). As opposed to photolithography, soft lithography provides a mean for producing nonplanar surfaces.

Microfabricated devices, also known as microelectromechanical systems (MEMS), are ideal tools for studying specific biological phenomena, for example, cell adhesion, as well as biological systems such as the microcirculation. For example, the fabrication of *in vitro* blood vessels can help to (1) determine blood cell distributions during blood flows through both arterial and venous type bifurcations, with successive bifurcations arranged as in microcirculation; (2) validate computer simulations and experimental methods used for *in vivo* measurements of parameters such as blood average velocity and hematocrits; and (3) to separate vessel or wall effects from hemodynamics effects. Figure 15 shows channels that were created using soft lithography. The different configurations shown are a series of 10 mm diameter channel in parallel, a series of

Series of 5 channels (150µm long × 10µm width) in parallel with smooth surface

Series of channels with endothelial cell pattern surface

Channel with constriction, smooth surface

Channel with bifurcation Smooth surface

channels with an endothelial cell like pattern surface, a channel with a constriction, and a channel with a bifurcation.

The application of MEMS in the area of microfluidics is a new and emerging field. It includes the development of miniature devices in fluid control, fluid measurement, and medical testing. Because of our need and interest in understanding, preventing, and treating diseases, most of the emerging MEMS applications are expected to be in biomicrofluidics. One of these applications is the development of gene chips and related deoxyribonucleic acid (DNA) tools. Others applications include microscale chemical analysis, known as microelectrophoresis, blood chemistry measurements using micromachined thin-film sensor, micropumps, drug delivery systems, glucose sensors, and chip-based microflow cytometry devices.

The major advantages of MEMS-based devices are that they are smaller and have the potential to be less expensive, more durable, and more reliable than conventional techniques. In addition, they can perform chemical tests much faster.

Finally, another area that will benefit from the advancement of technology is the development of blood substitutes. This is a needed area since the demand for blood continues to outpace the supply, especially in developing countries. With new technologies, the life span of blood substitutes based on cell-free hemoglobin, which is presently too short, could be lengthened. New methods could also be developed in order to produce human red cells, and other cell types, in culture.

Needless to say that, in order to be successful, all these new technical advances will need to be combined with an improved understanding of cell biology and rheology. This advancement will also depend on the successful incorporation of more sophisticated mathematical and computational techniques. In general, the field of biorheology is moving towards better understanding phenomena at the molecular level. For example, the knowledge of the signal transduction pathways associated with the responses of cells to deformation is essential in the field of tissue engineering, where mechanical environment during growth can affect cell response and the material properties of the tissue construct or living implant.

It is clear that blood rheology plays a major role in the maintenance of the human body and in the development of artificial organs and other medical devices, but our understanding, of that role and of the clinical implications of having an altered blood rheology, is far from being complete.

BLOOD, ARTIFICIAL

BRIAN WOODCOCK
University of Michigan
Ann Arbor, Michigan

INTRODUCTION

Blood has such a multitude of physiological functions; it provides a circulating volume to transport substrate and metabolites, and it transports the most valuable of substrates, oxygen. It is an organ intimately involved in the immune system, delivering antibodies and cellular elements to sites of infection. It carries the instruments for coagulation. It is the communication highway for the endocrine system. It is a metabolic organ containing enzyme systems to convert molecules to active and inactive forms. Blood is intimately involved in temperature regulation. The manufacture of an artificial substitute to fulfill all those purposes is beyond the capability of current science. However, several of the functional capabilities of blood have been incorporated into various blood substitutes.

The most basic function of blood is to provide a circulating volume for transportation of substrate and metabolites. Supplementation of intravascular volume with crystalloid and colloid fluids has been a part of medical practice for a century. Recent progress has concentrated on the development of substitute solutions that can transport oxygen. These solutions are known as oxygen therapeutics or red cell substitutes.

Currently, the only available oxygen therapeutic is typed and cross-matched allogeneic human blood. This is made available in the civilian setting by the Red Cross, the American Blood Centers, and the blood banking system. Blood shortages, due to increasing blood usage and declining blood donations (1), are one of the factors driving the

search for alternatives. In the past two decades there has also been an increasing concern regarding the infectious risks of blood borne pathogens (2,3). Awareness of the potential significance of the problem occurred with the increasing risk of human immunodeficiency virus (HIV) transmission from blood transfusion during the 1980s. Improved screening for HIV in the 1990s saw a dramatic improvement in blood safety so that now the risk of contracting HIV from a unit of blood is approaching 1/1,000,000. But there are still substantial concerns regarding not only the risk of contracting acquired immune deficiency syndrome (AIDS) or hepatitis, and also of other infectious diseases newly recognized as possibly being transmissible by transfusion, such as bovine spongiform encephalopathy (mad cow disease) and West Nile virus.

Another concern leading to the need for blood substitutes is that some groups Jehovah's Witnesses, have religious beliefs that cause them to refuse all blood products.

Banked blood is often wasted while active bleeding continues in the surgical setting. While hemorrhage continues, blood products administered are rapidly lost through the site of bleeding. Blood substitutes could be used as a resuscitation bridge until bleeding is controlled (4).

Initial research on artificial blood was lead by the U.S. military, which needed a ready supply of a substitute that could be stored easily and indefinitely in the field and not require typing or cross-matching. These considerations would also make a blood substitute valuable to the emergency medical services in ambulance and helicopter transfers.

All these concerns have stimulated efforts to develop red cell substitutes for use in the routine clinical setting. In an initial approach, prior to World War II, the defense department sought a hemoglobin solution that could be stored indefinitely at room temperature, preferably in a powdered form to be dissolved in normal saline, and that could be transfused without a need for cross-matching. Although the development of a reconstitutable powder has not been feasible, there are several hemoglobin-based products that are in various stages of clinical testing (5).

Other molecules apart from hemoglobin have been assessed for the function of oxygen transportation. Most success has been achieved with emulsions of perfluorochemicals.

Perfluorochemicals are inert liquids, which have a solubility for oxygen and carbon dioxide 20 times that of water. These liquids are immiscible in water and an emulsion form is required to allow them to mix with the recipient's blood after administration. A comparison of the advantages and disadvantages of perfluorocarbon and hemoglobin solutions is shown in Table 1.

Emulsions of perfluorochemicals have completed animal testing and have been investigated in the clinical setting. However, difficulties in their use have been observed, to date they have not been made available for routine use.

CURRENT RISKS OF BANKED BLOOD

Risks of Transfusion

Blood transfusion is safer today than it has ever been, with a death rate for each blood transfusion of ~ 1 in 300,000 (6).

Table 1. Comparison of Perfluorocarbon and Hemoglobin Solutions

	Advantages	Disadvantages
Perfluorocarbon Emulsions	High O ₂ Solubility Inert Ample supply	Requires high PO ₂ Long tissue life Short vascular life Toxicities
Hemoglobin Solutions	Carry O ₂ at normal P _a O ₂ Unloads like RBCs May be stored dry?	Vasoconstriction Supply Short vascular life Toxicities

Two-thirds of these deaths are due to clerical errors (i.e., the wrong blood given to the wrong patient). Other risks associated with blood transfusion include infection and immune reactions (7,8). However, 20 million blood transfusions are administered each year in the United States, with an impressive safety record (9).

Infection

The risk of transmission of infection includes viral agents, other exotic infectious agents, and the risk of bacterial contamination of blood products. Blood donors with a history of risk factors are excluded from donation. Screening donated units and elimination of units that contain known infectious agents eliminates most of the remaining risk of infection.

HIV

The risk of HIV transmission from blood transfusion has caused the most public concern, though it is difficult to accurately assess the true risk of transmission because it is small and cases can be determined only after a significant period. Initial testing for HIV consisted of antibody testing alone, but this was felt to leave a risk of HIV from individuals who were infected, but had not yet sero-converted. In March 1996, HIV antigen p24 testing was instituted in the United States and only 3 out of 18 million units were identified as being antibody negative and antigen positive over the next 18 months (10). Blood donations are now tested for HIV-1 and HIV-2 (11). The apparent risk of HIV transmission is currently ~ 1 in 1,000,000.

Hepatitis

Hepatitis has a higher prevalence; 1:60,000 for hepatitis B, and 1:103,000 for hepatitis C, but is much less feared by the general public. Antigen screening tests have reduced the risk of post-transfusion hepatitis (B or C) to < 1 in 34,000 (12). Hepatitis G has more recently been recognized, and has a high incidence worldwide of 1 (13)–7% (14). Approximately 2% of blood donors and 15–20% of intravenous drug abusers in the United States have detectable hepatitis G (15). It may be identified by the polymerase chain reaction test, but this has not been implemented as a routine screening test. Fortunately, it appears that the hepatitis G virus is not responsible for non-A, non-B, non-C post-

transfusion hepatitis and the results of infection appear to be minimal (16,17), although there is a weak link between hepatitis G and fulminant hepatitis in rare cases (18).

Other Viruses

Creutzfeldt–Jakob disease (vCJD) can be transmitted by transfer of central nervous system tissue (or extract). However, no cases have been definitively linked to blood transfusion (19).

In the United Kingdom an outbreak of bovine spongiform encephalopathy (BSE) or “Mad Cow Disease” has led to concern that a new variant vCJD could be transferred to the human population through consumption of contaminated beef products. Transmission of BSE by blood transfusion can occur in sheep (20). In the United Kingdom, blood products for transfusion are leucodepleted, which is thought to reduce the risk of transmission of vCJD. The possibility that infection might occur has led the U.S. Food and Drug Administration (FDA) to institute a policy “deferring”, that is, declining, blood donations from anyone who has lived in the United Kingdom for a cumulative period of more than 6 months during the years 1980–1996 (21).

West Nile virus transmission has occurred in four patients who received solid organ donations from an infected donor. The organ donor had received blood transfusions from 63 donors, and follow up of those donors showed that one of them was viremic at the time of donation (22).

Bacterial contamination of stored blood is rare (1:500,000), but has a mortality rate of 25–80%. The most common infectious contaminants in red cells are gram-negative species such as *Pseudomonas* or *Yersinia* (23). Platelets are stored at room temperature, allowing rapid bacterial proliferation, and there is a risk of 1:3000–7000 of bacterial infection with these units. Bacterial contamination of platelets is typically with Gram-positive staphylococci.

Immune Reactions

Minor immune reactions, such as febrile reactions, are common and may be discomforting to the patient, but are not associated with significant morbidity, though the transfusion may have to be stopped and the product discarded. The risk of serious immune reactions is small, but present. Most acute hemolytic reactions are due to clerical errors, because cross-matching should predict and prevent these events. However, immune reactions remain the most common cause of fatality associated with transfusions.

Graft versus host disease may occur rarely after transfusion, most commonly after transfusion of nonirradiated blood components to patients with immunodeficiency. Transfusion-associated graft versus host disease has a high mortality and is rapidly fatal. Immunodeficient patients should receive irradiated units. Immunocompetent individuals may develop graft versus host disease if common histocompatibility leukocyte antigen haplotypes between the donor and recipient prevent destruction of stem cells transfused. This can occur between first-degree family members and therefore, relative-to-patient-directed

donations, which are often preferred by patients because of a perceived reduction in risk of infection, may in fact carry an increased risk of initiating transfusion-associated graft versus host disease.

Transfusion-related immunomodulation has been recognized since the mid-1970s, but is not well quantified. Exposure to allogeneic blood can cause both allosensitization and immunosuppression. Studies have demonstrated a beneficial effect of allogeneic blood transfusion on transplant organ survival, but increases in the rates of cancer recurrence and postoperative infection have also been noted (23,24). Leukocyte depletion and removal of plasma may ameliorate the effects of TNF- suppression and interleukin induction (25).

The risk of infection and concerns regarding immune reactions and immunomodulation have been a large incentive to the development of oxygen-carrying colloids.

PERFLUOROCHEMICAL EMULSIONS

Perfluorochemicals (PFCs) are chemically inert liquids with a high solubility for gases. The PFCs that have been used as blood substitutes are 8–10-carbon atom structures that are completely fluorinated. The PFCs are chemically inert, clear, odorless liquids with a density nearly twice that of water. The solubility of PFCs for oxygen is nearly 20 times that of water.

In 1965, Clark and Gollan (26) performed an experiment to see whether an animal could survive if it breathed liquid PFC equilibrated with 1 atm of oxygen. A rat could be submerged beneath this liquid for 30 min and be retrieved in good condition. Respiration of liquid PFC allowed oxygen absorption from the lungs together with CO₂ excretion.

An intravenous injection of PFC is immediately lethal because the injectate is immiscible with water and forms a liquid embolus. An emulsion of an immiscible liquid can, however, mix with water or blood. In 1968, Gehes (27) produced a microemulsion (particle size, 0.1 μm) of a PFC in normal saline. An exchange transfusion could be done, eliminating all normal blood elements, and a rat with a hemoglobin of 0 could survive breathing 100% oxygen.

Because of the inert nature of these compounds, they are not metabolized, but are cleared from the vascular space by the reticulo-endothelial system (RES), and ultimately collected in the liver and spleen. Eventually, the PFC slowly leaves the body as vapor in the respiratory gas.

Perfluorochemical Oxygen Content

Because PFCs transport oxygen by simple solubility, the amount of oxygen they carry is directly proportional to the percentage of PFC in the bloodstream and to the P_aO_2 .

Hemoglobin carries most of the oxygen in whole blood and does so in a nonlinear fashion. The plot of oxygen content against P_aO_2 for hemoglobin, known as the oxygen dissociation curve, is seen in Fig. 1. Perfluorochemicals (PFCs) carry oxygen by direct solubility, as does plasma. Because of the shape of the oxygen dissociation curve, hemoglobin is fully saturated and carries little or no more oxygen above a PO_2 of 90 mmHg (11.99 kPa). Because oxygen content dissolved in plasma, or carried by PFCs,

is linearly related to PO_2 , additional oxygen is dissolved in the plasma phase or by PFC as oxygen tension increases.

Arterial content of oxygen (C_aO_2) is defined as the volume of oxygen in milliliters (mL) carried by each 100 mL of blood and is defined as follows:

$$C_aO_2 = (\text{Hb} \times 1.34 \times S_aO_2) + (0.003 \times P_aO_2) \quad (1)$$

$$\approx 20 \text{ mL}/100 \text{ mL}$$

(Hb = hemoglobin; S_aO_2 , arterial oxygen saturation; P_aO_2 , arterial oxygen tension)

With a normal 15 g of hemoglobin and normal P_aO_2 and S_aO_2 values of 90 mmHg (11.99 kPa) and 97%, respectively, an arterial oxygen content of 20 mL · dL⁻¹ is obtained.

When blood contains an oxygen carrying PFC, the oxygen content equation requires a third term to represent the contribution from perfluorocarbon.

$$C_aO_2 = (\text{Hb} \times 1.34 \times S_aO_2) + (0.003 \times P_aO_2) + (0.057 \times \text{Fct}/100 \times P_aO_2) \quad (2)$$

where Fct = fluorocrit, which is the fraction of the blood volume that is PFC (analogous to the Hct).

Note that the solubility factor of PFC in the third term should be 0.06, that is, 20 times that of the solubility factor for oxygen in plasma (0.003), however, it is reduced by the amount of the plasma solubility factor to account for the plasma displaced by the presence of PFC.

The PFCs carry much more oxygen than plasma, but hemoglobin itself is able to carry much more than any PFC. Figure 1 shows that blood with a Hct of 45% will have a C_aO_2 of 20 mL/100 mL at a PO_2 of 100 mmHg (13.33 kPa), but a solution with a Fct of 45% would have an oxygen content of 2.7 mL/100 mL. Because the PFC carries oxygen by direct solubility, it also releases it in direct proportion to the PO_2 , unlike the cooperative binding effect of Hg, with which the PO_2 has to fall below the elbow of the curve for

Figure 1. Oxygen content plotted against PO_2 for whole blood, plasma, and a perfluorochemical emulsion, with a 45% content of PFC. Hemoglobin saturates at a PO_2 of 100 mmHg (13.33 kPa), but the curve continues to rise because of the dissolved oxygen in plasma, so the whole blood and plasma lines are parallel above a PO_2 of 100. The line for perflubron is similar to plasma, but has a higher slope because of the greater affinity for oxygen (Hct = hemocrit).

oxygen release to occur. The potential contribution of PFCs to oxygen transport can be assessed by looking at the oxygen consumption required by tissues, the Fct and the PO_2 required to allow this quantity of oxygen to be released in the tissues (28).

Mixed venous blood has an oxygen content of 15 mL/100 mL; therefore 5 mL/100 mL of oxygen is consumed in the periphery.

If we assume a mixed venous oxygen tension (P_vO_2) level of 40 mmHg (5.33 kPa) and an oxygen extraction of 5 mL/dL, a bloodless animal could survive with a Fct of 45% with a P_aO_2 of 235 mmHg (31.33 kPa). Any increase in P_aO_2 above this value would raise the P_vO_2 by the same amount (Fig. 2). The elevated P_vO_2 in these circumstances could have the beneficial effect of increasing the pressure gradient for oxygen diffusion from the vascular space into the tissues and cells, theoretically increasing tissue oxygenation.

It is, however, difficult to manufacture a 45% emulsion of PFC. In the late 1970s, the Green Cross Corporation in Japan developed a product called Fluosol DA 20%. This solution contains only 10% PFC (Fluosol DA 20% is 20% by weight, 10% by volume). To supply 5 mL/100 mL of oxygen consumption and a P_vO_2 of 40 mmHg (5.33 kPa), a bloodless animal with a fluorocrit of 10% would require a P_aO_2 of 920 mmHg (122.65 kPa).

In practice, this would make it difficult to completely replace the blood with PFC emulsion. Although the emulsion is cleared from the vascular space within 24 h, the long tissue half-life of a PFC in the body (months to years), make it unfeasible to continuously redose the patient.

Figure 2. At an arterial PO_2 (P_aO_2) of 300 mmHg (13.33 kPa) blood has an oxygen content of 21 mL/100 mL. If 5 mL/100 mL are extracted the venous PO_2 (P_vO_2) will be < 50 mmHg. A PFC with a Fct of 45% could carry enough oxygen at a P_aO_2 of 235 to deliver 5 mL and give a similar P_vO_2 . Increasing the P_aO_2 to 300 mmHg (39.99 kPa), increases the oxygen carried by the PFC so the P_vO_2 will be > 100 mmHg (13.33 kPa) after delivery of 5 mL O_2 . (Adapted, with permission, from Woodcock BJ, Tremper KK. Red Blood Cell Substitutes. In: Evers AS, Maze M, editors. Anesthetic Pharmacology, Physiological Principles and Clinical Practice: A Companion to Miller's Anesthesia. Philadelphia: Churchill Livingstone; 2004.)

Figure 3. Structures of the constituents of Fluosol DA; perfluorodecalin (a) and perfluorotripropylamine (b).

CLINICAL STUDIES WITH PFCs

Fluosol DA

Fluosol DA 20% was developed in the 1970s and was an emulsion composed of two perfluorochemicals; perfluorodecalin, which has emulsion stability and perfluorotripropylamine, which has a shorter half-life (29) (Fig. 3). The surfactant used to maintain this emulsion of Fluosol DA was Pluronic F68, an emulsifier used in other medical products. The product needed to be frozen to maintain stability until used.

Initial clinical studies were in patients who were actively bleeding, required surgery, and refused blood transfusion. A 20-mL·kg⁻¹ body weight of Fluosol DA 20% PFC emulsion was transfused preoperatively with a maximum of one additional dose postoperatively (29,30). The patients achieved a maximal fluorocrit of <3% with an intravascular half-life of ~19 h. Subsequent studies confirmed the oxygen-carrying contribution of the PFC, but could not show a beneficial effect on patient outcome (31).

Fluosol DA 20% gained FDA approval, not for use as a red cell substitute but for intracoronary infusion in patients undergoing angioplasty. Fluosol is no longer being manufactured because of low demand.

Perflubron

Second generation PFC emulsions have been developed. One of these, Oxygent, employs perfluoro-octylbromide or perflubron (32) (Fig. 4). This PFC has one bromine replacing fluorine, making it radiopaque. The emulsion (Oxygent: Alliance Pharmaceutical, San Diego, CA) contains 60% PFC by weight, or 30% by volume. It is emulsified with lecithin (egg yolk phospholipids) and is stable at room temperature for >6 years.

Because of a short intravascular half-life and the need for a high F_iO_2 , it has been suggested that these PFC solutions should be used in conjunction with acute normovolemic hemodilution. In this setting, patients who are expected to have significant surgical blood loss should have two to four units of blood removed immediately before surgery. Initial volume expansion is with crystalloid or

Figure 4. Structure of perfluoro-octylbromide (Perflubron, Oxygent).

colloid. As surgical bleeding continues, the PFC is administered at the first transfusion trigger, allowing for adequate oxygen delivery at low hemoglobin levels. When surgical bleeding stops, the patient would receive the previously harvested autologous blood.

The European Perflubron Emulsion Study Group looked at this technique of normovolemic hemodilution in orthopedic surgery. Perflubron was administered in response to transfusion triggers of tachycardia, hypotension, increased cardiac, and decreased mixed venous PO_2 . The triggers for transfusion were at least as effectively reversed by perflubron, with 100% oxygen ventilation, as by autologous transfusion or colloid administration (33). Patients who received perflubron had higher mixed venous PO_2 levels, which continued for longer than the other treatment groups. Allogeneic blood transfusion requirements were not reduced by perflubron administration.

A phase III cardiac surgery study of perflubron was voluntarily suspended in 2001 because of an increased incidence of stroke, but it has not been determined if this was due to PFC administration.

A phase III study of perflubron in noncardiac surgery, again from the European Perflubron Emulsion Study Group (34), in 492 patients showed an intraoperative reduction in blood transfusion requirement, but there was no significant reduction by time of the postoperative period. Of the patients in the intent-to-treat population, 33% experienced low (<20 mL·kg⁻¹) blood loss. When these patients were excluded to leave a protocol defined target population, the patients treated by acute normovolemic hemodilution (ANH) and PFC administration experienced a reduction in transfusion that remained significant throughout the study (3.4 vs. 4.9 units). The PFC group also had a significantly greater avoidance of transfusion (26 vs. 16%). The clinical relevance of these findings is hard to elucidate. The control group did not undergo ANH and had higher transfusion triggers during the operative period, it is difficult to tell if the benefit accrued was due to the PFC or the hemodilution technique (35).

Microcirculation and Oxygen-Carrying Colloids

Oxygen-carrying colloids differ from red cells in terms of size. Free hemoglobin molecules in solution range in size from 68,000 to 500,000 Da, and the fluorochemical emulsion particles are ~0.2 μm. These sizes are within the range of many of the plasma proteins, and like plasma proteins, PFCs are able to cross the capillary basement membrane and participate in extravascular circulation. Animal data have shown that these oxygen-carrying colloids leave the intravascular space and rejoin it through lymphatic circulation (36). Thus, these colloids may be able to provide increased oxygen delivery to the extravascular space (37,38). In addition, studies on microcirculation have shown that plasma flow continues through capillaries even when the capillary is closed to red blood cells. Oxygen delivery to tissues can be provided, even though red cells are not present in the capillaries, through the circulation of oxygen-carrying colloids.

This potential application of blood substitutes, as “therapeutic oxygenating agents” for ischemic tissue, has been

investigated for myocardial ischemia (39–41) and for enhancing the effectiveness of radiation therapy and chemotherapy of ischemic tumors by rendering the tumor hyperoxic (42,43).

Perfluorochemicals have been used in other circumstances as oxygen-carrying molecules. The PFCs have been used for cardioplegia (44) and preservation of transplanted organs (45–47). The PFCs have also been studied in models of myocardial and cerebral infarcts to minimize infarct size (45,48,49).

Liquid Ventilation with PFC

Perfluorochemicals have been used for liquid ventilation in the treatment of acute respiratory distress syndrome (ARDS). The PFCs bind oxygen and carbon dioxide avidly. Perflubron (LiquiVent, Alliance Pharmaceutical Corp., San Diego, CA) can be instilled into the endotracheal tube of a ventilated patient with ARDS until a fluid level is seen outside the patient. The ET is then connected to the normal ICU ventilator and sufficient gas transfer occurs across the PFC–gas interface to allow oxygenation of the patient and CO₂ clearance (50,51). This PFC has excellent surfactant properties and is possibly able to stent open alveoli (leading it to be termed “liquid PEEP” or “PEEP in a bottle”) (52). There are also benefits of increased secretion clearance and possible antiinflammatory effects (53,54). Studies to date have not shown any benefit over conventional ventilation (55).

Future of PFCs

The PFCs have inherent limitations of a short endovascular half-life and the requirement for high inspired oxygen. These problems limit the use of PFC emulsions to acute settings in which supplemental oxygen is readily available. It is yet to be seen whether PFCs can have a useful role as blood substitutes.

HEMOGLOBIN SOLUTIONS

Hemoglobin Solutions: Oxygen Content

When a solution of free hemoglobin (FHb) has the same *P*₅₀ as blood (27 mmHg 3.59 kPa), there is no difference between the hemoglobin solution oxygen-content curve and the curve for normal whole blood.

$$C_{aO_2} = (\text{FHb} \times 1.34 \times \text{FS}_{aO_2}) + (\text{Hb} \times 1.34 \times \text{S}_{aO_2}) + (0.003 \times P_{aO_2}) \quad (3)$$

[FHb is the concentration of free hemoglobin solution in blood (g · dL⁻¹), and FS_{aO₂} is the saturation of FHb.]

In clinical practice, arterial content of oxygen can be calculated using a single term for hemoglobin and saturation. A spectrophotometrically measured total hemoglobin should be used, which will measure total hemoglobin present, whereas the hematocrit only measures red blood cell hemoglobin. The saturation measured by an oximeter gives a mean saturation of both forms of hemoglobin because the device measures the amount of oxyhemoglobin and divides it by total hemoglobin to achieve the calculated saturation.

Formulation of Hemoglobin Solutions

A solution of hemoglobin from lyzed human red cells is unusable as a blood substitute for a variety of reasons. Hemoglobin outside the red cell membrane loses its tetrameric form and breaks down into dimers. The abundance of dimers in plasma has a pronounced oncotic effect creating an excessively high colloid oncotic pressure (41). This would draw fluid from the extracellular space and would cause an increase in circulating blood volume. The dimers have a molecular weight of 32,000 Da and are able to cross the renal glomerular basement membrane leading to a potent osmotic diuretic effect. The loss of oxygenated hemoglobin in the urine gave the early solutions the reputation of being “red mannitol”.

The loss of 2,3-DPG, which is normally maintained inside the RBC, reduces the *P*₅₀ of hemoglobin to 12–14 mmHg (1.59–1.86 kPa) from a normal level of 26. This shifts the oxygen dissociation curve markedly to the left, meaning that the free hemoglobin will avidly bind oxygen during passage through the lungs but will not release it in the peripheral tissues unless the *P*_{O₂} is extremely low.

The early attempts at making a hemoglobin solution used resuspended hemoglobin filtered from lyzed, outdated, human blood. This solution caused a high incidence of renal failure, which proved not to be due to the free hemoglobin, but due to the “stroma” of residual red blood cell elements left after cell lysis (56).

Several types of hemoglobin solution have been developed, and have taken different approaches to these problems. One product is produced from modified polymerized bovine hemoglobin (Hemopure, HBOC-201, Biopure, Cambridge, USA) (57,58). The dimer form is polymerized to form a larger roughly octomeric molecules (Fig. 5). It is

Figure 5. Hemoglobin dimer subunits can be polymerized (a) to form tetramers. These can be further polymerized (b) to form octamers or larger units, or can be cross-linked (c) to increase molecular size.

Table 2. Hemoglobin Solutions in Clinical Trials

Product (Manufacturer)	Configuration	P50	Status
<i>Bovine Hemoglobins</i>			
HBOC201 Hemopure (Biopure)	Polymerized with glutaraldehyde	34 mmHg	Licensed in South Africa and for veterinary use. FDA review; further studies required
PEG-hemoglobin (Enzon)	PEG (polyethylene glycol) conjugated noncross-linked, encapsulated	20 mmHg	Phase 1 melanoma studies completed. Now discontinued
<i>Human Hemoglobins</i>			
Polyheme (Northfield)	Polymerized, tetramer-free	30 mmHg	Phase 3 study, before FDA review
Hemolink (Hemosol)	Polymerized with <i>o</i> -raffinose	32 mmHg	Under review United Kingdom and Canada
DCLHb (Baxter)	Cross-linked with diaspirin	32 mmHg	Discontinued
PHP (Curacyte)	Pyridoxylated		Studied in SIRS
<i>Recombinant Hemoglobins</i>			
Optro (Somatogen)	Genetically fused	17 mmHg	Discontinued

then filtered to remove the smaller molecular weight tetrameric hemoglobin molecules. This reduces the oncotic pressure and prevents passage of the molecule through the glomerulus into the urine. Polymerization also increases the *P50* into the normal range and allows the hemoglobin solution to release oxygen in the tissues (41).

Other products have been developed from outdated human blood: Cross-linking hemoglobin molecules with pyridoxal-5-phosphate (Fig. 5), which acts as an artificial 2, 3-DPG, can increase the *P50*. This technique is used in PolyHeme polymerized hemoglobin solution (Northfield Pharmaceutical, Chicago, IL) (59–61), and pyridoxylated hemoglobin polyoxyethylene conjugate or PHP hemoglobin (62). Diaspirin Cross-Linked Hemoglobin, DCLHb (Baxter Healthcare, Chicago, IL) (63,64) and Hemolink (Hemosol, Toronto, Ontario, Canada) also have a *P50* within the normal range and have an increased size due to cross-linking or polymerization.

The size of the hemoglobin molecule can also be increased by attaching the dimer to a large non-hemoglobin molecule, for example, polyethylene glycol used in PEG-hemoglobin (Enzon, Piscataway, NJ). A final method of increasing molecular size is to encapsulate hemoglobin in phospholipid vesicles or liposomes (65).

Hemoglobin cannot only be obtained from outdated human blood, but also from bovine blood. There is a tremendous supply of bovine blood, since nearly 1 million units/day are produced as a byproduct of meat production. Bovine hemoglobin does not normally require 2, 3-DPG, and maintains a *P50* in the range of 32 mmHg (4.26 kPa), even as a dimer (66). Concern over the spread of BSE or variant vCJD may impact the development of bovine products (67). The FDA has restricted the import of bovine products from Europe because of the outbreak of Mad Cow disease there (68).

Recombinant hemoglobin has been used as an alternative source of hemoglobin. Optro (Somatogen), was engineered to have a *P50* in the normal range. However, manufacture has been discontinued (67).

The hemoglobin solutions that have undergone clinical trial are listed in Table 2. Since these solutions are produced from different hemoglobin sources, and have different sizes and different *P50* values, each needs to be evaluated as a separate drug with its own effectiveness and toxicity profile.

All of these products have a relatively short intravascular half-life compared to hemoglobin contained in red blood cells, and are cleared from the vascular space by the reticuloendothelial system with a half-life of ~24 h.

Hemodynamic Effects of Hemoglobin Solutions

Pulmonary and systemic hypertension have been observed in studies in animals (63,69–72) and human clinical studies (36,38,57,64,73–78). The cause of this appears to be related to the nitric oxide (NO) scavenging properties of hemoglobin. Endothelium derived relaxant factor (EDRF) was identified as NO in the 1990s and its role in controlling vascular resistance was elucidated. Nitric oxide is produced in the endothelial cells of blood vessel walls, and produces smooth muscle relaxation, thereby causing vasodilatation. As blood flow increases, nitric oxide is carried away, reducing its concentration and causing vasoconstriction (79). Binding of nitric oxide to hemoglobin plays an important role in its removal, and thereby the control of vascular tone. Free hemoglobin binds nitric oxide more avidly than hemoglobin within the red cell and nitric oxide clearance is increased (80). This leads to hypertension in the pulmonary and systemic vascular beds. Smaller hemo-

globin molecule size appears to increase NO clearance, and pulmonary hypertension becomes more problematic. The severity of this side effect varies with the different forms and preparations of hemoglobin.

The observed vasoconstriction with hemoglobin solutions led to the evaluation of DCLHb solution as an “all-in-one” therapeutic strategy in vasodilated shock states (38) as a vasopressor in critically ill patients with septic shock. In septic shock or systemic inflammatory response syndrome, the vasodilated state may be due to excessive synthesis of NO. The scavenging effect of the hemoglobin solution may be beneficial in restoring vascular tone in this setting (37). Tissue perfusion may be improved because of the small size of the hemoglobin molecules compared to red cells, improving oxygen delivery through the microcirculation. In a mouse model of gram-negative sepsis, hemoglobin solution was associated with increased circulating tumor necrosis factor and increased lethality (81). In pigs with septic shock, DCLHb administration restored blood pressure and allowed a reduction in dopamine infusion being used for resuscitation (82). Further work is required to determine the utility of hemoglobin solutions in critical illness (83).

Although NO scavenging may play a major role in the vasoconstriction seen with hemoglobin solutions it may not explain the whole picture. Hemoglobin molecules with similar rates of NO binding may have strikingly different degrees of vasoconstriction. The fall in PO_2 in terminal arterioles may play a large role in the autoregulation of microvascular circulation by causing vasodilation. Hemoglobin solutions may deliver excess oxygen to the terminal capillaries causing vasoconstriction and paradoxically reducing oxygen delivery to the tissue (84).

This proposed effect on microcirculation has led to the adoption of a “counterintuitive” approach to hemoglobin solution development. An anemic but hyperoncotic solution with a very low $P50$ could delay oxygen release and prevent vasoconstriction (85). Such a solution has been developed in MalPEG-Hb (maleimide-activated polyethylene glycol conjugated hemoglobin). This MalPEG-Hb solution has a $P50$ of 5.5 mmHg and has been shown to improve microvascular circulation in hypovolemic shock in hamsters (86).

Duration of Action of Hemoglobin Solutions

Just as free hemoglobin is scavenged following intravascular hemolysis, the RE system scavenges hemoglobin solution from the blood stream. The effective intravascular life of the hemoglobin solution is ~12–48 h, depending on the dose (66). Therefore, hemoglobin solutions, like the PFCs, will not have a role in maintaining oxygen-carrying capacity in chronically anemic patients. They may be used in acute, limited blood-loss situations as resuscitative fluids, especially in combination with perioperative autologous hemodilution to minimize loss of the patients own blood (87,88).

Hematopoietic Effect of Hemoglobin Solutions

Hemoglobin solutions may have a profound effect in stimulating erythropoiesis. Studies in which animals are hemodiluted to a low Hct, and given a transfusion of

hemoglobin solution, demonstrate a pronounced level of red blood cell production exceeding that expected even with the administration of exogenous erythropoietin (36).

Free iron liberated when hemoglobin solutions are broken may stimulate erythropoiesis, reducing the requirement for subsequent red cell transfusion (89,90). Transfusion of diaspirin cross-linked hemoglobin (DCLHb) to transfuse cardiac surgery patients in the postbypass period resulted in 19% of patients not requiring packed red blood cell transfusion, although the DCLHb was rapidly cleared from the circulation (77). After acute normovolemic hemodilution (ANH) with HBOC-201 in human volunteers there were increases in serum iron, ferritin, and erythropoietin that did not occur following ANH with Ringer's lactate solution (91).

Other Uses of Hemoglobin Solutions

Hemoglobin solutions have an oxygen delivery curve similar to that of hemoglobin in red blood cells. At low temperatures the curve is shifted to the left, preventing release of the bound oxygen, they therefore may not be of any benefit as a constituent of cardioplegia solutions or organ preservatives used for transplanted organs.

Artificial oxygen carriers have a potential for abuse by elite athletes, and international sporting federations have already added the class of agent to their banned substance lists (92).

Clinical Trials: Hemoglobin Solutions

HBOC-201 (Hemopure). The bovine product HBOC-201 (Hemopure, Biopure, Cambridge, MA) is produced from modified polymerized bovine hemoglobin and has been studied in patients undergoing abdominal aortic aneurysm surgery. Treatment with the hemoglobin solution produced an increase in pulmonary and systemic vascular resistance and an associated decrease in cardiac output (57). In another study in aortic surgery HBOC-201, 27% of patients did not need blood transfusion, but the median transfusion requirement was not decreased. Mean arterial blood pressure increased by 15% in this study (75). Vasoconstriction and hypertension have been noted in many studies with HBOC-201. A study looking at preoperative hemodilution with bovine HBOC-201 before liver resection showed an increase in systemic vascular resistance and a fall in cardiac output (73). More recently, a study by Wahr et al. (36) found this product to be useful in reducing the amount of allogeneic blood in operative patients. Increases in pulmonary or systemic resistance were not seen, but a mild increase in blood pressure occurred.

In postoperative cardiac surgery patients, administration of up to 1000 mL HBOC-201 prevented packed red blood cell administration in 34% of patients who would otherwise have received it (93). Although the HBOC-201 had a short duration in the circulation, Hct was restored rapidly, perhaps due to a hematinic effect. The HBOC-201 patients had a slightly greater increase in blood pressure after transfusion.

HBOC-201 has been administered to patients with sickle cell anemia and may have a role in the treatment of vasoocclusive or aplastic crises in this disease (94,95).

The HBOC-201 can be used instead of PRBCs to transfuse patients with severe autoimmune hemolytic anemia, the hemoglobin solution does not have the surface antigens associated with red blood cells (96). In the presence of a Hct of 4.4% the hemoglobin solution reversed both lactic acidosis and myocardial ischemia.

In South Africa, HBOC-201 (Hemopure) has been licensed to treat anemia in surgical patients; this is the first time a hemoglobin solution has reached the market in humans. It is also licensed, as Oxyglobin, for veterinary use in the United States and Europe. The FDA approval for human use in the United States has been delayed pending a request for further information and animal testing.

Diaspirin Cross-Linked Hemoglobin, DCLHb

The DCLHb (Baxter Healthcare, Chicago, IL) has been developed from outdated human blood. Clinical studies to date have had varying results with DCLHb.

The DCLHb effectively scavenges NO and has been noted to increase pulmonary and systemic vascular resistance in the hemodilution model in animals to the point of reducing cardiac index and oxygen delivery relative controls (63). Pulmonary and systemic hypertension with rises in SVR and PVR also occurred in human studies of DCLHb given after cardiac surgery, and this led to decreased cardiac output compared to patients given red cell transfusion (77). Another study (76) showed that DCLHb could be used to reduce the number of patients requiring perioperative packed red blood cell (PRBC) transfusions following vascular, orthopedic, and abdominal surgery compared with patients randomized to PRBC transfusions. However, the total PRBC and other blood product requirements of the two groups were similar over the subsequent week. Side effects of hypertension, jaundice and hemoglobinuria were noted. One death from respiratory distress syndrome was attributed to DCLHb, and the study was terminated early.

This solution was also investigated in a randomized study of patients with acute ischemic stroke (64). Patients receiving the hemoglobin solution had more deaths, serious adverse outcomes, and worse outcome scale scores.

Studies in patients with hemorrhagic shock in the United States and Europe were discontinued because of increased mortality in the U.S. study, and a lack of benefit with DCLHb administration in the European study (97).

Because of these results Baxter has discontinued further work with DCLHb. He subsequently acquired Somatogen, manufacturer of Optro, a first generation recombinant hemoglobin, development of which has since been discontinued.

PolyHeme

PolyHeme (Northfield Pharmaceutical, Chicago, IL) has been used in trials treating acute trauma patients. Gould et al. administered 1–20 units of PolyHeme to 171 patients with urgent blood loss; 81 patients received 5 or more units and 34 received 10–20 units (98). Overall there was a mortality of 10.5 compared to 16% of historical controls who declined blood transfusion because of religious reasons during surgery, and had Hb levels < 8 g/dL. However, there was no comparison with controls receiving transfusion of

allogeneic packed red blood cells. An earlier study, also by Gould, randomly assigned 44 trauma patients to either receive blood (23 patients) or up to 6 units of PolyHeme (21 patients) (60). There were no adverse effects on pulmonary and systemic vascular resistance or cardiac output from the administration of PolyHeme. There were no differences in patient outcomes, although there was a reduced need for red blood cells in the PolyHeme group at day 1, which was no longer seen by day 3. The lack of effect of PolyHeme on systemic and peripheral vascular resistance is attributed to its manufacturing process, which filters out the smaller tetrameric hemoglobin (59,60). It is speculated that the smaller size hemoglobin elements can defuse through the vessel wall, increasing NO scavenging and producing vasoconstriction.

Studies have found an intravascular half-life of 24 h of PolyHeme, which is longer than that found in previous studies that found a half-life in the range of 9–12 h. It may be that the half-life of these products is dose dependent; studies showing a larger dose produces a longer half-life.

PolyHeme is currently being assessed in a large multicenter study compared to saline for trauma patients. An application to the FDA for approval may follow this study and PolyHeme could have a role in future clinical practice.

Hemolink

Hemolink (Hemosol, Toronto, Ontario, Canada) is an O-raffinose cross-linked human hemoglobin, which has been shown to cause vasoconstriction in animals (70). As with other cross-linked hemoglobin solutions, the hemodynamic effects are less pronounced than with unmodified hemoglobin solutions (99) but exceed that of polymerized hemoglobin solutions.

A Phase I study in healthy human volunteers showed the solution was well tolerated apart from some moderate to severe abdominal pain, which occurred in all subjects at higher doses. Blood pressure rose by 14% following administration, and with higher doses this elevation lasted 24 h (78). The findings of a Phase II study in coronary artery bypass (CAB) surgery (74) reported a 7–10% increase in blood pressure, which was not statistically significant, and a reduction in the number of patients requiring red cell transfusion from 57 to 10%. A further report by the same group using intraoperative autologous donation and volume replacement with Hemolink or pentastarch in CAB surgery abolished the need for intraoperative transfusion (0 vs. 17% in the pentastarch group) (100). The reduction in transfusion requirement continued at 1 day (7 vs. 37%) and 5 days (10 vs. 47%) after surgery. Adverse effects included hypertension (43 vs. 17%) and atrial fibrillation (37 vs. 17%).

A similar study in CAB patients using intraoperative autologous blood donation (IAD) and volume replacement with Hemolink or pentastarch showed a reduction in transfusion from 76% in the pentastarch group to 56% with Hemolink (101). This was compared to an historical group of patients in whom IAD was not used, who required transfusion in 95% of operations. Hypertension was again noted in the Hemolink treated group.

Hemolink is under review for approval by the drug agencies of the United States, Canada, and the United Kingdom.

PEG Hemoglobin

The PEG Hemoglobin (Enzon, Piscataway, NJ) is a bovine hemoglobin conjugated with polyethylene glycol. This increases the molecular size without using cross-linking between molecules. Retention in the circulation is increased as the conjugated molecule does not cross the glomerular basement membrane. Administration in dogs resulted in no elevation of blood pressure and it was well tolerated (102).

The PEG hemoglobin has been used to sensitize tumors to chemotherapy (103) and radiotherapy in rodents (104). The small molecular size, compared to red cells, improves microvascular oxygenation, and tumors that are hypoxic become more responsive to chemotherapy and radiotherapy.

The PEG hemoglobin has also been used in rabbits, in the preservative perfusate, and for protection of transplanted hearts during the ischemic period with improvement in cardiac function post-transplant (105).

PHP

Pyridoxilated hemoglobin polyoxyethylene conjugate or PHP (Curacyte, Chapel Hill, NC) is a human hemoglobin solution, cross-linked by pyridoxal-5-phosphate, which is being developed as a NO scavenger for use in septic shock and systemic inflammatory response syndrome (62). A Phase II study has been completed and a Phase III study is in progress looking at PHP for the treatment of NO induced shock.

Encapsulated Hemoglobins

The problems of small hemoglobin molecule size, leading to NO scavenging, high oncotic pressures, and osmotic diuresis can be countered by encapsulating the hemoglobin. This mimics the natural presentation of hemoglobin in whole blood and is sometimes referred to as "neo red cells" (65). Most work has used liposome encapsulated hemoglobin (LEH), but biodegradable polymer microcapsules have also been used (106). Circulation time of the hemoglobin is increased by encapsulation and can be increased, from 18 to 65 h, by polyethylene glycol (PEG) modification (107), these long-lasting derivatives have been named "stealth" liposomes. However, there is significant accumulation of liposomes in the liver and spleen, when LEH is given, causing vacuolization seen on liver biopsy. Liver transaminases may also be elevated (41).

INTRODUCTION

Bone has a variety of functions in the body of which some of the most important are structural in nature: protection of vulnerable body parts, support of the body, and to provide muscle attachments. A knowledge of the mechanical and adaptive properties of bone is useful in the design and use of prostheses that replace a bone or a portion of a bone. Mechanical properties of bone are also of interest in trauma biomechanics and in efforts to prevent injury to the body. As for teeth, they also are replaced by artificial materials which are called upon to perform the mechanical functions of the original tooth. This article contains a survey of known properties of bone and teeth and their components collagen and apatite, with an emphasis on bone and its mechanical properties.

A voluminous literature is available dealing with the properties of bone and to a lesser extent of teeth's major constituents: collagen and apatite. Reported properties are often found to differ. Some of the differences arise from the fact that bone and tooth structures are of biological origin and consequently vary depending on the individual and on the part of the body from which the specimen is taken. Other differences are due to experimental technique and variations in environmental conditions during experiments. Of necessity, results presented in this article are selected from a large mass of published reports. The authors have endeavored to select results obtained by good techniques and representative of accepted values. Nevertheless, other results obtained by equally good techniques may be expected to differ somewhat as a result of biological variability. Therefore, it is suggested that additional measurements of the properties of bone and teeth can be found in several of the source books listed in the Bibliography [see (1–10)].

MECHANICAL PROPERTIES OF COMPACT BONE

Compact Bone Structure

The mechanical properties of bone are inseparably related to its structure. Bone tissue is a complex composite material that at different levels of scale exhibits fibrous, porous, and particulate microstructural features (1–5). The following constituents are present in bone: mineral, protein, other organic materials, and fluids such as water. The mineral, principally a carbonated apatite, where the

carbonate group substitutes in part for the phosphate group $[\text{Ca}_{10}(\text{PO}_4)_6(\text{CO}_3)_2(\text{OH})_2]$ (5,6). In mature bovine cortical bone (similar to human cortical bone) it occurs as microcrystalline inclusions of plate-like shape (mineralites) of dimensions $\sim 0.7 \times 11 \times 17$ nm (11). However, in young postnatal bovine bone, the mineralites are thicker, shorter, and narrower, [i.e. $2 \times 6 \times 9$ nm (12)]. These mineralite sizes measured by AFM are closest to the actual values as, "AFM yields the full three-dimensional structure of mineralites rather than a projection . . ." thus providing the full shape of each mineralite measured. The other major techniques for measuring mineralite sizes, transmission electron microscopy (TEM) and X-ray diffraction line broadening, each suffer from artifacts that result in increased sizes of some of the dimensions (3).

On the ultrastructural level (nanoscale), the mineral crystallites are in intimate apposition with fibrils of the protein collagen. A, "(d)igrammatic depiction of the supra-molecular packing of collagen molecules in a fibril . . ." plus the possible arrangement of the mineralites within a fibril is given as Fig. 7 in Ref. 12. These fibrils are from 20 to 200 nm in diameter and are organized into fibers that are in turn arranged in bone into lamellae or layers. The fibers in each lamella run longitudinally, spirally, or nearly circumferentially. Moreover, the orientation of these layers are different in alternate lamellae. A micromechanical model for the Young's modulus of bone has been proposed, based on these histological features, however, it has not yet been tested experimentally. The organization of collagen fibrils differs in woven bone and lamellar bone. Mineralized collagen fibrils and isolated crystals from the mid-diaphyses of human fetal femurs were observed with scanning, TEM, and high resolution electron microscopy. The apatite crystals in woven bone are also platelet shaped, similar to mature crystals from lamellar bone. Average crystal dimensions are considerably smaller in woven bone than those of mature crystals in lamellar bone. In diseased bone such as that affected by osteogenesis imperfecta, the apatitic crystals occur in various sizes and shapes; they are oriented and aligned with respect to collagen in a manner that differs from that found in normal calcified tissues.

In compact cortical bone, the lamellae are layers arranged circumferentially around a central canal and form the Haversian system (secondary osteon). Haversian canals typically contain small blood vessels. Haversian bone occurs in the cortices of bones in adult humans (1–3,5) and in the bones of various large animals (1,2). Osteons are roughly cylindrical structures up to ~ 200 μm in diameter. In a long bone, they tend to run approximately parallel to each other and to the bone axis. Figure 1 displays the typical structure of human cortical bone, whereas Fig. 2 displays the typical structure of human cancellous (also known as trabecular or spongy) bone. The large circular or elliptical features in the former figure are the cross-sections of osteons, the concentric layers are lamellae, and the central dark circles are the cross-sections of Haversian canals. The numerous spots among the lamellae are the lacunae, in which the osteocytes, or bone cells live. The lacunae are roughly ellipsoidal and have dimensions of $\sim 10 \times 15 \times 25$ μm . The osteocytes have many thin processes that occupy channels in the bone matrix known as

Figure 1. Human Haversian bone. Reflected light micrograph of a specimen cut perpendicular to the bone axis. Scale mark: 200 μm .

canaliculi; they are too small to be visible in Fig. 1. The mechanical properties of bone depend on its degree of bulk and surface hydration and the details of its structure that depend on variables such as the age, state of health, and level of physical activity of the individual, the location of the bone in the body, as well as the rate and direction at which load is applied to the bone.

The emphasis in this article is on wet skeletal tissues, bone and teeth, from healthy adults, with occasional references to dry tissues for comparison. However, there are many studies of mammalian skeletal tissues as they provide a useful counterpart to the human studies; studies of the properties of bovine bone and teeth are the most numerous in this respect. The structures of both mature bovine cortical and cancellous bone are very similar to those corresponding human tissues Figs. 1 and 2, respectively. Young bovine cortical bone structure is quite different as seen in Fig. 3. This plexiform (or lamellar) bone resorbs and remodels to Haversian bone as the animal matures. Comparison of the young and mature bovine bone properties provides added insight into the importance of structure in determining the mechanical properties of bone. Thus, where appropriate, properties of bovine bone and teeth are included in Tables 1–7.

Figure 2. Human cancellous bone from the proximal femur. The marrow has been removed. Scale mark: 5 mm.

Figure 3. Bovine plexiform bone. Reflected light micrograph of a specimen cut perpendicular to the bone axis. Scale mark: 200 μm .

Elasticity of Compact Bone: Comparison with Teeth and Other Materials

Elastic materials deform under load; elasticity entails reversible behavior in which the material returns to its original configuration after the load is removed. If the load is sufficiently small, there is a linear relationship between stress and strain. For simple tension or compression, the constant of proportionality is referred to as Young's modulus E and for shear or torsion it is the shear modulus G (4,29). The stiffness of human compact bone as quantified by Young's modulus typically lies between 12 and 25 GPa for tension or compression depending on sample orientation and experimental technique (17), (1 GPa = 145,000 lb·in.⁻²). It has been suggested that the tensile and compressive elastic moduli are not equal, but at small strain, the best evidence indicates that tensile and compressive properties are identical (13).

In Table 1, some examples of the elastic moduli of wet human bone and teeth are compared with those of various other materials. The mechanical testing strain rates for bone are faster than those encountered by bones in walking, but are perhaps comparable to those in vigorous activities. They are slower than those that occur during

fracture. Compact bone is ~ 10 times stiffer than most "rigid" polymers, but is about one-tenth as stiff as common metals such as steel. Table 1 also shows the relationship between stiffness and density. This relationship governs the structural efficiency of whole bones. In view of the fact that the skeleton represents $\sim 17\%$ of the weight of the human body, structural efficiency of bones is relevant to their performance in the body. For example, the overall rigidity per unit weight of a bone acting as a short column or as a tensile member is proportional to the modulus to density ratio, E/ρ , of the bone *tissue* of which it is made. By contrast, for a given weight of material, the Euler buckling load of a bone acting as a slender column or the bending stiffness of a bone acting as a beam of constant shape is proportional to E/ρ^2 (2,6). Density enters these relations in a different way since the rigidity of a short column depends on its cross-sectional area while the bending rigidity of a beam is governed by its moment of inertia.

A more complete listing of the properties of both human and bovine bone and teeth is given in Table 2, the latter data are included because of the similarity in hierarchical structure and organization of mature bovine compact bone with that of human compact bone. These data were obtained using various techniques, mechanical testing, ultrasonic wave propagation (UWP). In the low megahertz (MHz) region (2–5 MHz), scanning acoustic microscopy (SAM) in the high megahertz region (400–600 MHz), and nanoindentation. The first three techniques also were used to obtain the teeth data. Here too, the properties are strongly dependent on the sample location and orientation, for example, the range in dentin properties over the sample surface obtained by SAM (21), Table 2. Corresponding properties of human trabecular bone volumes and individual trabeculae are given in Table 7.

Because SAM is not as well documented compared to either UWP or mechanical testing (MT) in obtaining elastic properties, a description of the technique follows below.

Scanning Acoustic Microscopy

The development of SAM (30,31); see also (9) enabled the analysis of the biomechanical properties of materials at much higher resolution than was previously achieved using traditional ultrasonic wave propagation techniques.

Table 1. Bone, Teeth, and Other Materials: Stiffness

Material	Young's Modulus E , GPa	Density (ρ), $\text{g} \cdot \text{cm}^{-3}$	E/ρ	E/ρ^2
Human compact bone

Concrete(compression)			

A significant advantage of SAM is the ability to investigate the properties of internal and subsurface structures in addition to the surface properties of most materials, including those that are optically opaque. Another advantage of special interest for studying biological materials is that a liquid couplant must be used to transmit the acoustic waves from the acoustic lens to the specimen being studied, thus the specimen is kept wet during all measurements. Therefore, fresh tissue specimens can be used as well as embedded specimens. In addition, the use of high quality,

^aCalculated from single-crystal elastic constants.

high frequency focusing acoustic lenses permits examination of the elastic properties of biological materials on a microscope scale comparable to the optical histology studies. The heart of the SAM is a spherical lens formed at the interface between a high acoustic velocity solid (e.g., sapphire) and the low acoustic velocity couplant liquid. Due to the high acoustic "refractive index", spherical aberration is negligible and an acoustic beam displaying significant convergence can be obtained. A radio frequency (RF) signal is generated from the transmitter. The acoustic lens is equipped with a piezoelectric transducer that converts the RF signal into an acoustic wave. This signal is then made to converge by the lens and propagates to the specimen through the coupling liquid. When reaching the surface of the specimen, a part of the acoustic wave is reflected back through the lens to the transducer, that, acting now as a receiver, transforms the acoustic signal into an RF signal. The amplitude of the echo reflected back to the lens is a measure of the acoustic reflectivity of the surface of the investigated material at the point in focus. It is proportional to the reflection coefficient, r , which is related to the acoustic impedances of the liquid couplant, Z_1 , and the investigated material, Z_2 , by the equation r given in Fig. 4. Acoustic impedance, Z , is measured in Rayls and is defined as $Z = \rho v$, where ρ is the material density and v is the velocity of the longitudinal (dilatational) acoustic wave propagating in the direction perpendicular to the surface. The images present the variations in acoustic signals that originate either from the intrinsic acoustic reflectivity of the material surface or through interference occurring between different surface and subsurface reflected signals. In the former case, surface imaging, the acoustic reflectivity variations are a result of the local changes in acoustic impedance (32).

Table 7. Elastic Modulus of Trabecular Bone Volumes and Trabeculae

Trabeculae	Elastic Modulus, GPa	Reference
Human trabecular bone (Trabeculae)	17.4 (S)	18
(longitudinal)	19.4 (N)	19
(transverse)	15.0 (N)	19
Human trabecular bone volumes (proximal tibia)	0.445 (M)	3

Figure 5 is a plot of elastic stiffness (GPa) versus reflection coefficient, r , for a wide range of materials. Bone has an acoustic impedance in the neighborhood of $Z = 7.5$ Mrayls, yielding a reflection coefficient in the neighborhood of $r = 0.67$. Of course, Z for bone can vary over a considerable range depending on a number of factors that would affect both the density and structural cohesivity of the specific specimen being measured. Likewise, Z for water will vary depending on the temperature at which the couplant fluid is maintained during the experiment, for example, at 0°C , $Z(\text{H}_2\text{O}) = 1.40$ Mrayl; at body temperature, 37°C , $Z(\text{H}_2\text{O}) = 1.51$ Mrayl; and at 60°C , $Z(\text{H}_2\text{O}) = 1.53$, due mainly to the variations in water's acoustic properties with temperature.

As described above, the high frequency mode at 400 and 600 MHz also has been used to study the *in vitro* micro-mechanical elastic properties of human trabecular and

Figure 6. (a) The 400 MHz SAM image of two hypomineralized osteons from human femoral cortical bone. (b) Same area as in part a showing the line along which an x - z interference image was taken. (c) The x - z Interference image taken along the line shown in part b.

compact cortical femoral bone (15,31). In this study, they were able to image the properties of the individual osteonic lamellae at high enough resolution so that three new micromechanical observations were made: (1) the outermost lamellae, always appear to be more compliant; (2) the outermost lamellae of adjacent abutting osteons appear to have the same acoustic impedance (and thus Young's modulus), even though structurally distinct; and (3) adjacent lamellae within an osteon alternate in their acoustic impedance (and thus Young's modulus).

Scanning acoustic microscopy is particularly powerful in providing physical evidence of the possible differences in sound velocity in regions of significant differences in gray level, that is, the darker the gray level, the lower the acoustic impedance, the brighter the gray level, the higher the acoustic impedance, Fig. 6a-c. Figure 6a is a SAM micrograph (400 MHz Burst mode, 120° aperture lens) of human femoral cortical bone (18). The two much darker Haversian systems in the middle of the image are surrounded by the types of Haversian systems (secondary osteons) usually observed in normal bone. The startling difference in gray levels could arise due to out-of-focus artifacts developed in cutting or polishing the specimen. However, performing a x - z curve along the line depicted in Fig. 6b, which goes through the lower, darker Haversian

system and the surrounding tissues, yields the image, Fig. 6c; note that the upper level of the broad band is essentially level, indicating that the specimen surface is everywhere level and normal to the acoustic beam. More important, the narrow band and secondary reflection corresponding to the dark Haversian reflects the lower Z and r for the Haversian. A possible explanation for the Haversians is that there was an arrested state of development leading possibly to a hypomineralized area. Unfortunately, we do not have information concerning the possibility of a disease state or a drug modality responsible for these two underdeveloped Haversians that possibly formed just prior to the death of the individual. They are illustrated here to show the ability of the SAM to permit highly sensitive measurements, at high resolution, of variations in Z and r due to remodeling.

In order to convert from reflection coefficient to Young's modulus on the SAM scans of materials of unknown properties, taken with the Olympus UH3 SAM, it is necessary to develop three calibration curves—voltage (V) versus reflection coefficient (r); reflection coefficient (r) versus acoustic impedance (Z); and acoustic impedance (Z) versus Young's modulus (E)—based on using the values of known materials ranging from polymers at the low end of r to metals and ceramics at the high end (18).

The stiffness of compact bone tissue depends on the bone from which it is taken. Fibular bone has a Young's modulus $\sim 18\%$ greater, and tibial bone $\sim 7\%$ greater than that of femoral bone (33). The differences are associated with differences in the histology of the bone tissue. Femoral bone, for example, has a high proportion of osteons that appear light in the polarizing microscope and that have a preponderantly circumferential collagen fiber orientation (34). The histology of a bone is unquestionably related to its function in the body. The relationship has been explored in some detail in the context of bones of very different function in various species of animals (1,2).

Bone is elastically anisotropic, that is, its properties depend on direction. Such behavior is unlike that of steel, aluminum, and most plastics, but is similar to that of wood. Anisotropic properties of bone are shown in Tables 3 and 4. As can be seen from the data in Table 4, human compact femoral bone is ~ 1.5 times as stiff in the longitudinal direction as it is in the transverse directions. The shear modulus G , determined from a torsion test upon a specimen aligned with the bone axis, is ~ 3.3 GPa (13), so that $E/G = 5.15$. Such a small value of G in comparison with Young's modulus E is a further manifestation of the anisotropy of cortical bone. For normal isotropic materials (positive Poisson's ratio), E/G , must lie between 2 and 3 and is typically ~ 2.6 . Detailed studies of the anisotropy of bone have been conducted using ultrasonic methods as well as by mechanical testing. The elastic constants given in Table 3 are components of the elastic modulus tensor C_{ijkl} in the following relation between stress σ_{ij} and strain e_{kl} in an anisotropic material. The 3 axis is here assumed to be the bone's longitudinal axis, the 2 direction is circumferential, and the 1 direction is radial.

$$\sigma_{ij} = \sum_{k=1}^3 \sum_{l=1}^3 C_{ijkl} e_{kl}$$

In this equation, indexes i and j can have values 1, 2, or 3, so that there are nine components of stress of which six are independent. Since there are six independent components of strain, the number of independent C values is reduced from 81 to 36. Consideration of conservation of mechanical energy further reduces the number of elastic constants to 21, for the least symmetric anisotropic material (7). Materials that have some structural symmetry are described by fewer anisotropic elastic constants. For example, an orthotropic material, (e.g., wood), with three perpendicular planes of symmetry is described by nine constants. A material with transverse isotropic symmetry, (i.e., one that appears the same under an arbitrary rotation about an axis), is described by five constants. In crystal physics, the former symmetry is referred to as orthotropic, while the latter is referred to as hexagonal. An isotropic material appears the same under any rotation and has the same properties in any direction. Two independent elastic constants are needed for the description of the elastic behavior of such a material. Equation 1 can be reduced to a more tractable form by a compaction of the counting indices, the so-called Einstein notation, that is, $\sigma_i = C_{ij}e_j$, where $11 \rightarrow 1$, $22 \rightarrow 2$, $33 \rightarrow 3$, $23 \rightarrow 4$, $13 \rightarrow 5$, $12 \rightarrow 6$ (e.g., $C_{1123} \rightarrow C_{14}$). This reduced notation is used in Table 3.

Both structural considerations and experiments indicate that human compact bone has five independent elastic constants and therefore exhibits transverse isotropic symmetry (27,35,36). Results of a different ultrasonic experiment suggest different stiffnesses in the radial and circumferential directions (16). Based on these results, it has been proposed that human compact bone is orthotropic. The difference between the stiffnesses in the radial and circumferential direction is, however, small and has been attributed to the gradient in porosity going from the periosteum to the endosteum. Thus, for modeling purposes transverse isotropy is the appropriate choice of symmetry (37,38).

Note that the elastic moduli found at high frequencies by ultrasonic methods are greater than those obtained statically or at low frequencies via mechanical testing machines. This is a result of the rate dependence (viscoelasticity) of bone. In the mechanics of whole bones, the principal macroscopic manifestation of cortical bone tissue anisotropy is that the bending rigidity of a bone (the femur) is much greater than its torsion rigidity (39). The degree of anisotropy and the symmetry of bone tissue depends on the species and on the location of the bone in the body. Bovine plexiform bone is stiffer than human Haversian bone, but dry bone is stiffer than the same type of bone when wet. Bovine plexiform bone is orthotropic and has significantly different elastic moduli in the longitudinal, radial, and circumferential directions (40). These properties reflect the laminar architecture of this type of bone, as shown in cross-section in Fig. 2. The scale mark is in the radial direction and is perpendicular to the laminae. Bovine plexiform bone is a type of primary bone that occurs in relatively young cattle. It is often used for experiments as a result of its availability. Canine femoral bone is also orthotropic (16), however, canine mandibular bone and possibly also human mandibular bone, is transversely isotropic (41).

Anisotropic properties of bone may also be expressed in terms of the technical elastic constants, Young's modulus E , shear modulus G , and Poisson's ratio, ν , for different directions. Poisson's ratio is minus the transverse strain divided by the axial strain in the direction of stretching or of compressing force. Representative values for dry human femoral bone are shown in Table 3. The 3 direction is the long axis of the bone, the 2 direction is circumferential, and the 1 direction is radial. We note that Poisson's ratio in isotropic materials must be less than one-half (7). In anisotropic materials, larger values are permissible, so that the values reported for bone do not violate any physical law.

Bone mineral density plays an important role in determining all of the elastic properties described above. Under normal physiological and physical conditions, as bone density increases so do the respective elastic properties. However, bone density alone does not always determine fracture risk in pathologies such as osteoporosis. A general term in vogue now, 'bone quality', is being used to qualify what is information is necessary to determine when bone is at risk of failure due to reduced density. Structure-property relationships are the key here, especially in understanding when trabecular bone will fail. Even under the conditions of reduced density, the appropriate structural organization

of the bone may still provide adequate support during normal function. Similarly, good density alone, if associated with a genetic pathology, such as found in osteopetrosis, will not provide adequate protection against fracture. The hardness and elastic moduli of osteopetrotic cortical bone are even well below that of osteoporotic bone even though the density of the former is in the normal range (26,42). Indeed, osteopetrotic bone tends to fracture quite readily.

It is clear that for a detailed modeling of the elastic properties of bone, its complex hierarchical structure must be taken into account (37,38,43).

Strength

The ultimate strength of bone tissue refers to the maximum stress the material can withstand before breaking. The tensile strength of human compact bone (17) in a direction parallel to the osteons is about 150 MPa or 21,000 lb·in.⁻² (1 MPa = 145 lb·in.⁻²). As indicated in Table 5, bone is stronger than various plastics, concrete, brick, some metals, (e.g., aluminum), and most woods. Although bone is stronger than aluminum, commonly used aluminum alloys are stronger than bone. Even so, bone has a lower density than aluminum and a much lower density than steel. The criterion for structural strength in beam bending is material strength divided by the 1.5 power of density [3.×]. For bending of plate-shaped structural elements the criterion is material strength divided by the square of the density. The strength to density ratio for bone is greater than that for structural steel. Therefore bone has very favorable properties in comparison with steel and is competitive with aluminum alloys. Bone is anisotropic in its strength as well as in its elastic behavior. In particular, bone is considerably weaker when loaded transversely than when loaded along the osteon direction. Fortunately, bone in the body does not normally experience significant transverse loads. Several investigators have explored the dependence of bone strength upon age. Tensile strength of adult compact bone decreases 4% per decade of age (44) as does its shear strength (45). In other studies, no significant age dependence of strength was found (46,47). More recently, it was found that the tensile strength of femoral bone decreases 2.1% per decade of age while that of tibial bone decreases 1.2% per decade of age (48). The decrease in strength was statistically significant in the case of femoral bone, but not in the case of tibial bone. Both kinds of bone exhibit significant decreases, 6.8% per decade for femur and 8.4% per decade for tibia, in energy absorption to fracture, a measure of toughness. No significant difference between age-matched males and females was found for any mechanical property (48). Tibial bone is stronger in tension than femoral bone by ~ 19% (49,50) and is ~ 4% stronger than fibular bone.

Currey observes that the average stiffness of human and sheep bone increases monotonically with age (in humans from age 2–50), while energy absorption to fracture decreases. The lower mineralization and stiffness and higher toughness seen in young bones is considered adaptive in view of the many falls and bumps experienced by children and young animals (1).

The fracture behavior of a material is not described fully by its yield and ultimate strengths alone; toughness is also

important. Toughness is seen as an important characteristic of bone in view of the microcracks that occur in living bone. Fracture of laboratory specimens containing controlled notches provides information concerning the toughness of materials (49,50). For example, the nominal fracture strength of a tensile specimen with an edge notch of length a is $\sigma_{ult} = K_{1c} a^{-1/2} / Y$ in which Y depends on the specimen geometry and K_{1c} is called the critical stress intensity factor. A large value of K_{1c} results in high strength even in the presence of a notch; K_{1c} is a measure of material toughness.

The critical stress intensity factor K_{1c} for fracture of compact tension specimens of bovine femur bone is from 2.2 to 4.5 MN·m^{-3/2}, and the specific surface energy for fracture is from 390 to 560 J·m⁻² (49). The toughness does not, however depend on the sharpness of the controlled notch in the expected way; the significance of this observation is discussed in the section Compact Bone as a Composite Material. As for the age dependence of bone fracture toughness, the energy absorbed to fracture is observed to decrease during childhood and early middle age, and the elastic modulus increases (51). Recently, fracture surfaces from accident victims have been examined microscopically (52). Such surfaces are observed to be much rougher and more intricate than fracture surfaces produced in laboratory specimens of dead bone, which suggests a greater toughness in living bone. The influence of bone viability on its mechanical properties is not well understood. The dependence of bone elastic modulus on viability has been explored in several studies, but the evidence for a difference in elasticity is not compelling.

Currey (1), compares density, modulus, strength and toughness of bones from deer antler, cow thigh, and whale tympanic bulla. As one might expect, modulus increases and toughness decreases with density. Strength is the highest for the femoral bone. Properties vary considerably between these types of bone; the difference is attributed largely to mineralization but partly to histology. The high mineralization of the whale ear bone is responsible for its stiffness, density and brittleness. The stiffness and density are useful given the acoustic function of the ear bone. The brittleness is not a problem since the ear bone is deep within the skull. Conversely, antler is subjected to repeated severe impacts during use, so toughness is beneficial.

Yielding and Plastic Deformation

Wet bone when loaded sufficiently exhibits a yield point, $\sigma_y = 114$ MPa (13). Beyond this critical stress level, the material does not recover upon the release of the load; permanent or plastic deformation has occurred. In bone as in most materials that exhibit yielding, the yield point is approximated by the proportional limit. The proportional limit is the boundary between the linear and nonlinear portions of the stress–strain curve. The mechanism for yield in bone differs from that in metals. In bone, yield occurs as a result of microcracking and other microdamage while in metals, yield results from motion of dislocations. Published reports have not been in agreement as to the amount of plastic deformation in bone. Much of the disagreement has been attributed to the fact that the observed

plastic deformation is highly sensitive to the hydration of the bone. Dry specimens or specimens with dried surfaces or dried and rewetted surfaces behave in a much more brittle manner than those which have been kept fully hydrated during preparation and testing. In the latter case (9), the maximum strain at fracture of bone under tension in the longitudinal direction is 0.031. Yielding of bone has considerable relevance to the function of bone in the body since very much mechanical energy can be absorbed in plastic deformation without fracture. In certain injuries, plasticity in bone can result in residual deformation, which is obvious on a clinical radiograph (53).

Bone Strain *In Vivo*

To ascertain the significance of bone elasticity and strength data in connection with the function of bone in the body, it is desirable to know what levels of stress and strain occur in bones during normal activities and under traumatic conditions. It is possible to make inferences from macroscopic measurements of forces acting on the extremities. The validity of such inferences is rendered uncertain by the fact that muscle forces cannot generally be uniquely determined. It has become possible to determine bone strains explicitly in various animals (54) and in humans (55) by directly cementing foil strain gages to bone surfaces (56). In a human volunteer, maximum strain along the tibia axis was $\sim 3.5 \times 10^{-4}$ during normal walking at $1.4 \text{ m} \cdot \text{s}^{-1}$ and 8×10^{-4} during running at $2.2 \text{ m} \cdot \text{s}^{-1}$. Strains of similar magnitudes have been observed in animals such as sheep (53). The largest strain magnitude observed in the normal activity of an animal was 3.2×10^{-3} in the tibia of a galloping horse (57). In comparison (5), in tension in the longitudinal direction human bone yields at a strain of 6.7×10^{-3} and fractures at a strain of 0.03. The strain levels observed *in vivo* are significant in view of the fatigue properties of bone. Race horses can experience bone strain exceeding 4.8×10^{-3} at maximum effort (58).

Fatigue

Bone, like other materials, accumulates damage when loaded repeatedly and this damage can lead to fracture at a lower stress than the ultimate strength measured using a single load cycle. The results of *in vitro* mechanical fatigue studies on dead bone suggest that bone may accumulate significant fatigue damage during normal daily activity. Biological bone remodelling is concluded to be essential to the long-term structural integrity of the skeletal system (59). It is notable that dead bone, unlike steel, does not exhibit an endurance limit. The endurance limit is defined as a stress below which the material can withstand an unlimited number of cycles of repetitive load without breaking in fatigue. In the absence of an endurance limit, dead bone subjected to the prolonged cyclic load of daily activity must eventually break. Living bone, by contrast, is able to repair microdamage generated during fatigue.

The resistance of human cortical bone to fatigue fracture is more strongly controlled by strain range than stress range. Fatigue strength shows a weak positive correlation with bone density and with bone modulus and a weak negative correlation with porosity (59). Fati-

gue strength in uniaxial tests is lower than in bending tests. In immature bone (60), bone fatigue resistance for a given strain range decreases with maturation, while the elastic modulus, density, and ash content increase with maturation. Cracking or fracture of bone due to fatigue manifests itself clinically as 'stress fractures' that can occur in individuals who suddenly increase their level of physical activity (61). In the case of a person in poor physical condition who sustains a fatigue fracture during military training, it is called a "march fracture". Laboratory results for fatigue in bone are not inconsistent with clinical experience with fatigue fractures in athletes and military recruits (62). In particular, a recruit may accumulate in 6 weeks of training a load history equivalent to 100–1000 miles of very rigorous exercise, associated with peak bone strains of 0.002 and a maximum strain range of 0.004, which can be sufficient to precipitate a fatigue fracture (62).

Stress Concentrations

It is common practice in orthopedic surgery to drill holes in bones for the placement of screws. Such holes cause the bone to be weaker than an intact bone, so that it may fracture as a result of less trauma than would ordinarily be required (63,64). This phenomenon may be understood in view of the fact that holes in elastic solids are known to cause a concentration of stress in the vicinity of the hole. According to the theory of elasticity, the stress concentration is not dependent on a decrease in the amount of material available to bear the load; it can be severe even for small holes. Laboratory studies of whole bone fracture have disclosed that a 3 mm diameter hole weakens a tibia by 40% in bending and 12% in torsion (65). A 2.8- or a 3.6-mm hole reduces the strength of dog bones (63) under rapidly applied torsion by a factor of 1.6. It is of interest to compare the observed stress concentration with predicted values based on the theory of elasticity. The predicted stress concentration factor for a hole in a field of shearing stress is 4.0 provided that the hole is small compared with the structure as a whole (66). The discrepancy has been attributed to the fact that intact bone already has stress raisers by virtue of its heterogeneous structure and porosity (63). However, in specimens loaded in the linear elastic range, well below yield or fracture, distributions and concentrations of strain differ from predicted values (67). Similar discrepancies have been reported in manmade fibrous composites without preexisting porosity (68,69). The role of the fibrous architecture of bone in relation to stress concentrations is discussed in the section on composite properties of bone.

Viscoelasticity

Bone exhibits viscoelastic behavior, that is, the stress depends not only on the strain, but also on the time history of the strain. Such behavior can manifest itself as creep, which is a gradual increase in strain under constant stress; stress relaxation, which is a gradual decrease in stress in a specimen held at constant strain; load-rate dependence of the stiffness; attenuation of sonic or ultrasonic waves; or energy dissipation in bone loaded dynamically (10).

Experimental modalities based on each of the above phenomena have been used in the study of bone (70–74). The results have been converted to a common representation via the interrelationships inherent in the linear theory of viscoelasticity, to permit a direct comparison of results (75,76). In the case of tension–compression, there is very significant disagreement among the published results. This disagreement may result from nonlinear viscoelastic behavior not accounted for in the transformation process, or from experimental artifacts. In the case of shear deformation, however, there is good agreement between results obtained in different kinds of experiments. The loss tangent, which is proportional to the ratio of energy dissipated to energy stored in a cycle of deformation, achieves a minimum value of ~ 0.01 at frequencies from 1 to 100 Hz. At lower and higher frequencies, the loss tangent, hence the magnitude of viscoelastic effects is greater (e.g., 0.08 at 1 MHz and at 1 μ Hz). To compare, the loss tangent of quartz may be $< 10^{-6}$, in metals, from 10^{-4} to 0.01, in hard plastics from 0.01 to 0.1, and in soft polymers, it may attain values > 1 . It is notable that the minimum energy dissipation in bone occurs in a frequency range characteristic of load histories during normal activities.

A synopsis of wet bone viscoelastic behavior in shear is presented in Fig. 7. The $\tan \delta$ attains a broad minimum over the frequency range associated with most bodily activities. Some authors have suggested that the viscoelastic behavior in bone confers a shock-absorbing role. The observed minimum in damping at frequencies of normal activities is not supportive of such an interpretation.

Some authors refer to three element spring dashpot models used in tutorials on viscoelasticity. The behavior of such a model corresponds to a Debye peak in $\tan \delta$, also

shown in the figure. This corresponds, by Fourier transformation, to a single exponential in the creep or relaxation behavior. The $\tan \delta$ of bone occupies a much larger region of the frequency domain than a Debye peak, so the spring dashpot model is not appropriate.

Compact Bone as a Composite Material

Early composite models (83–87) for bone were two-phase models involving the mineral and protein phases only. At the ultrastructural level one may imagine the mineral crystals as a particulate reinforcing phase and the surrounding collagen as a matrix phase. Strong arguments were presented that bone cannot be described simply as a compound bar or as a material similar to prestressed concrete. Based on measured Young's moduli of 114 GPa for hydroxyapatite (24) and 1.2 GPa for collagen derived from tendon (83), rigorous upper and lower bounds on the elastic modulus of compact bone were calculated (85,86). Young's modulus of bone lay between these bounds and was less than the value obtained by a simple rule of mixtures approach. Similar comparisons were made for other natural collagen-apatite composites such as dentin and enamel from human teeth.

The wide disparity in the upper and lower bounds in this approach limited its applicability. Later, a composite model of the elastic properties of cortical bone was attempted in order to explain the angular dependence of the elastic properties of both wet and dried bovine cortical bone as determined in an ultrasonic wave propagation experiment (87). However, this modeling failed due to the much stronger decay in the angular dependence of the elastic modulus calculated than was found experimentally. Both this

Figure 7. Viscoelastic behavior of wet compact bone in shear. Comparison of results of various authors, adapted from (3). Low frequency $\tan \delta$ inferred from slope of long-term creep by Park and Lakes, 1986 (77), center circles, \odot . Results calculated from integration of constitutive equation of Sasaki et al. 1993 (78) for torsion relaxation in bovine bone (slant squares, \square). Damping adapted from data of Lakes et al., 1979 (75) for wet human tibial bone at 37°C (Calculated from relaxation, circles, \circ ; directly measured, \blacktriangle). Direct $\tan \delta$ measurements by Garner et al., 2000 (79) for wet human bone in torsion, diamonds, \blacklozenge . Damping data of Thompson, 1971 (80) for whole dog radius at acoustic frequencies (diamonds, \square). Damping of wet human femoral bone by Lakes, 1982 (81) via a piezoelectric ultrasonic oscillator (cross, \times). Damping at ultrasonic frequency for canine bone by Adler and Cook (1975) (82) at room temperature (open triangles, \triangle). attempt (88) and the earlier calculations (84–87) failed to model the properties of compact bone because they did not incorporate the dependence of its properties on its complex hierarchical structure. Inclusion of the hierarchical structural organization of bone was accomplished by adaptation of the hollow fiber composite model (89) so that it resembled the structure of Haversian bone with the osteons viewed as hollow fibers embedded in a matrix (36,37). Subsequently, the same model (35,36,89) was adapted to calculate the viscoelastic properties of bone (90). In recent years, homogenization techniques have been applied to obtain even further improvements in the composite modeling (91,92).

The matrix is the ground substance that comprises the cement lines between osteons and is thought to be principally composed of mucopolysaccharides. The stiffness of the ground substance has not been determined experimentally, but it has been inferred from the composite model in conjunction with experimental data from the ultrasound studies on whole bone (93,94). Based on this calculation, the ground substance was computed to be about one-quarter as stiff as the osteon itself. The view of the ground substance as a compliant interface is also supported by the results of several experimental studies. Localized slippage occurs at the cement lines in specimens of bovine plexiform bone (95) of human Haversian bone (77) subjected to prolonged stress. Under such conditions, the ground substance at the cement lines appears to behave in a viscous manner. Considering the full range of load rates and frequencies, one may view the ground substance as a compliant and highly viscoelastic material. Such a conclusion is perhaps surprising (2) in view of the fact that the ground substance is highly mineralized (96). Nevertheless a view of the ground substance as a compliant interface is supported by further experiments. For example, studies of single osteons and osteon groups in torsion have revealed size effects to occur and the osteon to have a higher effective shear modulus than whole bone (97). Similar size effects were observed in torsional and bending experiments upon larger microsamples (98,99). These latter results have been interpreted in light of a generalized form of elasticity theory, known as Cosserat elasticity, which admits both strain of the material and local rotations of microscopic constituents, for example, the osteons (97–99). A twist per unit area or couple stress can occur in addition to a force per unit area or couple stress. By contrast, classical elasticity (Eq. 1), which describes most ordinary materials, involves only strains and stresses. Cosserat elasticity is likely to differ significantly from classical elasticity in its predictions of stress and strain around holes, cracks, and interfaces. For large, whole bones, conventional anisotropic elasticity has been shown to be entirely adequate (39).

The interface between osteons also appears to be important in conferring a measure of fracture toughness upon compact bone. In particular, the crack blunting mechanism of Cook and Gordon (100) confers toughness in fibrous media by the action of a *weak* interface between fibers in blunting a propagating crack (101). Evidence for the role of the cement substance as such a weak interface has been presented by Piekarski (102). Pullout of fibers can result in a large energy absorption in the fracture of fibrous compo-

sites (103). This toughening mechanism also appears to be operative in compact bone, as seen in micrographs of pullout of osteons in fractured bone specimens (51,104).

Consideration of bone as a composite material may provide insight regarding various phenomena in the mechanics of bone. In particular, stress concentration around holes is significantly less than the predicted value (63). The strength of notched specimens does not decrease with the sharpness of the notch as expected; instead, the strength is independent of notch sharpness (49). Residual strain around holes in bone does not follow the predictions of classical anisotropic elasticity (98,99). The fatigue life of bone specimens in bending exceeds that of specimens in tension by a factor of several thousand (59). Similar effects have been observed in various manmade fibrous composites such as boron-epoxy and graphite-epoxy (104). Such phenomena are not correctly predicted by elasticity theory, but may be accounted for in the context of structural models, composite theories, or generalized continuum models (77).

Polycrystalline elastic properties and single-crystal elastic constants of apatites that are useful in the modeling of calcified tissues elasticity are given in Table 6.

Mechanical Properties of Cancellous Bone

Cancellous or trabecular bone is a highly porous or cellular form of bone. In a typical long bone, the cortex or exterior of the shaft (diaphysis) and flared ends (metaphysis) is composed of compact bone while the interior, particularly near the articulating ends, is filled with cancellous bone. Cancellous bone may also be found to fill the interior of short bones and flat bones as well as in the interior of bony tuberosities under muscle attachments. The structure of cancellous bone is that of a latticework of bars and plates; typical structure is shown in Fig. 3. The volume fraction of solid material can be from 5 to 70%; the interstices are filled with marrow. The compressive strength σ_{ult} (in MPa) depends very much on the density ρ (in $\text{g} \cdot \text{cm}^{-3}$) and also varies with the strain rate de/dt (in s^{-1}) as follows (105).

$$\sigma_{ult} = 68(de/dt)^{0.06} \rho^2$$

This relation also models the compressive strength of compact bone (221 MPa, at a density of $\rho = 1.8 \text{ g} \cdot \text{cm}^{-3}$). To a certain degree of approximation, both compact and cancellous bone may be mechanically viewed as a single material of variable density (105). Density is not, however, the only determinant of the properties of cancellous bone. The microstructure can vary considerably from one part of the body to another (106). For example, in the vertebrae and in the tibia (107), a highly oriented, columnar architecture is observed. This kind of trabecular bone is highly anisotropic: the Young's modulus in the longitudinal direction can exceed that in the transverse direction by more than a factor of 10 (107). By contrast, in regions such as the proximal part of the bovine humerus, the cancellous bone can be essentially isotropic (108). This bone is about twice as strong in compression as in tension. In many ways, cancellous bone (109–111) is similar in its behavior to manmade rigid cellular foams (112). For example, in compression, the stress-strain curves contain a linear elastic region, up to a strain of ~ 0.05 , at which the cell walls bend or compress (112). A plateau

region of almost constant macroscopic stress is associated with elastic buckling, plastic yield, or fracture of the cell walls. The compressive failure of the cancellous bone proceeds at approximately constant stress until the cell walls touch each other; at this point any further compression causes the stress to rise rapidly (112). By contrast, fracture of cancellous bone in tension proceeds abruptly and catastrophically (108). The energy absorption capacity of cancellous bone is consequently much less in tension than it is in compression (109). This suggests that tensile and avulsion fractures of cancellous bone observed clinically are associated with minimal energy absorption, and therefore may be precipitated by relatively minor trauma (109). The elastic modulus E for cancellous bone increases as the square of the density ($E = k\rho^2$) if the structure consists of open cells forming a network of rods (110,111). In closed-cell cancellous structures consisting of plates, the modulus E is proportional to the cube of the density ($E = k\rho^3$). Based on study of micrographs and density maps of femora and vertebrae, it is suggested that an open cell structure of rods is found when the solid volume fraction is less than ~ 0.13 , while a closed cell plate structure occurs at a density of $> 350 \text{ kg} \cdot \text{m}^{-3}$ corresponding to a relative density or solid volume fraction of 0.20 (110). The relationship between density and structure may not be so straightforward in all situations. As for the highly oriented columnar cancellous bone from the human tibia (107), the modulus E in the longitudinal direction is proportional to the density ($E = k\rho$). Such behavior is anticipated on the basis of an axial compressional mode of deformation of the cell walls, in contrast to the bending mode that is expected in rod and plate structures (112).

It is important to distinguish the difference between the elastic moduli of volumetric samples of trabecular bone that are highly porous, low density structures, thus exhibiting low moduli, generally well below 1.0 GPa as obtained by mechanical testing techniques, and that of individual trabeculae, comparable in structure and density to cortical bone, thus exhibiting much higher moduli (10–20 GPa), as obtained in recent years by nanoindentation (19) and SAM (18) in addition to that obtained by mechanical testing. Values of the elastic moduli of both trabecular volumes and individual trabeculae are given in Table 7.

ADAPTIVE PROPERTIES OF BONE

Phenomenology

The relationship between the mass and form of a bone to the forces applied to it was appreciated by Galileo (113), who is credited with being the first to understand the balance of forces in beam bending and with applying this understanding to the mechanical analysis of bone. Wolff (114) published his seminal 1892 monograph on bone remodeling; the observation that bone is reshaped in response to the forces acting on it is presently referred to as Wolff's law. Cowin, in Chapter 25 of Ref. 3, discussed "The Problems with Wolff's Law". Many relevant observations regarding the phenomenology of bone remodeling have been compiled and analyzed by Frost (115,116). Salient points are as follows:

1. Remodeling is triggered not by principal stress but by "flexure".
2. Repetitive dynamic loads on bone trigger remodeling; static loads do not.
3. Dynamic flexure causes all affected bone surfaces to drift toward the concavity that arises during the act of dynamic flexure.

These rules are essentially qualitative and they do not deal with underlying causes. A critique of these ideas has been presented by Currey (1,2). Additional aspects of bone remodeling may be found in the clinical literature. For example, after complete removal of a metacarpal and its replacement with graft consisting of a strut of tibial bone, the graft becomes remodeled to resemble a real metacarpal; the graft continues to function after 52 years (117). In the standards of the Swiss Association for Internal Fixation it is pointed out that severe osteoporosis can result from the use of two bone plates in the same region as a result of the greatly reduced stress in the bone (118). Pauwels (119) suggested that as a result of bending stresses the medial and lateral aspects of the femur should be stiffer and stronger than the anterior and posterior aspects. Such a difference has actually been observed (120). Large cyclic stress causes more resorption than large static stress (121). Immobilization of humans causes loss of bone and excretion of calcium and phosphorus (122). Long spaceflights under zero gravity also cause loss of bone (123,124); hypergravity induced by centrifugation strengthens the bones of rats (125,126). Studies of stress-induced remodeling of living bone have been performed *in vitro* (127). Recently, *in vivo* studies in pigs (128) were conducted. In this study, strains were directly measured by strain gages before and after remodeling. Remodeling was induced by removing part of the pigs' ulna so that the radius bore all the load. Initially, the peak strain in the ulna approximately doubled. New bone was added until, after 3 months, the peak strain was about the same as on the normal leg bones. *In vivo* experiments conducted in sheep (129) have disclosed similar results. It is of interest to compare the response time noted in the above experiments with the rate of bone turnover in healthy humans. The life expectancy of an individual osteon in a normal 45 year old man is 15 years and it will have taken 100 days to produce it (130,131).

Remodeling of Haversian bone seems to influence the quantity of bone but not its quality, that is, young's modulus, tensile strength, and composition (132). However, the initial remodeling of primary bone to produce Haversian bone results in a reduction in strength (1,2). As for the influence of the rate of loading on bone remodeling, there is good evidence to suggest that intermittent deformation can produce a marked adaptive response in bone, whereas static deformation has little effect (127). Experiments (133) upon rabbit tibiae bear this out. In the dental field, by contrast, it is accepted that static forces of long duration move teeth in the jawbone. In this connection (134), the direction (as well as the type) of stresses acting on the bone tissue should also be considered. Currey (1,2) points out that the response of different bones in the same skeleton to mechanical loads must differ, otherwise lightly loaded

bones such as the top of the human skull, or the auditory ossicles, would be resorbed.

Failure of bone remodeling to occur normally in certain disease states is of interest: for example, osteopetrotic bone contains few if any viable osteocytes and usually contains a much larger number of microscopic cracks than adjacent living bone (135). This suggests that the osteocytes play a role in detecting and repairing the damage. In senile osteoporosis, bone tissue is removed by the body, often to such an extent that fractures occur during normal activities. Osteoporosis may be referred to as a remodeling error (116).

Some theoretical work, notably by Cowin and others (3,136) has dealt with the problem of formulating Wolff's law in a quantitative fashion. In this theory, constitutive equations are developed, which predict the remodeling response to a given stress. Stability considerations are invoked to obtain some constraints on the parameters in the constitutive equation.

Feedback Mechanisms

Bone remodeling appears to be governed by a feedback system in which the bone cells sense the state of strain in the bone matrix around them and either add or remove bone as needed to maintain the strain within normal limits. The process or processes by which the cells are able to sense the strain and the important aspects of the strain field are presently unknown. Bassett and Becker (137) reported that bone is piezoelectric, that is, that it generates electric fields in response to mechanical stress; they advanced the hypothesis that the piezoelectric effect is the part of the feedback loop by which the cells sense the strain field. This hypothesis obtained support from observations of osteogenesis in response to externally applied electric fields of the same order of magnitude as those generated naturally by stress via the piezoelectric effect. The study of bone bioelectricity has received impetus from observations that externally applied electric or electromagnetic fields stimulate bone growth (138). The electrical hypothesis, while favored by many, has not been proven. Indeed, other investigators have advanced competing hypotheses that involve other mechanisms by which the cells are informed of the state of stress around them.

For example, inhomogeneous deformation at the lamellae may impinge on osteocyte processes and thus trigger the osteocytes to initiate bone formation or remodeling (139). Motion at the cement lines was observed and it was suggested that such motion could act as a passive mechanism by which bone's symmetry axes may become aligned to the direction of time averaged principal stresses (99). Stress on bone may induce flow of fluid in channels, (e.g., canaliculi), and such flow could play a role in the nutrition and waste elimination of osteocytes, which may be significant in bone remodeling (140). In a related vein, theoretical arguments have been presented in support of the hypothesis that bone cells are directly sensitive to hydrostatic pressure transmitted to them from the bone matrix via the tissue fluid (141). Although no experimental test of this direct pressure hypothesis has been published, we observe with interest that direct hydrostatic pressure

has been observed to alter the swimming behavior of paramecia, possibly by means of action upon the cell membrane (142). Otter and Salman found that a hydrostatic pressure of 68 atm abolishes the reversing of direction of swimming, 170 atm stops swimming, and 400–500 atm irreversibly damages the cell. We observe that 100 atm corresponds to 1400 psi stress, or in bone, a strain of 0.07%, which is in the normal range of bone strain and 500 atm corresponds to 7000 psi or a strain of 0.35%, well above the normal range of bone strain. Stress in bone also results in temperature differences between osteons (143); the cells may be sensitive to sudden temperature changes during human activity. A mechanochemical hypothesis has been advanced, in which the solubility of calcium may be affected by stress in the bone matrix (144). Strain energy in bone might also influence the energetics of bone mineral nucleation (145). It has also been suggested that remodeling may be initiated in response to microcracks generated by mechanical fatigue of bone (146). In summary, many hypotheses have been proposed for the mechanism by which appropriate cells sense the state of strain in bone, but little or no experimental evidence is available to discriminate among them.

Cellular and Biochemical Aspects of Bone Remodeling

The adaptive response of bone to mechanical stimuli is mediated by living cells. A great deal is known concerning bone cell function and its control by ionic and hormonal factors, but little is known concerning the effect of mechanical strain in bone upon the biochemistry of its cells. Rasmussen and Bordier (147) have presented an extensive review of studies of bone cell physiology. Recently, the biochemical consequences of electrical stimulation of bone have been reported (148). Biochemical steps associated with cell activation are as yet poorly understood, but ion fluxes appear to play a role (149). Cyclic nucleotides mediate the effects of extracellular signals (150) and prostaglandins modulate them (149). Prostaglandin E_2 has been hypothesized to mediate bone resorption in trauma, malignancy, and periodontal disease. This prostaglandin, as well as the cellular constituents cyclic AMP and cyclic GMP, has been found in association with regions of bone stimulated electrically (148).

ELECTRICAL PROPERTIES OF BONE

Fukada and Yasuda (151) first demonstrated that dry bone is piezoelectric in the classic sense, that is, mechanical stress results in electric polarization, the indirect effect; and an applied electric field causes strain, the converse effect. The piezoelectric properties of bone are of interest in view of their hypothesized role in bone remodeling (137). Wet collagen, however, does not exhibit piezoelectric response. Studies of the dielectric and piezoelectric properties of fully hydrated bone raise some doubt as to whether wet bone is piezoelectric at all at physiological frequencies (152). Piezoelectric effects occur in the kilohertz range, well above the range of physiologically significant frequencies (152). Both the dielectric properties (153) and the piezoelectric properties of bone (154) depend strongly on

frequency. The magnitude of the piezoelectric sensitivity coefficients of bone depends on frequency, on direction of load, and on relative humidity. Values up to 0.7 pC/N have been observed (154), to be compared with 0.7 and 2.3 pC/N for different directions in quartz, and 600 pC/N in some piezoelectric ceramics. It is, however, uncertain whether bone is piezoelectric in the classic sense at the relatively low frequencies which dominate in the normal loading of bone. The streaming potentials examined originally by Anderson and Eriksson (155,156) can result in stress generated potentials at relatively low frequencies even in the presence of dielectric relaxation, but this process is as yet poorly understood.

Potentials observed in bent bone differ from predictions based on the results of experiments performed in compression (157). The piezoelectric polarization may consequently depend on the strain gradient (157) as well as on the strain. This piezoelectric theory has been criticized as ad hoc by some authors, however, the idea has some appeal in view of Frost's modeling (115,116) and Currey's suggestion (1,2) that strain gradients may be significant in this regard. The gradient theory is not ad hoc, but can be obtained theoretically from general nonlocality considerations (158). The physical mechanism for such effects is hypothesized to lie in the fibrous architecture of bone (26,78). Theoretical analyses of bone piezoelectricity (159–162) may be relevant to the issue of bone remodeling. Recent thorough studies have explored electromechanical effects in wet and dry bone. They suggest that two different mechanisms are responsible for these effects: Classical piezoelectricity due to the molecular asymmetry of collagen in dry bone, and fluid flow effects, possibly streaming potentials in wet bone (163).

Bone exhibits additional electrical properties which are of interest. For example, the dielectric behavior (e.g., the dynamic complex permittivity) governs the relationship between the applied electric field and the resulting electric polarization and current. Dielectric permittivity of bone has been found to increase dramatically with increasing humidity and decreasing frequency (152,153). For bone under partial hydration conditions, the dielectric permittivity (which determines the capacitance) can exceed 1000 and the dielectric loss tangent (which determines the ratio of conductivity to capacitance) can exceed unity. Both the permittivity and the loss are greater if the electric field is aligned parallel to the bone axis. Bone under conditions of full hydration in saline behaves differently: the behavior of bovine femoral bone is essentially resistive, with very little relaxation (164). The resistivity is $\sim 45\text{--}48\ \mu\Omega$ for the longitudinal direction, and three to four times greater in the radial direction. These values are to be compared with a resistivity of $0.72\ \mu\Omega$ for physiological saline alone. Since the resistivity of fully hydrated bone is ~ 100 times greater than that of bone under 98% relative humidity, it is suggested that at 98% humidity the larger pores are not fully filled with fluid (164).

Compact bone also exhibits a permanent electric polarization as well as pyroelectricity, which is a change of polarization with temperature (165,166). These phenomena are attributed to the polar structure of the collagen molecule; these molecules are oriented in bone. The orientation of

permanent polarization has been mapped in various bones and has been correlated with developmental events.

Electrical properties of bone are relevant not only as a hypothesized feedback mechanism for bone remodeling, but also in the context of external electrical stimulation of bone to aid its healing and repair (167,168).

The frequency of electrical stimulation influences its effectiveness (169). A frequency band of 20–30 Hz was found from analysis of strain data. Bone growth could be stimulated more easily in the avian ulna at relatively higher frequencies. Electromagnetic stimuli also prevent bone loss due to disuse as revealed in an isolated canine fibula model (170). Bone density may be maintained and increased by weight lifting, which involves no medical intervention. Indeed, bone mineral content values (as determined with dual photon absorptiometry) in the spines of athletes were extremely high and were closely correlated to the amount of weight lifted during training (171).

INTRODUCTION

Many years of intensive research by Rohm led to the development of poly(methyl methacrylate) (PMMA), the basis of bone cement, in 1934 (1,2). This polymer was reportedly first used to close cranial defects in monkeys in a medical application in the late 1930s (2). The use of acrylic bone cement in orthopedic surgery was first advocated in 1951 by Kiaer and Jansen. It was applied as pure anchoring material by fixing acrylic glass caps on the femoral head after removing the cartilage (2-4). At that time, the femoral components in total hip replacements were still implanted by simply press-fitting the prosthesis tightly into the prepared intramedullary (marrow) canal of the femur. Patients were confined to bed for a relatively long period of time after surgery and often experienced pain later from loosening of the implant. In 1958, Sir John Charnley first applied the self-curing bone cement for the fixation of artificial joints (4). In this surgery, the cement filled the free space between the prosthesis and the bone (2). Bone cement served as a mechanical interlock between the metallic prosthesis and the bone and it has been found to be an appropriate material to transfer the load consistently (5). In 1969, bone cement was approved for general use within the United States and since then the number of total hip and knee replacements has increased dramatically (3). Currently, it is the only material used for anchoring cemented arthroplasties to the contiguous bones (6). More than one-half million hip replacement surgeries are performed every year worldwide and 70% of the surgeries are performed using bone cements (7-10).

Bone cement is also extensively used in the fixation of pathological fractures, spinal surgery, and neurosurgery (11). Every year, osteoporosis results in >310,000 fractures in the United Kingdom alone (12). Vertebral compression fractures occur in 20% of people over the age of 70 years and in 16% of postmenopausal women (12). Although traditional conservative techniques, such as bed rest and the prescription of analgesics may be successful in a proportion of cases, a significant number of sufferers remain in long-term pain. Vertebroplasty is now being used extensively for vertebral compression fracture treatments (12,13). This technique entails the percutaneous injection of bone cement into the fractured vertebra in attempts to stabilize the fracture and reduce pain. Studies have reported excellent pain relief and improved function in most patients (12,13). Bone cements have also been applied as an adjunct to internal fixation for treating fractures. Bone cement fills voids in bone, thereby reducing the need for bone grafts, and may improve the holding strength around the devices in osteoporotic bone. Recently, the technique of PMMA bone cement injection into the osteoporotic proximal femur was proposed (14). Results indicated that cement injection increased the peak fracture load >80 and 20% in the simulated fall and one single limb stance configurations, respectively (14). This technique could become a treatment option to solve the problems with osteoporotic hip fractures in patients at risk. Such treatment may hold a significant impact on the economy and human health as hip fractures result in ~300,000 hospital admissions annually in the United States with an estimated \$9 billion in direct medical costs (14). Therefore, bone cements are significantly valuable for biomedical applications.

In many cases, the bone cemented implants perform satisfactorily for years. However, failure of the implants may be linked to bone cement properties. It is well recognized that there are a number of drawbacks that exist with the usage of bone cement, significant ones including its poor mechanical properties and the potential necrosis of bone tissues (6,15,16). For example, bone cement has been called the "weak link" in the prosthesis system and long-term loosening of the prosthesis has been attributed to its mechanical disintegration (10). It is worth pointing out that aseptic loosening of a cemented arthroplasty is a multifactorial phenomenon involving interfacial failure, bone failure, bone remodeling, and cement failure (6). It is not firmly established whether the drawbacks of bone cements contribute to the initiation or are the consequence of aseptic loosening of the implant (6). In spite of the many drawbacks of bone cement, the survival probabilities of recently cemented joint replacements are still high. Currently, cemented total hip arthroplasty shows survival rates of 90% at 15 years and 80-85% at 20 years (10,15,17-21). Increasing bone cement properties along with improving cementing techniques and implantation methods may further extend cemented implant longevity.

In recognizing the drawbacks of bone cement usage, there have been considerable efforts to secure the implants without using cement. Early noncemented prostheses were the press-fitted or screwed-in types (10). The press-fit

techniques must lead to good initial fixation; otherwise, mobility will occur and this will facilitate wear and/or formation of fibrous tissue. Such techniques have limited successes due to a number of reasons, including bone resorption, geometrical constraints, and increased operational fractures. Noncemented porous coated prostheses were also introduced to provoke bony ingrowth for improved fixation. The noncemented prostheses are used predominantly in younger patients (< 60 years), where it is assumed that these prostheses eventually simplify a revision operation (10). Bone ingrowth strategies are not appropriate for older patients. Research indicates that some of the noncemented devices have failed, but others are doing well in the mid- to long- term (10). The clinical applications of cementless total hip and knee arthroplasties induce a new set of problems, including perioperative osteolysis, high thigh pain, and failure of the bone-implant interface (6). Thus, there is currently a resurgence of interest in bone cement (6). Definite conclusions about the ultimate clinical performances of cement or cementless fixation devices require longer term studies (10). The debate is still open as to which fixation method is best. The development of cementless modes of fixation is an area of active research and clinical practice; however, acrylic bone cement continues to be the most commonly used nonmetallic implant material by orthopedic surgeons (6,11).

The literature on bone cement is voluminous with respect to its material development, manufacturing, thermal response, chemical and biological effects to bone, and its short- and long-term physical and mechanical properties (static, fatigue, etc.). This article discusses some of these aspects, especially on cement's material characteristics. For more ample assessment, the readers should refer to other excellent comprehensive reviews [e.g., Krause (3,11), Lewis (6,22), Kuhn (2), Saha (23), Kenny (5), Deb (24), Hasenwinkel (15), Serbetci and Hasirci (16)]. The article is arranged into several sections. It begins with the description of bone cement compositions, followed by a section on cement setting procedure and cementing technique. Then, the thermal and volumetric change effects are discussed. The final section focuses on the physical and mechanical properties of cement. Finally, the article ends with a brief summary.

CEMENT COMPOSITIONS

There are a number of bone cements [> 60 types (2)] available to the orthopedic community. Some popular cements currently available in the United States are given in Table 1 (2,6,11). Most of the present commercial bone cements have similar compositions (Table 2) (2,11,25). The presently used form of bone cement is predominantly the same as the one Sir John Charnley introduced. All acrylic bone cements on the market are chemically based on the identical basic substance: methyl methacrylate (MMA) (2). Pure MMA exhibits a shrinkage of $\sim 21\%$ during polymerization (2), and the polymerization temperature can increase to 100–120°C. Such a high shrinkage is intolerable for use in bone cement (2). For this reason, bone cements

Table 1. List of Popular Commercial Bone Cements Currently Available in the United States^a

^aSee Refs. 2,6, and 11.

are offered as two-component systems in the marketplace: a prepolymerized powder and a liquid monomer (2). The MMA in aqueous suspension is prepolymerized in easily cooled reaction boilers. The polymer, obtained in the form of tiny balls ($< 150 \mu\text{m}$), is easily dissolved in the MMA. By using the prepolymerized polymer powder, both the shrinkage of the sample and the temperature of the reaction can be considerably decreased. In most bone cements on the market, the mixing ratio is two to three parts powder to one part monomer. This reduces the shrinkage and the generation of heat by at least two-thirds, as only the monomer is responsible for these reaction symptoms (2).

Usually, the solid part of bone cement consists of prepolymerized PMMA beads ranging in size from 1 to 150 μm . Other kinds of polymers sometimes are added, including poly(ethyl acrylate), poly(methyl acrylate), poly(styrene), and poly(butyl methacrylate). Free radicals of benzoyl peroxide (BPO) are present within the beads as remnants from the emulsion polymerization process (the process by which most of the beads are manufactured). An additional amount of BPO is mixed with the solid to obtain 1–2.5% by weight benzoyl peroxide. In addition, bone cements generally contain $\sim 10\text{--}15\%$ by weight barium sulfate, zirconia, or other additive. The presence of barium sulfate or zirconium dioxide in the powder is necessary for

^bSee Refs. 2,6,11 and 25.

a clinical reason. The original bone cements, which did not contain radiopacifiers could not be visualized on radiographs. The main components in the liquid phase are MMA, and, in some bone cements, other esters of acrylic acid or methacrylic acid, one or more amines (as activators for the formation of radicals), a stabilizer and, possibly, a colorant (2). The amine in the bone cement, *N,N*-dimethyl-*p*-touluidine (DMPT), acts as an accelerator. The liquid component also consists of 50–100 ppm hydroquinone, which inhibits the polymerization reaction within the monomer and allows for storage of the liquid component. Some cement also contains chlorophyll that gives it a green color. This allows better distinction from body tissues during surgery.

Prosthesis-related infection is described as a devastating failure scenario of a cemented orthopedic implant. Infectious complications of a cemented prosthesis lead to a deterioration of function and increase pain. Buchholz and Engelbrecht first reported on the possibilities of mixing antibiotics in bone cement in 1970 (17). They considered gentamicin sulfate to be the antibiotic of choice because of its wide-spectrum antimicrobial activity, its excellent water solubility, its thermal stability and its low allergenicity. Apart from gentamicin, other antibiotics have also been used as an additive to bone cement. The combination of erythromycin and colistin is an example that made it to a commercial product (17). In most cases, the manufacturers make their antibiotic cements by simply mixing antibiotic to a plain cement version they have (2,15,16).

Currently, bone cement fracture is regarded as a major factor in the mechanical failure of implant fixation (26–28). It is directly related to the mechanical properties of the cement, especially the resistance to fracture of the cement in the mantle at the cement–prosthesis interface or the cement–bone interface. Thus, many investigators have attempted to incorporate second phase materials including polyethylene (29), hydroxyapatite (30), PMMA (31), Kevlar (32,33), carbon (34–36), titanium (37), and steel (38–40) to improve the fatigue properties and fracture toughness of the PMMA. Most of the results regarding the properties of these composite materials have been encouraging; however, the biocompatibility issues regarding some of these fibers are as yet unresolved (6). Consequently, none of the commercial bone cements have incorporated these fibers in cements on the market.

CEMENT SETTING AND CEMENTING TECHNIQUE

Most structural materials are fabricated under controlled conditions at a factory, then transported and assembled on site. Bone cement is one of the few structural materials that are created *in situ*. The surgeon prepares the bone cement directly at the operation table according to the manufacturer's instructions. All of the cements are supplied in sets of the polymer powder and the monomer liquid components packed in two separate containers within a package. At the time of surgery, the liquid monomer and powder are mixed, the DMPT reacts with the BPO to generate free radicals, which in turn are used in the

Table 3. Four Phases of Bone Cement Polymerization Process^a

Phases	Time Duration, min	Characteristics
I. Mixing	1–2	Wetting Cement relatively liquid (low viscous)
II. Waiting	2–3	Swelling + polymerization Increase of viscosity Polymer chains, less movable Sticky dough
III. Working	5–8	Chain propagation Reduced movability Increase of viscosity Heat generation
IV. Setting	2–6	Chain growth finished No movability Cement hardened High temperature

^aSee Ref. 2.

additional polymerization of the MMA monomers to form PMMA. Polymer chains from the PMMA become available for free radical polymerization and entanglements of these chains with newly formed chains lead to an intimate connection between the newly formed PMMA with what was already present. The resulting product is a doughy mixture that later polymerizes to a hard and brittle substance.

The curing process of acrylic PMMA bone cement can be divided into four basis steps (2): the mixing, waiting, working, and hardening phase. The characteristics of these phases, well described by Kuhn (2), are shown in Table 3. The time at which the cement does not stick to the surgeon's glove is referred to as dough time (Fig. 1). The waiting phase ends at this time point. This occurs ~2–3 min after the beginning of mixing for most PMMA cements in an ambient temperature of 23 °C (2,11). The working phase is the time during which the surgeon can easily apply cement to the femur. For manual application, the cement must no longer be sticky during this phase, and the viscosity must not to be too high. With the use of mixing systems, the user needs not to wait until the cement is no long sticky. The working time from the end of dough time to the cement is too stiff to manipulate is usually 5–8 min. The cement will fully polymerize to a hardened mass within 8–12 min after initial mixing (2,11).

The quality of the cement dough produced in the operation room will have considerable influence on the clinical long-term result of a cemented prosthesis. Mixing of cements is an important step, as it has a noticeable influence on the mechanical properties of acrylic bone cements (2,6,24). In the 1970s, loosening of the femoral stem was the most common reason for total hip arthroplasty revision, often occurring 5–10 years postoperatively with early component design and cement technique (21). Early methods of cement preparation involved hand mixing in open air of the MMA monomer with the prepolymerized powder mixture. A slurry was formed that could be hand patted or injected into the femoral canal. Many air bubble voids were

Figure 1. A typical temperature changes with respect to time during cement polymerization. Time zero is designated when the monomer liquid is added to the polymer powder.

created in the mixture during the hand-mixing process. To address this problem in cemented arthroplasty, intensive studies have attempted to improve the technique of cemented stem insertion (21). This results in advancing the cementing techniques from first generation cementing to second and third generation cementing (Table 4). Traditionally, bone cement was mixed using a spatula-bowl arrangement (first generation), which can have the consequence of introducing a high degree of porosity into the cement structure. In addition, the person mixing the cement was exposed to a high level of methyl methacrylate vapors. Second-generation cementing mainly consisted of the use of a canal plug, a cement gun and a high strength cement (21,41,42). Injection guns have been advocated for application of bone cement because long slender injection tips are useful for inserting the cement deep into the cavity, instead of trying to apply it by hand. Gun application also reduces the tendency to form laminations and voids in the cement and also reduces the inclusion of blood into the cement. Substantial improvements in stem survival were reported using such techniques, resulting in stem loosening rates of < 5% at 5–10 years (21,42). The introduction of porosity reducing measures marked the start of third generation cementing techniques. Cracks may initially occur at the voids in bone cements, which act as stress concentration points (24). Vacuum mixing is a typical ways to achieving pore reduction. Other third-generation devel-

opments in cementing techniques are the use of prosthesis positioning devices that ensure correct placement of the prosthesis, pressurization, and enhanced surface finishes (21,43). Attempts to improve cement-bone interlock using techniques such as endosteal preparation, retrograde cement insertion and cement pressurization improve implant survival. Improving cementing techniques have assisted to dramatically decrease the number of failure in the last three decades. Currently, cemented total hip arthroplasty shows survival rates of 90% at 15 years and 80–85% at 20 years (10,17,18,21).

POLYMERIZATION HEAT

Bone cement generates significant thermal energy during cement setting (an energy of $52 \text{ kJ} \cdot \text{mol}^{-1}$ of MMA (2)) and this may result in a temperature increase in the cemented system. The exothermic response of the bone cement can be characterized according to American Society for Testing and material (ASTM) standard F451 (44) or international standard ISO 5833. In the ASTM test, a package of cement is mixed at an air conditioned room ($23 \pm 1^\circ\text{C}$, $50 \pm 10\%$ relative humidity) as directed by the manufacturer's instructions. Within 1 min after doughing time, $\sim 25 \text{ g}$ of the dough is then gently packed into an ASTM specified test mold to achieve a 60 mm diameter with 6 mm thick disk cement mantle (44). The setting curve of temperature change with respect to time (Fig. 1) is recorded with a thermocouple (usually No. 24 gage wire k-type thermocouple) placed at the cement mantle center from the onset of mixing until cooling is observed. The setting time is defined as the time from initial mixing to the time at which the temperature of the polymerising mass has reached half of the maximum temperature (peak temperature) (44). The setting times range from 6 to 14 min and peak temperatures range from 54 to 83°C for the popular commercial bone cements (2,11). A number of variables will affect the measured setting time and peak temperature, including the powder/liquid ratio of the cement, cement preparing method, cement mantle thickness, the initial temperature of the cement, and the ambient conditions (11). By mixing bone cement with Howmedica Mix-Kit I system and the Zimmer Osteobond vacuum system, Dunne and Orr (45)

Table 4. Developments in Cementing Techniques

Generations	Techniques	Time
1st Generation	Finger packing No cement restrictor	1960s
2nd Generation	Intramedullary femoral plug Cement gun High-strength cement	1970s
3rd Generation	Pressurization of cement after insertion Porosity reduction (vacuum mixing) Surface roughening or texturing Precoating Avoiding trochanteric osteotomy	mid-1980s–

found peak temperatures increased from 36 to 46 °C and 41 to 59 °C for Palacos R and CMW3 bone cement, specifically. Cold cement in a cold room takes longer to set. Precooling cement prior to use extends the cure time and decreases the peak temperature (46). Using a test mold and cementing techniques that simulated a clinical situation, Iesaka et al. (47) showed that the peak temperatures at the bone-cement interface were 53.1, 50.2, and 48.8 °C, while the polymerization time was 4.1, 8.3 and 11.2 min, when the monomer component of bone cement was initially at 37, 23, and 4 °C, respectively. Research also found that bone cement thickness has significant effects on the thermal responses. Meyer et al. (48) found a setting temperature of 60 °C with 3 mm thick specimens of Simplex R, and 107 °C with 10 mm thick specimens. Sih and Connelly (49) showed that the temperatures were 41, 56, and 60 °C for cement thicknesses of 1, 5, and 6-7 mm, respectively. Vallo (50) and Li et al. (51) demonstrated similar results with finite element modeling. Test mold materials also affect the measured setting time and peak temperature (50,51). According to the ASTM methodology, there is no limit to the setting time. However, the maximum allowable temperature for bone cements is 90 °C (44). There are limits stipulated for setting time and doughing time with ISO 5833 Standard.

The importance of temperature rise is that it may result in thermal necrosis of the bone tissue surrounding the implant (2,11,52-56). *In vitro* studies have shown that maximum temperature of bone cement can be reach higher than 100 °C, varied between 37 and 122 °C in different reports (57). Wang et al. (58) measured four different brands of bone cement (Palacos R, Simplex P, Sulfix, and CMW 1) during polymerization and the peak temperature in the cement was 46-124 °C. Clinical tests show a considerable lower temperature in the body (2,55). The bone-cement interface temperatures have ranged from 35 to 70 °C (2,11,52,3,54,55,57,59). Reasons for this observation are the thin layer of cement (~3-5 mm) and the blood circulation and heat dissipation in the vital tissue connected with it (2). Moreover, further heat dissipation of the system is attained via the prosthesis (2). Belkoff and Molloy (59) found that peak temperatures at the anterior cortex ranged from 44 to 113 °C, in the center ranged from 49 to 112 °C, and 39 to 57 °C at the spinal canal in the *ex vivo* vertebroplasty tests. Toksvig-Larsen (57) performed tests with 31 total hip replacements and showed that the maximum temperature in the acetabulum ranged from 38 to 52 °C and in the femur from 29 to 56 °C. It has been found that not only the temperature, but also the exposure time plays a significant role in direct thermal cell necrosis (52,60-63). The findings of Moritz and Henriques (60) suggest that epithelial cell necrosis occurs 30 s after exposure to a temperature of 55 °C and 5 h after exposure to 45 °C. Lundskog (61) roughly confirmed these trends for bone cells, although he found a slightly lower threshold level. For example, he observed bone cell necrosis after 30 s at 50 °C. He also established that the regenerative capacity of the bone tissue is only damaged after exposure to temperatures of 70 °C and above. Eriksson and Albergsson (64) found the temperature threshold for impaired bone regeneration to be in the range of 44-47 °C for 1 min exposure.

Thermal damage to bone tissue caused by cement polymerization cannot be ruled out and attempts to lower the potential degree of thermal necrosis have been investigated. To reduce the risk of thermal injury it is necessary to avoid exposing bone to temperatures above a certain threshold (62). The thermal responses rely on the quantity of heat produced by the bone cement (cement formulations and cement volume, etc.), rate of heat produced and how the heat conducts (55). The temperature peak can only be influenced to a small extent by adding heat-conducting radiopaque media or by slightly changing the chemical composition of the liquid (2). This, will, however, result in quite different dissolution properties with the polymer, which means it will result in different working properties and, usually, a significant reduction in mechanical stability (2). The thicker the cement mantle, the greater the volume of material and hence the more heat generated. However, simply reducing the thickness of the mantle is not a favorable option as the mechanics of the joint is affected by this. A slightly reduced level of heat generation has been shown by vacuum mixing the bone cement (45,57). Precooling the cement constituents prior to mixing increases the setting time, but has only minor effects on the maximum temperature of the cement (56). The use of a precooled femoral prosthesis did not affect the peak temperature as well (56,57). To avoid local tissue damage, surgeons may irrigate the implant with ice-cold saline during the polymerization process to decrease both the duration and the level of temperature elevation. Without cooling, the temperature was 49 °C (41-67) at the bone-cement interface, while it decreased to 41 °C (37-47) with water cooling in 19 cases of arthroplasties (65). Investigations on the potential tissue thermal necrosis have obtained varied results: while thermal bone necrosis due to cement curing heat has not been widely reported, some studies showed that thermal necrosis of bone did occur (52,54,59). Nevertheless, few would disagree that a clear understanding of the potential thermal necrosis problem requires further investigations.

VISCOSITY

During the working stage of the cement, its viscosity must be low enough to make it easy to force the cement dough through the delivery system and cause it to flow and penetrate into the interstices of the bone surface in a very short time (6,11,22). *In vitro* determination of viscosity is usually accomplished with the use of a capillary extrusion or rotational rheometer (6,11,22). The viscosity of the material can be determined by causing the material to flow at a specific shear rate and measuring the shear stress of the fluid against the stationary instrument (11). Viscosity varies across cements. The dynamic viscosity of its dough during the mixing period has been used to categorize bone cement materials into low viscosity brands (e.g., Osteopal), medium-viscosity brands (e.g., Simplex P), and high viscosity brands (e.g., Palacos R) (22). High viscosity bone cements typically have a doughy consistency; low viscosity cements are similar to viscous oil in consistency. Low viscosity cements have a long liquid

phase, or low viscosity wetting phase. The cement remains sticky for quite some time. Viscosity increases rapidly during the working phase, and the doughy cement becomes warm and sets quickly. High and low viscosity bone cements have different handling characteristics and require different cementing techniques. For optimal results, it is necessary to observe the specific mixing instructions for a given bone cement in combination with a given mixing system. Although some researchers suggest that low viscosity brands may have longer fatigue lives compared to high viscosity ones, some report no significant difference (22).

POROSITY, VOLUMETRIC CHANGES, AND RESIDUAL STRESS

Polymerized bone cement is a porous material, containing macropores (pore diameter > 1 mm) and micropores (pore diameter \approx 0.1–1 mm) (6). The degree of porosity varies with cement brands and mixing methods. Jasty et al. (66) found that the porosities were 11.99% (CMW), 9.70% (Palacos R), 9.39% (Simplex P), 12.38% (Zimmer Regular), and 5.00% (Zimmer LVC) using manual mixing, while they were 6.00% (CMW), 4.25% (Simplex P), 6.00% (Zimmer Regular) and 4.15% (Zimmer LVC) with centrifugation. For CMW 1 cement, Muller et al. (67) found that the porosity decreased from 6.67 to 1.28% when using vacuum-mixing instead of hand-mixed methods. The pores generated in polymerized bone cement have been attributed to several sources (6,68–72). It may result from the air that is initially present in the powder interstices; entrapped during blending, mixing, transfer, or delivery; or entrained during insertion of the metal stem. Evaporation of the liquid monomer at the high temperatures of polymerization may contribute. Another aspect of porosity development is polymerization shrinkage.

The presence of pores in the polymerized cement may affect its mechanical properties. Pores may act as stress risers and initiation sites for cracks, rendering the cement susceptible to early fatigue failure (6). However, pores also may play a role in blunting crack propagation, thereby prolonging the life of the implant (73). *In vitro* experiments, the static and fatigue strength of bone cement both usually decrease with increased porosity (6,22,23,69,70). Reducing the porosity of both bulk cement and its interfaces should be of clinical benefit. Several methods of reducing the porosity of the bone cement have been developed (66). One commonly used method of void reduction is the centrifugation of a chilled, premixed bone cement prior to insertion into the bone. The other one is the mixing of the bone cement in a vacuum environment. Both techniques have been shown to substantially reduce the porosity of bone cement. It has been observed that mixing procedures plays a significant role in determining the quality of bone cement produced (2,74,75). The influence of vacuum mixing on the pores results in a 15–30% improvement of the bending strength of Palacos R while centrifuging Simplex P cement reduced its porosity from 9.4 to 2.9%. Experiments have shown that relative to hand mixing, centrifugation or vacuum mixing leads to a substantial reduction in porosity (2,6). The extent of such a

reduction depends on many mixing variables, including mixing system, monomer storage temperature, vacuum pressure and centrifugation speed, and durations. In the hand-mixing process, air bubbles are mixed into the dough by thorough mixing. The porosity of the material is high and mechanical stability is endangered. Slower mixing of cement over a shorter time decreases air voids within cement and thus improves the strength characteristics. A high degree of porosity is found to exist in cement that is inadequately mixed (74). Monomer bubbles can easily appear, which may develop during the evaporation of the monomer while evacuating the system or later during polymerization under high pressure by the faulty use of vacuum-mixing systems.

Cement porosity distributions, especially at the bone–cement interface, may affect the cemented system. There is strong evidence that cracks in the cement are initiated at voids, particularly at the cement–prostheses interface (69). The preferential formation of voids at this site results from shrinkage during bone cement polymerization and the initiation of this process at the warmer bone–cement interface, which causes bone cement to shrink away from the prosthesis (2,68,69). It is expected that a reversal of polymerization direction would shrink the cement onto the prosthesis and reduce or eliminate the formation of voids at this interface (69). One innovative surgical approach to affect this behavior is to preheat the prosthesis prior to implantation. Results indicated that voids near the cement–prosthesis interface decreased significantly (69,76). The porosity at the cement–prosthesis decreased from 16.4 to 0.1% when the prosthesis was preheated to 37°C from room temperature, 23 °C. Additionally, the residual stress due to such polymerization curing was shown to decrease significantly at the cement–prosthesis interface (77). Studies also showed that preheating the prosthesis prior to implantation is unlikely to produce significant thermal damage to the bone when compared to implanting a prosthesis initially at room temperature (46,69). However, this procedure may induce more voids at the bone–cement interface, and its effects on the damage at this region should be studied (69,78).

The conversion of the monomer molecules into a polymer network is accompanied with a closer packing of the molecules, which leads to bulk contraction (68,79). A number of devices for determining the volumetric changes have been applied, including using a mercury dilatometer or a water displacement dilatometer (79,80). Theoretical calculations predict that bone cement polymerization will produce a volumetric shrinkage of 8% (81). Muller et al. (67) found volume shrinkages of CMW 1 bone cement were 3.43 and 5.99% with hand and vacuum mixing, respectively. Gilbert et al. (68) found shrinkages of Simplex P cement were 5.09 and 6.67%, respectively. The measured volume shrinkage is less than the theoretical prediction. This can be explained by void growth during polymerization (67).

In a situation where a curing material is bonded on all sides to rigid structures or constrained, bulk contraction cannot occur freely, and shrinkage must be compensated for by some kind of volume generation. This can come from a strain on the material and mainly for dislodgement of the bond, increase in porosity or internal loss of coherence (79).

Table 5. Comparison of the Values of Three Mechanical Properties of Six Different Bone Cements Under Same Test Regimes^a

Cement Brands	ISO 5833 Bending Strength, MPa	Bending Modulus, MPa	Compressive Strength, MPa	DIN53435 Bending Strength, MPa	Impact Strength, kJ·m ⁻²
CMW1	67.0	2634	94.4	86.2	3.7
CMW3	70.3	2764	96.3	72.4	2.9

Shrinkage of the polymerizing cement *in vivo* (i. e., a constrained state) therefore might result in the development of porosity, both at the interfaces and inside the bulk cement. Thus, polymerization shrinkage may be a significant factor in porosity development (68). On the other hand, polymerization may induce high residual stresses. Shrinkage stress occurs when the material contraction is obstructed and the material is rigid enough to resist sufficient plastic flow to compensate for the original volume (79). The process of cement curing is a complex solidification phenomenon where transient stresses are generated and the residual stresses vary with different initial and boundary conditions during curing. A number of approaches have been used to estimate or measure the level of shrinkage stress in bone cement around femoral replacements, including theoretical model, finite element analysis, strain-gage methods and photoelastic methods (52,77,82–88). Currently, the subject of residual stress has often been neglected because it is assumed that residual stress will relax due to the viscoelastic properties of the cement. However, transient and residual stresses are believed to affect cement mechanical responses. Inclusion of the residual stress at the interface resulted in up to a four-fold increase in the von Mises cement stresses compared to the case without residual stresses (83,84). Recently, Orr et al. proposed that residual stresses are sufficient to initiate crack propagation in the cement before any load is applied (85). Lennon and Prendergarst have experimentally observed that residual stresses in the cement may induce cracking even before weight bearing of the cement (89). The initial residual stresses may have immediate effects influencing the possible initiation of cracks and debonding at the cement–prosthesis interface.

MECHANICAL PROPERTIES

Bone cement fills the space between the prosthesis and the bone; this connection is only a mechanical bond (1). Cement mechanical properties are therefore of particular significance for the performance of acrylic bone cement because cement must endure considerable stresses *in vivo*. There are many physical and mechanical properties of the cement that are considered germane to its clinical performance in the construct, including quasistatic tensile and compressive strength, modulus and ultimate strain, flexural

strength and modulus, shear strength and modulus, fatigue properties (e.g., work of fracture, fracture toughness, fatigue resistance, fatigue crack propagation resistance), and creep (6). The mechanical properties of acrylic bone cement have been widely reported in the literature. Kuhn (2) investigated the static bending and compressive characteristics of a number of bone cements under the same test regimes (2). Test results of some of the most commonly used bone cement in United States are listed in Table 5. Osteobond cement was shown to have both the highest ISO 5833 bending strength and compressive strength among these six cement brands, while Zimmer dough has both the lowest ISO 5833 bending strength and compressive strength. All the measured bending strengths of the bone cement using the DIN53435 standard were larger than the ones using ISO 5833 standard, with Palacos R bone cement having the highest bending strength in this case. Harper and Bonfield (90) found a wide range of tensile strength (Table 6) and fatigue failure cycles (Table 7) results. They found that the Palacos R and Simplex P cements were significantly higher in tensile strength compared to the other cements tested with exception of CMW 3. There was no statistical difference between the values obtained for CMW 1 and Osteobond. The differences among the fatigue results for the different cements were much larger than those found with the static tensile results. The highest Weibull median fatigue cycles to failure obtained for Simplex P and Palacos R were considerably higher than found for Zimmer dough type. Harper and Bonfield (90) found that there was some correlation between the static and fatigue strengths, but the ranking of static strength does not exactly follow that of fatigue life. The fatigue results were found to correlated well to the clinical data (91): the order of success of implants with the cement brand was the same as that obtained from the fatigue test.

It has long been recognized that PMMA surgical bone cement undergoes viscoelastic (creep) deformation under physiological loads (92,93). Many studies have been performed to assess the viscoelastic properties of bone cement (6,23). Radiological observations of hip stems have shown subsidence of the stem within the cement mantle without visible cement fractures (94). Creep has been implicated in prosthesis subsidence, in particular subsidence of the femoral stem in hip replacements (6,95). Excessive subsidence can lead to prostheses loosening. Lu and McKellop (92) studied the effects of cement creep on the subsidence of

Table 6. Comparison of Tensile of Six Different Bone Cements^a

Cement Brands	Ultimate Strength, MPa	Modulus of Elasticity, GPa	Strain at Fracture, %
CMW1	39.1	2.96	1.60
CMW3	44.7	3.53	1.36
Palacos	51.4	3.21	2.25

Osteobond	38.2	3.38	1.41
Zimmer dough	31.7	2.79	1.43

^aSee Ref. 90.

the stem and on the stress within the cement using a cyclic load and three interface bonding conditions (bonded, frictional, and debonded). Results showed that the creep deformation of the cement was accompanied by additional subsidence of the stem and a decrease in the stress components within the cement. The results agreed with an experimental study using stems cemented into cadaver femora (96). Cement creep would accumulate for the frictional stem-cement interface, resulting in 0.46 mm total stem subsidence and a 13% decrease in the stress within the cement (92). Ling et al. (97) concluded that, at least for smooth tapered stems, that substantial hoop and radial creep of the cement not only occurs, but also is essential for the optimum clinical performance of the prosthesis. On the other hand, a limited degree of creep may help in maintaining the cement-implant interface. Also, Harris (98) stated that creep of the cement mantle surrounding a hip prosthesis may be negligible under cyclic physiological loading. The role of creep of the bone cement on the chance of failure of the cement mantle is still a subject of controversy. Due to its viscoelastic nature, cement tested at different strain rates may have changing characteristics (11). There is still lack of tests of bone cement in ways that represent real-life loading patterns that mimic those experienced by the cement *in vivo* (99). The true understanding of the mechanical behavior of bone cement can only be attained if the testing procedure is truly representative (99).

There are considerable differences between the values of physical and mechanical properties of bone cement reported in the literature. This disagreement may be the result of cement type, cement preparation technique, specimen geometry, measurement technique, test parameters, and

Table 7. Comparison of Fatigue Test Results of Six Different Bone Cements^a

Cement Brands	Cycles to Failure	
	Range	Weibull Median

testing environment (11). Therefore it may be impossible to compare results from different investigations (90). However, results with specific conditions may be found in a number of the excellent comprehensively reviews (1–3,6,11,22,23). It has been shown that cement formulations play a significant role on the cement mechanical properties (Table 5). Also, the test methods will affect the values obtained, which can be easily seen by comparing the bending strength results using ISO 5833 standard to that using DIN 53435 standard (Table 5). Cement mixing methods (hand mixing, vacuum mixing, or centrifugation) have been shown to affect the physical properties of bone cement (74,100,101). Even with vacuum mixing, using different vacuum mixing systems have resulted in different bone cement porosity, static strength, and fatigue strength (75,102). The storage temperature of cement constitutive was shown to have minor effects on porosity and fatigue performance (100). Ishihara et al. (103) showed that the fatigue of bone cements at 1 Hz are shorter by one to two order of magnitude as compared with fatigue lives at 20 Hz. On the other hand, Lewis et al. (104) found that frequency (over the range used) did not exert a statistically significant effect on the fatigue life of cement tested in their investigations.

SUMMARY

Acrylic bone cement has been widely used in orthopedic surgery. Currently, the cement is not without its drawbacks as discussed previously. One major research area focusing on modifications of cement formulations may lead to obtain more favorable cement mechanical properties and biological compatibilities. One example of these developments is to incorporate second phase materials (bioactive agents, reinforcement fibers, etc.) into the existing bone cement. Another approach to overcome cement weakness is to manipulate cement processing procedure and the surgical techniques. A good example is to reduce cement porosity by vacuum mixing techniques. It is worth pointing out that considerable research is needed to develop techniques for accurate characterizations of cement properties, monitoring cement curing process and evaluations of potential bone cement failure.

BONE DENSITY MEASUREMENT

YIXIAN QIN
ERIK MITTRA
Stony Brook University
New York

INTRODUCTION

Chronic diseases, such as musculoskeletal complications, have a long-term debilitating effect that greatly impacts quality of life. Osteoporosis is a reduction in bone mass or density that leads to deteriorated and fragile bones and is the leading cause of bone fractures in postmenopausal women and in the elderly population for both men and women. About 13–18% of women aged 50 years and older, and 3–6% of men aged 50 years and older, have osteoporosis in the United States alone. These rates correspond to 4–6 million women and 1–2 million men who suffer from osteoporosis (1). One-third of women over 65 will have vertebral fractures and 90% of women aged 75 and older

have radiographic evidence of osteoporosis (2–4). Another 37–50% of women aged 50 years and older, and 28–47% of men of the same age group, have some degree of osteopenia. Thus, approximately a total of 24 million people suffer from osteoporosis in the United States alone, with an estimated annual direct cost of over \$18 billion to national health programs. Hence, early diagnosis that can predict fracture risk and result in prompt treatment is extremely important. Early identification of fracture risk, most commonly caused by osteoporosis-induced bone fragility, is also important in implementing appropriate treatment and preventive strategies. Indeed, the ability to accurately assess bone fracture risk noninvasively is essential for improving the diagnostic as well as therapeutic goals (i.e., assessing temporal changes in bone during therapy) for bone loss from such varied etiologies as osteoporosis, microgravity, bed rest, or stress-shielding around an implant.

Assessment of bone mineral density (BMD) has become an essential element in the evaluation of patients at risk for osteopenia and osteoporosis (2,5–8). Bone density was initially estimated from the conventional X ray by comparing the image density of the skeleton to the surrounding soft tissues. Although demineralized bone has an image density closer to soft tissues, dense mineralized skeletal tissues appear relatively white on an X-ray image. Hence, the mineral density of bone can be estimated by the degree of gray color of the X-ray image in the bone region. However, because of its resolution and variations generated in the X-ray image, it has been suggested that bone mineral losses of at least 30% are required before they may be visually measured using a conventional X ray (9,10). Growing awareness of the impact of osteoporosis on the elderly population and the consequent costs of health care, together with the development of new treatments to prevent fractures, have led to a rapid increase in the demand for bone densitometry measurements. Many image modalities and techniques have been developed to improve the quality and the accuracy of the measurement for bone mineral and dense assessment. Two major densitometry techniques are commonly used in assessing bone density, that is, radiography-based densitometry and ultrasound-based assessment.

RADIOGRAPHY-BASED DENSITOMETRY

To improve the sensitivities of X-ray images to bone density changes and assessment, several technologies have been developed. *Bone densitometry* is a term that is defined as a method for imaging density of bone. However, the “true” density is not applicable in the current radiography-based techniques. In the field of densitometry, the term “bone mineral density”, referred to as BMD, is related to the mass of bone in the tissue level, which includes both bone and marrow components as well as surrounding soft tissues. Furthermore, most densitometric techniques are projectional for the image formation that provides a two-dimensional image of the three-dimensional (3D) bone volume being measured. Therefore, the BMD defined from the projectional techniques is the mass of bone tissue mass (including marrow and/or soft surroundings) per unit area

Table 1. Radiography-Based Bone Densitometry^a

Technique	ROI	Unit	Precision, %CV	Effective Dose, μSv
SXA	Total body	BMD ($\text{g}\cdot\text{cm}^{-2}$)	1	3
QCT	Spine	BMD ($\text{g}\cdot\text{cm}^{-2}$)	3	50–500
pQCT	Forearm	BMD ($\text{g}\cdot\text{cm}^{-2}$)	1–2	1–3
RA	Phalanx	BMD ($\text{g}\cdot\text{cm}^{-2}$)	1–2	10
SPA	Forearm	BMD ($\text{g}\cdot\text{cm}^{-2}$)	3–4	1–10
DPA	Total body	BMD ($\text{g}\cdot\text{cm}^{-2}$)	1	1–10
DXA	PA spine	BMD ($\text{g}\cdot\text{cm}^{-2}$)	1	1–10
	Proximal femur		1–2	1–10
	Total body		1	3

^aSee Refs. 5,6, 12–14.

in the image, not per unit volume of the tissue. Hence, what is actually measured is the apparent bone mineral density, which is defined by the bone mineral content contained in the area scanned, or expressed as gram per squared centimeter in unit. To detect osteoporosis accurately, several methods are developed for the noninvasive measurement of the skeleton for the diagnosis of osteopenia, osteoporosis, and/or the evaluation of an increased risk of fracture (11). These methods include single-energy X-ray absorptiometry (SXA), dual energy X-ray absorptiometry (DXA or DEXA), quantitative computed tomography (QCT), peripheral quantitative computed tomography (pQCT), radiographic absorptiometry (RA), dual photon absorptiometry (DPA), and single photon absorptiometry (SPA). There are two types of BMD measurements, peripheral BMD and central BMD. The peripheral BMD instruments are usually smaller, less expensive, and more portable than the central BMD. Central BMD is capable of measuring multiple skeletal sites, that is, the spine, the hip, and the forearm. Table 1 lists these methods currently available for the noninvasive measurement of the skeleton for the diagnosis of osteoporosis. These techniques differ substantially in physical principles, in the particular physical body sites (e.g., spine, hip, or total body), in the clinical discrimination and interpretation, and in availability of the facility and cost.

Single-Energy Densitometry

This instrumentation passes a beam of radiation through the limb of the body (e.g., forearm) and determines the difference between the incoming (or incident) radiation and the outgoing (or transmitted) radiation, referring to the attenuation. The higher the bone mineral content, the greater the attenuation. Mineral content can be calculated by the attenuation of the radiation. BMD can then be calculated by dividing the mineral content by the detected bone area. The relation between incoming and outgoing X-ray energy can be expressed as

$$I = I_0 \exp(-\lambda d) \quad (1)$$

where I_0 = incoming radiation intensity, I = transmitted radiation intensity, λ = mass attenuation coefficient, and d = area density of the attenuating materials ($\text{g}\cdot\text{cm}^{-2}$). The mass attenuation coefficient is a physical property that describes how much a given material attenuates and X-ray energy. If the attenuation coefficient can be

experimentally determined, the equation becomes explicit, and the area density can be determined by

$$d = k \log(I_0/I) \quad (2)$$

where k is an experimentally determined constant for the attenuation coefficient. This technology is relatively simple and easy to understand. However, biological tissues and body are composed by multiple materials (e.g., bone, muscle, and other soft tissues). The accuracy of the technology is limited.

Single-Photon Absorptiometry

Bone density can be measured by passing a monochromatic or single-energy photon beam through bone and soft tissue. This procedure is referred as SPA. The amount of mineral content can be quantified by the attenuation of the beam intensity. After the photon beam attenuation is calculated, the value of the attenuation can be compared with a calibration parameter derived from a standard mineral content (e.g., using ashed bone of known weight). This procedure can finally determine the BMD with measured attenuation. Iodine-125 at 27 keV, or americium-241 at 59.5 keV, was initially used for generating of the SPA beam. SPA is rarely used in clinical practice today. SPA determined bone mineral content is calculated through uniform thickness of the soft tissue in the path of the beam. The targeted scan site (e.g., limb or forearm) had to be submerged in the water or a tissue-equivalent material, which limited the practical applications of the SPA. The advantages of this technique include a low dose of radiation, portable, and use for particular body sites with relatively precisely measurement. Although the SPA is an approximate method, the limitations of SPA include limited accuracy of the measurement, radiation, and used only on the particular peripheral sites, like forearm and heel.

Dual-Photon Absorptiometry

To overcome the limitations of single-energy or photon densitometry, if a dual radiation source was used, the influence of soft tissues could be eliminated. The basic principle involved in DPA for bone density measurement was similar to SPA. The degree of attenuation of the photon energy beam between incoming and outgoing energy through bone and soft tissue is quantified. As with SPA, the beam source was originally used, but with an isotope

used, which emitted photon energy at two distinct photoelectric peaks. When the beam was passed through a region of the body with both hard and soft tissues, attenuation of the photon beam appeared to both photon energy peaks. The contributions of soft tissue to beam attenuation can be determined by the quantifications of the relative relations between two attenuations (15). Because of its capability to distinct bone from soft tissue, DPA has been used to quantify bone density in deep tissue and large skeletal areas where bone is surrounded by large volume of soft masses (e.g., spine and hip) (16). DPA was considered a major advance from SPA due to its ability to quantify BMD and mineral content in such deep areas like spine and hip, as well as its capability of quantifications of effects from soft tissues. However, DPA has many notable limitations. First, the maintenance of the beam source was expensive, which had to be replaced yearly. Second, the radioactive source decay increased as much as 0.6% per month, which added difficulties for the calibration. These factors may result in the precision of 2–4% for DPA measurements in the region of interests. This precision (e.g., 2%) would limit its clinical application, in which a great change (e.g., 5–6%) from the baseline value had to be observed before one could reach the 95% confidence level for the change of bone density. Nevertheless, the concept of dual-photon densitometry has impacted the development of new technologies such as DXA.

Dual-Energy X-ray Absorptiometry

Perhaps the most popular bone densitometry used in clinical practice is the DXA or DEXA. The basic principles of DXA are the same as DPA. To overcome the major limitation of DPA, it did not take long for manufacturers who originally had the DPA product to replace the decaying isotope beam source with a highly stable dual-energy X-ray tube. There are several advantages of using X-ray sources over radioactive isotopes (i.e., no beam decay concerned in the X-ray tube and no calibration required for correction of the drifting because of the source decay in the DPA). The fundamental basis for DXA is the measurement of the transmission through the body of X rays of two different photon energies. The radiation source is collimated to a pencil beam and aimed at a radiation detector placed directly opposite the objective to be measured (Fig. 1). The patients are positioned on a table in the path of the X-ray beams. Due to the dependence of the attenuation coefficient on atomic number and photon energy, assessment of the transmission factors and attenuations at two energies enables the 2D apparent density, that is, bone density per unit projected area, of two different types of tissues to be inferred (17–19). The X-ray source and detector pair is scanned back and forth across the region of interests in the body, generating annotation images, which the BMD is calculated as the ratio of the bone content to the measured area. Radiation dose to the patients is very low on the order of 1–10 μSv. The DXA system can measure the BMD of the spine, proximal femur, forearm, and the total body. Recent technology uses a fan beam geometry in the DXA scanners that can increase the speed and reduce the acquisition time (GE Medical System Inc.). The image

Figure 1. Scan path pattern for DXA densitometer using pencil-beam format.

quality of recent DXA has improved significantly via computational capability for better visualization. In addition to the body DXA scanners, recent technology has also adapted for development of lower cost, small, and particular site densitometries (Fig. 2). These systems are available to the clinic for specific body regions (e.g., spine, hip, leg, arm, and hand). The DXA systems are available for the diagnostic clinical use by many major manufacturers (e.g., GE Medical Systems of Madison, Norland, and Hologic Inc. of Bedford).

The basic working principle of DXA and its ability to reduce the effects of soft tissue is to use two X-ray sources and mathematically solve the bone thickness and soft-tissue thickness (15). By using two X-ray energies, two equations can be derived by scanning the measurement site twice with low (L) and high (H) energies once at each.

$$I^L = I_0^L [\exp - (\lambda_b^L d_b + \lambda_s^L d_s)] \tag{3}$$

$$I^H = I_0^H [\exp - (\lambda_b^H d_b + \lambda_s^H d_s)] \tag{4}$$

where I_0 = incoming radiation intensity, I = transmitted radiation intensity, λ = mass attenuation coefficient, d = area density of the attenuating materials ($\text{g} \cdot \text{cm}^{-2}$), and b and s refer to the bone and soft tissue. Two scans are usually performed simultaneously with either two energies or rapid switching between two energies. When the

Figure 2. DEXA machine for a whole-body scan (QDR4500 fan-beam scanner, Hologic Inc., Bedford, MA) (left). DEXA bone densitometry is widely used in.

Figure 3. QCT allows selection of the region of interest.

attenuation coefficients for bone and soft tissue are known for both low and high energies, the apparent or area bone mineral density can be calculated as

$$d_b = \frac{(\lambda_s^L/\lambda_s^H)\log(I^H/I_0^H) - \log(I^L/I_0^L)}{\lambda_b^L - \lambda_b^H(\lambda_s^L/\lambda_s^H)} \quad (5)$$

The attenuation coefficient for bone is relative constant but varied to persons. The soft-tissue attenuation coefficient, however, is contributed by fat and other soft tissues and varied greatly in the body. This is the source for the errors generated in the measurement. The manufacturers usually provide phantoms for calibration for the system.

Traditionally, the focus of clinical bone evaluation has been apparent or area BMD as measured by DXA or DEXA (20–23). DEXA provides an effective way to measure BMD in a specific region of interest and is the most widely used diagnostic modality for assessing osteoporosis and osteopenia (8,24–26). However, in particular, DEXA suffers from several shortcomings. Although density (quantity) does positively correlate with strength (27,28) and fracture risk (29–31), anywhere from 10–90% of the variability in bone strength remains unexplained (32). Additionally, as discussed below, the stereology of trabecular bone is one of its distinguishing features (especially with respect to its mechanical behavior), but because DEXA provides only a 2D image of apparent density, it is inherently limited in this regard. DEXA also suffers from an inability to differentiate trabecular from cortical bone. Although it is true that cortical bone also deteriorates with age (33,34), the effects of bone loss are more prevalent in trabecular bone due to its much higher surface area, and the greater net amount of bone mineral content in cortical bone can conceal small changes in the trabecular bone when measuring only BMD. Nevertheless, as one of the key factors that contribute to the bone's quality evaluation, BMD measured by DEXA is a most popular modality used in assessing the status of bone and the risk of fracture.

Quantitative Computed Tomography (QCT)

QCT provides the true volumetric 3D bone density ($\text{mg} \cdot \text{cm}^{-3}$) compared with the 2D apparent or areal density

measurement with DEXA (35–43). Because of its high resolution, QCT can provide the measurement in the trabecular region (e.g., femoral neck and vertebral bodies) (39,40,44,45). Compared with DXA the advantage of QCT is the image-based cross-sectional anatomy, which allows for a selection of the region of interests (ROI) and a better assessment of geometrical properties (Fig. 3). Most CT systems provide a software package to automate the placement of the ROI within a particular body volume, e.g., vertebral bodies. QCT scans are generally performed using a single kilovolt setting (single-energy QCT). It is possible to use a dual-energy QCT, which can provide further improvement of the resolution, but at the price of poorer precision and higher radiation dose. New 3D volumetric techniques acquire datasets with which analysis of bone macroarchitecture may be further optimized. Due to its capability of high resolution, geometric and structural parameters determined in QCT may contribute to determine bone strength when integrated with other technology (i.e., finite element analysis). The advantage of spinal QCT is the high responsiveness of the vertebral trabecular bone to aging and disease, whereas the principal disadvantage is the cost of the equipment and the dosage received for the scanning (higher than DEXA).

Peripheral QCT (pQCT)

pQCT systems are available for measuring the forearm. The advantages of these devices are the capability of separating the trabecular and cortical bone of the ultradistal radius and of reporting volumetric density. Several clinical used pQCT devices are available (e.g., the Stratec XCT 2000, that are suitable for use in a physician's office or in primary care).

QUANTITATIVE ULTRASONOMETRY

Quantitative ultrasound (QUS) for measuring the peripheral skeleton has raised considerable interest in recent years. New methods have emerged with the potential to estimate trabecular bone modulus more directly. QUS provides an intriguing method for characterizing the

Table 2. Summary of Current QUS Devices for Calcaneus

Device	Performance	Resolution	Predict Parameter	Cost, \$K
Sahara (Hologic)	Index	Nonimage	Z score	20–25
QUS-2 (Metra Biosystem)	Index	Nonimage	Z score	20–25
UBA 575 (Walker Sonix)	Index	Nonimage	Z score	20–25
Achilles (GE-Lunar)	Index + image	Image, 5 mm	Z score	40–50
UBIS 5000 (DMS)	Index + image	Image, 2 mm	Z score	30–35
DTU-one (Osteometer)	Index + image	Image, 2 mm	Z score	25–30
New SCAN	Image + index	Image, 1 mm	Stiffness, BMD, Z	20

material properties of bone in a manner that is noninvasive, nonionizing, nondestructive, and relatively accurate. The primary advantage of QUS is that it is capable of measuring not only bone quantity (e.g., BMD), but also bone quality (i.e., estimation of the mechanical property) of bone. Over the past 15 years, several research approaches have been developed to quantitate bone mass and structural stiffness using QUS (46–48). Preliminary results for predicting osteoporosis using QUS are promising, and it has great potential for widespread applications (including screening for prevention). As such, many QUS machines have been developed, and there are currently many different devices on the market. Most available systems measure the calcaneus using plane waves that use either water or gel coupling [e.g., Sahara (Hologic Inc., MA), QUS-2 (Metra Biosystems Inc., CA), Paris (Norland Inc., WI), and UBA 575 (Walker Sonix Inc., USA)] (Table 2). Recently, an image-based bone densitometry device for calcaneus ultrasound measurement is also made available using an array of plane ultrasound wave (GE-Lunar, Inc., USA). Using several available clinical devices, studies *in vivo* have shown the ability of QUS to discriminate patients with osteoporotic fractures from age-matched controls (49–51). It has been demonstrated that QUS predicts risk of future fracture generally as well as DEXA (51–54). However, there are several noted limitations, including the tissue boundary interaction, the nonlinear function of density associated with bone ultrasonic attenuation, the single index covering a broad range of tissues (including the cortical and trabecular regions), and the interpolation of the results. Recently, a focused ultrasound sonometer device was developed to obtain the likelihood of a broadband ultrasound attenuation (BUA) image in the human calcaneus region (center frequency 0.5 MHz, focus 50 mm) (55,56) (UBIS 5000, Diagnostic Medical Systems; and DTU-one, Osteometer MediTech). These devices provide ultrasound images in the calcaneus region, in which the parameter compares with DEXA data. Perhaps the major drawbacks of these ultrasound osteometers are low resolution and lack of physical interrelation with meaningful bone strength. Although only showing the correlation between BUA data and BMD, these devices mostly provide qualitative information for assessment of osteoporosis, not the true prediction for bone structural and strength properties. Therefore, QUS remains at a stage as a screening tool (Fig. 4), because of the nonuniformity of the porous structure in the bone tissue and its associated effects in resolution (14). Research attention is focused on developing systems to provide true images reflecting the bone's struc-

tural and strength properties at multiple skeletal sites, i.e., in the hip, which can provide a true diagnostic tool (instead of just for screening) that surpasses the radiation based DEXA machines.

If QUS bone densitometry can be developed to provide a “true” bone quality parameter-based diagnostic tool (i.e., directly related to the bone's structural and strength properties) and to target multiple and critical skeletal sites (e.g., hip and distal femur), QUS would have a greater impact on the diagnosis of bone diseases (e.g., osteoporosis) than current available bone densitometry. Research efforts are made in this regard (55–59). As an example, a new QUS modality, called the scanning confocal acoustic diagnostic system, has been developed (57–60), which is intended to provide true images reflecting the bone's structural and strength properties at a particular skeletal site at a peripheral limb and potentially at deep tissue like great trochanter. The technology may further provide both density and strength assessment in the region of interests for the risk of fracture (57–60).

Fundamental QUS Parameters in Bone Measurement

In an effort to use QUS for predicting bone quality, a variety of approaches have been explored with many studies published in the past decade, that have examined the utility of QUS and its potential application as a diagnostic tool for osteoporosis. The physical mechanisms of ultrasound applied to bone may include several fundamental approaches, [i.e., speed of sound (SOS) or ultrasonic wave propagating velocity (UV), sound energy attenuation

Figure 4. A QUS bone densitometry test in a heel region. Reproduced courtesy of GE-Lunar Inc.

(ATT), BUA, and critical angle ultrasound parameters] that closely relate to acoustic transmission in a porous structure. Most commonly, parameters for QUS measurement are BUA and SOS, which can be used to identify those persons at risk of osteoporotic fracture as reliably as BMD (52–54,61,62). It has been shown that both BUA and SOS are decreased in persons with risk factors for osteoporosis, that is, primary hyperparathyroidism (63–66), kidney disease (67), and glucocorticoid use (68,69). The proportion of women classified into each diagnostic category was similar for BMD and QUS. Using the World Health Organization (WHO) criteria to classify osteoporosis for BMD measurement using DEXA and QUS testing, approximately one third of postmenopausal women aged 50+ years with clinical risk factors were diagnosed as osteoporotic compared with only 12% of women without clinical risk factors. This suggests that the measurement of QUS with calcaneal BUA and SOS is to some extent the same as the BMD Z-score measurement.

Background of BUA in Trabecular Bone Measurement

BUA and SOS are currently two commonly used methods for QUS measurements, which make it potentially possible to predict bone density and strength. As an ultrasound wave propagates through a medium, BUA measures the acoustic energy that is lost in bone (unit: dB/MHz). The slope at which attenuation increases with frequency is generally between 0.2 and 0.6 MHz, and it characterizes BUA. The slopes of the frequency spectrum may reflect the density and structure of bone. Although relatively little is known about the fundamental interactions that determine ultrasound attenuation in bone, the potential sources contributing to the attenuation include absorption, scattering, diffraction, and refraction (70–73). Although absorption predominates in cortical bone attenuation, the mechanism of BUA in cancellous bone is believed to be scattering (14,74–76). The importance of scattering has been alluded to in the literature. Scattering is also suggested to contribute to the nonlinear variation in BUA with density observed in cancellous bone and a porous medium (77–79).

Background of SOS or UV for Bone Measurement

The strength of trabecular bone is an important parameter for bone quality. *In vitro* studies have correlated the ultrasound velocity with stiffness in trabecular bone samples (80–82). This indicates that ultrasound has the potential to be advantageous over the X-ray based absorptiometry in assessing the quality of bone in addition to the quantity of bone. The mechanism of SOS in predicting bone strength is believed to be due to the fact that the velocity of an ultrasound wave depends on the material properties of the medium through which it is propagating, but it also depends on the mode of propagation. By determining the wave velocity through a bone, the elastic modulus of bone specimens can be evaluated, or at least be approximated (80,83). When ultrasound travels through a porous material, e.g., trabecular bone, it carries information concerning material properties, such as density, elasticity, and architecture. A relationship exists between the ultrasound velocity

(unit: m/s) and the material elasticity E and density ρ (14,80)

$$V = \sqrt{E/\rho} \quad (6)$$

The velocity with which ultrasound passes through normal bone is fast and varies depending on whether the bone is cortical or trabecular. Speeds of 2800–3000 $\text{m} \cdot \text{s}^{-1}$ are typical in cortical bone, whereas speeds of 1550–2300 $\text{m} \cdot \text{s}^{-1}$ are typical in trabecular bone.

It is demonstrated that trabecular bone strength is highly correlated with elastic stiffness (84). With the introduction of QUS, several new diagnostic parameters and experimental results, both *in vitro* and *in vivo*, have shown potential for evaluating not only bone quantity (i.e., BMD), but also bone quality (i.e., structure and strength). Two principal variables, BUA and UV, have been confirmed to identify those persons at risk of osteoporotic fracture as reliably as BMD from DEXA. However, SOS and BUA are related to bone density and strength as well as to trabecular orientation, the proportion of trabecular bone and cortical shell, the composition of organic and inorganic components, and the conductivity of the cancellous structure. Thus, QUS of trabecular bone depends on a variety of factors that contribute to the measured ultrasound parameters.

Other Bone Status Measurement Methods and Motivation to Assess Bone Quality

Beyond bone quantity, the quality (the integrity of its structure and strength) has become an equally or even more important measure to understand the bone structure and mechanical integrity. Most osteoporotic fractures occur in cancellous bone. Therefore, noninvasive assessment of trabecular bone strength and stiffness is extremely important in predicting the quality of the bone. The strength of the trabecular bone mostly depends on the mechanical properties of the bone at the local and bulk tissue level, and on its spatial distribution (i.e., the micro-architecture). A better understanding of the factors that influence bone strength is a key to developing improved diagnostic techniques and more effective treatments. To overcome the current hurdles, to improve the “quality” of the noninvasive diagnostic instrumentations, and to apply the technology for future clinical application, new clinical modality may concentrate in several main areas: (1) increasing the resolution, sensitivity, and accuracy in diagnosing osteoporosis through unique methods for improvement of signal/noise ratio; (2) directly measuring bone’s strength as one of the primary parameters for the risk of fracture; (3) generating real-time compatible imaging to identify local region of interest; (4) validating structural and strength properties with new modalities; and (5) predicting local trabecular and bulk stiffness and microstructure of bone, and generating a physical relationship between measurement and bone quality. In an attempt to achieve these goals, recent advances of emerging technologies are developed primarily for animal studies at this stage. These include high resolution pQCT, micro-MR-derived measures of structure, micro-CT-based BMD, and combined assessment of strength using geometry, density, and computational simulation. These methods

will further lead to a better understanding of the progressive deterioration of bone in aging populations, and ultimately they may provide early prediction of fracture risk and associated musculo-skeletal complications such as osteoporosis.

BONE UNUNITED FRACTURE AND SPINAL FUSION, ELECTRICAL TREATMENT OF

AR LIBOFF
Oakland University
Rochester, Michigan

DEFINING THE UNUNITED FRACTURE

Within hours following a fracture in bone and the rapidly resulting hematoma, an endogenous repair process is initiated, characterized by increased cell division in the periosteum and endosteal stem-cell differentiation leading to organization of the hematoma into fibrocartilaginous callus. The latter represents the source of osteogenic potential from which ossification and subsequent bone remodeling occurs. In the ideal case, with proper management, those suffering bone fractures will normally find themselves fully recovered within a few months, with this time varying according to the specific bone involved, the type of fracture, and the age of the patient.

However, a small percentage of fractures fall outside the norm and do not heal as readily. There are upward of 5 million fractures occurring each year in the United States (1). Approximately 5–10% of these remain ununited after a few months. One can identify two types of ununited fractures, those undergoing *delayed* fracture healing, as evidenced by a lack of full healing in 3–6 months, and *nonunions*, where there is a lack of healing 6–12 months after the fracture has occurred. Marsh (2) suggests that the best measure of fracture healing in humans may be recovery of bending stiffness (i.e., the torque measured in Newton-meters that will bend bone by 1°). He defines delayed union as failure to reach a stiffness of $7 \text{ N} \cdot \text{m} \cdot \text{deg}^{-1}$ at 20 weeks following fracture. Both the periosteum and the *endosteum*

are deeply involved in the process of fracture healing, and it has been suggested (2) that delayed healing may be the result of cessation of the periosteal response before bridging has occurred, while nonunion may be indicative of a breakdown of both the periosteal and the endosteal repair mechanisms. A more general term for nonunion is pseudarthrosis, or false joint. Worth noting is that this problem is also infrequently found at birth (congenital pseudarthrosis). Electric and electromagnetic treatment is prescribed for both types of pseudarthroses, those that are the result of ununited fractures, and those that are found at birth. Further, because spinal fusion following back surgery can be problematic, electromagnetic treatment is also being used as an adjunctive procedure to promote spine fusion (3).

THE ELECTRIC CHARACTER OF BONE

Bone has a number of remarkable physical properties, particularly its electric character. Its electrical properties and the intimate relation of these properties to the growth process in bone were brought to light in a series of experimental discoveries, beginning in the 1950s. These revealed

1. A piezoelectric effect in bone.
2. A striking bioelectric signature specifically associated with developing bone.
3. A characteristic signature in adult unstressed bone.
4. A characteristic bioelectric signature following bone fracture.

Piezoelectricity is the rather unique property in which mechanical force is transformed into electric polarization (Fig. 1). Bone was shown to be piezoelectric by Yasuda in the early 1950s, but the work leading to this conclusion was not made generally available until 1957(4). Fukada and Yasuda (5) later found that this property could be traced to the intrinsic collagen component in bone. Since that time, a number of observers (6–8) suggested that this mechanical stress–electric polarization property should more properly be referred to as a stress-generated potential (SGP), reflecting the fact that what actually happens may not be the result of the special sort of crystal or textural structure that underlies the piezoelectric effect, but might instead result from the well-known electrokinetic effect of streaming potential. Streaming potentials, similar to piezoelectric signals, are characterized by the transformation of mechanical stress into a potential difference. However, streaming potentials do not occur because of any intrinsic crystal structure, but rather because fluid displacement through porous materials or tubes results in electric charge separation. It is generally agreed that dry bone indeed exhibits piezoelectricity, but opinions vary on whether this effect actually plays a role when bone is in its usual (i.e., wet) physiological environment. Part of the difficulty in resolving this issue is that the piezoelectric effect is not easily measured in wet bone. Whatever the pros and cons concerning studies on wet bone, it is difficult to put aside the seminal experiment by McElhaney (9). More than 600 silver epoxy electrodes were attached to cover the surface of a dried intact human femur from autopsy, and a vertical

Figure 1. Piezoelectric Effect. Here, a tensile force results in a net electrical polarization in a material that ordinarily does not exhibit any polarization. Note that a compressive force will also result in electrical polarization. The source of the piezoelectric effect in bone is collagen.

mechanical load was applied to the proximal end of the entire femur, mimicking the femur's weight bearing function. This load produced piezoelectric potentials from each of the electrode points, in effect mapping the piezoelectric response of the entire bone to this load. The voltages obtained varied widely in intensity, and included both positive and negative signs. These results were interpreted by Marino and Becker (10) as showing that, if one assumes that negative potentials tend to activate osteoblasts and positive voltages act to enhance osteoclastic function, then the voltage map (Fig. 2) represents the locus of the new remodeling surface for the femur: Areas of negative polarity are found where the femur needs thickening and areas of positive polarity are located where the bone must be reduced in thickness. Thus the potential remodeling response of the femur to the applied load is related in a very direct way to the polarity and intensity distribution of the piezoelectric signal. The McElhaney experiment showed convincingly that the piezoelectric effect in bone, *in the dry state*, conveys the information necessary to provide a remodeling template for bone under mechanical stress, in effect explaining Wolff's law (11), the empirical statement that bone remodeling follows the distribution of forces applied to the bone. Nevertheless, it is conceivable that the locus of voltages supplied by the piezoelectric effect in bone also requires local electrokinetic potentials to implement the remodeling process at the cellular level, either through cellular differentiation to produce the required osteoblasts and osteoclasts necessary for bone remodeling, or perhaps to separate the osteoblasts and osteoclasts by galvanotaxis (12).

Even in the absence of mechanical stress, bone exhibits a variety of intrinsic electric signals. One such effect is apparently part of the growth and development process. Measuring the electric potential in the same way for the same vertebral element from a group of cadavers covering a wide range of ages, Athenstaedt (13) found that this voltage

Figure 2. Map of piezoelectric voltages in dry stressed femur. When a 50-lb (220 N) load is impressed on dry human femur, piezoelectric voltages appear over the entire surface. One such set, given in millivolts (mV), is shown (9). The interpretation by Marino and Becker (10) is that the locus of these voltages, as shown by the dotted line for one slice through the femur, corresponds to the way that the bone will remodel under a specific load.

was clearly connected to the age of the individual, greatest in infancy and ultimately falling to a level voltage plateau with maturity. The implication is that electric polarization in bone plays a role in the growth process. Something similar happens in long bone. One can measure voltage differences, usually referred to as bioelectric potential (BEP) along the length of a long bone (14) (Fig. 3). The BEP is always a relative measurement, where, for example, one can fix one electrode at one end (the epiphysis) and measure the potential difference at various points along the shaft of the bone (the diaphysis). Particular attention has focused on the growth plate, that region between epiphysis and diaphysis where the bone actually is ossifying as it grows. The BEP measured at the growth plate relative to the epiphysis in immature, growing, bone is markedly negative by as much as 5 mV (15), but as growth ceases, this potential difference becomes less pronounced. Furthermore, it has been demonstrated by means of tetracycline labeling (16) that the formation of new bone corresponds closely with the BEP profile.

Bone also exhibits an intrinsic electrical character even if it is not actively growing or under mechanical stress. For example, a BEP profile is also found in adult bone, albeit with a different signature. In measurements of this voltage, it is observed that the proximal metaphysis is always

Figure 3. The BEP Profile. Bioelectric potential profile of a rabbit tibia (14). Voltage differences are obtained relative to the proximal end (on the left) by means of salt bridge electrodes.

negative with respect to the midshaft and distal portions of the bone. Because the BEP is unaffected by local nerve denervation or reduced blood flow, but slowly disappears following animal death, it is believed (17) that the origin of this voltage stems from functioning bone cells, acting in concert.

Other than this likely connection to bone cells, it is difficult to pin down a reasonable physical explanation for the ubiquitous potential profile associated with long bone. Electric polarization is readily observed in specimens of mature bone when they are even slightly heated. The origin of this effect is still unclear, but it may reflect a pyroelectric response having a textural origin (18), or perhaps, as Mascarenhas has suggested (19), bone is inherently an electret, a type of material, like many biopolymers, with the interesting property of being capable of storing electric charge. Electrets are the electrical equivalent of magnets, and some observers have suggested that bone exhibits ferroelectric properties. The characteristic property seen in electrets is a slow release of charge when heated. For example, long-term currents on the order of 100 fA can be observed (20) for bone specimens heated to 40°C. Regardless of the cause, it is most likely the case, as stated by Brighton (21), that: *...in living, non-stressed bone, areas of active growth...[are] electronegative when compared with less active areas.*

There is one more impressive electric property associated with living bone, again reflecting this question of the role of negative potentials. Only a few hours following bone fracture, the bone becomes more negative relative to the prefracture BEP (22) (Fig. 4). There is some dispute as to whether this effect is limited to the fracture site or is distributed more widely along the length of the bone (14,23). This uncertainty is in all likelihood due to the fact that there are obvious measurement problems in obtaining a BEP profile for a fractured bone. As an injury current one might expect a more specific and localized expression. However, it is possible that the entire periosteum may be affected in a bone fracture at any point along its length. Worth noting are the experiments by Becker and Murray (24) on fracture healing in amphibian systems indicating a

Figure 4. Effect of fracture of an 8 cm rabbit tibia on BEP. Measured potentials are shown before and after the fracture, which is at the 4 cm point.

discrete electrical negativity at the fracture site, which led him to characterize the innate ability of bone to heal itself in higher animals as a form of regenerative healing.

Viewed in the context of its other electrical properties, the change in voltage profile associated with bone fracture has to be regarded as consistent with the overarching concept that bone makes extensive use of electricity in all of its growth, repair, loadbearing, and homeostatic processes. Because of this, it is hardly surprising that exogenous electric currents have been widely applied in attempts to grow and/or repair bone.

The FDA-approved devices for electric repair of ununited fractures fall either into invasive or noninvasive categories. The invasive devices make use of implanted direct current (dc) and (ac) electric signal sources, both pulsed and continuously sinusoidal. The noninvasive types are either purely electric (capacitive coupling or CC), or electromagnetic, using pulsed magnetic fields (PMF or PEMF) or ion cyclotron resonance (ICR) tuned magnetic field combinations.

DIRECT CURRENT OSTEOGENESIS

The surgeon who first observed that bone is piezoelectric, Iwao Yasuda, was also the first to demonstrate (25) that electric fields applied to long bone *in vivo* are capable of producing callus. He wrapped a few turns of wire around rabbit femur, and, maintaining this point at a negative potential, passed a small (1 μ A) current to an anode located away from the bone. It was consistently observed that after 3 weeks this current resulted in spicules of osseous callus (called electric callus by Yasuda) (Fig. 5). Surprisingly, these spicules were not directed along the bone itself, but instead along the direction of the current, in some cases actually pointing away from the bone. To the orthopedic surgeon, one of the most positive signs during the course of fracture repair is the appearance of callus. Thus the observation by Yasuda cannot be overemphasized.

Figure 5. Formation of callus in response to 1 μA dc current. After original sketch by Yasuda (26), showing wires wrapped around the bone.

Although the reasons why electricity is capable of forming callus are still not clear, the implication of Yasuda's work was that electrical stimulation might be of assistance in bringing ununited fractures to closure.

Most of the follow-up experiments to Yasuda's discovery concentrated on determining the effects of electrical signals on normal and fractured bone. A commonly used animal experimental design was to apply an electrical signal to one femur while using the contralateral femur in the same animal as a control. Intrinsic to this approach was the use of dummy electrodes, carrying no current, but serving to affect the contralateral limb by its mere presence in whatever way the electrodes were affecting the activated side. It was in this manner that Bassett et al. (27) used implanted battery packs to deliver microampere-level currents to platinum-iridium wire electrodes extending into the medullary cavities of femora in dogs. The results clearly indicated that more bone was formed in the intermedullary space in the vicinity of the cathodes than near the anodes. Follow-up experiments (28) reinforced the finding that bone growth appeared to be effective at the cathode, but also that bone necrosis occurred at anodes for currents in excess of 20 μA . In this work Friedenberg et al. (28) found that bone growth was most pronounced for currents between 5 and 20 μA . There is some question concerning this optimal current in that the required levels may be dependent on the mode of application. In rabbit femur, circular defects ~ 2.8 mm in diameter were repaired within 3 weeks when subjected to currents ranging between 2.5 and 3 μA applied by two electrodes on either side of the defect (29). Not only was the current lower than that suggested by Friedenberg et al. (28), but there was no particular advantage to either polarity. Similarly, Ham-bury et al. (30) studying ^{85}Sr uptake in rabbit femur observed osteogenesis at 3 μA , again with no difference due to polarity. In another attempt (31) to establish the optimal current for repairing bone defects in dog, it was reported that 0.2 μA was more effective than either 2.0 or 20 μA .

Further complicating the issue of what level of current is required to initiate osteogenesis were a number of earlier reports in which callus was formed using currents that were orders of magnitude smaller than microampere

levels. Fukada and Yasuda (4) wrapped a charged Teflon electret around bone to initiate callus, work that was later successfully repeated in Japan (32,33). Three different types of current application were employed in the latter experiment: that emitted by an electret, that obtained from the piezoelectric poly- γ -methyl-L-glutamate (PMLG) film, and a battery delivering 8–10 μA . The two current levels for the electret and the film, respectively, were 1 and 10 pA, levels smaller by huge factors of 10^{-7} and 10^{-6} from the "optimal" value of 10 μA . Marino and Becker (34) raised the issue as to whether this enormous difference in currents, both seemingly effective, means that more than one mechanism is involved, with the microampere (μA) results indicative of a nonspecific osteogenic stimulus while the picoamp (pA) currents more closely mimicking the endogenous piezoelectric response.

ELECTROMAGNETIC OSTEOGENESIS

Among his other important discoveries, Michael Faraday was the first to show that voltage is induced in a conductor when a nearby magnetic field is changing rapidly. This phenomenon, often referred to as Faraday's law, can be mathematically expressed by the following expression:

$$dB/dt = -V/A \quad (1)$$

where dB/dt is the time rate of change of the magnetic field B through a region of area A , and V is the voltage induced by dB/dt along the path that is circumferential to A by this rate of change. If B is varying at some frequency f , the product fB is a good measure of the relative effectiveness of dB/dt . When the region in question is electrically conducting, as in living tissue, one can use Ohm's law to rewrite the above expression in terms of the current I instead of V . Thus if R is the resistance of the circumferential path around A , Eq. 1 is changed to read

$$dB/dt = -I(R/A) \quad (2)$$

In this way, one can induce a current in the vicinity of a bone defect by employing a nearby magnetic field that is changing rapidly—the faster the rate of change, the greater the current. One achieves a faster change (i.e., a larger dB/dt) by merely increasing the frequency at which B is changing. Further, it is important to realize that the current so induced is no different from currents that are produced by purely electrical means (Fig. 6). Most important, since the source of the magnetic field can be deployed externally, Faraday's law enables the clinician to generate the required therapeutic currents in a completely noninvasive manner.

In 1974, following 5 years of intensive effort, Bassett and Pilla(35) reported on the successful use of the Faraday induction concept (PMF) to repair fibular osteotomies in beagle. Coils were placed on either side of the leg in such a manner that the magnetic fields from the coils traversed the defect and were additive (Fig. 7). The currents through each coil were pulsed in two ways, at 1 pulse \cdot s $^{-1}$ and at 65 pulses \cdot s $^{-1}$. As revealed by mechanical testing of the fibula subsequent to treatment, there was greater indication of recovery with 65 pulses \cdot s $^{-1}$, a finding that was consistent

Figure 6. The current density J produced in tissue by a voltage source V acting through electrodes E is no different from the current density induced by a changing magnetic field B according to Faraday's law. The B field is produced by a current I that energizes a coil C , whose plane is perpendicular to the page.

with the prediction from Eq. 2 of a larger current with higher frequency.

INVASIVE (IMPLANTED) ELECTRIC TREATMENTS

Although the use of pulsed magnetic fields provides a means by which one avoids electrode implantation, some surgeons still prefer the extra advantages that come with direct observation of the pseudarthrosis defect. In addition, there is a very lengthy literature background on delivering dc directly to bony defects.

In late 1971, groups at New York University (NYU) and at the University of Pennsylvania independently demonstrated that electrical stimulation using implanted dc devices was successful in repairing pseudoarthrosis defects in humans. In both cases, electrodes and battery were surgically implanted with provisions for percutaneously monitoring the current. Otherwise, however, the methods employed were strikingly different. The NYU group, led by L.S. Lavine (37) used platinum wire electrodes on either side of a congenital pseudoarthrosis in the lower tibia of a 14 year old male, in effect allowing the current to pass through the defect (Fig. 8). The polarity of the current was such that the proximal side of the defect was negative. This approach was the same as successfully used in this group's previous experiment (29) to repair defects in rabbit femur. The current was monitored and maintained over the 18-week treatment period at $3.9 \mu\text{A}$.

By contrast, Friedenberget al. (38) in treating a non-union in the medial malleolus of a 51 year-old woman, used a technique (Fig. 8) that had been previously been found to be successful in producing callus in rabbit fibula (28,39). A stainless steel cathode was located directly in the defect

Figure 7. The PMF technique uses two flat coils connected in series to generate a magnetic field (dashed line) through the bone defect. Because the magnetic field is changing rapidly, a voltage is induced, producing a current in the vicinity of the defect. The process is completely noninvasive. In this sketch (36) the two parallel coils, whose planes are perpendicular to the page, are shown outside the cast.

and the anode, an aluminum grid, was taped to the skin. A constant-current power source maintained the current at $10 \pm 2 \mu\text{A}$ over the 9 week treatment period. Again, as with the nonunion treatment employed by the NYU group, the outcome was successful.

These differences in treatment, both leading to repair of the nonunions, remain unresolved. The one treatment (37) is consistent with prior animal work in which the proximal side of bone was found to be intrinsically negative, while the second result (38) fits those observations (24) claiming that fractures are more negative than the rest of the bone. These differences tend to highlight a key difficulty connected to the research on the electric treatment of bone. Apart from the essentially empirical nature of measurements such as the BEP profile, there is no fundamentally sound basis with which to explain the underlying mechanisms, resulting in continuing uncertainties in the clinical techniques.

A number of investigators have attempted to shed light on this question of mechanisms. Almost all such "explanations" have focused on the electrically related regulation of different factors: parathyroid hormone (PTH) (40), adenosine 3', 5'- monophosphate (cAMP) (41,42), insulin-like growth factor II (IGF-II) (43), bone morphogenetic protein (BMP) (44), transforming growth factor-beta 1 (TGF- β 1) (45), and calcium ion channel transport (46). These are contributors, in varying degrees, to the cellular signal transduction pathways controlling bone growth. However, it would be truly surprising if these factors were *not* involved in all types of osteogenic processes, including electrical osteogenesis. At best, such factors must be regarded as merely *indicators* of metabolic activity in bone. At this point in time, they provide little, if any clue as to the reason why bone is responsive to electrical stimulation.

Figure 8. Two ways of using μA -level dc currents to repair defects in bone. In one case, the electrodes are applied so as to bridge the defect. In the other case, the cathode is placed directly into the defect. Both approaches have been successful (37,38) in treating human nonunions.

Presently, there are two FDA-approved implantable direct current devices for treating bony defects, both marketed by ElectroBiology Inc. (Parsippany, NJ). These are shown in Figs. 9 and 10. The Osteogen Bone Growth Stimulator supplies $40 \mu\text{A}$ through mesh electrodes. Although the cathode is located at the defect, similar to the original placement by Friedenberget al. (38), the current is far in excess of what was thought to lead to bone necrosis (28). Apparently, the nature of the electrodes used by Friedenberget al. (28) may have played a role in this discrepancy. The second implantable dc device is the SpF Spinal Fusion Stimulator, prescribed for spinal fusion. The positive and negative leads, in this case carrying $60 \mu\text{A}$, are located on either side of the repair site.

NONINVASIVE ELECTRIC TREATMENT: (CC)

One method for applying an electric current to a defect in bone in a noninvasive manner is by means of capacitive coupling (CC). The background for this technique were

experiments (47,48) in which 60 kHz sinusoidal voltages were capacitively transferred to bone cell cultures resulting in an electric field within the culture medium of $20 \text{ mV} \cdot \text{cm}^{-1}$ and a current density of $300 \mu\text{A} \cdot \text{cm}^{-2}$. The first clinical use of this was to treat nonunions (49) (Fig. 11). An overall efficacy of 77% was achieved in a group of 22 cases with a mean time to healing of 23 weeks. The FDA-approved version of this technique is marketed by EBI (Fig. 12) As in the earlier studies on cell culture, the pictured device makes use of a 60 kHz alternating electric field that is applied to the skin on either side of the defect using disk electrodes and conducting gel. The current density within the tissue is considerably less than the levels used in cell culture, only $\sim 7 \mu\text{A} \cdot \text{cm}^{-2}$. The term *capacitive* may not be warranted for the devices pictured in Figs. 11 and 12. Unlike the lack of ohmic coupling in the earlier, *in vitro* studies, there is a much larger ohmic contribution to the overall impedance when disk electrodes are used. A better description for this device category might be ac (i.e., simply alternating current) instead of CC.

Figure 9. Implantable device for bone growth stimulation. EBI (Electro-Biology, Inc.)

Figure 10. Implantable device for adjunctive treatment of spinal repair (EBI)

A wide range of parameters have been used in studying the clinical and experimental aspects of the CC signal, with various voltages applied to the skin between 1 and 10 V, and frequencies between 20 and 200 kHz. The electric field strengths generated within tissue has ranged from 1 to 100 $\text{mV} \cdot \text{cm}^{-1}$ and the current densities from 0.5 to 50 $\mu\text{A} \cdot \text{cm}^{-2}$.

NONINVASIVE ELECTROMAGNETIC DEVICES: (PMF)

The successful use of PMF (also called PEMF) by Bassett et al. (35) to repair bone defects in animals noninvasively

Figure 11. Capacitive Coupling. Electrodes are attached on either side of the bony defect external to skin (here, external to cast) supplying a 60 kHz sinusoidal signal.

Figure 12. Mode of action of EBI capacitive coupling spinal fusion stimulator (EBI).

led to a number of different devices aimed at applying pulsed magnetic fields. One such early design, successfully applied to the treatment of a tibial nonunion (50,51), made use of an iron-cored electromagnet driven by a square pulse with a repetition rate of 1 pps. However, this design suffered because the large inductive reactance of the iron core acted as a constraint on the repetition rate of the coil current pulses.

With this constraint in mind, Bassett's group succeeded in designing (52) a low inductance air-coil system that could be pulsed at higher frequencies to repair recalcitrant pseudarthroses and nonunions in humans (Figs. 13–16). The success rate that was reported (85%) was greatly in excess of the salvage rate usually obtained by orthopedists using conventional, nonelectrical procedures. However, later (55), reviewing PMF treatments for a wider, all-inclusive group of pseudarthrosis cases, including those with the worst prognosis, Bassett lowered the success rate downward, to 54%.

The pulsed magnetic field that was originally used by Bassett was (and still is) based on the saw-tooth signal common to the fly-back refresher circuit in television receivers. A saw-tooth voltage (Fig. 17) is applied to a pair of many turn coils, creating a current in both coils that generates a single magnetic field. The planes of the coils are roughly parallel, and deployed on opposite sides of the defect (see Fig. 7), creating a commonly directed magnetic field through the defect. The sawtooth signal applied to the coils results in a rapidly changing magnetic field, ~ 10 tesla per second ($\text{T} \cdot \text{s}^{-1}$), maximized at those times when the voltage applied to the coils is falling sharply. Faraday's law results in the induced voltage shown in Fig. 18. The net induced signal that appears in the vicinity of the defect consists of bursts of 21 pulses, each individual pulse 260 μs in duration, with the bursts repeating at 15 Hz. The magnetic field that actually appears in the area of the defect rises, with each pulse, to ~ 10 G (1 mT), before dropping precipitously in ~ 25 μs . It is this rapid change in B that contributes the most to the induction of current (see Eq. 2). For example, if a sine wave signal of 10 G at 60 Hz were applied to the same region instead of this pulse, the maximum current would be 600 times smaller.

Figure 13. Treatment of ununited scaphoid fracture with PMF (53).

The various PMF clinical and experimental signal repetition rates that have been attempted vary between 1 and 100 Hz, with the maximum magnetic field intensity at the defect site ranging from 0.1 to 30 G, and the induced electric field at the site ranging between 0.01 and 10 $\text{mV} \cdot \text{cm}^{-1}$.

NONINVASIVE ELECTROMAGNETIC DEVICES (ICR)

Magnetic fields are also used in bone repair in ways that have nothing to do with Faraday induction. It was shown in 1985 (56) that the results embodied in the so-called calcium efflux effect (57,58) were in close agreement with predictions based on the resonance characteristics of certain biological ions subject to the Lorentz force. Specifically, the shape of the nonlinear frequency dependence of

calcium binding to chick brain tissue was what might be expected for a particle with the charge-to-mass ratio of the potassium ion moving in combined parallel sinusoidal and dc magnetic fields whose ac frequency and dc intensity corresponded to the ICR condition for K^+ . This observation also explained earlier work (59,60) in cell culture demonstrating that weak low frequency magnetic fields enhance DNA synthesis in a manner that is clearly not related to Faraday induction, since the additional DNA synthesis does not scale with either frequency or intensity. Ion cyclotron resonance is a magnetic effect that is fundamentally different from Faraday's law as expressed in Eq. 1. More specifically, as regards possible effects of magnetic fields on bone, it entails a totally different phenomenon than the induction of current in bone using pulsed magnetic fields.

Unlike previous attempts to arrive at the electromagnetic conditions required for electrical osteogenesis, exact predictions are possible using the ICR effect. One can focus on a specific ion and adjust the intensity of the dc magnetic

Figure 14. Treatment of congenital pseudarthrosis of the tibia with PMF (54).

Figure 15. PMF Bone healing system (EBI).

Figure 16. PMF device in place on patient (EBI).

field and the frequency of the ac magnetic field to “tune” to this ion. This is because a resonant condition occurs when the ratio of the frequency of the ac field to the intensity of the dc field is equal to the charge-to-mass ratio of the ion. The simple expression governing this resonance is

$$\omega/B = q/m \tag{3}$$

where ω is the (angular) frequency of the ac field, in $\text{rad} \cdot \text{s}^{-1}$, B is the intensity of the dc magnetic field, in Tesla, and, q/m is the mass-to-charge ratio of the ion. For practical applications, the angular frequency ω is replaced by its equivalent, $2\pi f$, where f is the frequency in hertz (Hz). The underlying interaction mechanism for this effect in living tissue is still in question (61), but the most reasonable explanation is that ions in resonance are

Figure 17. Sawtooth voltage applied to PMF coil.

Figure 18. Voltage induced in tissue by PMF.

more likely to stimulate the gating mechanism for ion channel transport.

A great deal of work has been done in examining the effects on biological expression when tuning to Ca^{2+} , Mg^{2+} , and K^+ , not only in bone cell culture (Fig. 19) (62), but also in neural cell culture, in animal behavior, and in plants (61). It is generally agreed that ICR tuning to these ions can have striking effects on growth. One such example (63) is shown in Fig. 20 illustrating the relative effects on explanted embryonic chick femora cultured under Ca^{2+} and under K^+ ICR magnetic field conditions.

Figure 19. Frequency response of insulin-like growth factor in bone cell culture under combined ac and dc magnetic field exposure 62. The dc field was maintained at $20 \mu\text{T}$ for each of the points shown. There is a clear peak at 15.3 Hz, corresponding to the predicted ICR condition for Ca^{2+} resonance in Table 1.

Figure 20. Effect of ICR magnetic exposures on chick embryonic growth (63). The topmost femur, the shortest, was grown under K^+ ICR tuning, while the bottom femur was grown under Ca^{2+} ICR magnetic field conditions. The middle femur was not exposed to any ICR field.

Diebert et al. (64) examined the efficacy of ICR in repairing defects in rabbit fibula, basically reusing the animal model that had been previously employed to study electrical osteogenesis (29), but applying an ICR magnetic field combination instead of a dc current. It was found that the 28-day ICR treatment yielded results equivalent to or better than those employing direct current and pulsed magnetic fields. For animals exposed to Ca^{2+} resonance magnetic fields for as little as $30 \text{ min} \cdot \text{day}^{-1}$, there was an average increase in stiffness of 175% over controls, rising to nearly 300% when the exposures were maintained for 24 h. Somewhat smaller increases in stiffness were also observed for exposures tuned to the Mg^{2+} charge-to-mass ratio.

Another aspect of the ICR effect is that one can also use harmonics, that is, multiples of the frequency condition given in Eq. 3. For theoretical reasons (65) only odd harmonics are allowed. Thus, the most general expression for cyclotron resonance frequencies is

$$f_n = (2n + 1)(1/2\pi)(qB/m) \quad n = 0, 1, 2, 3, \dots \quad (4)$$

Table 1 lists the frequency/field ratios (f_n/B) for the three ions, Mg^{2+} , Ca^{2+} , and K^+ for the first three harmonics from Eq. 4. Note that some of these ratios are numerically close to one another. The 5th harmonic of Ca^{2+} is slightly > 1% greater than the 3rd harmonic for Mg^{2+} (3.83 vs. 3.79). This observation led S.D. Smith to suggest that using a frequency/field ratio of 3.8 might be particularly effective in bone where growth is indicated for both Ca^{2+} and Mg^{2+} stimulation (66). This ratio is the basis for a number of bone stimulation devices manufactured by the djOrthopedics

Table 1.

Ion	Fundamental $f_0/B, \text{ Hz} \cdot \mu\text{T}$	3rd Harmonic $f_1/B, \text{ Hz} \cdot \mu\text{T}$	5th Harmonic $f_2/B, \text{ Hz} \cdot \mu\text{T}$
Mg^{2+}	1.26	3.79	6.31
Ca^{2+}	0.77	2.30	3.83
K^+	0.39	1.18	1.97

Figure 21. ICR bone repair device for treating nonunions. (djOrthopedics Corp.)

Corporation for treating pseudarthroses and enhancing spinal fusion (Figs. 21,22). The time variation of the magnetic field generated by these devices is shown in Fig. 23. Because the ac and dc magnetic field directions must be maintained parallel to ensure the resonance condition, these clinical devices achieve the frequency/field ratio by fixing the frequency of the applied sinusoidal magnetic field at 76.9 Hz, while using a second coil to continuously adjust for changes in the parallel component of the local dc magnetic field, to maintain this dc level at $20 \mu\text{T}$.

Some observers incorrectly use the term *combined magnetic field* (CMF), to characterize this clinical technique. It is important to understand that the fields that are combined are highly specific, following the rules expressed in Eq. 4. In addition, it is possible to achieve the same conditions in tissue with a single magnetic field, using a prepared current derived from an arbitrary waveform generator. For these reasons, the term ICR should be used for all clinical and research techniques that are otherwise termed CMF.

Figure 22. ICR device for adjunctive use in spinal fusion. (djOrthopedics Corp.)

Figure 23. Comparing ICR signal to PMF signal. In the one case, there is a 20 μT peak sinusoidal magnetic field, and in the other a very short magnetic pulse ~ 100 times larger in intensity (Orthologic Corporation).

It is also sometimes incorrectly reported that ICR is an *inductive* procedure. However, the inductive current generated in the ICR device is negligible, approximately a factor of 10^{-5} smaller than the currents induced by PMF devices. While clearly noninductive, the actual ICR interaction mechanism is still in question (45). It is most likely coupled to events occurring at membrane bound ion channels (40), as evidenced that the calcium channel blocker nifedipene prevents the ICR response (67). It has been suggested, in this regard, that the channel gating process may be sensitive to the resonance tuning of specific ions (45).

SUMMARIZING EFFICACIES FOR THE VARIOUS TREATMENT

The three types of noninvasive treatments for bone defects, PMF, ICR, and CC, have each been subjected to randomized, double-blind trials and are shown to be efficacious, with an overall success rate of between 50 and 70%. One reason for this variation is undoubtedly the inclusion, or lack therein, of patients with defects that are intrinsically more difficult to repair. As the gap in a pseudarthrosis extends to widths > 5 mm, the likelihood of successful treatment diminishes. For this reason, some clinicians choose to exclude patients with radiographic gaps > 5 mm from electrical treatment (21,68).

More than 20 years after Bassett's original use (52) of pulsed magnetic fields to repair nonunions, a definitive work on using PMF to treat delayed unions was published by Sharrard (69). A total of 45 fractures of the tibia were examined in a double-blind multicenter trial, with active PMF stimulation in 20 patients and dummy control units in 25 patients for 12 weeks at 12 h/day. The results, 9

unions in the active group compared to only 3 in the control group, were "*very significantly in favour of the active group* ($p=0.002$)". This effectiveness of PMF stimulation was confirmed for the case of tibial osteotomies in still another randomized, double blind study (70). Similarly, the successful use of CC and ICR, respectively, in treating nonunions, was reported by Scott and King (71) and by Longo (72). Recently, there has been increasing interest in the use of these electromagnetic techniques as an adjunctive to spine fusion. Again, as with the treatment of pseudarthroses, randomized, double-blind trials carried out for the PMF (73), CC (74) and ICR (75) techniques, have indicated that each is also efficacious in the adjunctive treatment of spine fusion.

GENERAL REMARKS

A summary of the electrical and electromagnetic treatments for nonunions and spinal fusion is given in Table 2. It is difficult to make simple comparisons based solely on the relative electrical characteristics, since each modality is based on different types of specifications, including current, current density, time rate of change of magnetic field, frequency, and magnetic intensity. As mentioned above, the levels of current that have been used to achieve osteogenesis extends over a range that has many orders of magnitude, a fact that seems to preclude any mechanism that is simply connected to current alone. It is highly likely that the larger of these successful current levels achieve osteogenesis, as Becker has suggested, by acting as an irritant, and that the smaller levels are perhaps related to the sorts of currents that might occur naturally, perhaps as the result of stress-generated potentials. One measure of

Table 2. Summary of Electrical and Electromagnetic Treatments for Nonunions and Spinal Fusion

	Modality	Designation	Characteristics	Daily Treatment
Invasive Noninvasive	dc electric	dc	1 pA–60 μA	24 h
	ac electric	CC	60 kHz, $7\mu\text{A} \cdot \text{cm}^{-2}$	24 h
	Pulsed magnetic field	PMF, PEMF	$dB/dt=100 \text{ T} \cdot \text{s}^{-1}$ Repetition rate=15 Hz	3 h
	Sinusoidal magnetic field	ICR, CMF	77 Hz ac frequency 20 μT dc Field	30 min

this potential dichotomy is the remarkable fact that both ICR and PMF techniques are equally successful in treating nonunions, despite the fact that the induced currents differ by a factor of 10^5 .

There is undoubtedly room for improvement in the efficacy of the various electromagnetic treatments to repair bony nonunion. Note that both treatments, PMF and ICR, were each adopted for clinical use on the basis of the original designs, with no subsequent studies before or after FDA approval that might have been initiated to search for waveforms and signals that conceivably could be used to optimize treatment. Thus for pulsed magnetic fields, it remains to be seen what roles are played by variables such as pulse width, rise time, repetition rate, and so on, and whether marked improvements in efficacy would follow optimization of these key variables. At least one report (76) claims that peak magnetic fields 100 times smaller than used in the EBI PMF device are just as effective in treating nonunions. Similarly, positive results were obtained in treating tibial osteotomies in rabbit with very different pulse characteristics from that of the EBI clinical device (77). Not only was the magnetic pulse reduced by a factor of 15, but the pulse repetition rate was reduced by a factor of 10, and the frequency components in excess of 20 kHz were filtered from the signal. This lack of optimization is equally true for the djOrthopedics ICR therapeutic signal, based on an approximate simultaneous stimulation of Ca^{2+} and Mg^{2+} ions as well as a very specific ratio of ac to dc magnetic intensities. The ICR device presently approved by the FDA sets this ratio at unity, despite the fact that a number of investigators (78–80) suggested that this ratio may have important consequences for the efficacy of the resonance interaction.

Furthermore, it has been suggested (31,81) that the fundamental reason why some electrical treatments of pseudarthroses are successful may have little to do with the nature of the electrical signal itself, but rather that the initiation of callus formation is known to be tied to local irritants, such as occurs with mechanical, thermal, or chemical sources. It is not inconceivable that the efficacy of treatments such as PMF may result from its role as an irritant. There is evidence (82,83) indicating an increased expression of heat shock proteins in response to low level electromagnetic fields. This type of genetic expression can result from a wide range of stress factors.

The fact that electrical osteogenesis occurs naturally, in growth, homeostasis, and repair and, further, that it can be brought about by exogenous application, begs the question as to whether the present 50–70% repair rate might be substantially improved with further research into the actual underlying mechanism.

INTRODUCTION

High grade gliomas, and specifically glioblastoma multiforme (GBM), are still extremely resistant to all current forms of therapy, including surgery, chemotherapy, radiotherapy, immunotherapy, and gene therapy after decades of intensive research (1–5). Despite aggressive treatment using combinations of therapeutic modalities, the 5 year survival rate of patients diagnosed with GBM in the United States is less than a few percent (6,7). By the time they have had surgical resection of their tumors, malignant cells have infiltrated beyond the margins of resection and have spread into both gray and white matter (8,9). As a result, high grade supratentorial gliomas must be regarded as a whole brain disease (10). Glioma cells and their neoplastic precursors have biochemical properties that allow them to invade the unique extracellular environment of the brain (11,12) and biologic properties that allow them to evade a tumor associated host immune response (13). Chemo- and radiotherapy's inability to cure patients with high grade gliomas is due to their failure to eradicate microinvasive tumor cells within the brain. The challenge facing us is how to develop molecular strategies that can selectively target malignant cells with little or no effect on normal cells and tissues adjacent to the tumor. However, recent molecular genetic studies of glioma suggest that it may be much more complicated than this (14).

In theory, boron neutron capture therapy (BNCT) provides a way to selectively destroy malignant cells and spare normal cells. It is based on the nuclear capture and fission reactions that occur when boron-10, which is a nonradioactive constituent of natural elemental boron, is irradiated with low energy thermal neutrons to yield high linear energy-transfer (LET) alpha particles (^4He) and recoiling lithium-7 (^7Li) nuclei, as shown below.

In order for BNCT to be successful, a sufficient amount of ${}^{10}\text{B}$ must be selectively delivered to the tumor ($\sim 20 \mu\text{g}\cdot\text{g}^{-1}$ weight or $\sim 10^9$ atoms/cell), and enough thermal neutrons must be absorbed by them to sustain a lethal ${}^{10}\text{B}(n, \alpha) {}^7\text{Li}$ capture reaction. Since the high LET particles have limited boron pathlengths in tissue (5–9 μm), the destructive effects of these high energy particles is limited to cells containing boron. Clinical interest in BNCT has focused primarily on the treatment of high grade gliomas (15), and either cutaneous primaries (16) or cerebral metastases of melanoma (17), and most recently head and neck and liver cancer. Since BNCT is a biologically rather than physically targeted

type of radiation treatment, the potential exists to destroy tumor cells dispersed in the normal tissue parenchyma, if sufficient amounts of ^{10}B and thermal neutrons are delivered to the target volume. This article covers radiobiological considerations upon which BNCT is based, boron agents and optimization of their delivery, neutron sources, which at this time are exclusively nuclear reactors, past and ongoing clinical studies, and critical issues that must be addressed if BNCT is to be successful. Readers interested in more in-depth coverage of these and other topics related to BNCT are referred to several recent reviews and monographs (15,18–20).

RADIOBIOLOGICAL CONSIDERATIONS

Types of Radiation Delivered

The radiation doses delivered to tumor and normal tissues during BNCT are due to energy deposition from three types of directly ionizing radiation that differ in their LET characteristics: (1) low LET γ rays, resulting primarily from the capture of thermal neutrons by normal tissue hydrogen atoms [$^1\text{H}(\text{n},\gamma)^2\text{H}$]; (2) high LET protons, produced by the scattering of fast neutrons and from the capture of thermal neutrons by nitrogen atoms [$^{10}\text{N}(\text{n},\text{p})^{14}\text{C}$]; and (3) high LET, heavier charged alpha particles (stripped down ^4He nuclei) and lithium-7 ions, released as products of the thermal neutron capture and fission reactions with ^{10}B [$^{10}\text{B}(\text{n},\alpha)^7\text{Li}$]. The greater density of ionizations along tracks of high LET particles results in an increased biological effect compared to the same physical dose of low LET radiation. Usually, this is referred to as relative biological effectiveness (RBE), which is the ratio of the absorbed dose of a reference source of radiation (e.g., X rays) to that of the test radiation that produces the same biological effect. Since both tumor and surrounding normal tissues are present in the radiation field, even with an ideal epidermal neutron beam, there will be an unavoidable, nonspecific background dose, consisting of both high and low LET radiation. However, a higher concentration of ^{10}B in the tumor will result in it receiving a higher total dose than that of adjacent normal tissues, which is the basis for the therapeutic gain in BNCT (21). As recently reviewed by one of us (18), the total radiation dose delivered to any tissue can be expressed in photon-equivalent units as the sum of each of the high LET dose components multiplied by weighting factors, which depend on the increased radiobiological effectiveness of each of these components.

Biological Effectiveness Factors

The dependence of the biological effect on the microdistribution of ^{10}B requires the use of a more appropriate term than RBE to define the biological effects of the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ reaction. Measured biological effectiveness factors for the components of the dose from this reaction have been termed compound biological effectiveness (CBE) factors and are drug dependent (21–23). The mode and route of drug administration, the boron distribution within the tumor, normal tissues, and even more specifically within cells, and even the size of the nucleus within the target cell

population all can influence the experimental determination of the CBE factor. Therefore, CBE factors are fundamentally different from the classically defined RBE, which primarily is dependent on the quality (i.e., LET) of the radiation administered. The CBE factors are strongly influenced by the distribution of the specific boron delivery agent, and can differ substantially, although they all describe the combined effects of alpha particles and ^7Li ions. The CBE factors for the boron component of the dose are specific for both the boron-10 delivery agent and the tissue. A weighted gray (Gy) unit [Gy(w)] has been used to express the summation of all BNCT dose components and indicates that the appropriate RBE and CBE factors have been applied to the high LET dose components. However, for clinical BNCT the overall calculation of photon-equivalent [Gy(w)] doses requires a number of assumptions about RBEs, CBE factors, and the boron concentrations in various tissues that have been based on the currently available human or experimental data (24,25).

Clinical Dosimetry

The following biological weighting factors, summarized in Table 1, have been used in all of the recent clinical trials in patients with high grade glioma, using BPA in combination with an epidermal neutron beam. The $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ component of the radiation dose to the scalp has been based on the measured boron concentration in the blood at the time of BNCT, assuming a blood:scalp boron concentration ratio of 1.5:1 (26,27,29) and a CBE factor for BPA in skin of 2.5 (29). An RBE of 3.2 has been used in all tissues for the high LET components of the beam: protons resulting from the capture reaction with nitrogen, and recoil protons resulting from the collision of fast neutrons with hydrogen (26,27,30). It must be emphasized that the tissue distribution of the boron delivery agent in humans should be similar to that in the experimental animal model in order to use the experimentally derived values for estimation of Gy(w) doses in clinical radiations.

Dose calculations become much more complicated when combinations of agents are used. At its simplest, this could be the two low molecular weight drugs boronophenylalanine (BPA) and sodium borocaptate (BSH). These have been shown to be highly effective when used in combination to treat F98 glioma bearing rats (31,32), and currently are being used in combination in a clinical study in Japan (33). Since it currently is impossible to know the true

Table 1. Assumptions Used in the Clinical Trials of BPA Based BNCT for Calculation of the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ Component of the Gy(w) Dose in Various Tissue

Tissue	Boron Concentration ^a	CBE Factor
Blood	measured directly	
Brain	1.0 × blood (26,27)	1.3 (23)
Scalp–skin	1.5 × blood (26–28)	2.5 (29)
Tumor	3.5 × blood (28)	3.8 (21)

^aAn RBE of 3.2 is used for the high LET component of the beam dose: protons from the $^{14}\text{N}(\text{n},\text{n})^{14}\text{C}$ reaction, and the recoil protons from fast neutron collisions with hydrogen. Literature references are given in parentheses.

biodistribution of each drug, dosimetric calculations in experimental animals have been based on independent boron determinations in other tumor bearing animals that have received the same doses of drugs but *not* BNCT. More recently, the radiation delivered has been expressed as a physical dose rather than using CBE factors to calculate an RBE equivalent dose (34). The calculations are further complicated if low and high molecular weight delivery agents are used in combination with one another. Tumor radiation dose calculations, therefore, are based on multiple assumptions regarding boron biodistribution, which may vary from patient to patient, as well as within different regions of the tumor and among tumor cells. However, normal brain boron concentrations are much more predictable and uniform, and therefore, it has been shown to be both *safe* and *reliable* to base dose calculations on normal brain tolerance.

BORON DELIVERY AGENTS

General Requirements

The development of boron delivery agents for BNCT began ~50 years ago and is an ongoing and difficult task of the highest priority. The most important requirements for a successful boron delivery agent are (1) low systemic toxicity and normal tissue uptake with high tumor uptake and concomitantly high tumor/brain (T/Br) and tumor/blood (T/Bl) concentration ratios (>3-4:1); (2) tumor concentrations in the range of ~20 $\mu\text{g }^{10}\text{B}\cdot\text{g}^{-1}$ tumor; (3) rapid clearance from blood and normal tissues and persistence in tumor during BNCT. However, at this time *no* single boron delivery agent fulfills all of these criteria. With the development of new chemical synthetic techniques and increased knowledge of the biological and biochemical requirements needed for an effective agent and their modes of delivery, a number of promising new boron agents has emerged (see examples in Fig. 1). The major challenge in their development has been the requirement for selective tumor targeting in order to achieve boron concentrations sufficient to deliver therapeutic doses of radiation to the tumor with minimal normal tissue toxicity. The selective destruction of GBM cells in the presence of normal cells represents an even greater challenge compared to malignancies at other anatomic sites, since high grade gliomas are highly infiltrative of normal brain, histologically complex, and heterogeneous in their cellular composition.

First- and Second-Generation Boron Delivery Agents

The clinical trials of BNCT in the 1950s and early 1960s used boric acid and some of its derivatives as delivery agents, but these simple chemical compounds were non-selective, had poor tumor retention, and attained low T/Br ratios (35,36). In the 1960s, two other boron compounds emerged from investigations of hundreds of low molecular weight boron-containing chemicals, one, (L)-4-dihydroxy-borylphenylalanine, referred to as BPA (compound 1) was based on arylboronic acids (37), and the other was based on a newly discovered polyhedral borane anion, sodium mercaptoundecahydro-*closo*-dodecaborate (38), referred to as

BSH (compound 2). These “second” generation compounds had low toxicity, persisted longer in animal tumors compared with related molecules, and their T/Br and T/Bl boron ratios were > 1. As described later in this article, ^{10}B enriched BPA, complexed with fructose to improve its water solubility, and BSH have been used clinically in Japan, the United States, and Europe. Although these drugs are not ideal, their safety following intravenous (i.v.) administration has been established. Over the past 20 years, several other classes of boron-containing compounds have been designed and synthesized in order to fulfill the requirements indicated at the beginning of this section. Detailed reviews of the state-of-the-art in compound development for BNCT have been published (39–42), and in this overview, only the main classes of compounds are summarized with an emphasis on recently published work in the area. The general biochemical requirements for an effective boron delivery agent are also discussed.

Third Generation Boron Delivery Agents

So-called “third” generation compounds mainly consist of a stable boron group or cluster attached via a hydrolytically stable linkage to a tumor-targeting moiety, such as low molecular weight biomolecules or monoclonal antibodies (MoAbs). For example, the targeting of the epidermal growth factor receptor (EGFR) and its mutant isoform EGFRvIII, which are overexpressed in gliomas and squamous cell carcinomas of the head and neck, also has been one such approach (43). Usually, these low molecular weight biomolecules have been shown to have selective targeting properties and many are at various stages of development for cancer chemotherapy, photodynamic therapy (PDT) or antiviral therapy. The tumor cell nucleus and DNA are especially attractive targets since the amount of boron required to produce a lethal effect may be substantially reduced, if it is localized within or near the nucleus (44). Other potential subcellular targets are mitochondria, lysosomes, endoplasmic reticulum, and the Golgi apparatus. Water solubility is an important factor for a boron agent that is to be administered systemically, while lipophilicity is necessary for it to cross the blood–brain barrier (BBB) and diffuse within the brain and the tumor. Therefore, amphiphilic compounds possessing a suitable balance between hydrophilicity and lipophilicity have been of primary interest since they should provide the most favorable differential boron concentrations between tumor and normal brain, thereby enhancing tumor specificity. However, for low molecular weight molecules that target specific biological transport systems and/or are incorporated into a delivery vehicle (e.g., liposomes) the amphiphilic character is not as crucial. The molecular weight of the boron-containing delivery agent also is an important factor, since it determines the rate of diffusion both within the brain and the tumor.

LOW MOLECULAR WEIGHT AGENTS

Boron-Containing Amino Acids and Polyhedral Boranes

Recognizing that BPA and BSH are not ideal boron delivery agents, considerable effort has been directed toward

Figure 1. Some low molecular weight BNCT agents under investigation. Compound **1** (BPA) and compound **2** (BSH) are currently in clinical use in the United States, Japan, and Europe. Compound **3** (GB-10) has shown promise in animal models, as have the nucleoside derivatives D-CDU (compound **4**) and N5-2OH (compound **5**). Compound **6**, a trimethoxyindole derivative, has shown promise *in vitro* and compound **7**, a porphyrin derivative, was shown to be tumor selective. The maltose derivative **8** has shown low cytotoxicity and tumor cell uptake *in vitro*, the biphosphonate **9** has tumor targeting ability and the dequalinium derivative DEQ-B (compound **10**) has shown promise in *in vitro* studies.

the design and synthesis of third generation, boron-containing amino acids and functionalized polyhedral borane clusters. Examples include various derivatives of BPA and other boron-containing amino acids (e.g., glycine, alanine, aspartic acid, tyrosine, cysteine, methionine), as well as non-naturally occurring amino acids (45–50). The most recently reported delivery agents contain one or more boron clusters and concomitantly larger amounts of boron by weight compared with BPA. The advantages of such compounds are that they potentially can deliver higher concentrations of boron to tumors without increased toxicity. The polyhedral borane dianions, *closo*-B₁₀H₁₀²⁻ and *closo*-B₁₂H₁₂²⁻ and the icosahedral carboranes *closo*-C₂B₁₀H₁₂ and *nido*-C₂B₉H₁₂, have been the most attractive boron clusters for linkage to targeting moieties, due to their relatively easy incorporation into organic molecules, high boron content, chemical and hydrolytic stability, hydrophobic character and, in most cases, their negative charge.

The simple sodium salt of *closo*-B₁₀H₁₀²⁻ (GB-10, compound **3**) has been shown to have tumor-targeting ability and low systemic toxicity in animal models (42) and has been considered as a candidate for clinical evaluation (51). Other polyhedral borane anions with high boron content include derivatives of B₂₀H₁₈²⁻, although these compounds have shown little tumor specificity, and therefore may be better candidates for encapsulation into either targeted or non-targeted liposomes (52,53) and folate receptor targeting, boron containing polyamidoamino (PAMAM) dendrimers (54) and liposomes (55). Boron-containing dipeptides also have shown low toxicity and good tumor-localizing properties (56,57).

Biochemical Precursors and DNA Binding Agents

Several boron-containing analogs of the biochemical precursors of nucleic acids, including purines, pyrimidines,

nucleosides, and nucleotides, have been synthesized and evaluated in cellular and animal studies (58–62). Some of these compounds [e.g., β -5-*o*-carboranyl-2'-deoxyuridine (D-CDU, compound 4) and the 3-(dihydroxypropyl-carboranyl-pentyl)thymidine derivative N5-2OH (compound 5), have shown low toxicities, selective tumor cell uptake, and significant rates of phosphorylation into the corresponding nucleotides (63–65). Intracellular nucleotide formation potentially can lead to enhanced tumor uptake and retention of these types of compounds (64,65).

Another class of low molecular weight delivery agents are boron-containing DNA binding molecules (e.g., alkylating agents, intercalators, groove binders, and polyamines). Some examples are derivatives of aziridines, acridines, phenanthridines (compound 6), trimethoxyindoles, carboranyl polyamines, Pt(II)–amine complexes, di- and tribenzimidazoles (66–69). A limitation of boron-containing polyamines is their frequently observed *in vitro* and *in vivo* toxicity, although promising derivatives with low cytotoxicity have been synthesized (70–73). Other nuclear-targeting molecules are *nido*-carboranyl oligomeric phosphate diesters (OPDs). Despite their multiple negative charges, OPDs have been shown to target the nuclei of TC7 cells following microinjection (74), suggesting that the combination of OPDs with a cell-targeting molecule capable of crossing the plasma membrane could provide both selectivity and nuclear binding. Such a conjugate has been designed and synthesized (75), although its biological evaluation has yet to be reported.

Boron-Containing Porphyrins and Related Structures

Several boron-containing fluorescent dyes, including porphyrin, tetrabenzoporphyrin, and phthalocyanine derivatives have been synthesized and evaluated (76–79). These have the advantage of being easily detected and quantified by fluorescence microscopy, and have the potential for interacting with DNA due to their planar aromatic structures. Among these macrocycles, boron-containing porphyrins (e.g., compound 7: H₂DGP) have attracted special attention due to their low systemic toxicity compared with other dyes, easy synthesis with high boron content, and their remarkable stability (79–82). Porphyrin derivatives have been synthesized that contain up to 44% boron by weight using *closo*- or *nido*-carborane clusters linked to the porphyrin macrocycle via ester, amide, ether, methylene, or aromatic linkages (76–85). The nature of these linkages is believed to influence their stability and systemic toxicity. Therefore, with these and other boron delivery agents, chemically stable carbon–carbon linkages have been preferred over ester and amide linkages that potentially can be cleaved *in vivo*. Boron-containing porphyrins have excellent tumor-localizing properties (76–82) and have been proposed for dual application as boron delivery agents and photosensitizers for PDT of brain tumors (85–91). Our own preliminary data with H₂TCP (tetra[*nido*-carboranylphenyl]porphyrin), administered intracerebrally by means of convection enhanced delivery

(CED) to F98 glioma bearing rats, showed tumor boron concentrations of 150 $\mu\text{g}\cdot\text{g}^{-1}$ tumor with concomitantly low normal brain and blood concentrations (92). Ozawa et al. recently described a newly synthesized polyboronated porphyrin, designated TABP-1, which was administered by CED to nude rats bearing intracerebral implants of the human glioblastoma cell line U-87 MG (93). High tumor and low blood boron concentrations were observed and both we and Ozawa have concluded that direct intracerebral administration of the carboranyl porphyrins by CED is superior to systemic administration. Furthermore, despite the bulkiness of the carborane cages, carboranylporphyrins have been shown to interact with DNA and thereby produce *in vitro* DNA damage following light activation (94,95). Boronated phthalocyanines have been synthesized, although these compounds usually have had decreased water solubility and an increased tendency to aggregate compared to the corresponding porphyrins (76,77,86,87). Boron-containing acridine molecules also have been reported to selectively deliver boron to tumors with high T/Br and T/Bl ratios, whereas phenanthridine derivatives were found to have poor specificity for tumor cells (94–98).

Other Low Molecular Weight Boron Delivery Agents

Carbohydrate derivatives of BSH and other boron-containing glucose, mannose, ribose, gulose, fucose, galactose, maltose (e.g., compound 8) and lactose molecules have been synthesized, and some of these compounds have been evaluated in both *in vitro* and *in vivo* studies (99–105). These compounds usually are highly water soluble and as a possible consequence of this, they have shown both low toxicity and uptake in tumor cells. It has been suggested that these hydrophilic low molecular weight derivatives have poor ability to cross tumor cell membranes. However, they might selectively accumulate within the glycerophospholipid membrane bilayer and in other areas of the tumor, such as the vasculature.

Low molecular weight boron-containing receptor-binding molecules have been designed and synthesized. These have been mainly steroid hormone antagonists, such as derivatives of tamoxifen, 17 β -estradiol, cholesterol, and retinoic acid (106–110). The biological properties of these agents depend on the density of the targeted receptor sites, although to date very little biological data have been reported. Other low molecular weight boron-containing compounds that have been synthesized include phosphates, phosphonates (e.g., compound 9) phenylureas, thioureas, nitroimidazoles, amines, benzamides, isocyanates, nicotinamides, azulenes, and dequalinium derivatives (e.g., dequalinium-B, compound 10) (111–113). Since no single chemical compound, as yet synthesized, has the requisite properties, the use of *multiple* boron delivery agents is probably essential for targeting different subpopulations of tumor cells and subcellular sites. Furthermore, lower doses of each individual agent would be needed, which could reduce systemic toxicity while at the same time enhancing tumor boron levels to achieve a therapeutic effect.

HIGH MOLECULAR WEIGHT AGENTS

Monoclonal Antibodies, Other Receptors Targeting Agents and Liposomes

High molecular weight delivery agents (e.g., MoAbs and their fragments), which can recognize a tumor-associated epitope, have been (114–116) and continue to be of interest to us (117,118) as boron delivery agents. Although they can be highly specific, only very small quantities reach the brain and tumor following systemic administration (119) due to their rapid clearance by the reticuloendothelial system and the BBB, which effectively limits their ability to cross capillary vascular endothelial cells. Boron-containing bioconjugates of epidermal growth factor (EGF) (120,121), the receptor which is overexpressed on a variety of tumors, including GBM (122,123), also have been investigated as potential delivery agents to target brain tumors. However, it is unlikely that either boronated antibodies or other bioconjugates would attain sufficiently high concentrations in the brain following systemic administration, but, as described later in this section, direct intracerebral delivery could solve this problem. Another approach would be to directly target the vascular endothelium of brain tumors using either boronated MoAbs or VEGF, which would recognize amplified VEGF receptors. The use of boron-containing VEGF bioconjugates would obviate the problem of passage of a high molecular weight agent across the BBB, but their use would most likely require repeated applications of BNCT, since tumor neovasculature can continuously regenerate. Backer et al. reported that targeting a Shiga-like toxin-VEGF fusion protein was selectively toxic to vascular endothelial cells overexpressing VEGFR-2 (124). Recently, a bioconjugate has been produced by chemically linking a heavily boronated PAMAM dendrimer to VEGF (125). This selectively targeted tumor blood vessels overexpressing VEGFR-2 in mice bearing 4T1 breast carcinoma. There also has been a longstanding interest on the use of boron-containing liposomes as delivery agents (52,53,126,127), but their size has limited their usefulness as brain tumor targeting agents, since they are incapable of traversing the BBB unless they have diameters <50 nm (128). If, on the other hand, they were administered intracerebrally or were linked to an actively transported carrier molecule (e.g., transferrin), or alternatively if the BBB was transiently opened, these could be very useful delivery agents, especially for extracranial tumors (e.g., liver cancer).

Recent work of one of us (R.F.B.) has focused on the use of a chemeric MoAb, cetuximab (IMC-C225 also known as Erbitux), produced by ImClone Systems, Inc. This antibody recognizes both wild-type EGFR and its mutant isoform, EGFRvIII (129), and has been approved for clinical use by the U.S. Food and Drug Administration (FDA) for the treatment of EGFR(+) recurrent colon cancer. Using previously developed methodology (114), a precision macromolecule, a polyamido amino (PAMAM or “starburst”) dendrimer has been heavily boronated and then linked by means of heterobifunctional reagents to EGF (121), cetuximab (118) or another MoAb, L8A4, which is specifically directed against EGFRvIII (130). In order to

completely bypass the BBB, the bioconjugates were administered by either direct intratumoral (i.t.) injection (131) or CED (132) to rats bearing intracerebral implants of the F98 glioma that had been genetically engineered to express either wildtype EGFR (131) or EGFRvIII (133). Administration by either of these methods resulted in tumor boron concentrations that were in the therapeutic range (i.e., $\sim 20 \mu\text{g}\cdot\text{g}^{-1} \text{wt}^{-1}$ tumor). Similar data also were obtained using boronated EGF, and based on the favorable uptake of these bioconjugates, therapy studies were initiated at the Massachusetts Institute of Technology nuclear reactor (MITR). The mean survival times (MST) of animals that received either boronated cetuximab (134) or EGF (135) were significantly prolonged compared to those of animals bearing receptor negative tumors. A further improvement in MSTs was seen if the animals received BPA, administered i.v., in combination with the boronated bioconjugates, thereby validating our thesis that combinations of agents may be superior to any single agent (32). As can be seen from the preceding discussion, the design and synthesis of low and high molecular weight boron agents have been the subject of intensive investigation. However, optimization of their delivery has not received enough attention, but nevertheless is of critical importance.

OPTIMIZING DELIVERY OF BORON CONTAINING AGENTS

General Considerations

Delivery of boron agents to brain tumors is dependent on (1) the plasma concentration profile of the drug, which depends on the amount and route of administration; (2) the ability of the agent to traverse the BBB; (3) blood flow within the tumor, and (4) the lipophilicity of the drug. In general, a high steady-state blood concentration will maximize brain uptake, while rapid clearance will reduce it, except in the case of intraarterial (i.a.) drug administration. Although the i.v. route currently is being used clinically to administer both BSH and BPA, this may not be ideal and other strategies may be needed to improve their delivery. Delivery of boron-containing drugs to extracranial tumors, such as head and neck and liver cancer, present a different set of problems, including nonspecific uptake and retention in adjacent normal tissues.

Intra-arterial Administration with or without Blood–Brain Barrier Disruption

As shown in experimental animal studies (31,32,134–136) Enhancing the delivery of BPA and BSH can have a dramatic effect both on increasing tumor boron uptake and the efficacy of BNCT. This has been demonstrated in the F98 rat glioma model where intracarotid (i.c.) injection of either BPA or BSH doubled the tumor boron uptake compared to that obtained by i.v. injection (31). This was increased fourfold by disrupting the BBB by infusing a hyperosmotic (25%) solution of mannitol via the internal carotid artery. Mean survival times (MST) of animals that received either BPA or BSH i.c. with BBB-D were increased 295 and 117%, respectively, compared to irradiated controls (31). The best survival data were obtained using both BPA and BSH in

combination, administered by i.c. injection with BBB-D. The MST was 140 days with a cure rate of 25%, compared to 41 days following i.v. injection with no long-term surviving animals (32). Similar data have been obtained using a rat model for melanoma metastatic to the brain. BPA was administered i.c. to nude rats bearing intracerebral implants of the human MRA 27 melanoma with or without BBB-D. The MSTs were 104–115 days with 30% long-term survivors compared to a MST of 42 days following i.v. administration (134). A similar enhancement in tumor boron uptake and survival was observed in F98 glioma bearing rats following i.c. infusion of the bradykinin agonist, RMP-7 (receptor mediated permeabilizer-7), now called Cereport (136,137). In contrast to the increased tumor uptake, normal brain boron values at 2.5 h following i.c. injection were very similar for the i.v. and i.c. routes with or without BBB-D. Since BNCT is a binary system, normal brain boron levels only are of significance at the time of irradiation and high values at earlier time points are inconsequential. These studies have shown that a significant therapeutic gain can be achieved by optimizing boron drug delivery, and this should be important for both ongoing and future clinical trials using BPA and/or BSH.

Direct Intracerebral Delivery

Different strategies may be required for other low molecular weight boron-containing compounds whose uptake is cell cycle dependent, such as boron-containing nucleosides, where continuous administration over a period of days may be required. We recently have reported that direct i.t. injection or CED of the boron nucleoside N5-2OH (compound 5) were both effective in selectively delivering potentially therapeutic amounts of boron to rats bearing intracerebral implants of the F98 glioma (61). Direct i.t. injection or CED most likely will be necessary for a variety of high molecular weight delivery agents such as boronated MoAbs (138) and ligands such as EGF (132), as well as for low molecular weight agents (e.g., nucleosides and porphyrins). Recent studies have shown that CED of a boronated porphyrin derivative similar to compound 7, designated H₂DCP, resulted in the highest tumor boron values and T/Br and T/Bl ratios that have been seen with any of the boron agents that have been studied (92).

NEUTRON SOURCES FOR BNCT

Nuclear Reactors

Neutron sources for BNCT currently are limited to nuclear reactors and in the present section only information that is described in more detail in a recently published review will be summarized (139). Reactor derived neutrons are classified according to their energies as thermal ($E_n < 0.5$ eV), epithermal (0.5 eV $< E_n < 10$ keV), or fast ($E_n > 10$ keV). Thermal neutrons are the most important for BNCT since they usually initiate the $^{10}\text{B}(n,\alpha)^7\text{Li}$ capture reaction. However, because they have a limited depth of penetration, epithermal neutrons, which lose energy and fall into the thermal range as they penetrate tissues, are now preferred for clinical therapy. A number of reactors with very good

neutron beam quality have been developed and currently are being used clinically. These include (1) MITR, shown schematically in Fig. 2 (140); (2) clinical reactor at Studsvik Medical AB in Sweden (141); (3) the FRi1 clinical reactor in Helsinki, Finland (142); (4) R2-0 High Flux Reactor (HFR) at Petten in the Netherlands (143); (5) LVR-15 reactor at the Nuclear Research Institute (NRI) in Rez, Czech Republic (144); (6) Kyoto University Research Reactor (KURR) in Kumatori, Japan (145); (7) JRR4 at the Japan Atomic Energy Research Institute (JAERI) (146); and (8) the RA-6 CNEA reactor in Bariloche, Argentina (147). Other reactor facilities are being designed, notably the TAPIRO reactor at the ENEA Casaccia Center near Rome, Italy, which is unique in that it will be a low-power fast-flux reactor (148), and a facility in South Korea. Two reactors that have been used in the past for clinical BNCT are the Musashi Institute of Technology (MuITR) reactor in Japan and the Brookhaven Medical Research Reactor (BMRR) at the Brookhaven National Laboratory (BNL) in Upton, Long Island, New York (26,27,149). The MuITR was used by Hatanaka (150) and later by Hatanaka and Nakagawa (151). The BMRR was used for the clinical trial that was conducted at the Brookhaven National Laboratory between 1994 and 1999 (27,152) and the results are described in detail later in this section. Due to a variety of reasons, including the cost of maintaining the BMRR, it has been deactivated and is no longer available for use.

Reactor Modifications

Two approaches are being used to modify reactors for BNCT. The first or direct approach, is to moderate and filter neutrons that are produced in the reactor core. The second, the fission converter-plate approach, is indirect in that neutrons from the reactor core create fissions within a converter-plate that is adjacent to the moderator assembly, and these produce a neutron beam at the patient port. The MITR (153), which utilizes a fission converter-plate, currently sets the standard for the world for the combination of high neutron beam quality and short treatment time. It operates at a power of 5 MW and has been used for clinical as well as experimental studies for BNCT. Although the power is high compared to the majority of other reactors that are being used, the treatment time is unusually short, since it utilizes a fission converter-plate to create the neutron beam. All other reactors use the direct approach to produce neutron beams for BNCT. Three examples are the FRi1 reactor in Finland (142), the Studsvik reactor in Sweden (141), and the Washington State University (WSU) reactor in the United States (154), which was built for the treatment of both small and large experimental animals.

Accelerators

Accelerators also can be used to produce epithermal neutrons and accelerator based neutron sources (ABNSs) are being developed in a number of countries (155–161), and interested readers are referred to a recently published detailed review on this subject (28). For ABNSs, one of the more promising nuclear reactions involves bombarding a ^7Li target with 2.5 MeV protons. The average energy of

Figure 2. Schematic diagram of the MITR. The fission converter based epithermal neutron irradiation (FCB) facility is housed in the experimental hall of the MITR and operates in parallel with other user applications. The FCB contains an array of 10 spent MITR-II fuel elements cooled by forced convection of heavy water coolant. A shielded horizontal beam line contains an aluminum and Teflon filter-moderator to tailor the neutron energy spectrum into the desired epithermal energy range. A patient collimator defines the beam aperture and extends into the shielded medical room to provide circular apertures ranging from 16 to 8 cm in diameter. The in-air epithermal flux for the available field sizes ranges from 3.2 to 4.6×10^9 $\text{n}\cdot\text{cm}^{-2}\cdot\text{s}^{-1}$ at the patient position. The measured specific absorbed doses are constant for all field sizes and are well below the inherent background of 2.8×10^{-12} $\text{RBE Gy}\cdot\text{cm}^2\cdot\text{n}^{-1}$ produced by epithermal neutrons in tissue. The dose distributions achieved with the FCB approach the theoretical optimum for BNCT.

the neutrons that are produced is 0.4 MeV and the maximum energy is 0.8 MeV. Reactor derived fission neutrons have greater average and maximum energies than those resulting from the ${}^7\text{Li}(p,n){}^7\text{Be}$ reaction. Consequently, the thickness of the moderator material that is necessary to reduce the energy of the neutrons from the fast to the epithermal range is less for an ABNS than it is for a reactor. This is important since the probability that a neutron will be successfully transported from the entrance of the moderator assembly to the treatment port decreases as the moderator assembly thickness increases. Due to lower and less widely distributed neutron source energies, ABNS potentially can produce neutron beams with an energy distribution that is equal to or better than that of a reactor. However, reactor derived neutrons can be well collimated, while on the other hand, it may not be possible to achieve good collimation of ABNS neutrons at reasonable proton beam currents. The necessity of good collimation for the effective treatment of GBM, is an important and unresolved issue that may affect usefulness of ABNS for BNCT. The ABNSs are also compact enough to be sited in hospitals thereby allowing for more effective, but technically more complicated procedures to carry out BNCT. However, to date, no accelerator has been constructed with a beam quality comparable to that of the MITR, which can be sited in a hospital and that provides a current of

sufficient magnitude to treat patients in <30 min. Furthermore, issues relating to target manufacture and cooling must be solved before ABNS become a reality. The ABNS that is being developed at the University of Birmingham in England, by modifying a Dynamitron linear electrostatic accelerator (155), may be the first facility where patients will be treated, although progress has been slow. Another ABNS being constructed by LINAC Systems, Inc. in Albuquerque, New Mexico (162), and this could be easily sited in a hospital and produce an epithermal neutron beam.

Beam Optimization

For both reactors and ABNSs, a moderator assembly is necessary to reduce the energy of the neutrons to the epithermal range. The neutrons comprising the neutron beam have a distribution of energies and are accompanied by unwanted X rays and gamma photons. A basic tenet of BNCT is that the dose of neutrons delivered to the target volume should not exceed the tolerance of normal tissues, and this applies to neutron beam design, as well as to treatment planning (25). The implications of this for beam design is that the negative consequences of increased normal tissue damage for a more energetic neutron beams at shallow depths, outweighs the benefits of more deeply penetrating energetic neutrons. For fission reactors, the

average energy of the neutrons produced is ~ 2 MeV, but small numbers have energies as high as 10 MeV. There is generally a trade off between treatment time and the optimum beam for patient treatment in terms of the energy distribution of the neutrons and the contamination of the neutron beam with X rays and gamma photons. Not surprisingly, reactors with the shortest treatment time (i.e., the highest normal tissue dose rate) operate at the highest power, since the number of neutrons that is produced per unit time is proportional to the power, measured in megawatts. Furthermore, high beam quality is most easily achieved using reactors with high power, since a larger fraction of the neutrons can be filtered, as the neutrons traverse the moderator assembly without making the treatment time exceedingly long.

CLINICAL STUDIES OF BNCT FOR BRAIN TUMORS

Early Trials

Although the clinical potential of BNCT was recognized in the 1930s (163), it was not until the 1950s that the first clinical trials were initiated by Farr at the BNL (145,163) and by Sweet and Brownell at the Massachusetts General Hospital (MGH) using the MIT reactor (36,164,165). The disappointing outcomes of these trials, which ended in 1961 and subsequently were carefully analyzed by Slatkin (166), were primarily attributable to (1) inadequate tumor specificity of the inorganic boron chemicals that had been used as capture agents; (2) insufficient tissue penetrating properties of the thermal neutron beams; and (3) high blood boron concentrations that resulted in excessive damage to normal brain vasculature and to the scalp (36,164,165).

Japanese Clinical Trials

Clinical studies were resumed by Hatanaka in Japan in 1967, following a 2 year fellowship in Sweet's laboratory at the MGH, using a thermal neutron beam and BSH, which had been developed as a boron delivery agent by Soloway at the MGH (38). In Hatanaka's procedure (150,151), as much of the tumor was surgically removed as possible (debulking), and at some time thereafter, BSH (compound 2) was administered by a slow infusion, usually intra-arterially (150), but later intravenously (151). Later (12–14 h) BNCT, was carried out at one or another of several different nuclear reactors. Since thermal neutrons have a limited depth of penetration in tissue, this necessitated reflecting the skin and raising the bone flap in order to directly irradiate the exposed brain. This eliminated radiation damage to the scalp and permitted treatment of more deep-seated residual tumors. As the procedure evolved over time, a ping-pong ball or silastic sphere was inserted into the resection cavity as a void space to improve neutron penetration into deeper regions of the tumor bed and adjacent brain (150,151,167,168). This is a major difference between the procedure carried out by Hatanaka, Nakagawa and other Japanese neurosurgeons and the BNCT protocols that have been carried out in the United States and Europe, which have utilized epithermal neutron beams that have not required reflecting the scalp and

raising the bone flap at the time of irradiation. This has made it difficult to directly compare the Japanese clinical results with those obtained elsewhere, and this has continued on until very recently when the Japanese started using epithermal neutron beams (33). Most recently, Miyatake et al. initiated a clinical study utilizing the combination of BSH and BPA, both of which were administered i.v. at 12 and 1 h, respectively, prior to irradiation with an epithermal neutron beam (33). A series of 11 patients with high grade gliomas have been treated, and irrespective of the initial tumor volume, magnetic resonance imaging (MRI) and computed tomography (CT) images showed a 17–51% reduction in tumor volume that reached a maximum of 30–88%. However, the survival times of these patients were not improved over historical controls and further studies are planned to improve the delivery of BPA and BSH, which may enhance survival.

Analysis of the Japanese Clinical Results

Retrospective analysis of subgroups of patients treated in Japan by Hatanaka and Nakagawa (167,168) have described 2, 5, and 10 year survival rates (11.4, 10.4, and 5.7%, respectively) that were significantly better than those observed among patients treated with conventional, fractionated, external beam photon therapy. However, a cautionary note was sounded by Laramore and Spence (169) who analyzed the survival data of a subset of 12 patients from the United States who had been treated by Hatanaka between 1987 and 1994. They concluded that there were no differences in their survival times compared to those of age matched controls, analyzed according to the stratification criteria utilized by Curran et al. (6). In a recent review of Hatanaka's clinical studies, Nakagawa reported that the physical dose from the $^{10}\text{B}(n,\alpha)^7\text{Li}$ reaction, delivered to a target point 2 cm beyond the surgical margin, correlated with survival (168). For 66 patients with GBMs, those who survived <3 years ($n = 60$) had a minimum target point dose of 9.5 ± 5.9 Gy, whereas those who survived >3 years ($n = 6$) had a minimum target point dose of 15.6 ± 3.1 Gy from the $^{10}\text{B}(n,\alpha)^7\text{Li}$ reaction (168). The boron concentrations in brain tissue at the target point, which are required to calculate the physical radiation dose attributable to the $^{10}\text{B}(n,\alpha)^7\text{Li}$ capture reaction, were estimated to be 1.2X that of the patient's blood boron concentration (170).

OTHER RECENT AND ONGOING CLINICAL TRIALS

Beginning in 1994 a number of clinical trials, summarized in Table 2, were initiated in the United States and Europe. These marked a transition from low energy thermal neutron irradiation to the use of higher energy epithermal neutron beams with improved tissue penetrating properties, which obviated the need to reflect skin and bone flaps prior to irradiation. Up until recently, the procedure carried out in Japan required neurosurgical intervention immediately prior to irradiation, whereas the current epithermal neutron-based clinical protocols are radiotherapeutic procedures, performed several weeks after debulking surgery. Clinical trials for patients with brain tumors were initiated at a number of locations including (1) the

BMR at BNL from 1994–1999 for GBM using BPA with one or two neutron radiations, given on consecutive days (171–173); (2) the MITR from 1996–1999 for GBM and intracerebral melanoma (174,175); (3) the HFR, Petten, The Netherlands and the University of Essen in Germany in 1997 using BSH (176); (4) the Fir1 at the Helsinki University Central Hospital (142) in 1999 to the present; (5) the Studsvik reactor facility in Sweden from 2001 to June 2005, carried out by the Swedish National Neuro-Oncology Group (141), and finally (6) the NRI reactor in Rez, Czech Republic by Tovarys using BSH (177). The number of patients treated in this study is small and the followup is still rather short.

Initially, clinical studies using epithermal neutron beams were primarily Phase I safety and dose-ranging trials and a BNCT dose to a specific volume or critical region of the normal brain was prescribed. In both the BNL and the Harvard/MIT clinical trials, the peak dose delivered to a 1 cm³ volume was escalated in a systematic way. As the dose escalation trials have progressed, the treatments have changed from single-field irradiations or parallel opposed irradiations, to multiple noncoplanar irradiation fields, arranged in order to maximize the dose delivered to the tumor. A consequence of this approach has been a concomitant increase in the average doses delivered to normal brain. The clinical trials at BNL and Harvard/

MIT using BPA (compound 1) and an epithermal neutron beam in the United States have now been completed.

Analysis of the Brookhaven and MIT Clinical Results

The BNL and Harvard/MIT studies have provided the most detailed data relating to normal brain tolerance following BNCT. A residual tumor volume of 60 cm³ or greater lead to a greater incidence of acute CNS toxicity. This primarily was related to increased intracranial pressure, resulting from tumor necrosis and the associated cerebral edema (152,173,174). The most frequently observed neurological side effect associated with the higher radiation doses, other than the residual tumor volume-related effects, was radiation related somnolence (178). This is a well-recognized effect following whole brain photon irradiation (179), especially in children with leukemia or lymphoma, who have received CNS irradiation. However, somnolence is not a very well-defined radiation related endpoint because it frequently is diagnosed after tumor recurrence has been excluded. Therefore, it is not particularly well suited as a surrogate marker for normal tissue tolerance. In the dose escalation studies carried out at BNL (152,173), the occurrence of somnolence in the absence of a measurable tumor dose response was clinically taken as the maximum tolerated normal brain dose. The volume-averaged whole brain

dose and the incidence of somnolence increased significantly as the BNL and Harvard/MIT trials progressed (175). The volume of tissue irradiated has been shown to be a determining factor in the development of side effects (180). Average whole brain doses greater than ~ 5.5 Gy(w) were associated with somnolence in the trial carried out at BNL, but not in all of the patients in the Harvard/MIT study (18,152,176). The BNL and Harvard/MIT trials were completed in 1999. Both produced median and 1-year survival times that were comparable to conventional external beam photon therapy (6). Although both were primarily Phase I trials to evaluate the safety of dose escalation as the primary endpoint for radiation related toxicity, the secondary endpoints were quality of life and time to progression and overall survival. The median survival times for 53 patients from the BNL trial and the 18 GBM patients from the Harvard/MIT trial were 13 months and 12 months, respectively. Following recurrence, most patients received some form of salvage therapy, which may have further prolonged overall survival. Time to progression, which would eliminate salvage therapy as a confounding factor, probably would be a better indicator of the efficacy of BNCT, although absolute survival time still is the "gold standard" for any clinical trial. The quality of life for most of the BNL patients was very good, especially considering that treatment was given in one or two consecutive daily fraction(s).

Clinical Trials Carried Out in Sweden and Finland

The clinical team at the Helsinki University Central Hospital and VTT (Technical Research Center of Finland) have reported on 18 patients using BPA as the capture agent ($290 \text{ mg}\cdot\text{kg}^{-1}$ infused over 2 h) with two irradiation fields and whole brain average doses in the range of 3–6 Gy(w) (142). The estimated 1-year survival was 61%, which was very similar to the BNL data. This trial is continuing and the dose of BPA has been escalated to $450 \text{ mg}\cdot\text{kg}^{-1}$ and will be increased to $500 \text{ mg}\cdot\text{kg}^{-1}$, infused over 2 h (H. Joensuu, personal communication). Since BNCT can deliver a significant dose to tumor with a relatively low average brain dose, this group also has initiated a clinical trial for patients who have recurrent GBM after having received full-dose photon therapy. In this protocol, at least 6 months must have elapsed from the end of photon therapy to the time of BNCT and the peak brain dose should be < 8 Gy(w) and the whole brain average dose < 6 Gy(w). As of August 2005, only a small number of patients have been treated, but this has been well tolerated.

Investigators in Sweden have carried out a BPA-based trial using an epithermal neutron beam at the Studsvik Medical AB reactor (141). This study differed significantly from all previous clinical trials in that the total amount of BPA administered was increased to $900 \text{ mg}\cdot\text{kg}^{-1}$, infused i.v. over 6 h. This approach was based on the following preclinical data: (1) the *in vitro* observation that several hours were required to fully load cells with BPA (181); (2) long-term i.v. infusions of BPA in rats increased the absolute tumor boron concentrations in the 9L gliosarcoma model, although the T:B1 ratio remained constant (182,183), and (3) most importantly, long-term i.v. infu-

sions of BPA appeared to improve the uptake of boron in infiltrating tumor cells at some distance from the main tumor mass in rats bearing intracerebral 9L gliosarcomas (184). The longer infusion time of BPA was well tolerated (185–187) by the 30 patients who were enrolled in this study. All patients were treated with two fields, and the average weighted whole brain dose was 3.2–6.1 Gy(w), which was lower than the higher end of the doses used in the Brookhaven trial, and the minimum dose to the tumor ranged from 15.4 to 54.3 Gy(w). At 10 months following BNCT 23 of 29 evaluable patients had died with a median time to progression following BNCT of 5.8 months and a median survival time of 14.2 months. These results are comparable but not better than those obtained with external beam radiation therapy. Furthermore, they emphasize the need to improve the delivery of BPA, as well as BSH. As part of a broader plan to restructure the company, a decision was made by Studsvik AB in June 2005 to terminate operation of both the R2-0 reactor, which was used for this clinical trial, and the R2 reactor.

CLINICAL STUDIES OF BNCT FOR OTHER TUMORS

Treatment of Melanoma

Other than patients with primary brain tumors, the second largest group that has been treated by BNCT were those with cutaneous melanomas. Mishima and co-workers previously had carried out extensive studies in experimental animals with either primary or transplantable melanomas using ^{10}B enriched BPA as the capture agent (188,189). The use of BPA was based on the premise that it would be selectively taken up by and accumulate in neoplastic cells that were actively synthesizing melanin (190). Although it was subsequently shown that a variety of malignant cells preferentially took up large amounts of BPA compared to normal cells (191), nevertheless, Mishima's studies clearly stimulated clinical interest in BPA as a boron delivery agent. Since BPA itself has low water solubility, it was formulated with HCl to make it more water soluble. The first patient, who was treated by Mishima in 1985, had an acral lentiginous melanoma of his right toe that had been amputated (192). However, 14 months later he developed a subcutaneous metastatic nodule on the left occiput, which was determined to be inoperable due to its location. The tumor was injected peritumorally at multiple points for a total dose of 200 mg of BPA. Several hours later, by which time BPA had cleared from normal skin, but still had been retained by the melanoma, the tumor was irradiated with a collimated beam of thermal neutrons. Based on the tumor boron concentrations and the neutron fluence, an estimated 45 RBE-Gy equivalent dose was delivered to the melanoma. Marked regression was noted after 2 months, and the tumor had completely disappeared by 9 months (188,189,192). This successful outcome provided further evidence for *proof-of-principle* of the usefulness of BNCT to treat a radioresistant tumor. Subsequently, at least an additional 18 patients with either primary or metastatic melanomas have been treated by Mishima and co-workers (193). The BPA either was injected peritumorally or administered orally as a slurry (194) until Yoshino et al.

improved its formulation and water solubility by complexing it with fructose, following which it was administered i.v. (195). This important advance ultimately led to the use of BPA in the clinical trials in patients with brain tumors that were described in the preceding section. In all of Mishima's patients, there was local control of the treated primary or metastatic melanoma nodule(s) and several patients were tumor free at 4 or more years following BNCT (193).

Several patients with either cutaneous or cerebral metastases of melanoma have been treated by Busse et al. using BPA fructose as the delivery agent (18,196). The most striking example of a favorable response was in a patient with an unresected cerebral metastasis in the occipital lobe. The tumor received a dose of 24 RBE-Gy and monthly MRI studies revealed complete regression over a 4 month interval (196). As evidenced radiographically, a second patient with a brain metastasis had a partial response. Several other patients with either cutaneous or metastatic melanoma to the brain have been treated at other institutions, including the first in Argentina (197), and the consensus appears to be that these tumors are more responsive to BNCT than GBMs. This is supported by experimental studies carried out by two of us (R.F.B. and J.A.C.) using a human melanoma xenograft model (198,199), which demonstrated enhanced survival times and cure rates superior to those obtained using the F98 rat glioma model (200). In summary, multicentric metastatic brain tumors, and more specifically melanoma, which cannot be treated either by surgical excision or stereotactic radiosurgery, may be candidates for treatment by BNCT.

Other Tumor Types Treated by BNCT

Two other types of cancer recently have been treated by BNCT. The first is recurrent tumors of the head and neck. Kato et al. reported on a series of six patients, three of whom had squamous cell carcinomas, two had sarcomas, and 1 had a parotid tumor (201). All of them had received standard therapy and had developed recurrent tumors for which there were no other treatment options. All of the patients received a combination of BSH (5 g) and BPA (250 mg·kg⁻¹ body weight), administered i.v. In all but one patient, BNCT was carried out at the Kyoto University Research Reactor using an epithermal neutron beam in one treatment that was given 12h following administration of BSH and 1 h after BPA. The patient with the parotid tumor, who received a second treatment one month following the first, had the best response with a 63% reduction in tumor volume at 1 month and a 94% reduction at 1 year following the second treatment without evidence of recurrence. The remaining five patients showed responses ranging from a 10–27% reduction in tumor volume with an improvement in clinical status. This study has extended the use of BNCT to a group of cancers that frequently are ineffectively treated by surgery, radio-, and chemotherapy. However, further clinical studies are needed to objectively determine the clinical usefulness of BNCT for head and neck cancers, and another study to assess this currently is in progress at Helsinki University Central Hospital.

The second type of tumor that recently has been treated by BNCT is adenocarcinoma of the colon that had metastasized to the liver (202). Although hepatectomy followed by allogeneic liver transplantation, has been carried out at a number of centers (203,204), Pinelli and Zonta et al. (202) in Pavia, Italy, have approached the problem of multicentric hepatic metastases using an innovative, but highly experimental procedure. Their patient had >14 metastatic nodules in the liver parenchyma, the size of which precluded surgical excision. Before hepatectomy was performed, the patient received a 2 h infusion of BPA fructose (300 mg·kg⁻¹ b.w.) via the colic vein. Samples of tumor and normal liver were taken for boron determinations and once it was shown that boron selectively had localized in the tumor nodules with small amounts in normal liver, the hepatectomy was completed (202). The liver then was transported to the Reactor Laboratory of the University of Pavia for neutron irradiation, following which it was reimplanted into the patient. More than 2 years later in October 2004, the patient had no clinical or radiographic evidence of recurrence and CEA levels were low (205). Although it is unlikely that this approach will have any significant clinical impact on the treatment of the very large number of patients who develop hepatic metastases from colon cancer, it nevertheless again provides *proof of principle* that BNCT can eradicate multicentric deposits of tumor in a solid organ. The Pavia group has plans to treat other patients with metastatic liver cancer and several other groups (206–208) are exploring the possibility of treating patients with primary, as well as metastatic tumors of the liver using this procedure.

CRITICAL ISSUES

There are a number of critical issues that must be addressed if BNCT is to become a useful modality for the treatment of cancer, and most specifically, brain tumors. *First* and foremost, there is a need for more selective and effective boron agents, which when used either alone or in combination, could deliver the requisite amounts (~20 μg·g⁻¹) of boron to the tumor. Furthermore, their delivery must be optimized in order to improve both tumor uptake and cellular microdistribution, especially to different subpopulations of tumor cells (185). A number of studies have shown that there is considerable patient-to-patient as well-intratumor variability in the uptake of both BSH (209,210) and BPA (184,211,212). At this point in time, the dose and delivery of these drugs have yet to be optimized, but based on experimental animal data (31,32,34,137,183), improvement in dosing and delivery could have a significant impact on increasing tumor uptake and microdistribution.

Second, since the radiation dosimetry for BNCT is based on the microdistribution of ¹⁰B (209,213), which is indeterminable on a real-time basis, methods are needed to provide semiquantitative estimates of the boron content in the residual tumor. Imahori and co-workers (214–216) in Japan and Kabalka (217) in the United States have carried out imaging studies with ¹⁸F-labeled BPA, and have used to establish the feasibility of carrying out BNCT. This

^{18}F -PET imaging also has been used as a prognostic indicator for patients with GBM who may or may not have received BNCT (214,215). In the former group, it has been used to establish the feasibility of carrying out BNCT based on the uptake and distribution of ^{18}F -BPA within the tumor and in the latter to monitor the response to therapy. The possibility of using MRI for either ^{10}B or ^{11}B has been under investigation (218), and this may prove to be useful for real-time localization of boron in residual tumor prior to BNCT. Magnetic resonance spectroscopy (MRS) and magnetic resonance spectroscopic imaging (MRSI) also may be useful for monitoring the response to therapy (219). Kojimoto and Miyatake et al. recently used MRS to analyze the target specificity of BPA and the effects of BNCT in a group of six patients using multivoxel proton MRS (220). There was a reduction in the choline/creatine ratio without a reduction of the *N*-acetylaspartate/creatine ratio at 14 days following BNCT, strongly suggesting that there was selective destruction of tumor cells and a sparing of normal neurons (220). Noninvasive procedures (e.g., MRSI) may be a powerful way to follow the clinical response to BNCT in addition to MRI. However, in the absence of real-time tumor boron uptake data, the dosimetry for BNCT is very problematic. This is evident from the discordance of estimated doses of radiation delivered to the tumor and the therapeutic response, which would have been greater than that which was seen if the tumor dose estimates were correct (152).

Third, there is a discrepancy between the theory behind BNCT, which is based on a very sophisticated concept of selective cellular and molecular targeting of high LET radiation, and the implementation of clinical protocols, which are based on very simple approaches to drug administration, dosimetry, and patient irradiation. This in part is due to the fact that BNCT has not been carried out in advanced medical settings with a highly multidisciplinary clinical team in attendance. At this time BNCT has been totally dependent on nuclear reactors as neutron sources. These are a medically unfriendly environment and are located at sites at varying distances from tertiary care medical facilities, which has made it difficult to attract patients, and the highly specialized medical team that ideally should be involved in clinical BNCT. Therefore, there is an urgent need for either very compact medical reactors or ABNS that could be easily sited at selected centers that treat large numbers of patients with brain tumors.

Fourth, there is a need for randomized clinical trials. This is especially important since almost all major advances in clinical cancer therapy have come from these, and up until this time no randomized trials of BNCT have been conducted. The pitfalls of nonrandomized clinical trials for the treatment of brain tumors have been well documented (221,222). It may be somewhat wishful thinking to believe that the clinical results with BNCT will be so clearcut that a clear determination of efficacy could be made without such trials. These will require a reasonably large number of patients in order to provide unequivocal evidence of efficacy with survival times significantly better than those obtainable with promising currently available therapy for both GBMs (223,224) and metastatic brain tumors (225). This leads to the issue of

conducting such trials, which might best be accomplished through cooperative groups such as the Radiation Therapy Oncology Group (RTOG) in the United State or the European Organization for Research Treatment of Cancer (EORTC).

Finally, there are several promising leads that could be pursued. The upfront combination of BNCT with external beam radiation therapy or in combination with chemotherapy has not been explored, although recently published experimental data, suggest that there may be a significant gain if BNCT is combined with photon irradiation (34). The extension of animal studies, showing enhanced survival of brain tumor bearing rats following the use of BSH and BPA in combination, administered intraarterially with or without BBB-D, has not been evaluated clinically. This approach is promising, but it is unlikely that it could be carried out at a nuclear reactor.

As is evident from this article, BNCT represents an extraordinary joining together of nuclear technology, chemistry, biology, and medicine to treat cancer. Sadly, the lack of progress in developing more effective treatments for high grade gliomas has been part of the driving force that continues to propel research in this field. BNCT may be best suited as an adjunctive treatment, used in combination with other modalities, including surgery, chemotherapy, and external beam radiation therapy, which, when used together, may result in an improvement in patient survival. Clinical studies have demonstrated the safety of BNCT. The challenge facing clinicians and researchers is how to get beyond the current impasse. We have provided a road map to move forward, but its implementation still remains a daunting challenge

ACKNOWLEDGMENTS

BRACHYTHERAPY, HIGH DOSAGE RATE

RUPAK DAS
University of Wisconsin
Madison, Wisconsin

INTRODUCTION

Brachytherapy is a form of radiotherapy whereby a radioactive source is used inside or at short distance from the tumor. There are three different forms of brachytherapy: interstitial, intracavitary, and skin therapy. In interstitial brachytherapy, the radioactive sources are implanted inside and throughout the tumor volume; in intracavitary brachytherapy the sources are placed in the body cavities very close to the tumor; while in skin therapy the sources are placed on the skin surface. Conventionally, brachytherapy implants have delivered the radiation at a low dose rate (dose rates of $<1 \text{ Gy} \cdot \text{h}^{-1}$). Low dose-rate (LDR) interstitial implants can be temporary (meaning that the radioactive sources are left in place for a period of time, usually a few days, and then removed) or permanent (left in place without removal), while intracavitary implants are temporary. The advent of methods to deliver the dose at a much higher dose rates, in the range of $1\text{--}5 \text{ Gy} \cdot \text{min}^{-1}$, brought an increase in the use of brachytherapy. All high dose-rate (HDR) brachytherapy treatments are temporary and treatments are administered using discrete fractions.

What Is a Remote Afterloader?

A remote afterloader (RAL) is a computer driven system that transports the radioactive source from a shielded safe into the applicator placed in the patient. Upon termination or interruption of the treatment, the source is driven back to its safe. The device may move the source by one of several methods, most commonly pneumatic air pressure or cable drives.

What is Stepping-Source Remote Afterloader?

A stepping source RAL is a particular design of the treatment unit that consists of a single source at the end of a cable that moves the source through applicators placed in the treated volume. The treatment unit can treat implants consisting of many needles or catheters in the patient. Multiple catheters are often required to cover the target with adequate radiation doses. Each catheter or part of an applicator is connected to the RAL through a channel. The computer drives the cable so that the source moves from the safe through a given channel to the programmed position in the applicator (dwell position) for a specific amount of time (dwell time). In any applicator, there may be many dwell positions. After treating all the positions in a given catheter (channel) the source is retracted to its safe and then driven to the next channel. The dwell positions and the dwell time in each channel are independently programmable, thereby giving a high level of flexibility of dose delivery. All currently available HDR RALs use the stepping-source design.

Currently there are three types of HDR RALs available in the market: MicroSelectron (Fig. 1, vendor Nucletron,

Veenendaal, Netherlands), Gamma-Med (Fig. 2), and VariSource (Fig. 3, both marketed by Varian Associates, Palo Alto, CA).

The specific features of the three different RALs are shown in Table 1.

COMPONENTS OF A HIGH DOSE RATE REMOTE AFTERLOADER

While different in detail, all available HDR RALs consist of the same general components. Figure 4 gives an overview of the systems, with the major parts described below.

Shielded Safe

To provide a dose rate in the range of $1\text{--}5 \text{ Gy} \cdot \text{min}^{-1}$ in a RAL requires a ^{192}Ir source of 4–10 Ci. A shielded safe, which is an integrated part of the treatment unit, provides enough radiation shielding to house the source while not in treatment mode. Once in treatment mode, the source is driven out of the safe while it follows the program through the dwell positions. In the event of an interruption or termination of the treatment, the source is driven back to the shielded safe.

Radioactive Source

While delivering the HDR brachytherapy requires an intense source, passing the source through needles placed through a tumor requires one of a small size. The radioactive source in an HDR RAL is usually 3–10 mm in length

Figure 1. The Nucletron MicroSelectron V2 HDR RAL. The RAL wheels allow it to be conveniently positioned near the patient. The treatment head is mounted on a telescopic base that allows the head to be raised or lowered to the required height for treatment without moving the patient.

Figure 2. The Varian GammaMed RAL.

Figure 3. The Varian VariSource RAL.

and < 1 mm in diameter, fixed at the end of a steel cable (Figs. 5 and 6). The Nucletron source is placed in a stainless steel capsule and welded to the cable, while the Varian source is placed in a hole drilled into the cable and closed by welding. The ^{192}Ir radionuclide is now used for all HDR RALs, although early versions of HDR RAL used ^{60}Co . A new source has an activity near 10 Ci. Since ^{192}Ir has a half-life of 74 days, the source should be replaced every 3 months to keep the treatment in the HDR radiobiological regime. A trained medical physicist calibrates the source after each installation using a re-entrant well-type ionization chamber (Fig. 7). The chambers themselves are calibrated by secondary calibration laboratories known as

Accredited Dosimetry Calibration Laboratories (ADCL). The resulting source calibration is verified against the manufacturer's source calibration.

Source Drive Mechanism

When the RAL unit receives a command to initiate a treatment, the stepper motor connected to the reel containing the drive cable turns, causing the source cable to advance from the shielded safe along a path constrained by transfer tubes to the first treated dwell position in the applicator attached to the first channel. The source dwells at that position for a predetermined duration (dwell time) as calculated by the treatment planning system (see below). After completing that dwell, it goes on to the subsequent dwell positions. Some units step as the source drives out (MicroSelectron), stopping first at the dwell position most proximal to the afterloader, while the other (VariSource and Gamma-Med) the source travels first to the most distal dwell (toward the tip of the applicator), and a bit farther, and then steps as the source returns toward the safe. Stepping on the outward drive obviates any concern about the effect of slack in the drive mechanism affecting the accuracy of the source position. The unit that steps on the way back into the unit includes correction for slack in the calibration of the source location. Upon completion of the treatment for the first channel, the source is retracted into the safe, and redirected to travel to the second channel. The process is repeated for all the subsequent treatment channels. The programmed movement of the source is verified by means of an optical encoder or other devices that compare the angular rotation of the stepper motor or cable length ejected or retracted with the number of pulses sent to the drive motor. This system is capable of detecting catheter obstruction or constriction as increased friction in the cable movement. Under certain fault conditions, if the stepper motor fails to retract the source, a high torque direct current (dc) emergency motor will retract the source.

The confirmation of the source exit from and return to the safe is carried out by an "optopair", consisting of a pair of light-sensitive detector and infrared (IR) light source, that detects the cable when its tip obstructs the light path. All the currently marketed after-loaders are also equipped with check cables or dummy sources. The check cable is an exact duplicate of the radioactive source along with its cable, except not radioactive. Before the ejection of the radioactive source, the check cable is first ejected to check the integrity of the catheter system. After a noneventful check by this "dry run" with the dummy source, the radioactive source is then sent for treatment.

Indexer

The RALs are equipped with an indexer, shown in Fig. 8. The indexer consists of an S-tube (item 14 in Fig. 4) that directs the source cable from the exit of the safe to one of the exit ports from the unit (channels). The various catheters or applicator parts connect to these channels, usually through connecting guides called transfer tubes. Different units have between 3 and 24 channels available for

Table 1. Specific Features of the Three Currently Marketed HDR RALs

	MicroSelectron V2	Gamma Med+	VariSource 200/200t
Vendor	Nucletron	Varian	Varian
Sources	10 Ci of ¹⁹² Ir	10 Ci of ¹⁹² Ir	10 Ci of ¹⁹² Ir
Source dimension	3.5 mm L, 1.1 mm OD	4.52 mm L, 0.9 mm OD	5 mm L, 0.59 mm OD
Channels	18	3 or 24	20
Source extension	1500 mm	1300 mm	1500 mm
Channel length	Variable	Fixed	Variable
Source movement	Stepping forward	Stepping backward	Stepping backward
Step sizes	2.5, 5 or 10 mm	1–10 mm, 1 mm steps	2–99 mm, 1 mm steps
Dwells/channel	48	60	20
Speed of source	50 cm · s ⁻¹	60 cm · s ⁻¹	50–60 cm · s ⁻¹

Figure 6. A ¹⁹²Ir HDR source for the MicroSelectron at the end of a steel drive cable, as shown in Fig. 5.

connection. If a patient's treatment requires more than the number of channels on a given treatment unit, the treatment must be broken into sessions, where the catheters are connected up to the number of channels available and treated. Then the transfer tubes are disconnected from the catheters just treated and reconnected to the next set of catheters for continuation of the treatment.

Figure 5. Schematics of the two types of sources used in stepping-source RALs. The VariSource is an earlier version, while the new source has a length of 5 mm.

Figure 7. A re-entrant well-type ionization chamber used for calibration of the HDR brachytherapy sources.

Transfer Tubes

Transfer or guide tubes are long tubes that act as a conduit to transfer the source from the RAL to the applicators or catheters for treatment. One end of the transfer tube is attached to the indexer of the RAL (Fig. 9), while the other end is attached to the interstitial, intracavitary, or trans-

Figure 8. The frontal view of an indexer from the Nucletron, MicroSelectron HDR RAL, consisting of 18 channels.

Figure 9. A view of two types of transfer tubes hooked up to the indexer of a RAL.

luminal applicators (Fig. 10). The applicator-end of the transfer tube contains spring-loaded ball bearings that block the path through the tube if no applicator is attached. When an applicator is inserted, it pushes aside the ball bearings, opening the path for the source cable. When the

Figure 10. View of the transfer tubes connected to a gynecological applicator. Ball bearings beneath the gray polymer coating allow verification of the proper connection of the transfer tubes to the applicator. The number 1 and 2 represents that these transfer tubes must connect the channel 1 and 2 of the indexer ring and the similarly numbered parts of the applicator.

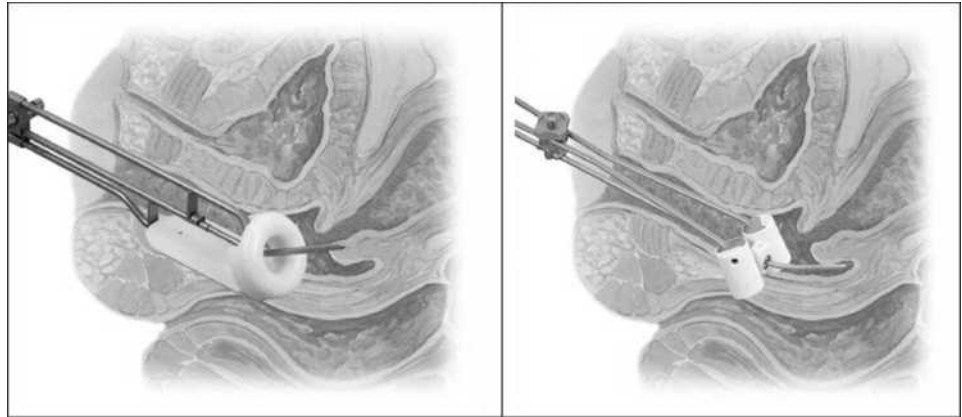

Figure 11. Gynecological applicator used for the treatment of cervical cancer. (Courtesy of Nucletron Corporation, Columbia, MD.)

check cable makes its test run, if no applicator is attached to the transfer tube, the check cable hits the obstacle of the ball bearings, and prevents ejection of the source. Each type of applicator has its own type of transfer tube.

Applicators

An array of applicators for different treatment sites are marketed by each vendor. Each vendor designs their own applicators that can only be used with their transfer tubes and HDR RALs. Figure 11 shows two cervical applicators marketed by Nucletron used for the treatment of cervical cancer.

Treatment Control Station

The treatment control station (Fig. 12) allows the user to select the source travel and dwell sequence to be used in each channel. This can be entered by three ways: (1) manually by the keyboard/mouse at the control station; (2) recalling a standard plan from the computer and then

Figure 12. A view of the monitor of the RAL treatment control station.

editing the data without affecting the standard plan from which it originated; or (3) by importing the data from a treatment planning system via transfer medium or a network connection to the treatment control station.

Treatment Control Panel

The treatment control station transfers the data to the treatment control panel. A hard or soft START button initiates the execution of the treatment according to the program. In addition, there is an INTERRUPT button, which when pressed retracts the source and stops the timer, allowing the user to enter the treatment room without receiving radiation exposure. A RESUME or START button resumes the treatment from the time and the dwell position where it was interrupted. A master EMERGENCYOFF button initiates the high torque dc emergency motor to retract the source. In the normal course of a successful termination of the treatment, the timer runs to zero and the machine automatically retracts the source. Figure 13 shows an example of the treatment control panel.

SAFETY FEATURES

The HDR RALs are complicated devices containing very high activity radioactive sources. Serious accidents can

Figure 13. The Treatment Control Panel of the Nucletron, micro-Selectron HDR RAL. The START button is the white button on the right side of the panel, while the EMERGENCY OFF button is the top button on the left side of the panel.

Figure 14. A view of the access panel of the MicroSelectron treatment unit. The center button is an emergency stop button on the treatment unit. Also showing are the manual retraction of the radioactive source cable (left) and the check cable (right).

happen quickly. All such units have many safety features and operational interlocks to prevent errant source movement or facilitate rapid operator response in the event of a system failure.

Emergency Switches

Numerous EMERGENCY OFF switches are located at convenient places and are easily accessible, in case a situation arises. One EMERGENCY OFF switch is located on the control panel. Another EMERGENCY OFF button is located on the top of the remote afterloader treatment head. Vendors usually install one or two emergency switches in the walls of the treatment room. In the event a treatment is initiated with someone other than the patient in the treatment room, that person can stop the treatment and retract the source by pressing the EMERGENCY OFF button. Figure 14 shows the EMERGENCY OFF switch on the treatment unit.

Emergency Crank

All HDR RALs have emergency cranks to retract the source cable if the source fails to retract normally and the emergency motor also fails to reel in the source. Figure 14 shows such a crank for the MicroSelectron and Fig. 15 for the VariSource. Using the crank requires the operator to enter the room with the source unshielded. Exposure rates for this situation are considered below.

Door Interlock

Interlock switches prevent initiation of a treatment with the door open. While in progress, opening the door interrupts the treatment. This safety feature protects the medical personnel from radiation exposure, in the event somebody enters the treatment room without the knowledge of the operator. If a door is inadvertently opened during the treatment, the treatment is interrupted and

Figure 15. The back panel of the VariSource showing the crank for manual source retraction in an emergency.

the source returns to the safe. The treatment can be resumed at the same point where it was interrupted by closing the door and pressing the START or the RESUME button at the control panel.

Audio-Visual System

All HDR brachytherapy suites are equipped with a closed circuit television system (CCTV) or shielded windows and/or mirrors for observing the patient, and a two-way audio system to communicate with the patient during treatment.

Radiation Monitor and Treatment on Indicator

Three separate independent systems alert personnel when the source is not shielded. One radiation detector is part of the treatment unit and indicates on the control panel when it detects radiation. An independent unit, usually mounted on the treatment room wall with displays both inside and outside the room also alerts the operator and other personnel when the radioactive source is out of the safe. A TREATMENT ON Indicator outside the room, activated when the source passes the reference optical pair discussed above and shown in Fig. 4, also indicates that a treatment is in progress.

Table 2. Exposure Rates from an Exposed 10 Ci ^{192}Ir Source

Typical Situation	Distance, m	Dose Equiv Rates, Sv · h ⁻¹	Time, min, to Receive	
			10 Gy (likely injury)	0.5 Sv (annual body limit)
In Patient	0.01	460	1.25 min	0.07 min
Handling with Kelly Clamps, to hands	0.1	4.6	2.1 h	6.5 min
Handling with Kelly Clamps, to body	0.3	0.5	18.8 h	98 min for hand limit
Standing near	1	0.046	8.7 days	11 h
Standing far	2	0.012	34.8 days	43 h

Emergency Service Instruments

In the event the radioactive source fails to retract after termination, interruption, pushing the EMERGENCY SWITCH, or cranking the stepper motor manually, the immediate priority is to remove the source from the patient. Table 2 gives the exposure rates at various distances from a 10 Ci ^{192}Ir source. Table 2 shows that the dose to the patient, with the source in contact, can cause injury in a very short time. On the other hand, the operator, working at a greater distance, is unlikely to receive a dose exceeding regulatory limits for a year, let alone one that would cause health problems. Once the source is removed from the patient and moved to a distance of even a meter, the exposure rate is quite low, and whatever actions need be taken to remove the patient from the room can be performed safely.

The effective annual limit to the body should actually be 10 times < the 0.5 Sv in keeping with the principle to keep exposures as low as reasonable achievable (ALARA), and ideally should not be received in one, short exposure. The allowed exposure to the hands is 15 times that to the body.

The preferred approach to a source that will not retract by any of the methods is to remove the applicator from the patient as quickly as possible, and place the applicator containing the source in a shielded container (Fig. 16). If it is clear that the cable is caught in the transfer tube and not in the applicator itself, the applicator or catheter may be disconnected from the transfer tube and the source pulled from the applicator. In some cases, this will be faster than removing the applicator. The reason to avoid disconnecting the applicator from the transfer tube is that a source may stay in the applicator if the source capsule shatters. In that case, removing the applicator attached to the transfer tube keeps the system closed, while disconnecting the two opens a path for parts of a broken source to fall from the applicator into body cavities or crevices, or roll onto the floor.

A situation may arise when the source needs to be detached manually from the treatment unit. One (still unlikely) scenario would be if the source were stuck out of the treatment unit, the sources or the closed applicator had been removed from the patient, a person were pinned very close to the source so neither they, nor the treatment unit, could be moved, and the source on the cable could not reach the shielded container. In this special situation, the source cable should be cut from the unit and the source placed in the shielded container always present in the room. In cutting the source cable, it must be clear that the cut is *not* through the source capsule. For units with the

capsule welded on the cable, the cut must be through the braided cable as opposed to the smooth steel capsule (Fig. 17). For sources imbedded in the cable, a sufficient length of the cable must be seen to assure the cut occurs behind the source. Thus, emergency tools that must be present in the treatment room and always readily accessible include a wire cutter, a pair of forceps, and a shielded service container.

Back-Up Battery

In case of a power failure during the treatment, the machine is equipped with a back-up battery to provide retraction of the source to its safe. The batteries should be tested with each source exchange.

Figure 16. The shielded container for emergency placement of an unretracted source.

Figure 17. Cutting the source cable from a treatment unit. This procedure should only be performed in very special, rare situations as described in the text. Great care must be taken to assure the cut is through the cable and not the source capsule.

TREATMENT PLANNING SYSTEM

Software and hardware for the treatment planning system are provided by the vendor selling the treatment unit. Three-dimensional (3D) patient data [computed tomography (CT), magnetic resonance imaging (MRI)] can be directly transported and loaded in the planning system. Two dimensional (2D) data (e.g., from radiographs) usually are loaded interactively by computer peripherals (scanners, digitizers) although some automated input systems are available. With 2D input, the target information must be inferred since tumors are generally not visible on the images, while the 3D imaging often visualizes tumors as well as surrounding normal tissue structures. With either input, tumor volume is entered on these images, and the treatment-planning volume is constructed by adding some margin to the tumor volume. Various computer algorithms help the planner conform the prescribed dose to the target volume. Data characteristic for the radioactive source are usually supplied by the vendor and included in the software. The medical physicist enters the source strength data both in the planning system and the treatment unit at the time of the installation of the new source in the treatment unit after calibration.

Dose Calculation

The treatment-planning computer calculates the dose distribution for a patient containing an applicator with a given set of dwell positions, each with their own dwell time. In calculating the dose distribution, the computer first calculates the dose to a set of grid points. Usually, the operator wishes to see the results presented as isodose lines. An isodose line on a given plan connects all points receiving the same dose, much like elevation lines on a contour map of part of the Earth connects points with the same altitude. From the dose values at the grid points, the computer interpolates to find the path of the isodose line

Figure 18. Geometry and legend for the dosimetry of a line source as given in Eq. 1.

value specified by the user. The calculation of the dose from one dwell position, identified with the subscript i , to a point $P(r_i, \theta_i)$ as shown in Fig. 18, uses the formula (1),

$$D_i(r_i, \theta) = S_K \cdot \Lambda \cdot [G_i(r, \theta) / G(r_o, \theta_o)] \cdot g_i(r_i) \cdot F_i(r_i, \theta) \cdot t_i \quad (1)$$

where

$D_i(r_i, \theta)$ = The radiation dose to water, in units Gy, at position $P(r, \theta)$

S_K = The air kerma strength of the source in $\mu\text{Gym}^2 \cdot \text{h}^{-1}$.

The strength of photon-emitting brachytherapy sources usually is specified by the intensity of the radiation at some distant outside of the source rather than by the amount of radioactivity contained inside. In this manner, variations in the source encapsulation, which may attenuate varying amounts of the radiation given off by the contained radionuclide, have no effect on the dose delivered to the patient. While the strength of a new HDR source is often quoted as 10 Ci (the approximate activity in the capsule), the actual source strength determination accounts for the energy of radiation from the source, transferred to a mass of air at a given point. Air kerma is the energy transferred from the radiation to kinetic energy in the medium per unit mass, where the medium must be specified. That point for air kerma strength is at 1 m, and a new source would have an air kerma strength of $\sim 40 \text{ mGy} \cdot \text{m}^2 \cdot \text{h}^{-1}$, or in shorthand, 40 kU, where $1 \text{ U} = \mu\text{Gy} \cdot \text{m}^2 \cdot \text{h}^{-1}$. A radiation dose of 1 gray (Gy), equals 1 joule per kilogram ($1 \text{ J} \cdot \text{kg}$).

Λ = The dose rate constant, that is the absorbed dose rate in $\text{cGy} \cdot \text{h}^{-1}$ at 1 cm from the source in the perpendicular plane that bisects the source axis per unit air kerma strength. For ^{192}Ir sources, $\Lambda = 1.12 \text{ cGy} \cdot \text{h}^{-1}/\text{U}$.

$[G_i(r_i, \theta_i) / G(r_o, \theta_o)]$ = The geometry function, which accounts for changes in dose rate due to the relative positions of the source and the calculation point and the

shape of the source. The numerator expresses the geometric dose pattern for the point of calculation while the denominator gives that for the reference condition, where $r_o = 1$ cm and $\theta_o = 90^\circ$. The geometric dose pattern usually is approximated as $1/r^2$ for a point source, and for a line source (L-h) as shown in Fig. 18.

$g_i(r_i)$ = The radial dose function, variation in the dose rate with distance from the source due to the attenuation and scatter due to the tissue between the source and the point of calculation at distance r , normalized at 1 cm, and not including any effect in dose rate due to geometry (i.e., the geometric function has been removed from the dose at the calculation distance and at 1 cm for the ratio).

$F_i(r_i, \theta)$ = The anisotropy function, which describes the deviation of the shaped of the isodose lines from a circle. The function $F_i(r_i, \theta)$ = the dose at the calculation point $P(r, \theta)$ divided by the dose at the same distance, r_i but on the perpendicular bisector, that is with $\theta_o = 90^\circ$, and, as with the radial dose function, with the geometrical effects removed.

t_i = the dwell time for dwell position i .

Dose Optimization

The treatment planning addresses first which dwell positions will be used. Then for each of the dwell positions, the dwell time must be calculated. The goal is to match the resulting dose distribution with the target volume, a process referred to as optimization. There are several methods to assist the operator in optimizing the dwell times. The methods fall into three main categories:

Analytic methods use relatively simple algorithms to calculate the dwell time for each dwell position. One of the most common, geometric optimization (2,3), weights the dwell time for a position inversely to the sum of the doses to that position from the other dwell positions. For an intracavitary application, where the dose distribution is intended to more or less conform to the shape of the applicator tracks, “distance optimization” is used, where the contributions of all of the other dwell positions are included in the summation of the dose. For interstitial application, where the implant usually treats a volume, the process becomes “volume optimization”, with the dose contributions from dwell position along the same track excluded in the summation.

Dose specification methods attempts to calculate the dwell times to deliver a specified dose to designated points (dose points or optimization points) placed throughout the volume or on the surface of the target (4–6). The dose to each specified point described an equation with the dose to the point on one side and the contributions from each of the dwell positions on the other,

$$\text{Dose} = S_K \cdot \Lambda \cdot \sum_i^{\text{all dwells}} \{ [G_i(r_i, \theta) / G(r_o, \theta_o)] \cdot g_i(r_i) \cdot f_i(r_i, \theta) \cdot t_i \} \tag{2}$$

In the simplest situation, such an approach becomes solving a set of simultaneous equations for the doses to the optimiza-

tion points for the unknown dwell times. The problem comes when there are more equations than unknowns (more dose points than dwell positions and the set is over determined) or the converse (when the set is underdetermined). In the general case, the set is solved by a least-squares method to find the values for the dwell times that minimizes the square of the difference between the doses desired and the doses resulting from times in the set of equations. However, it is very helpful to add an additional criterion on the dwell times: controlling the fluctuation in dwell times between adjacent positions. The optimization equation becomes

$$X^2 = \sum_{j=1}^{\text{All dose points}} (D_j^{\text{prescribed}} - D_j^{\text{calculated}})^2 + V \sum_{i=1}^{\text{dwells}-1} (t_{i+1} - t_i)^2 + u \sum_{i=1}^{\text{all dwells}} t_i \tag{3}$$

where the first term considers the difference between the prescribed dose and that calculated dose for each specified point. The value of the second term depends on the differences in dwell times between each dwell position and its neighbor. The factor, the dwell weight gradient factor, v , determines how important minimizing this fluctuation is. Large values for v (> 1) tend to force the dwell times to be the same, not producing a very conformal dose distribution; small values (< 0.2) permit negative times to result from the optimization (not a physical situation). The last term minimizes the overall exposure time, assuming that the set of dwell times that adequately treats the target volume with the least total time results in the lowest dose to the rest of the patient. The factor u determines how important minimizing dwell time is for the optimization. The optimized set of dwell times minimizes X^2 .

Stochastic methods use iterative techniques to find adequate values for the dwell times. Generally, these approaches establish an objective function, such as the difference in dose to a set of point between that prescribed and that achieved. The function may also include penalties for excessive doses to normal tissue structures or lack of homogeneity through an implanted volume. The goal of the optimization is to obtain the best score for the objective function. The process begins with a set of values for the dwell times, evaluates the objective function, and then makes changes in the dwell times. If the new set of times improves the value of the objective function, the new set becomes the current best set. If the old set of times gave a better value for the objective function, it remains the current best set. Obviously, the strategy for how to pick each new set of values in the core of the methodology, and a more complete discussion is beyond the scope of this text. The most common approaches in the literature are simulated annealing (7) and the genetic algorithm (8).

The goal of all the optimization methods is to adequately treat the target tissues while sparing the sensitive normal structures. A resultant plan is shown in Fig. 19.

SHIELDING

The radioactive source in the high dose rate machine starts ~ 10 Ci with an exposure rate at a distance of 1 m from the

Figure 19. A 3D view of dose distribution of a breast catheter implant with 25 catheters. The inner volume is the tumor volume (lumpectomy cavity), while the outer volume (planning treatment volume) has been generated by adding some margins to the tumor volume. The gray cloud is the dose distribution generated by the treatment planning system.

source of $\sim 46 \text{ mSv} \cdot \text{h}^{-1}$. According to the rules and regulations of the United States Nuclear Regulatory Commission (USNRC), the annual limit for radiation exposure to the public is 1 mSv and the annual occupational limit is 5 mSv. (The actual limit for occupationally exposure persons is $50 \text{ mSv} \cdot \text{year}^{-1}$, but following the principle of maintaining exposures as low as reasonable achievable, the NRC usually holds licensees to exposure 0.1 of the limit.) In addition to the annual limit, NRC requires that in an unrestricted area the dose equivalent rate should not be $> 0.02 \text{ mSv}$ in any given hour. Thus, the HDR machine needs to be housed in an adequately shielded room. To meet these requirements in a HDR brachytherapy suite, where the walls and the ceiling are at least 1.5 m from the machine head, concrete wall of $\sim 43\text{--}50 \text{ cm}$ (or 4–5 cm of lead) are needed. For larger rooms the concrete wall thickness will be lower since the exposure rate is inversely proportional to the square of the distance from the radioactive source. For details on the procedures for calculating the thickness of barriers for a particular facility, see health physics texts such as Cember (9) or McGinley (10).

QUALITY ASSURANCE

In order to maintain the quality of patient care, a quality management program is required in every facility that provides HDR brachytherapy treatment. Such a program generally follows standards set by professional organizations and intends to minimize untoward events caused by the malfunction of the machine or human error. Such programs become exceedingly important in HDR brachytherapy because the planning and the treatments tend to happen very quickly, increasing the likelihood of accidents and mistakes. Quality Assurance (QA) tests measure some performance aspect of the treatment unit and compare the results with expectations in order to demonstrate

proper operation. QA is performed at various intervals: some for each patient, some once each treatment day, and others with each source change. Moreover, for HDR RAL, the USNRC mandates that users meet certain standards, including education and training on operating the machine, emergency procedures, radiation monitoring, pre-treatment safety checks, safe and accurate delivery of the treatment, and monthly/initial calibration of the source. Since the details of quality assurance is outside the scope of this literature, interested readers can refer to the report of Task Groups 59 (11) and 56 (12) of the American Association of Physicists in Medicine and relevant texts (13).

In general, the problem of quality assurance becomes assuring that the treatment will deliver the correct dose, to the correct location, safely. Thus, the tests generally follow the outline below:

Verification of dose variables.

- Checking the strength of the source compared with that projected from the initial calibration based on radioactive decay.
- Checking the proper operation of the controlling timer.

Verification of position control.

- Checking that the source goes to the location programmed.
- Checking coincidence between the programmed positions and the respective positions indicated by imaging markers.
- Checking consistent movement of the source.

Verification of proper operation of safety features.

- Checking operation of the door interlocks.
- Checking the operation of a handheld radiation detector.
- Checking the operation of the on-board and on-wall radiation detectors.
- Checking the operation of the check cable runs and interlocks.
- Checking the operation of the EMERGENCY OFF and TREATMENTINTERRUPT buttons.

COSTS

Currently, two vendors (Nucletron Corporation and Varian Medical Systems) market their RAL treatment unit in the United States. Both the devices requires a capital expenditure of $\sim \$500,000\text{--}750,000$, which includes the treatment unit, a variety of transfer tubes, along with the software and hardware for the treatment planning system. Applicators that are needed to be placed in the tumor costs extra. The costs of preparing a shielded room along with ancillary equipment for X-ray imaging and operating room

procedures can be another \$500,000–750,000. Hence, the total cost can run in between \$1–1.5 million (14).

ADVANTAGES AND DISADVANTAGES

HDR comparing with LDR brachytherapy offers several advantages and disadvantages. Being aware of these permits safe and effective operation and application of HDR brachytherapy.

Advantages of HDR Brachytherapy

Safety. One of the major advantages of a RAL is the reduction or elimination of radiation exposure to the radiotherapy staff. In conventional LDR, manual afterloading, the radiotherapy staff receives radiation exposure while loading the applicators with the radioactive sources, and the nursing personnel are exposed during patient care through the duration of the treatment (1–4 days). With either HDR or LDR remote afterloading, the radiotherapy personnel are outside the shielded room during the treatment, and hence are exposed to minimal radiation.

Optimization. The design of the HDR RAL with the stepping source allows greater flexibility and control over dose distribution. The stepping source allows optimization of the dose distribution by adjustment of the dwell times for each dwell position in each channel. The dwell times can be varied infinitely, permitting very fine control of the dose distribution. In LDR, either manual or using an RAL, the finite number of activities available (usually four at most) and the larger sources used with manual applications impose a restriction on the ability to conform the dose distribution to the target.

Stability. Because HDR intracavitary treatments take so little time (~ 1 h), applicators can be fixed in place much more stably than for the several day treatments using LDR brachytherapy.

Dose Reduction to Normal Tissue. As with stability, the short duration of HDR intracavitary treatments allows displacement of normal tissue structure (i.e., pushing them away from the source paths) to a greater extent than with LDR treatment.

Applicator Size. The small size of the HDR source permits the use of smaller applicators than those required for the LDR applications, increasing the comfort to the patient.

Outpatient Treatment. Almost all HDR patients are treated on an outpatient basis compared to LDR patients who usually are treated as inpatients. Outpatient treatment is more convenient for the patients and generally results in lower overall costs.

Disadvantages of HDR Brachytherapy

Investment. The initial expense of HDR RAL is very high. Machines and site preparation costs can be anywhere between \$0.5 and 1 M.

Complexity. The technological complexity of HDR RAL opens the increased probability of errors, and leads to increased regulatory scrutiny.

Compressed Time Frame. As mentioned above, the rapidity with which procedures progress in HDR brachytherapy increases the probability of executing errors.

Radiobiology. As the dose rate increases, the radiosensitivity (damage per unit dose) increases for both normal tissues and tumors. Unfortunately, the radiosensitivity for the normal tissue increases faster than that for tumors, increasing the likelihood of injuring the patient while controlling the tumor. Overcoming this radiobiological handicap requires the use of the advantages of *optimization, stability, and dose reduction to normal tissues*, in addition to fractionization. As with external-beam radiotherapy delivered using a linear accelerator, which also operates in the HDR regime, spreading the treatments over many smaller fraction delivered over several days reduces the difference in radiosensitivities between the tumor and the normal tissues.

INTRODUCTION

Intravascular brachytherapy (IVB) is a novel treatment modality that delivers ionizing radiation to a coronary artery to prevent renarrowing, that is, restenosis caused by stent placement within the artery. The term *brachy* is the Greek word for near since the radioactive source is placed inside or near the target cells. In general, the field of brachytherapy has been practiced for decades in the field of radiation oncology for treatment of intracavitary (vagina, bronchus, esophagus, rectum, nasopharynx, etc.) and interstitial (muscle sarcoma, prostate, breast, etc.) cancers. As a subspecialty, IVB is relatively new where most of its development took place in the 1990s. Ionizing radiation describes both electromagnetic (γ rays, X rays) and particulate (neutrons, beta, and alpha particles) of sufficient energy to remove electrons from the target atom (thus ionizing). Unlike conventional brachytherapy where the target is mostly centimeters away from the source, IVB targets the adventitia of the vessel wall, located within 1–5 mm from the radioactive source. To obtain accurate dosimetry data in such close range is a challenge. The scope of this article is on the delivery devices for IVB and tools needed to assess the dosimetric properties of such brachytherapy devices. (Dosimetry is a subspecialty of radiation physics that deals with the measurement of the absorbed dose or dose rate resulting from the interaction of ionizing radiation with matter.) Such techniques are useful and can be applied in other future applications that require delivery of ionizing radiation to a target within a few millimeters from a radioactive source.

Mechanisms of Restenosis

A diseased coronary vessel is mainly caused by atherosclerotic plaque formation containing mostly cholesterol and lipids. This condition can lead to a heart attack and chest pain (angina) where the blood flow within the lumen is compromised. Coronary artery bypass surgery (CABG) is the traditional method to alleviate this condition. In the last few decades, minimally invasive procedures have been developed in a field known as *Interventional Cardiology*.

Percutaneous transluminal coronary angioplasty (PTCA), first performed by Gruentzig in 1977 (1); and endovascular prosthetic devices (stents), first performed by Dotter et al. (2) and Cragg et al. (3) in 1983, are the most common devices used in interventional cardiology today. Charles Thomas Stent (1807–1885), an English dentist who lent his name to a tooth mould. Charles Dotter used the word “stent” in 1963 to name endoluminal scaffolding devices. However, these interventions have created a new problem, restenosis.

Restenosis is a wound healing process occurring directly at the angioplasty balloon or stent site. It is believed that three processes cause restenosis: elastic recoil, neointimal hyperplasia, and negative vascular remodeling. Elastic recoil, or vessel spasm, occurs in the healthy (plaque-free) portion of the vessel within minutes after balloon expansion (angioplasty balloon or stent-expanding balloon). Elastic recoil causes a luminal cross-sectional area reduction of $\sim 50\%$, but only for a short time after the procedure. The second component of restenosis is neointimal hyperplasia resulting in new tissue growth occupying the microcracks and rupture within the plaque mass, in some patients this process can be overcompensating, filling more tissue within the vessel lumen thus compromising blood flow. The blood vessel wall (any vessel larger than capillaries) has three major layers called tunica, the innermost layer is the intima followed by a middle concentric layer called the media where mostly the smooth muscle cells reside, and then the outer most layer called the adventitia. The adventitia contains a connective tissue with mainly collagen and myofibroblasts. Some controversy still remains as to which cells are responsible for neointimal hyperplasia, media smooth muscle cells, or myofibroblasts migrating from the adventitia. In IVB, the prescription dose should reach the tunica adventitia to insure full therapeutic benefit. The third component of restenosis is negative remodeling. The term negative remodeling refers to contraction of the arterial wall following an arterial injury inflicted by an interventional procedure occurring slowly over the first 3–9 months after the angioplasty. Negative remodeling is believed to play a major factor in restenosis after a PTCA intervention. However, the stent is a mechanical scaffolding device that prevents negative remodeling. Hence, in-stent restenosis appears to derive almost exclusively from neointimal hyperplasia, even more than seen in balloon angioplasty. Schwartz and Holmes (4) provide a detailed discussion on restenosis and remodeling. Hall et al. (5) present on the radiobiological response of vascular tissue to IVB. (5).

Epidemiology and Clinical Trials

Restenosis is a very likely event (within few months of the initial intervention) and has been a frustrating problem in interventional cardiology. For example, > 1 million people worldwide had percutaneous coronary interventions in 2001 and of these $> 85\%$ received a stent. Restenosis occurred in $> 50\%$ of the stented patients ($\sim 425,000$ patients worldwide), with the United States share of $\sim 150,000$ patients.

Restenosis as measured using quantitative coronary angiography (QCA) is arbitrarily defined as a narrowing

Figure 1. Percent restenosis reduction reported in bare-metal stent (STRESS and BENESTENT), and in intravascular brachytherapy clinical trials Gamma I (^{192}Ir), START ($^{90}\text{Sr}/^{90}\text{Y}$), and INHIBIT (^{32}P).

of the vessel lumen of at least 50% relative to the adjacent healthy vessel lumen ratio of minimum lumen diameter (MLD) to the reference lumen diameter (RLD). Mehran et al. (6) studied several risk factors from angiographic patterns of in-stent restenosis (ISR). The MLD, lesion length, and diabetes were found to be important factors predicting in-stent restenosis risk. Risk increased as a function of lesion length (10–40 mm) and decreased as a function of the MLD (2.5–4 mm diameter). Further, the ISR pattern is important where diffused restenosis has a larger risk those with a focal pattern.

The main complications of PTCA are acute vessel occlusion and late restenosis. Two important trials started in 1991, the North American STRESS (STent REStenosis Study) (7) and the European BENESTENT (Belgium Netherlands STENT trial) (8) using metal-bare stents (Palmaz-Schatz stent) transformed the practice of interventional cardiology. (Bare-metal stent is a term used here to make a distinction from the drug-coated stent briefly discussed in this article.) However, in-stent restenosis incidence of > 50% was still observed. The introduction of IVB in the 1990s revamped the hope to eradicate restenosis. Conrado et al. (9) in 1997 conducted the first small human trial showing reduction in restenosis over a 5 year follow-up period; this study, however, had some dosimetric issues. Definite multicenter double-blinded randomized clinical trials for IVB for the indication of in-stent restenosis are the GAMMA I (10), the START (Strontium-90 Treatment of Angiographic Restenosis Trial) (11), and the INHIBIT (INTimal Hyperplasia Inhibition with Beta In-stent restenosis Trial) (12). With over 5000 patients treated with IVB, this modality has recently proven its safety and efficacy. As shown in Fig. 1, IVB (GAMMA I, START, INHIBIT) clinical trials had about twofold reduction of in-stent restenosis than found from the STRESS and BENESTENT bare-metal stent versus. PTCA trials. Initial problems in the IVB trials, like edge failure due to geographic miss and increased incidence of later thrombosis, were quickly remedied by increasing the radioactive source length and prolonged use of antiplatelet therapy. Table 1 is a detailed summary of these IVB clinical trials. Many other

clinical IVB clinical trials were conducted using various isotopes, delivery system, and other clinical indications.

THEORY AND DETAILED DESCRIPTION OF IVB DEVICES

Based on the clinical trials discussed above, the Food and Drug Administration (FDA) granted a premarket approval (PMA) to three IVB devices. The Checkmate system (Cordis Corporation, a Johnson & Johnson Company, Miami Lakes, FL) using ^{192}Ir and BetaCath system using ^{90}Sr (Novoste Corp. Norcross, GA) were both approved on November 3, 2000. About 1 year later, the GALILEO Intravascular Radiotherapy System (Guidant Corp., Santa Clara, CA) using ^{32}P was also approved by the FDA. All of these devices are classified as catheter-based radiation delivery systems using sealed radioactive sources. Catheter-based means the source in the form of a source wire or a train of seeds (ribbon) is placed inside a closed-tip lumen catheter. The catheter is first placed into the target vessel and the source wire or ribbon is delivered or after-loaded using manual or computer-based delivery systems. The radiation safety considerations for these devices have been greatly discussed in the literature (13,14).

Other irradiation techniques were also investigated, including inflation of dilatation balloon catheter with radioactive liquid or gas; insertion of miniature X-ray tubes; implantation of radioactive stents; and postangioplasty external beam irradiation. These techniques did not make it to the market due to variable reasons including suboptimal efficacy, safety, or practicality. Table 2 summarizes several other isotopes and delivery systems investigated for IVB applications. Tables 3 and 4 list a few radiation characteristics for important gamma and beta sources for IVB.

Cordis Checkmate System

Checkmate is indicated by the FDA for the delivery of therapeutic doses of gamma radiation for the purpose of reducing in-stent restenosis. The system is for use in the treatment of native coronary arteries (2.75–4.0 mm in

Table 1. Summary of Pivotal IVB Clinical Trial Used to Obtain FDA Approval for In-Stent Restenosis in Native Arteries Indication

Trial	Target Lesion	Source	Dose, Gy	Patients, <i>n</i>	Angiographic Restenosis		TLR	
					Rad., %	Placebo %	Rad. %	Placebo, %
Gamma-1	In-stent (< 45 mm)	¹⁹² Ir ribbon	8–30	252	22	50 (6 months)	24	42 (9 months)
START	In-stent (< 20 mm)	⁹⁰ Sr/ ⁹⁰ Y Seed train	16–20 Gy at 2 mm	476	14	41 (8 months)	16	24 (8 months)
INHIBIT	In-stent (< 45 mm)	³² P wire	20 Gy at 1 mm into vessel wall	332	16	48 (9 months)	11	29 (9 months)

diameter and lesions up to and including 45 mm in length) with in-stent restenosis following percutaneous revascularization using current interventional techniques. Outside of the FDA approved indication, Waksman et al. (15) also examined the effects of intravascular gamma radiation in patients with in-stent restenosis of saphenous-vein bypass grafts and found favorable results.

Radioactive Source Ribbon. The Checkmate catheter-based brachytherapy system uses ¹⁹²Ir seeds that are pre-assembled in 6, 10, and 14 seed strand inside nylon ribbons (Best Medical International, Springfield, VA). Treatment lengths are 23, 39, and 55 mm for the 6-, 10-, and 14-seed ribbons, respectively (16). Iridium-192 has an average energy of 370 keV and a half-life of 73.83 days. The ¹⁹²Ir radioactive metal (30% Ir, 70% Pt) is 3 mm long and 0.1 mm in diameter encapsulated within a 3 mm long × 0.5 mm diameter stainless steel capsule. The seeds are placed

inside a nylon ribbon with an interseed spacing of 1 mm. The overall ribbon length is 230 cm and the outer diameter is 0.76 mm (2.4 F). [1 French (F) = 1/π mm.] At both distal and proximal edges of the seed strand, radiopaque markers are placed for visualization under X rays. A nonradioactive dummy ribbon is preloaded inside the delivery catheter to provide reinforcement during shipping and to improve maneuverability during initial positioning of the catheter across the target lesion. The dummy ribbon has the same length and configuration of the radioactive source ribbon to aid in IVB therapy planning during the procedure. A source lumen plug is used to prevent the movement of the dummy ribbon inside the Checkmate delivery catheter during initial catheter placement via the femoral artery. Dosimetry characterization of the Checkmate source ribbon are discussed in the literature (17).

Delivery Catheter. This is a single lumen catheter with a distal rapid exchange tip and a closed-ended source lumen for isolation from patient blood contact. Both the radioactive source and the nonradioactive dummy ribbon use this lumen to reach the target. A single radiopaque marker at the distal end of the source lumen is to aid in catheter placement under fluoroscopy. A guidewire is used to guide the catheter along the tortuous pathway into the coronary artery. The guidewire exits the catheter 4 mm from the distal tip of the catheter. The overall length of the Checkmate catheter is 230 cm with a usable length of 145 cm. At the distal portion of the catheter, the outer diameter is 3.7 F (0.049 in.), which is deliverable with 7 F (mm) or larger guiding catheter.

Table 2. Gamma and Beta Sources with Different Delivery Systems Investigated for Intravascular Brachytherapy Applications

Gamma Delivery Systems	Beta Delivery Systems
¹⁹² Ir-seed train	³² P - wire, stent, balloon

Figure 2. Checkmate delivery device (Cordis Corporation, a Johnson & Johnson Company, Miami Lakes, FL) is mainly a lead shielded cylinder housing both the radioactive ^{192}Ir source ribbon and dummy ribbon.

Delivery Device. As shown in Fig. 2, the Checkmate delivery device is mainly a lead shielded cylinder housing both the radioactive ^{192}Ir source ribbon and the dummy ribbon. This is a simple device where the proximal end of the source ribbon (nonradioactive part) protrudes from the proximal end of the delivery device and is coiled when not in use. When in use, a threaded cap on the distal end of the delivery device is replaced with a luer connector, which is connected to the hub of the delivery catheter. The source ribbon is pushed forward by hand from the proximal end of the delivery device into the delivery catheter.

Dosimetry. The Checkmate IVB system dosimetry was initially based on intravascular ultrasound (IVUS). From these images, the distance from the center of the IVUS catheter to the outer edge of the media tissue, called the external elastic membrane (EEM) is measured. A minimum of three axial images is taken along the stented vessel segment to determine the maximum and minimum distance from the source to the EEM. The dwell time is then calculated to insure that 8 Gy is delivered to the EEM farthest from the source, provided that no >30 Gy is delivered to the closest EEM. The IVUS-based dosimetry was later simplified to prescribe a fixed dose of 14 Gy at a distance of 2 mm from the centerline of the source. This provided a logistic solution to shorten procedure time and

to spread the use of this system since many of catheterization labs in the United States do not have IVUS image modality.

Novoste BetaCath

The first generation BetaCath is a 5.0 F (1.59 mm) system. This system was indicated by the FDA to deliver beta radiation to the site of successful percutaneous coronary intervention for the treatment of in-stent restenosis in native coronary arteries with discrete lesions of ≤ 20 mm in length using the 30 or 40 mm system and for longer lesions up to 40 mm using a longer source train (60 mm) in a reference vessel diameter ranging from 2.7 to 4.0 mm. The second generation BetaCath is a 3.5 F (1.17 mm) system, which has an equivalent radioactivity to the 5 F (1.59 mm) system, but is smaller in diameter and fits easily inside a (1.91 mm) guide catheter. This system is intended to deliver beta radiation.

The 3.5 F (1.17 mm) BetaCath system has three main components, the ^{90}Sr source train, the β -Rail 3.5 F delivery catheter, and the 3.5 F delivery device.

Radioactive Source. Strontium-90/Yttrium-90 is a pure beta emitter with any energy spectrum with maximum energy of 2.27 MeV and an average of 0.934 MeV. The long half-life (29.1 years) simplifies treatment planning due to the almost unchanged dose rate of the device during the life cycle of the device (6 month). Each seed is 2.5 mm long and 0.38 mm in diameter for the 3.5 F system (0.64 mm seed diameter for the 5 °F system), manufactured by AEA Technology GmbH, Germany or BEBIG Isotopen- und Medizintechnik GmbH, Berlin, Germany. The radioactive source train consists of a wire jacketed “train” of 12 (30 mm source train), 16 (40 mm source train), or 24 (60 mm source train). The jacketed design was a major improvement over the initial design to eliminate seed movement thus providing uniform dose distribution. A radiopaque mark is placed one each side of each source train to provide visualization under fluoroscopy. Dosimetry characterization of the BetaCath sources are discussed in the literature (18,19).

Delivery Catheter. Only details of the second-generation delivery catheter, β -Rail 3.5 F (1.17 mm), will be discussed. This is a closed-end catheter with a total length of 180 cm (Fig. 3). A longer catheter called β -Rail 3.5 F XL delivery catheter has an overall length of 267 cm if desired. The catheter has a guidewire exit port at 1 cm from the distal tip, that is, a rapid exchange design. This catheter accommodates all source train lengths (30, 40, or 60 mm) that reach a most distal radiopaque marker located inside the delivery catheter. The β -Rail delivery catheter is preloaded with an Indicator of Source Train (IST), this Novoste terminology is used for the nonradioactive dummy source to aid in the measurement and positioning of the delivery catheter to insure adequate radiation coverage. The IST includes two radiopaque markings to delineate 30, 40, and 40 mm source lengths. At the proximal end of the delivery catheter, a proprietary connector is provided to insure a secure connection to the delivery device described next.

Figure 3. The β -Rail 3.5 F delivery catheter (Novoste, Norcross, GA) is a closed-end catheter with a total length of 180 cm. A longer catheter called β -Rail 3.5 F XL delivery catheter has an overall length of 267 cm is available. (Courtesy of Novoste Corporation.)

Delivery Device. This is a handheld battery-powered device used to store the radioactive source train (only one length). Hence, three separate delivery devices are needed to accommodate the 30, 40, and 60 mm source trains described above. The source train is sent into and returned from the delivery catheter using hydraulic pressure. To insure safe attachment of the delivery catheter, a connector lock latch is provided at the exit port of the delivery device. Several electronic pressure sensors are used to provide the operator with feedback on the pressure required using a saline-filled syringe to send, hold, or return the source train. Two source train position indicator lights (Green: In/Amber: Out), adjacent to the source chamber-viewing window (see Fig. 4). A fluid control lever controls the fluid flow and direction of the source train movement. A treatment counter tracks the number of procedures or test runs, a maximum of 125 transfers is allowed.

Dosimetry. The BetaCath IVB system dose prescription is the simplest out of the three systems discussed. The dose prescription is given relative to the source axis at 2 mm radial distance. The recommended dose is 18.4 Gy for a measured reference vessel diameter < 3.35 mm, but > 2.7 mm;

and 23 Gy for a diameter > 3.35 mm, but < 4.0 mm. Vessel diameters < 2.75 mm or > 4.0 mm can be treated with this system; however, this is considered an off-label use of the device as defined by the FDA. The appropriate source train length (30, 40, or 60 mm) is selected after measuring the injured length using angiography and adding a margin on the distal and proximal side of a minimum of 5 mm.

Guidant Galileo

This IVB system is the only computer-based device. The GALILEO Intravascular Radiotherapy System (Guidant Corp., Santa Clara, CA) consists of three main components: the GALILEO ^{32}P Source Wire, the GALILEO Centering Catheter, and GALILEO Source Delivery Unit (SDU). The first generation product used a 27 mm long ^{32}P source and spiral centering catheter. The second generation, called GALILEO III uses a 20 mm long ^{32}P source, a trichannel centering catheter, and an automated high precision stepping algorithm.

The first generation GALILEO was indicated to deliver beta radiation to the site of successful percutaneous coronary intervention for the treatment of in-stent restenosis

Figure 4. The BetaCath 3.5 F system (Novoste, Norcross, GA) is a handheld battery-powered device used to store the radioactive source train (only one length of 30, 40, or 60 mm source trains). Source train transfer depends on hydraulic pressure. Several electronic pressure sensors are used to provide the operator with feedback on the pressure required using a saline-filled syringe to send, hold, or return the source train. (Courtesy of Novoste Corporation.)

in native coronary arteries with discrete lesions ≤ 47 mm in reference vessel diameter 2.4–3.7 mm. The second generation GALILEO III system extended the indication to treat injured arterial length up to 52 mm.

Radioactive Source. The active wire contains linear solid-form phosphorus 32 (^{32}P) in ceramic glass fiber sealed in the distal end of a flexible nitinol (NiTi) hypotube, which is welded to a nitinol wire (total wire length is 2430 mm). The nominal active length is 27 mm (first generation system) 20 mm (second generation system). Both source wires have an outer diameter of 0.46 mm. Phosphorus-32 is a pure beta-emitting isotope with a maximum energy of 1.71 MeV, an average energy of 0.690 MeV, and a half-life of 14.28 days. The active wire can be used in multiple procedures for ~ 4 weeks (two half-lives). The active wire has two 1 mm tungsten X-ray markers, one proximal and one distal from the source, for visualization (see Fig. 5). A dummy source is used before the active wire is delivered to verify positioning, to check for kinks and catheter obstructions that could prevent the active wire from reaching the treatment site, and to achieve accurate positioning at the treatment site. Similar to the active wire, the dummy source also has two

tungsten markers, making it visually identical to that of the active wire. Dosimetry characterization of the Galileo sources are discussed in the literature (20,21).

Delivery Catheter. This is a dual-lumen catheter with a spiral-shaped (first generation) or triloped balloon (second generation) to provide source centering within the lumen to improve dose homogeneity (see Fig. 6a and b). Such balloon profiles are designed to center the source within the lumen and to allow distal and side-branch perfusion during the dwell time that can take up to 10 min. This would make the procedure more tolerable for patients. The design of the second generation was found to provide better perfusion than the spiral design, in particular for the longer balloons to treat longer lesions. One lumen allows the automatic advancement of the source wire. At the proximal end of this lumen, a key connector attaches the delivery catheter to the delivery device. The key connector has a special code that reads using an optical sensor at the entry port to automatically determine the balloon length and the number of dwell positions based on the centering catheter used. The distal end of this lumen is closed to prevent contact of the source wire with the patient blood. The second lumen

Figure 5. Cross-section of the ^{32}P source wire (Guidant Corporation, Santa Clara, CA) is shown. The radioactive core has a nominal length of 20 mm and 1 mm tungsten X-ray markers, one on each side of the core. All dimensions are in millimeters. (Courtesy of Guidant Corporation: GALIELO system is no longer manufactured or for sale.)

allows inflation (recommended pressure is 4 atm) and deflation of the centering balloon. This lumen terminates in a luer-lock connector allowing the attachment of standard inflation devices. A third lumen is 5 mm long at the most distal tip of the catheter; this is used to place the delivery catheter over a standard 0.014 in. (0.36 mm) coronary guide wire using a Rapid Exchange approach. Radiopaque markers located at the distal and proximal end of the balloon allows proper placement of the delivery catheter under fluoroscopy. Proximal shaft markers are located at 95 and 105 cm to aid in gauging catheter position relative to the tip of a brachial or femoral guiding catheter, respectively. The trilobed GALILEO III centering catheter is provided with a balloon diameter of 2.5, 3.0, and 3.5 mm and balloon lengths of 32 and 52 mm. (Balloon length is defined as the distance between radiopaque balloon markers and does not include balloon tapers that extend beyond these markers). The MLD determines the appropriate centering catheter balloon diameter to use in the

artery segment being treated (see Table 5). The lesion length determines the appropriate centering catheter length to use (see Table 6).

Delivery Device. The delivery device or the SDU has three main components: the head, base, and cartridge.

The front of the SDU head (Fig. 7) includes the touch screen monitor, status indicator lights, and housing for the cartridge. It also contains the manual retract wheel, the cartridge key port, the catheter key port and catheter eject button, and the red STOP button. On the back of the SDU head are the touch screen tilt lever, the swivel handle, and the system key port. The SDU head houses two motor drives—a primary motor and a battery-operated emergency retract motor. The emergency-retract motor works automatically if the primary motor fails to retract the active wire.

The SDU base provides a stable foundation for the SDU head and allows the unit to be transported easily.

Figure 6. (a) Galileo first generation spiral centering catheter (Guidant Corporation, Santa Clara, CA) is shown inside a 3 mm diameter curved lumen, balloon is inflated to 4 atm with saline to provide optimal source centering and distal blood perfusion (Courtesy of Guidant Corporation—GALIELO system is no longer manufactured or for sale.) (b) Cross-section of a Galileo second generation trilobed centering catheter (Guidant Corporation, Santa Clara, CA) is shown. Source lumen is central and the three lobes are inflated to 4 atm with saline to provide optimal source centering and distal blood perfusion. Note guide wire lumen inside one of the lobes. (Courtesy of Guidant Corporation—GALIELO system is no longer manufactured or for sale.)

Table 5. Balloon Diameter Selection for the Guidant Galileo Centering Catheter as a Function of the Measured MLD

Balloon Diameter, mm	MLD, mm
2.5	2.25–2.75
3.0	2.75–3.25
3.5	3.25–3.7

Table 6. Balloon and Equivalent Source Length Selection

Balloon Length, mm	Injured Arterial Length, mm	Equivalent Source Length, mm
32	≤ 32	40
52	33–52	60

Components of the base include the head release, the handle bar, the emergency compartment, the wheels and wheel locks, and the power cord port. The emergency compartment contains the equipment necessary to handle an emergency, including the emergency safe, the emergency wire cutter, and the emergency tongs.

The cartridge, which is inserted into the SDU head, contains the active (³²P source) wire, the dummy wire, and the operating software. It also contains the catheter key port, the tungsten safe, which shields the active wire when not in use, and the wire drive mechanisms. Figure 8 is an example of the GALILEO software screen of the countdown clock.

Figure 8. A screen shot of the Galileo software of the countdown clock for a treatment with two-source positions using the automatic source positioning system. (Courtesy of Guidant Corporation—GALILEO system is no longer manufactured or for sale.)

Dosimetry. Based on the measured minimal lumen diameter and lesion length via fluoroscopy, online QCA, or IVUS, a proper centering balloon size is chosen. Also the lumen diameter of the nondiseased vessel is measured immediately proximal and immediately distal to the treatment area. The average of these two diameters is the RLD. The GALILEO prescription point for radiation delivery is 1 mm beyond the RLD. The SDU automatically calculates the dwell time required to deliver the prescribed dose of radiation (20 Gy) at the prescription point. The GALILEO

Figure 7. A front view of the Galileo source delivery system. It includes the Touch Screen Monitor, Status Indicator Lights, and housing for the Cartridge. It also contains the Manual Retract Wheel, the Cartridge Key Port, the Catheter Key Port and Catheter Eject Button, and the red STOP Button. (Courtesy of Guidant Corporation—GALILEO system is no longer manufactured or for sale.)

Figure 9. An example of 60 mm equivalent source length resulting from stepping twice a 20 mm ^{32}P source to treat a 47 mm lesion. Note the added margin of 2.5 mm to the minimal margin of 4 mm to provide adequate radiation coverage.

SDU automatically steps the 20 mm ^{32}P source from most distal position to the most proximal position to yield an equivalent source length sufficient to cover the injured length with a minimal margin of 4 mm (Table 6). Equivalent source length (ESL) is defined as the total source length that will be result by stepping the 20 mm active source in tandem, either in two dwell positions (40 mm equivalent source length) or in three dwell positions (60 mm equivalent source length). Figure 9 is an example of 60 mm ESL to treat a 47 mm lesion, note the added margin of 2.5 mm to the minimal margin of 4mm to provide adequate radiation coverage.

DESIGN CONSIDERATION FOR IVB DEVICES AND DOSIMETRY

For beta emitters ($^{90}\text{Sr}/^{90}\text{Y}$, ^{32}P) used currently in intravascular brachytherapy, the prescribed dose is greatly influenced by several perturbation factors. These perturbation factors are divided into two categories; the first is *applicator* dependent and the second is *patient anatomy* dependent. Important applicator perturbation factors include the placement of a guidewire during irradiation, the source lumen eccentricity within the applicator and centering capability with the vessel lumen, use of contrast, X-ray markers, and source stepping precision (if injured lengths longer than the source radioactive length are treated). Patient perturbation factors include vessel anatomy (size, curvature, and cross-section eccentricity), plaque morphology (composition, density, and spatial distribution), and stent type. High energy gamma emitters like ^{192}Ir (J&J Checkmate system) are influenced by such factors as well, but with almost negligible magnitudes (22), hence the next discussion will focus on the does distributions perturbation of the beta sources only.

Applicator Dependent Perturbations

The applicator dependent factors discussed in this report are specific for two commercially available IVB beta source

systems, that is, Novoste ($^{90}\text{Sr}/^{90}\text{Y}$) and Guidant (^{32}P) systems. Five factors are discussed and considered most important, but are not inclusive, (1) guidewire, (2) source lumen eccentricity within the applicator and centering capability within the vessel lumen, (3) use of contrast, (4) X-ray markers, and (5) source stepping precision (manual vs. automatic).

Guide Wire Perturbation. The guide wire (GW) is used to navigate through the cardiovascular arteries during common interventional procedures, such as balloon angioplasty, stenting, and IVB. Commonly used guide wires are made of stainless steel and have a solid cross-section with diameter of 0.014 in. (0.36 mm). Several authors have reported on the dose perturbation due to the guide wire in IVB (23–25). Figure 6b depicts the cross-section of 3.0 mm GIII centring catheter with a 0.014 in. (0.36 mm) guide wire inside the upper lobe. The distance from the center of the GW and source axis is not fixed in this design and the GW location can vary (shown at closest distance from the source lumen center). Also Fig. 10 depicts the location of the guide wire inside the 5 Fr BetaCath catheter. Shih et al. (24) provides a detailed study on dose perturbation as a function of the GW position relative to the source axis. A dose perturbation

Figure 10. Cross-section of the BetaCath 5 F delivery catheter. Note the location of the guide wire lumen relative to the source lumen. (Courtesy of Novoste Corporation.)

factor (DPF), defined as the ratio of the doses with and without the presence of a guidewire was introduced to quantify the effects.¹⁰⁰ The authors reported a DPF of up to 70% behind a GW for the beta sources. The dose reduction for the beta sources was found to be dependent on the guidewire location. For example, the dose reduction was 10% higher for a stainless steel guidewire located at 0.5 mm than that for the guidewire at 2 mm from the central axis of the source. The portion of the target volume affected (shadowed) dosimetrically by the guidewire was reduced when the guidewire was positioned farther away from the source. The shadow volume (in which the dose reduction occurs) can be reduced by up to 45% as the guidewire is moved away from the source axis from 0.5 to 2 mm.

Fluhs et al. (25) measured the GW [0.014 in. (0.3556 mm), stainless steel] perturbation using a plastic scintillator. The authors pointed that the insertion of a GW into the catheter close to the beta source causes a large angular asymmetry of the radiation emission. For a guide wire positioned eccentrically to the catheter the dose reduction is dominantly limited to a region of some 20° around the angle defined by catheter centerline and guide wire. At the catheter surface the maximal dose reduction in this region was found to be (30 ± 2%, DPF = 10%). At the typical dose prescription depth of 2 mm from the source axis the shielding effect decreased to (24 ± 2%) (or DPF = 76%). This value is remarkably larger than the dose reduction caused by any typical stent design.

Source Lumen Eccentricity. Sehgal et al. (26) reports on the dosimetric consequences of source centering (eccentricity) within the arterial lumen as one potentially important factor for the uniform delivery of dose to the arterial tissue. In this study, they have examined the effect of source centering on the resulting dose to the arterial wall from clinical intravascular brachytherapy sources containing ³²P and ⁹⁰Sr/⁹⁰Y. Monte Carlo simulations using the MCNP code (described in Advanced Topics section below) were performed for these catheter-based sources with offsets of 0.5 and 1 mm from the center of the arterial lumen in homogenous water medium as well as in the presence of residual plaque. Three different positions were modeled and the resulting dose values were analyzed to assess their impact on the resulting dose distribution. The results are shown in Table 7. The debate on the importance of centering of beta emitters used in IVB to treat native coronary vessels has been extensively published (27).

Contrast Perturbation. Contrast agents with high atomic number materials are usually injected into blood vessels to help in the determination of lesion location and to verify source placement during the IVB procedure (small

^aThe contrast remains in the balloon for the entire ³²P irradiation dwell time. Data calculated by Mourtada using MCNP Monte Carlo code (unpublished data).

fraction of the entire dwell time). Common contrast agents like Omnipaque and Hypaque are discussed. Omnipaque contains ~25% of iodine (in mass), and Hypaque contains ~23% of iodine. Iodine has an atomic number (*Z*) of 53. Nath et al. (22) discussed the perturbation factor of these contrast agents on ³²P and ⁹⁰Y IVB sources when the contrast is injected directly in the blood stream, however, this paper did not provide the average DPF over the treatment dwell time. Mourtada used a Monte Carlo simulation of the Galileo III centering catheter (Fig. 6b) to calculate the average dose reduction at 1 mm tissue depth if the three catheter lobes are filled with saline (as recommended by the product instruction for use) and 50:50 Omnipaque contrast. The results are reported in Table 8. The simulations were done for the three different sizes of the GALILEO III centering balloon.

X-Ray Markers Perturbation. The GALILEO III centering catheter has distal and proximal X-ray markers made of 90% Pt and 10% Ir (effective density is 21.6 g cm⁻³). The X-ray markers are 0.635 mm long and the inner and outer diameter are 0.394 and 0.432 mm, respectively. The GALILEO 20 mm source first position inside the GIII centering catheter is positioned 4 mm beyond the proximal edge of the distal X-ray marker to provide adequate margins. Figure 11a depicts the 20 mm source wire (red) and distal X-ray marker (gold). Using the Monte Carlo simulation MCNP, the dose distribution in water around a 20 mm ³²P source was calculated with and without the distal X-ray marker. Figure 11b depicts the two-dimensional (2D) isodose map with the distal X-ray marker in place. As expected due to scattering, the X-ray marker perturbation is reduced quickly as a function of depth. For a 3.0 mm diameter vessel example, the intimal surface maximum DPF is 23% and at the prescription depth of 1 mm into the vessel wall, the maximum DPF is 15%. The effect of the radiopaque marker in the BetaCath ⁹⁰Sr/⁹⁰Y system has not been reported, but it is expected to be minimal since the catheter markers are along the side of the radioactive seed train.

Source Stepping. Lesions that are longer than available IVB sources require stepping the source (i.e., tandem positioned) from mostly distal to most proximal lesion segment to provide adequate radiation coverage. First-generation clinical beta-source systems have gained FDA approval for clinical indication for focal lesions (< 22 mm) (12,28). For injured lesions > 22 mm, but ≤ 47 mm, the manual tandem positioning (MTP) technique was investi-

Figure 11. (a) Schematic of the distal X-ray marker of the Galileo second generation centering catheter (GIII) relative to nominal position of the 20 mm ^{32}P source inside the GIII catheter. Note the large dose perturbation at closer depth (< 1 mm).

gated in the INHIBIT clinical trial using the 27 mm ^{32}P source (12). From the INHIBIT data analysis; for the 56 patients treated who had a tandem-positioning procedure (and the core lab had reported the size of gap or overlap), 44% had no gap or overlap. But, 19 and 11% of the patients had a 1 (32% increase in dose at junction) and 2 mm (56% increase in dose at junction) overlap respectively. Only one patient (1.9%) had a 1 mm gap (32% decrease in dose at junction). Hence, a 2 mm overlap and 1 mm gap are defined as the upper limits allowed for tandem positioning. Crocker et al. (29) also investigated the MTP procedure with 30 and 40 mm $^{90}\text{Sr}/^{90}\text{Y}$ source trains, and concluded from their data that the MTP technique was safe from both a dosimetric and a clinical point of view. However, Coen et al. (30) published a retrospective evaluation of the accuracy of manual multisegmental irradiation with 30 and 40 mm $^{90}\text{Sr}/^{90}\text{Y}$ source trains for irradiation of long (re)stenotic lesions in coronary arteries, following PTCA. They concluded that the positioning inaccuracy of MTP caused unacceptable dose inhomogeneities at the junction between source positions, and the procedure was not recommended. Coen et al. (30) suggested using longer line sources or source trains, or preferably an automated stepping source to insure reliable and safer technique for treatment of long lesions. Table 9 lists the dose perturbation at stepping junction due to an overlap or gap at the reference depth of 2 mm in water for GALILEO ^{32}P and Novoste $^{90}\text{Sr}/^{90}\text{Y}$ sources.

To reduce MTP dosimetric errors and to allow adequate coverage of radiation to longer injured lengths using the same source, an afterloader can be used to automatically step the radiation source to yield a longer equivalent source length. The only IVB system capable of this is the second generation GALILEO automated stepping system using a 20 mm ^{32}P source wire (33).

Patient Anatomy Dependent Perturbations

Patient perturbation factors discussed in this article include (1) vessel geometry (size, curvature, tapering,

Figure 12. A typical vessel cross-section is eccentric, and the vessel center does not necessarily lie on the lumen center.

and cross-sectional eccentricity); (2) plaque morphology (composition, density, and spatial distribution); (3) stenting.

Vessel Geometry Perturbation. The native coronary vessel diameter has a range from 2 to 4 mm. Due to plaque formation and tapering, the lumen diameter is a variable. It is expected that the dose perturbation factor to be worse for larger vessels, especially for the BetaCath IVB system whose dose does not have active centering. Also, a typical vessel cross-section is eccentric, and the vessel center does not necessarily lie on the lumen center (Fig. 12). As pointed by Kaluza et al. (27) in reality, plaque thickness can vary from 0.1 to 2.3 mm. The average eccentricity index was 6.38 ± 5.95 in the 59 PREVENT patients. The intimal hyperplasia of in-stent restenosis complicates the vessel cross-section. Mehran et al. (6) developed an angiographic classification of in-stent restenosis mainly under two categories: focal and diffused (6).

Another important vessel geometry factor is curvature. Xu et al. (34) studied the effect of curvature on ^{32}P beta dosimetry. As expected, the curvature causes an increase in dose in the inner surface (concave side) of the coronary vessel and a decrease in dose in the outer surface (convex side). For a maximum theoretical bend of 180° , the dose increases by as much as 20% along the inner radial distance, but decreased by as much as 20% along the outer radial distance compared to the dose along a straight wire. The authors concluded that for curvatures normally encountered in a clinical situation, the dose rate was changed by $< 5\%$.

Plaque Morphology Perturbation. The artery mostly consists of normal healthy tissue, but may also contain plaque, whose density may be unknown. Plaque is a material that develops inside the artery over time and is considered responsible for blockage of the artery. Plaque may range widely in histologic structure, density, and chemical composition. Density is expected to depend on the plaque's collagenous matrix and degree of calcification. Rahdert et al. (35) measured the density and calcium concentration

Table 10. DPF Values at 2 mm Radial Distance for ^{32}P and $^{90}\text{Sr}/^{90}\text{Y}$ Sources^a

No plaque	1.0	1.0
1.45	0.93	0.97
1.55	0.91	0.96
3.10	0.70	0.83

^aThe plaque layer has a thickness of 0.2 mm for all the different cases. The relative error is within 5% for the given dose rate values. (See Ref. 26).

in 13 cadaveric plaque specimens. This study concluded that based on the plaque calcification, the density range is between 1.25 and $1.5 \text{ g} \cdot \text{cm}^{-3}$.

Several studies on dose perturbation due to plaque have been reported in the literature for catheter-based beta sources (36–38). Nath et al. (36) assumed a 1 mm thick plaque with cortical bone density of $1.84 \text{ g} \cdot \text{cm}^{-3}$ and 27% Ca composition. Both values are relatively higher than those reported by Rahdert et al. (35). For this extreme condition, however, Nath et al. (36) reported ~ 0.8 mm reduction in penetration for $^{90}\text{Sr}/^{90}\text{Y}$ and ^{32}P beta sources when the calcified plaque was located next to the source, and by ~ 0.9 mm when the plaque was located 1 mm away from the source.

Li et al. reported $\sim 30\%$ reduction due to plaque for the Novoste $^{90}\text{Sr}/^{90}\text{Y}$ source (37). The modeled calcified plaque density range in this study was 1.2 – $1.60 \text{ g} \cdot \text{cm}^{-3}$ with a nominal density of $1.45 \text{ g} \cdot \text{cm}^{-3}$ as reported for B100 bone equivalent by ICRU Report 26 (39). Li et al. (37) calculated the DPF as a function of the radial distance from the source axis. Sehgal et al. (26) reported on the perturbation due to concentric plaque with constant thickness of 0.2 mm and three different densities as shown in Table 10 for both the GALILEO ^{32}P and Novoste $^{90}\text{Sr}/^{90}\text{Y}$ sources. Comparing with Li et al. (37) the 0.2 mm thick plaque with $1.45 \text{ g} \cdot \text{cm}^{-3}$ DPF results are similar.

Stent Perturbation. Even though a stent is not part of the actual vessel anatomy, it is assumed that an expanded stent is predisposed into the intima and surrounded by new tissue growth as a result of in-stent neointimal hyperplasia. Hence, the stent becomes part of the diseased vessel segment. In a few instances, a vessel could receive a second or even a third stent, as part of the intervention of a recurrent in-stent restenosis.

For all stent types, a similar behavior can be observed. At a distance of 0.5 mm and more the typical overall dose reduction does not exceed a value of 5–15% (40). In the close vicinity of the stent struts, an increased dose reduction effect reaches up to some 30–40%. The large dose reduction directly behind the stent struts are caused by the absorption effect that is not compensated by scattering contributions from regions outside of the shielded area until a depth of ~ 0.5 mm from the strut surface (41).

Recently, a new stent made of cobalt chromium L-605 alloy (CoCr, $\rho = 9.22 \text{ g} \cdot \text{cm}^{-3}$) (MULTI-LINK VISION) was introduced as an alternative to the commonly used 316L stainless steel stent design (SS, $\rho = 7.87 \text{ g} \cdot \text{cm}^{-3}$) (MULTI-LINK PENTA). Mourtada and Horton (42) used the Monte

Figure 13. A 3 mm diameter stainless steel stent DPF along the source axis ($x = 0$ is the coordinate system origin at source bisector). The parameter $r = 1.55$ mm is the radial distance from the source axis and is the centroid of the scoring bin directly behind the stent (score bin radial thickness is 0.1 mm). The parameter $r = 2.55$ mm is the centroid of the scoring bin at the 2.5 mm prescription point. Data calculated using MCNPX Monte Carlo code. (Reference 42 with permission from Medical Physics journal.)

Carlo code MCNPX to compare the dose distribution for the ^{32}P GALILEO source in CoCr and SS 8 mm stent models. The DPF, defined as the ratio of the dose in water with the presence of a stent to the dose without a stent, was used to compare results. Both stent designs were virtually expanded to diameters of 2.0, 3.0, and 4.0 mm using finite element models (ABQUS Inc., Pawtucket, RI). The complicated strut shapes of both the CoCr and SS stents were simplified using circular rings with an effective width to yield a metal/tissue ratio identical to that of the actual stents. The mean DPF at a 1 mm tissue depth, over the entire stented length of 8 mm, was 0.935 for the CoCr stent and 0.911 for the SS stent. The mean DPF at the intima (0.05 mm radial distance from the strut outer surface), over the entire stented length of 8 mm, was 0.950 for CoCr, and 0.926 for SS. The maximum DPFs directly behind the CoCr and SS struts were 0.689 and 0.644, respectively. Figures 13 and 14 depict the dose profiles behind the stainless steel stent as an example. The authors concluded that although the CoCr stent has a higher effective atomic number and greater density than the SS stent, the DPFs for the two stents are similar because the metal/tissue ratio and strut thickness of the CoCr stent are lower than those of the SS stent.

ADVANCED TOPICS

Figure 15 is the general dosimetry characterization paradigm of brachytherapy sources. This requires three important steps including the experimental measurement of the dose rate ($\text{cGy}^{-1} \cdot \text{s}$) as a function of distance from the source using a calibrated dosimeter, a measurement of the source contained activity (SI unit is the Becquerel = $\text{Bq} = 1$ decay s^{-1}). The normalized measure dose rate to the measured

Figure 14. Dose perturbation factor as a function of the radial distance from source axis in water and through a strut located 1.5 mm from the source axis (expanded inside a 3.0 mm vessel model). (Reference 42 with permission from Medical Physics journal.)

contained activity can then be compared to a theoretical calculation such as a Monte Carlo simulation, which is inherently has dose rate units per particle emitted, that is, contained activity. This section will discuss briefly an example of each component that is important in the IVB dosimetry paradigm.

Theoretical Dosimetry: Monte Carlo Simulations

The Monte Carlo technique used for IVB dosimetry is considered the most accurate theoretical tool, particularly suited in handling the complex interactions of the emitted beta particles with the surrounding medium. Fox has published a review of IVB (43), including a rather thorough review of the theoretical dosimetry applied to these sources. Detailed reviews and discussion of the Monte Carlo method can also be found in the literature (44–46). Monte Carlo codes utilized for IVB dosimetry include CYLTRAN from the Integrated Tiger Series (ITS version 3.0, Sandia National Laboratory, Albuquerque, NM), the MCNP series (MCNP4C and MCNPX, Los Alamos

Figure 15. A general dosimetry characterization paradigm of brachytherapy sources.

National Laboratory, Los Alamos, NM), the EGS series (EGS4 Stanford Linear Accelerator Center, Stanford, CA, and EGSnrc National Research Council of Canada, Ottawa, Ontario, Canada), and PENELOPE (University of Barcelona, Barcelona, Catalonia, Spain).

Theoretical modeling is being increasingly used to supplement measurements in IVB. The Monte Carlo method, for example, is based on the idea that if all materials and dimensions of a problem, and all the probabilities of the various possible radiation interactions are known, then emitted particles can be tracked and scored as they are transported from the source through the media of the problem. A random number generator is used to select emitting source element location, emitted particle energy and direction, and results of various interactions and secondary radiations as the particle is tracked to either absorption or out of the problem boundaries. Obviously, the more "histories" (emitted particles) are tracked, the more accurate is the resulting calculation. With the advent of faster and faster computers, Monte Carlo calculations are becoming more and more attractive for determining dose distributions for brachytherapy sources in complex geometries. Often, the combination of a Monte Carlo calculation, which yields dose rate per unit contained activity, and a contained activity measurement, will give better accuracy than a dosimetric measurement. An excellent review of the Monte Carlo method has recently been published (44).

MC simulations of electron transport, for example, beta-particle transport, are usually different from those used in photon or neutron transport, for which the simulated radiation history is followed individually based on conventional methods since uncharged radiation interactions are characterized by relatively infrequent isolated collisions. For example, in photon transport, the distance to the next photon interaction is sampled from the attenuation coefficient distribution; and the change in attenuation coefficient as the photon crosses material boundaries is modeled. The type of interaction is sampled from the appropriate relative probabilities. The history of each photon is continued from collision to collision until the photon either is absorbed, escapes the problem boundary, or its energy falls below a chosen cutoff threshold at which the remaining energy of the photon is locally deposited.

For high energy electrons, such a detailed history is not practical for energies > 100 keV, because many individual elastic and inelastic Coulomb collisions per history are generated through the media resulting in very long computational time. Instead, a "condensed history" is used, where the electron trajectories are divided into many path segments (47). For each path segment, the net angular deflection and the net energy loss are sampled from relevant multiple-scattering distributions. The choice of the step size is important for accuracy and is chosen with conflicting requirements. On the one hand, the steps should be short enough that (1) most of the electron history steps are completely inside the boundary of a predefined surface, so that the use of multiple-scattering theories of unbounded media is valid; (2) the energy loss is, on average, small within a step; and (3) the net angular deflection is, on average, small so that the path within the step is approximated by a straight line. On the other hand, the

step size should be large enough to contain a sufficient number of collisions per step to justify the use of the multiple-scattering theories and to limit the number of steps per history to reduce computing time. Further discussion can be found in the literature (45).

Experimental Dosimetry: Radiochromic Film Measurements

Both MD-55 and HD-810 radiochromic dye films (RCF) (GAFChromic type, Nuclear Associates, Carle Place, NY) are widely used in IVB dose-field measurement due to their superior spatial resolution. Also, RCF is used instead of other types of films mainly for its linear dose response. A full description of both film types is reported by AAPM Task Group 55 (48). For beta field measurements, it is recommended that the RCF dosimeter be calibrated using the same $^{90}\text{Sr}/^{90}\text{Y}$ ophthalmic applicator (New England Nuclear S/N 0258) calibrated at the National Institute of Standards and Technology (NIST), Gaithersburg, Maryland (20). Polystyrene or other tissue-equivalent materials are used to fabricate high precision blocks for the film measurements. Each block has a hole with a diameter slightly larger than the source diameter to reduce positional error (in IVB 0.1 mm could translate to 13% error in the measured dose rate). Several blocks are made with nominal depths (distance from center of hole to block surface) ranging from 0.5 to 5 mm. Actual depths must be verified using a traveling microscope or an optical comparator. At each of these depths, several radiochromic films should be exposed for a range of times to gain a good image of the radiation field. Digitization of film is typically done with a high resolution 2 scanning densitometer (Pharmacia LKB) using a 633 nm laser (HeNe) with a 100 μm diameter spot size and a 40 μm minimum step size. Alternatively, scanning is done using a high resolution (242×375) CCD densitometer (CCD100, Photoelectron, Lexington, MA) with a 665 nm LED array and a 160×200 μm pixel size. To account for optical-density growth as a function of time after exposure, film readout should be done 72 h postirradiation for both the calibration and experimental films. The net optical density measurements of each film were converted into a 2D dose map as shown in Fig. 16. Estimated dose uncertainties for radiochromic film are $\pm 15.6\%$ ($k=2$); the individual components of this uncertainty are shown in Table 11.

Other radiation dosimeters mostly lack the spatial resolution of submillimeters required in IVB. However, recently Amin et al. (49) proposed using a polyacrylamide gel (PAG) dosimeter and a high field 4.7 T MRI scanner for IVB. The get/scanner final in-plane resolution of 0.4×0.2 mm is approaching the film resolution, but not quite. The authors confirmed that both absorbed dose and dose distributions for high gradient vascular brachytherapy sources can be measured using PAG, but the disadvantages of gel manufacture and the need for access to a high resolution scanner suggests that the use of radiochromic film is the method of choice (49).

Determination of Contained Activity. The activity content of this wire must be known in order to relate the measurements and calculations of the absorbed-dose spatial

Figure 16. A 2D HD810 radiochromic film image dose (Gy) distribution for a ³²P source, measured in a plane parallel to the source’s longitudinal axis at 1.97 mm radial distance from the source axis in the polystyrene block.

distribution. For the 27 mm ³²P source design, Mourtada et al. briefly described the determination of the absolute contained activity from the original work of Collé (50). The contained activity was then related to a calibration factor for the NIST Capintec. The CRC-12 ionization chamber (51). Similar work was done on the Novoste ⁹⁰S/⁹⁰Y seed and other beta sources used for IVB to establish radioactivity standards by NIST, Gaithersburg, MA (52,53).

For example, Fig. 17 is the Galileo 20 mm ³²P source wire measured radiochromic film (MD55 and HD810) depth dose curve plotted along with Monte Carlo estimates from MCNP4C and PENELOPE. The error bars estimate the 95% confidence interval. All data are measured or calculated in polystyrene (21).

Beyond IVB Treatments of Heart Disease, Other Applications, and Future Roles

In the United States, there are ~8–12 million patients affected with peripheral vascular disease. An estimated 600,000 interventional procedures are performed each year, including percutaneous transluminal angioplasty (PTA), bypass surgery, and amputation. Percutaneous transluminal angioplasty restenosis rates are high with a success rate of <23% at 6 months follow-up. Intravascular brachytherapy has been investigated to reduce restenosis in the superficial femoral and popliteal arteries after PTA. The main IVB clinical trial for peripheral vessel is the Peripheral Artery

Figure 17. Measured data (Film and EC: extrapolation chamber) depth dose curve plotted along with Monte Carlo estimates from MCNP4C and PENELOPE. The error bars estimate the 95% confidence interval. All data are measured or calculated in polystyrene. (Reference 21 with permission from Medical Physics journal.)

Radiation Investigation Study (PARIS) using the Nucletron Ir-192 HDR source (mHDR v2). The PARIS study used the Nucletron micro-Selectron high dose rate (HDR) afterloader and the Guidant PARIS centering catheter (10–20 cm long and 4–8 mm diameter) (54). More recently, the MOBILE clinical trial a ⁹⁰Sr/⁹⁰Y source and the Corona gas-filled centering is being investigated (Novoste Corporation) (55).

Other possible applications of IVB include treatment of recurrent narrowing of the arteriovenous (AV) dialysis graft (56), renal artery stenosis, transjugular intrahepatic porto-systemic (TIPS) stenosis, carotid artery (57), and subclavian vein stenosis. Further application of IVB might be for treatment of atrial fibrillation, a most common cardiac arrhythmia. It is proposed that IVB radiation dose can electrically isolate ectopic foci located mostly in the adventitia of the pulmonary vein (PV), which are responsible for atrial fibrillation episodes (58). The IVB approach might alleviate undesirable side effects (PV stenosis due to heating) of rf ablation; a commonly used treatment modality to ablate myocardial tissue.

Intravascular Brachytherapy in the Drug-Eluting Stent Era

The recent introduction of drug-eluting stents (DES) in the interventional cardiology arena has a tremendous impact on the IVB practice. By incorporating antiproliferative agents onto the surface of the stent, neointimal hyperplasia

Table 11. Estimated Relative Uncertainties of the Radiochromic-Film Dose Interpretations per Measured Unit Activity

Uncertainty Component	Relative Standard Uncertainty, %
Calibration of the NIST standard ⁹⁰ Sr/ ⁹⁰ Y calibration source	6
Response of the film exposed to the calibration source	3
Response of the films exposed to the source under test	3
Activity calibration	2.6
Combined standard uncertainty	7.8
Expanded uncertainty (<i>k</i> = 2)	15.6

occurring within the stent is markedly reduced. Stents coated with agents, like Sirolimus, Paclitaxel, Tacrolimus, Everolimus, and so on, when compared to bare-metal stents, had shown remarkable reduction in binary restenosis and target vessel revascularization (TVR) rates in several clinical trials (31,59).

As discussed earlier in this article, IVB has demonstrated its safety and efficacy in limiting recurrence of in-stent restenosis with positive long-term follow-up outcome. However, the utility of IVB is being rethought in relation to its use after the placement of drug eluting stents. It is expected that the role of IVB will decrease primarily due to the simplicity of placement of drug eluting stents and the relative complexity of performing intravascular brachytherapy. The published pivotal clinical restenosis rates from both the Paclitaxel (TAXUS) (32) and Sirolimus (RAVEL, SIRIUS) drug eluting stents suggests that the need to perform an IVB will be in < 1 in 20 patients (60–62). Recently reported registry data from Europe and the United States demonstrates similar efficacy of DES to that of IVB for treatment of in-stent restenosis (63,64). However, DES technology still has to go through further investigations in more complex lesions and higher risk patients in the general population to appreciate its full potential. Other agents with potential benefits like Statins, local gene therapy, and further innovations in polymer technology (biodegradable polymers, multiple-drug release polymers) are in under evaluation (31).

DEFINITION OF TERMS

MACE: Major Adverse Cardiac Events, a composite of death, MI, target, or repeat lesion revascularization.

Angiographic Binary Restenosis: Stenosis of 50% or more of the luminal diameter.

TLR and TVR: Target Lesion and Vessel Revascularization: Describes a rate measuring how many stented lesions had to be retreated, due to clinically driven restenosis, given a specific time period.

MLD: Minimal lumen diameter, the smallest diameter of an artery in a specified segment.

RLD: Reference lumen diameter, the average of two diameters, the lumen diameter of the nondiseased vessel immediately proximal and distal to the target treatment area.

Lumen Diameter: The inner diameter of an artery in a specified segment.

Neointimal Hyperplasia: Wound-healing response to arterial injury that leads to restenosis.

Late Loss: A cardiology term referring to the angiographic measurement of neointimal hyperplasia. It's one of the most important indicators of long-term efficacy in coronary intervention.

Percutaneous Transluminal Coronary Angioplasty (PTCA): A method of treating blood vessel disorders that involves the use of a balloon catheter to enlarge the blood vessel and thereby improve blood flow.

Restenosis: Narrowing of a vessel dilated by angioplasty or other interventional procedure.

In-stent Restenosis (ISR): Narrowing of a vessel after a stent is in place; this may be acute due to a thrombus formation or late (few months) due to wound healing process (neointimal hyperplasia and remodeling).

PREFACE

This six-volume work is an alphabetically organized compilation of almost 300 articles that describe critical aspects of medical devices and instrumentation.

It is comprehensive. The articles emphasize the contributions of engineering, physics, and computers to each of the general areas of anesthesiology, biomaterials, burns, cardiology, clinical chemistry, clinical engineering, communicative disorders, computers in medicine, critical care medicine, dermatology, dentistry, ear, nose, and throat, emergency medicine, endocrinology, gastroenterology, genetics, geriatrics, gynecology, hematology, hepatology, internal medicine, medical physics, microbiology, nephrology, neurology, nutrition, obstetrics, oncology, ophthalmology, orthopedics, pain, pediatrics, peripheral vascular disease, pharmacology, physical therapy, psychiatry, pulmonary medicine, radiology, rehabilitation, surgery, tissue engineering, transducers, and urology.

The discipline is defined through the synthesis of the core knowledge from all the fields encompassed by the application of engineering, physics, and computers to problems in medicine. The articles focus not only on what is now useful but also on what is likely to be useful in future medical applications.

These volumes answer the question, "What are the branches of medicine and how does technology assist each of them?" rather than "What are the branches of technology and how could each be used in medicine?" To keep this work to a manageable length, the practice of medicine that is unassisted by devices, such as the use of drugs to treat disease, has been excluded.

The articles are accessible to the user; each benefits from brevity of condensation instead of what could easily have been a book-length work. The articles are designed not for peers, but rather for workers from related fields who wish to take a first look at what is important in the subject.

The articles are readable. They do not presume a detailed background in the subject, but are designed for any person with a scientific background and an interest in technology. Rather than attempting to teach the basics of physiology or Ohm's law, the articles build on such basic concepts to show how the worlds of life science and physical science meld to produce improved systems. While the ideal reader might be a person with a Master's degree in biomedical engineering or medical physics or an M.D. with a physical science undergraduate degree, much of the material will be of value to others with an interest in this growing field. High school students and hospital patients can skip over more technical areas and still gain much from the descriptive presentations.

The *Encyclopedia of Medical Devices and Instrumentation* is excellent for browsing and searching for those new divergent associations that may advance work in a peripheral field. While it can be used as a reference for facts, the articles are long enough that they can serve as an educational instrument and provide genuine understanding of a subject.

One can use this work just as one would use a dictionary, since the articles are arranged alphabetically by topic. Cross references assist the reader looking for subjects listed under slightly different names. The index at the end leads the reader to all articles containing pertinent information on any subject. Listed on pages xxi to xxx are all the abbreviations and acronyms used in the *Encyclopedia*. Because of the increasing use of SI units in all branches of science, these units are provided throughout the *Encyclopedia* articles as well as on pages xxxi to xxxv in the section on conversion factors and unit symbols.

I owe a great debt to the many people who have contributed to the creation of this work. At John Wiley & Sons, Encyclopedia Editor George Telecki provided the idea and guiding influence to launch the project. Sean Pidgeon was Editorial Director of the project. Assistant Editors Roseann Zappia, Sarah Harrington, and Surlan Murrell handled the myriad details of communication between publisher, editor, authors, and reviewers and stimulated authors and reviewers to meet necessary deadlines.

My own background has been in the electrical aspects of biomedical engineering. I was delighted to have the assistance of the editorial board to develop a comprehensive encyclopedia. David J. Beebe suggested cellular topics such as microfluidics. Jerry M. Calkins assisted in defining the chemically related subjects, such as anesthesiology. Michael R. Neuman suggested subjects related to sensors, such as in his own work—neonatology. Joon B. Park has written extensively on biomaterials and suggested related subjects. Edward S. Sternick provided many suggestions from medical physics. The Editorial Board was instrumental both in defining the list of subjects and in suggesting authors.

This second edition brings the field up to date. It is available on the web at <http://www.mrw.interscience.wiley.com/emdi>, where articles can be searched simultaneously to provide rapid and comprehensive information on all aspects of medical devices and instrumentation.

JOHN G. WEBSTER
University of Wisconsin, Madison

ABBREVIATIONS AND ACRONYMS

AAMI	Association for the Advancement of Medical Instrumentation	ALS	Advanced life support; Amyotropic lateral sclerosis
AAPM	American Association of Physicists in Medicine	ALT	Alanine aminotransferase
ABC	Automatic brightness control	ALU	Arithmetic and logic unit
ABET	Accreditation board for engineering training	AM	Amplitude modulation
ABG	Arterial blood gases	AMA	American Medical Association
ABLB	Alternative binaural loudness balance	amu	Atomic mass units
ABS	Acrylonitrile–butadiene–styrene	ANOVA	Analysis of variance
ac	Alternating current	ANSI	American National Standards Institute
AC	Abdominal circumference; Affinity chromatography	AP	Action potential; Alternative pathway; Anteroposterior
ACA	Automated clinical analyzer	APD	Anterioposterior diameter
ACES	Augmentative communication evaluation system	APL	Adjustable pressure limiting valve; Applied Physics Laboratory
ACL	Anterior chamber lens	APR	Anatomically programmed radiography
ACLS	Advanced cardiac life support	AR	Amplitude reduction; Aortic regurgitation; Autoregressive
ACOG	American College of Obstetrics and Gynecology	Ara-C	Arabinosylcytosine
ACR	American College of Radiology	ARD	Absorption rate density
ACS	American Cancer Society; American College of Surgeons	ARDS	Adult respiratory distress syndrome
A/D	Analog-to-digital	ARGUS	Arrhythmia guard system
ADC	Agar diffusion chambers; Analog-to-digital converter	ARMA	Autoregressive-moving-average model
ADCC	Antibody-dependent cellular cytotoxicity	ARMAX	Autoregressive-moving-average model with external inputs
ADCL	Accredited Dosimetry Calibration Laboratories	AS	Aortic stenosis
ADP	Adenosine diphosphate	ASA	American Standards Association
A-D-T	Admission, discharge, and transfer	ASCII	American standard code for information interchange
AE	Anion exchange; Auxiliary electrode	ASD	Antisiphon device
AEA	Articulation error analysis	ASHE	American Society for Hospital Engineering
AEB	Activation energy barrier	ASTM	American Society for Testing and Materials
AEC	Automatic exposure control	AT	Adenosine-thiamide; Anaerobic threshold; Antithrombin
AED	Automatic external defibrillator	ATA	Atmosphere absolute
AEMB	Alliance for Engineering in Medicine and Biology	ATLS	Advanced trauma life support
AES	Auger electron spectroscopy	ATN	Acute tubular necrosis
AESC	American Engineering Standards Committee	ATP	Adenosine triphosphate
AET	Automatic exposure termination	ATPD	Ambient temperature pressure dry
AFO	Ankle-foot orthosis	ATPS	Ambient temperature pressure saturated
AGC	Automatic gain control	ATR	Attenuated total reflection
AHA	American Heart Association	AUC	Area under curve
AI	Arterial insufficiency	AUMC	Area under moment curve
AICD	Automatic implantable cardiac defibrillator	AV	Atrioventricular
AID	Agency for International Development	AZT	Azido thymidine
AIDS	Acquired immune deficiency syndrome	BA	Biliary atresia
AL	Anterior leaflet	BAEP	Brainstem auditory evoked potential
ALG	Antilymphocyte globulin	BAPN	Beta-amino-propionitril
		BAS	Boston anesthesia system
		BASO	Basophil
		BB	Buffer base
		BBT	Basal body temperature

BCC	Body-centered cubic	CCTV	Closed circuit television system
BCD	Binary-coded decimal	CCU	Coronary care unit; Critical care unit
BCG	Ballistocardiogram	CD	Current density
BCLS	Basic cardiac life support	CDR	Complimentary determining region
BCRU	British Committee on Radiation Units and Measurements	CDRH	Center for Devices and Radiological Health
BDI	Beck depression inventory	CEA	Carcinoembryonic antigen
BE	Base excess; Binding energy	CF	Conversion factor; Cystic fibrosis
BET	Brunauer, Emmett, and Teller methods	CFC	Continuous flow cytometer
BH	His bundle	CFR	Code of Federal Regulations
BI	Biological indicators	CFU	Colony forming units
BIH	Beth Israel Hospital	CGA	Compressed Gas Association
BIPM	International Bureau of Weights and Measurements	CGPM	General Conference on Weights and Measures
BJT	Bipolar junction transistor	CHO	Carbohydrate
BMDP	Biomedical Programs	CHO	Chinese hamster ovary
BME	Biomedical engineering	CI	Combination index
BMET	Biomedical equipment technician	CICU	Cardiac intensive care unit
BMO	Biomechanically optimized	CIF	Contrast improvement factor
BMR	Basal metabolic rate	CIN	Cervical intraepithelial neoplasia
BOL	Beginning of life	CK	Creatine kinase
BP	Bereitschafts potential; Break point	CLAV	Clavicle
BR	Polybutadiene	CLSA	Computerized language sample analysis
BRM	Biological response modifier	CM	Cardiomyopathy; Code modulation
BRS	Bibliographic retrieval services	CMAD	Computer managed articulation diagnosis
BSS	Balanced salt solution	CMI	Computer-managed instruction
BTG	Beta thromboglobulin	CMRR	Common mode rejection ratio
BTPS	Body temperature pressure saturated	CMV	Conventional mechanical ventilation; Cytomegalovirus
BUN	Blood urea nitrogen	CNS	Central nervous system
BW	Body weight	CNV	Contingent negative variation
CA	Conductive adhesives	CO	Carbon monoxide; Cardiac output
CABG	Coronary artery by-pass grafting	COBAS	Comprehensive Bio-Analysis System
CAD/CAM	Computer-aided design/computer-aided manufacturing	COPD	Chronic obstructive pulmonary disease
CAD/D	Computer-aided drafting and design	COR	Center of rotation
CADD	Central axis depth dose	CP	Cerebral palsy; Closing pressure; Creatine phosphate
CAI	Computer assisted instruction; Computer-aided instruction	CPB	Cardiopulmonary bypass
CAM	Computer-assisted management	CPET	Cardiac pacemaker electrode tips
cAMP	Cyclic AMP	CPM	Computerized probe measurements
CAPD	Continuous ambulatory peritoneal dialysis	CPP	Cerebral perfusion pressure; Cryoprecipitated plasma
CAPP	Child amputee prosthetic project	CPR	Cardiopulmonary resuscitation
CAT	Computerized axial tomography	cps	Cycles per second
CATS	Computer-assisted teaching system; Computerized aphasia treatment system	CPU	Central Processing unit
CAVH	Continuous arteriovenous hemofiltration	CR	Center of resistance; Conditioned response; Conductive rubber; Creatinine
CB	Conjugated bilirubin; Coulomb barrier	CRBB	Complete right bundle branch block
CBC	Complete blood count	CRD	Completely randomized design
CBF	Cerebral blood flow	CRL	Crown rump length
CBM	Computer-based management	CRT	Cathode ray tube
CBV	Cerebral blood volume	CS	Conditioned stimulus; Contrast scale; Crown seat
CC	Closing capacity	CSA	Compressed spectral array
CCC	Computer Curriculum Company	CSF	Cerebrospinal fluid
CCD	Charge-coupled device	CSI	Chemical shift imaging
CCE	Capacitance contact electrode	CSM	Chemically sensitive membrane
CCF	Cross-correlation function	CT	Computed tomography; Computerized tomography
CCL	Cardiac catheterization laboratory	CTI	Cumulative toxicity response index
CCM	Critical care medical services	CV	Closing volume
CCPD	Continuous cycling peritoneal dialysis		

C.V.	Coefficient of variation	EBS	Early burn scar
CVA	Cerebral vascular accident	EBV	Epstein–Barr Virus
CVP	Central venous pressure	EC	Ethyl cellulose
CVR	Cardiovascular resistance	ECC	Emergency cardiac care; Extracorporeal circulation
CW	Continuous wave	ECCE	Extracapsular cataract extinction
CWE	Coated wire electrodes	ECD	Electron capture detector
CWRU	Case Western Reserve University	ECG	Electrocardiogram
DAC	Digital-to-analog converter	ECM	Electrochemical machining
DAS	Data acquisition system	ECMO	Extracorporeal membrane oxygenation
dB	Decibel	ECOD	Extracranial cerebrovascular occlusive disease
DB	Direct body	ECRI	Emergency Care Research Institute
DBMS	Data base management system	ECS	Exner's Comprehensive System
DBS	Deep brain stimulation	ECT	Electroconvulsive shock therapy; Electroconvulsive therapy; Emission computed tomography
dc	Direct current	EDD	Estimated date of delivery
DCCT	Diabetes control and complications trial	EDP	Aortic end diastolic pressure
DCP	Distal cavity pressure	EDTA	Ethylenediaminetetraacetic acid
DCS	Dorsal column stimulation	EDX	Energy dispersive X-ray analysis
DDC	Deck decompression chamber	EEG	Electroencephalogram
DDS	Deep diving system	EEI	Electrode electrolyte interface
DE	Dispersive electrode	EELV	End-expiratory lung volume
DEN	Device experience network	EER	Electrically evoked response
DERS	Drug exception ordering system	EF	Ejection fraction
DES	Diffuse esophageal spasm	EF	Electric field; Evoked magnetic fields
d.f.	Distribution function	EFA	Estimated fetal age
DHCP	Distributed Hospital Computer Program	EGF	Epidermal growth factor
DHE	Dihematoporphyrin ether	EGG	Electrogastrogram
DHEW	Department of Health Education and Welfare	EIA	Enzyme immunoassay
DHHS	Department of Health and Human Services	EIU	Electrode impedance unbalance
DHT	Duration of hypothermia	ELF	Extra low frequency
DI	Deionized water	ELGON	Electrical goniometer
DIC	Displacement current	ELISA	Enzyme-linked immunosorbent assay
DIS	Diagnostic interview schedule	ELS	Energy loss spectroscopy
DL	Double layer	ELV	Equivalent lung volume
DLI	Difference lumen for intensity	EM	Electromagnetic
DM	Delta modulation	EMBS	Engineering in Medicine and Biology Society
DME	Dropping mercury electrode	emf	Electromotive force
DN	Donation number	EMG	Electromyogram
DNA	Deoxyribonucleic acid	EMGE	Integrated electromyogram
DOF	Degree of freedom	EMI	Electromagnetic interference
DOS	Drug ordering system	EMS	Emergency medical services
DOT-NHTSA	Department of Transportation Highway Traffic Safety Administration	EMT	Emergency medical technician
DPB	Differential pencil beam	ENT	Ear, nose, and throat
DPG	Diphosphoglycerate	EO	Elbow orthosis
DQE	Detection quantum efficiency	EOG	Electrooculography
DRESS	Depth-resolved surface coil spectroscopy	EOL	End of life
DRG	Diagnosis-related group	EOS	Eosinophil
DSA	Digital subtraction angiography	EP	Elastoplastic; Evoked potentiate
DSAR	Differential scatter-air ratio	EPA	Environmental protection agency
DSB	Double strand breaks	ER	Evoked response
DSC	Differential scanning calorimetry	ERCP	Endoscopic retrograde cholangiopancreatography
D-T	Deuterium-on-tritium	ERG	Electron radiography; Electroretinogram
DTA	Differential thermal analysis	ERMF	Event-related magnetic field
d.u.	Density unit	ERP	Event-related potential
DUR	Duration	ERV	Expiratory reserve volume
DVT	Deep venous thrombosis		
EA	Esophageal accelerometer		
EB	Electron beam		
EBCDIC	Extended binary code decimal interchange code		

ESCA	Electron spectroscopy for chemical analysis	GC	Gas chromatography; Guanine-cytosine
ESI	Electrode skin impedance	GDT	Gas discharge tube
ESRD	End-stage renal disease	GFR	Glomerular filtration rate
esu	Electrostatic unit	GHb	Glycosylated hemoglobin
ESU	Electrosurgical unit	GI	Gastrointestinal
ESWL	Extracorporeal shock wave lithotripsy	GLC	Gas-liquid chromatography
ETO, Eto	Ethylene oxide	GMV	General minimum variance
ETT	Exercise tolerance testing	GNP	Gross national product
EVA	Ethylene vinyl acetate	GPC	Giant papillary conjunctivitis
EVR	Endocardial viability ratio	GPH	Gas-permeable hard
EW	Extended wear	GPH-EW	Gas-permeable hard lens extended wear
FAD	Flavin adenine dinucleotide	GPO	Government Printing Office
FARA	Flexible automation random analysis	GSC	Gas-solid chromatography
FBD	Fetal biparietal diameter	GSR	Galvanic skin response
FBS	Fetal bovine serum	GSWD	Generalized spike-wave discharge
fcc	Face centered cubic	HA	Hydroxyapatite
FCC	Federal Communications Commission	HAM	Helical axis of motion
Fct	Fluorocrit	Hb	Hemoglobin
FDA	Food and Drug Administration	HBE	His bundle electrogram
FDCA	Food, Drug, and Cosmetic Act	HBO	Hyperbaric oxygenation
FE	Finite element	HC	Head circumference
FECG	Fetal electrocardiogram	HCA	Hypothermic circulatory arrest
FEF	Forced expiratory flow	HCFA	Health care financing administration
FEL	Free electron lasers	HCL	Harvard Cyclotron Laboratory
FEM	Finite element method	hcp	Hexagonal close-packed
FEP	Fluorinated ethylene propylene	HCP	Half cell potential
FES	Functional electrical stimulation	HDPE	High density polyethylene
FET	Field-effect transistor	HECS	Hospital Equipment Control System
FEV	Forced expiratory volume	HEMS	Hospital Engineering Management System
FFD	Focal spot to film distance	HEPA	High efficiency particulate air filter
FFT	Fast Fourier transform	HES	Hydroxyethylstarch
FGF	Fresh gas flow	HETP	Height equivalent to a theoretical plate
FHR	Fetal heart rate	HF	High-frequency; Heating factor
FIC	Forced inspiratory capacity	HFCWO	High-frequency chest wall oscillation
FID	Flame ionization detector; Free-induction decay	HFER	High-frequency electromagnetic radiation
FIFO	First-in-first-out	HFJV	High-frequency jet ventilation
FITC	Fluorescent indicator tagged polymer	HFO	High-frequency oscillator
FL	Femur length	HFOV	High-frequency oscillatory ventilation
FM	Frequency modulation	HFPPV	High-frequency positive pressure ventilation
FNS	Functional neuromuscular stimulation	HFV	High-frequency ventilation
FO	Foramen ovale	HHS	Department of Health and Human Services
FO-CRT	Fiber optics cathode ray tube	HIBC	Health industry bar code
FP	Fluorescence polarization	HIMA	Health Industry Manufacturers Association
FPA	Fibrinopeptide A	HIP	Hydrostatic indifference point
FR	Federal Register	HIS	Hospital information system
FRC	Federal Radiation Council; Functional residual capacity	HK	Hexokinase
FSD	Focus-to-surface distance	HL	Hearing level
FTD	Focal spot to tissue-plane distance	HMBA	Hexamethylene bisacetamide
FTIR	Fourier transform infrared	HMO	Health maintenance organization
FTMS	Fourier transform mass spectrometer	HMWPE	High-molecular-weight polyethylene
FU	Fluorouracil	HOL	Higher-order languages
FUDR	Floxuridine	HP	Heating factor; His-Purkinje
FVC	Forced vital capacity	HpD	Hematoporphyrin derivative
FWHM	Full width at half maximum	HPLC	High-performance liquid chromatography
FWTM	Full width at tenth maximum	HPNS	High-pressure neurological syndrome
GABA	Gamma amino buteric acid	HPS	His-Purkinje system
GAG	Glycosaminoglycan	HPX	High peroxidase activity
GBE	Gas-bearing electrodyamometer		

HR	Heart rate; High-resolution	IMIA	International Medical Informatics Association
HRNB	Halstead-Reitan Neuropsychological Battery	IMS	Information management system
H/S	Hard/soft	IMV	Intermittent mandatory ventilation
HSA	Human serum albumin	INF	Interferon
HSG	Hysterosalpingogram	IOL	Intraocular lens
HTCA	Human tumor cloning assay	IPC	Ion-pair chromatography
HTLV	Human T cell lymphotropic virus	IPD	Intermittent peritoneal dialysis
HU	Heat unit; Houndsfield units; Hydroxyurea	IPG	Impedance plethysmography
HVL	Half value layer	IPI	Interpulse interval
HVR	Hypoxic ventilatory response	IPPB	Intermittent positive pressure breathing
HVT	Half-value thickness	IPTS	International practical temperature scale
IA	Image intensifier assembly; Inominate artery	IR	Polyisoprene rubber
IABP	Intraaortic balloon pumping	IRB	Institutional Review Board
IAEA	International Atomic Energy Agency	IRBBB	Incomplete right bundle branch block
IAIMS	Integrated Academic Information Management System	IRPA	International Radiation Protection Association
IASP	International Association for the Study of Pain	IRRAS	Infrared reflection-absorption spectroscopy
IC	Inspiratory capacity; Integrated circuit	IRRS	Infrared reflection spectroscopy
ICCE	Intracapsular cataract extraction	IRS	Internal reflection spectroscopy
ICD	Intracervical device	IRV	Inspiratory reserve capacity
ICDA	International classification of diagnoses	IS	Image size; Ion-selective
ICL	Ms-clip lens	ISC	Infant skin servo control
ICP	Inductively coupled plasma; Intracranial pressure	ISDA	Instantaneous screw displacement axis
ICPA	Intracranial pressure amplitude	ISE	Ion-selective electrode
ICRP	International Commission on Radiological Protection	ISFET	Ion-sensitive field effect transistor
ICRU	International Commission on Radiological Units and Measurements	ISIT	Intensified silicon-intensified target tube
ICU	Intensive care unit	ISO	International Organization for Standardization
ID	Inside diameter	ISS	Ion scattering spectroscopy
IDDM	Insulin dependent diabetes mellitus	IT	Intrathecal
IDE	Investigational device exemption	ITEP	Institute of Theoretical and Experimental Physics
IDI	Index of inspired gas distribution	ITEPI	Instantaneous trailing edge pulse impedance
I:E	Inspiratory: expiratory	ITLC	Instant thin-layer chromatography
IEC	International Electrotechnical Commission; Ion-exchange chromatography	IUD	Intrauterine device
IEEE	Institute of Electrical and Electronics Engineers	IV	Intravenous
IEP	Individual educational program	IVC	Inferior vena cava
BETS	Inelastic electron tunneling spectroscopy	IVP	Intraventricular pressure
IF	Immunofluorescent	JCAH	Joint Commission on the Accreditation of Hospitals
IFIP	International Federation for Information Processing	JND	Just noticeable difference
IFMBE	International Federation for Medical and Biological Engineering	JRP	Joint replacement prosthesis
IGFET	Insulated-gate field-effect transistor	KB	Kent bundle
IgG	Immunoglobulin G	Kerma	Kinetic energy released in unit mass
IgM	Immunoglobulin M	KO	Knee orthosis
IHP	Inner Helmholtz plane	KPM	Kilopond meter
IHSS	Idiopathic hypertrophic subaortic stenosis	KRPB	Krebs-Ringer physiological buffer
II	Image intensifier	LA	Left arm; Left atrium
IIIES	Image intensifier input-exposure sensitivity	LAD	Left anterior descending; Left axis deviation
IM	Intramuscular	LAE	Left atrial enlargement
IMFET	Immunologically sensitive field-effect transistor	LAK	Lymphokine activated killer
		LAL	Limulus amoebocyte lysate
		LAN	Local area network
		LAP	Left atrial pressure
		LAT	Left anterior temporalis
		LBBB	Left bundle branch block
		LC	Left carotid; Liquid chromatography

LCC	Left coronary cusp	MDP	Mean diastolic aortic pressure
LCD	Liquid crystal display	MDR	Medical device reporting
LDA	Laser Doppler anemometry	MDS	Multidimensional scaling
LDF	Laser Doppler flowmetry	ME	Myoelectric
LDH	Lactate dehydrogenase	MED	Minimum erythema dose
LDPE	Low density polyethylene	MEDPAR	Medicare provider analysis and review
LEBS	Low-energy brief stimulus	MEFV	Maximal expiratory flow volume
LED	Light-emitting diode	MEG	Magnetoencephalography
LEED	Low energy electron diffraction	MeSH	Medline subject heading
LES	Lower esophageal sphincter	METS	Metabolic equivalents
LESP	Lower esophageal sphincter pressure	MF	Melamine-formaldehyde
LET	Linear energy transfer	MFP	Magnetic field potential
LF	Low frequency	MGH	Massachusetts General Hospital
LH	Luteinizing hormone	MHV	Magnetic heart vector
LHT	Local hyperthermia	MI	Myocardial infarction
LL	Left leg	MIC	Minimum inhibitory concentration
LLDPE	Linear low density polyethylene	MIFR	Maximum inspiratory flow rate
LLPC	Liquid-liquid partition chromatography	MINET	Medical Information Network
LLW	Low-level waste	MIR	Mercury-in-rubber
LM	Left masseter	MIS	Medical information system; Metal-insulator-semiconductor
LNNB	Luria-Nebraska Neuropsychological Battery	MIT	Massachusetts Institute of Technology
LOS	Length of stay	MIT/BIH	Massachusetts Institute of Technology/ Beth Israel Hospital
LP	Late potential; Lumboperitoneal	MMA	Manual metal arc welding
LPA	Left pulmonary artery	MMA	Methyl methacrylate
LPC	Linear predictive coding	MMECT	Multiple-monitored ECT
LPT	Left posterior temporalis	MMFR	Maximum midexpiratory flow rate
LPV	Left pulmonary veins	mm Hg	Millimeters of mercury
LRP	Late receptor potential	MMPI	Minnesota Multiphasic Personality Inventory
LS	Left subclavian	MMSE	Minimum mean square error
LSC	Liquid-solid adsorption chromatography	MO	Membrane oxygenation
LSI	Large scale integrated	MONO	Monocyte
LSV	Low-amplitude shear-wave viscoelastometry	MOSFET	Metal oxide silicon field-effect transistor
LTI	Low temperature isotropic	MP	Mercaptopurine; Metacarpal-phalangeal
LUC	Large unstained cells	MPD	Maximal permissible dose
LV	Left ventricle	MR	Magnetic resonance
LVAD	Left ventricular assist device	MRG	Magnetoretinogram
LVDT	Linear variable differential transformer	MRI	Magnetic resonance imaging
LVEP	Left ventricular ejection period	MRS	Magnetic resonance spectroscopy
LVET	Left ventricular ejection time	MRT	Mean residence time
LVH	Left ventricular hypertrophy	MS	Mild steel; Multiple sclerosis
LYMPH	Lymphocyte	MSR	Magnetically shielded room
MAA	Macroaggregated albumin	MTBF	Mean time between failure
MAC	Minimal auditory capabilities	MTF	Modulation transfer function
MAN	Manubrium	MTTR	Mean time to repair
MAP	Mean airway pressure; Mean arterial pressure	MTX	Methotroxate
MAST	Military assistance to safety and traffic	MUA	Motor unit activity
MBA	Monoclonal antibody	MUAP	Motor unit action potential
MBV	Maximum breathing ventilation	MUAPT	Motor unit action potential train
MBX	Monitoring branch exchange	MUMPI	Missouri University Multi-Plane Imager
MCA	Methyl cryanoacrylate	MUMPS	Massachusetts General Hospital utility multiuser programming system
MCG	Magnetocardiogram	MV	Mitral valve
MCI	Motion Control Incorporated	MVO ₂	Maximal oxygen uptake
MCM1	Millon Clinical Multiaxial Inventory	MVTR	Moisture vapor transmission rate
MCT	Microcatheter transducer	MVV	Maximum voluntary ventilation
MCV	Mean corpuscular volume	MW	Molecular weight
MDC	Medical diagnostic categories		
MDI	Diphenylmethane diisocyanate; Medical Database Informatics		

NAA	Neutron activation analysis	OPG	Ocular pneumoplethysmography
NAD	Nicotinamide adenine dinucleotide	OR	Operating room
NADH	Nicotinamide adenine dinucleotide, reduced form	OS	Object of known size; Operating system
NADP	Nicotinamide adenine dinucleotide phosphate	OTC	Over the counter
NAF	Neutrophil activating factor	OV	Offset voltage
NARM	Naturally occurring and accelerator- produced radioactive materials	PA	Posteroanterior; Pulmonary artery; Pulse amplitude
NBB	Normal buffer base	PACS	Picture archiving and communications systems
NBD	Neuromuscular blocking drugs	PAD	Primary afferent depolarization
N-BPC	Normal bonded phase chromatography	PAM	Pulse amplitude modulation
NBS	National Bureau of Standards	PAN	Polyacrylonitrile
NCC	Noncoronary cusp	PAP	Pulmonary artery pressure
NCCLS	National Committee for Clinical Laboratory Standards; National Committee on Clinical Laboratory Standards	PAR	Photoactivation ratio
NCRP	National Council on Radiation Protection	PARFR	Program for Applied Research on Fertility Regulation
NCT	Neutron capture theory	PARR	Poetanesesthesia recovery room
NEEP	Negative end-expiratory pressure	PAS	Photoacoustic spectroscopy
NEMA	National Electrical Manufacturers Association	PASG	Pneumatic antishock garment
NEMR	Nonionizing electromagnetic radiation	PBI	Penile brachial index
NEQ	Noise equivalent quanta	PBL	Positive beam limitation
NET	Norethisterone	PBT	Polybutylene terephthalate
NEUT	Neutrophil	PC	Paper chromatography; Personal computer; Polycarbonate
NFPA	National Fire Protection Association	PCA	Patient controlled analgesia; Principal components factor analysis
NH	Neonatal hepatitis	PCG	Phonocardiogram
NHE	Normal hydrogen electrode	PCI	Physiological cost index
NHLBI	National Heart, Lung, and Blood Institute	PCL	Polycaprolactone; Posterior chamber lens
NIR	Nonionizing radiation	PCR	Percent regurgitation
NIRS	National Institute for Radiologic Science	PCRC	Perinatal Clinical Research Center
NK	Natural killer	PCS	Patient care system
NMJ	Neuromuscular junction	PCT	Porphyria cutanea tarda
NMOS	N-type metal oxide silicon	PCWP	Pulmonary capillary wedge pressure
NMR	Nuclear magnetic resonance	PD	Peritoneal dialysis; Poly-p-dioxanone; Potential difference; Proportional and derivative
NMS	Neuromuscular stimulation	PDD	Percent depth dose; Perinatal Data Directory
NPH	Normal pressure hydrocephalus	PDE	Pregelged disposable electrodes
NPL	National Physical Laboratory	p.d.f.	Probability density function
NR	Natural rubber	PDL	Periodontal ligament
NRC	Nuclear Regulatory Commission	PDM	Pulse duration modulation
NRZ	Non-return-to-zero	PDMSX	Polydimethyl siloxane
NTC	Negative temperature coefficient	PDS	Polydioxanone
NTIS	National Technical Information Service	PE	Polyethylene
NVT	Neutrons versus time	PEEP	Positive end-expiratory pressure
NYHA	New York Heart Association	PEFR	Peak expiratory now rate
ob/gyn	Obstetrics and gynecology	PEN	Parenteral and enteral nutrition
OCR	Off-center ratio; Optical character recognition	PEP	Preejection period
OCV	Open circuit voltage	PEPPER	Programs examine phonetic find phonological evaluation records
OD	Optical density; Outside diameter	PET	Polyethylene terephthalate; Positron-emission tomography
ODC	Oxyhemoglobin dissociation curve	PEU	Polyetherurethane
ODT	Oxygen delivery truck	PF	Platelet factor
ODU	Optical density unit	PFA	Phosphonoformic add
OER	Oxygen enhancement ratio	PFC	Petrofluorochemical
OFD	Object to film distance; Occiputo-frontal diameter	PFT	Pulmonary function testing
OHL	Outer Helmholtz layer	PG	Polyglycolide; Propylene glycol
OHP	Outer Helmholtz plane		
OIH	Orthoiodohippurate		

PGA	Polyglycolic add	PURA	Prolonged ultraviolet-A radiation
PHA	Phytohemagglutinin; Pulse-height analyzer	PUVA	Psoralens and longwave ultraviolet light photochemotherapy
PHEMA	Poly-2-hydroxyethyl methacrylate	P/V	Pressure/volume
PI	Propidium iodide	PVC	Polyvinyl chloride; Premature ventricular contraction
PID	Pelvic inflammatory disease; Proportional/integral/derivative	PVI	Pressure-volume index
PIP	Peak inspiratory pressure	PW	Pulse wave; Pulse width
PL	Posterior leaflet	PWM	Pulse width modulation
PLA	Polylactic acid	PXE	Pseudo-xanthoma elasticum
PLATO	Program Logic for Automated Teaching Operations	QA	Quality assurance
PLD	Potentially lethal damage	QC	Quality control
PLED	Periodic lateralized epileptiform discharge	R-BPC	Reverse bonded phase chromatography
PLT	Platelet	R/S	Radiopaque-spherical
PM	Papillary muscles; Preventive maintenance	RA	Respiratory amplitude; Right arm
PMA	Polymethyl acrylate	RAD	Right axis deviation
p.m.f.	Probability mass function	RAE	Right atrial enlargement
PMMA	Polymethyl methacrylate	RAM	Random access memory
PMOS	P-type metal oxide silicon	RAP	Right atrial pressure
PMP	Patient management problem; Poly(4-methylpentane)	RAT	Right anterior temporalis
PMT	Photomultiplier tube	RB	Right bundle
PO	Per os	RBBB	Right bundle branch block
P_{O_2}	Partial pressure of oxygen	RBC	Red blood cell
POBT	Polyoxybutylene terephthalate	RBE	Relative biologic effectiveness
POM	Polyoxymethylene	RBF	Rose bengal fecal excretion
POMC	Patient order management and communication system	RBI	Resting baseline impedance
POPRAS	Problem Oriented Perinatal Risk Assessment System	RCBD	Randomized complete block diagram
PP	Perfusion pressure; Polypropylene; Postprandial (after meals)	rCBF	Regional cerebral blood flow
PPA	Phonemic process analysis	RCC	Right coronary cusp
PPF	Plasma protein fraction	RCE	Resistive contact electrode
PPM	Pulse position modulation	R&D	Research and development
PPSFH	Polymerized phyridoxalated stroma-free hemoglobin	r.e.	Random experiment
PR	Pattern recognition; Pulse rate	RE	Reference electrode
PRBS	Pseudo-random binary signals	REM	Rapid eye movement; Return electrode monitor
PRP	Pulse repetition frequency	REMATE	Remote access and telecommunication system
PRO	Professional review organization	RES	Reticuloendothelial system
PROM	Programmable read only memory	RESNA	Rehabilitation Engineering Society of North America
PS	Polystyrene	RF	Radio frequency; Radiographic-nuoroscopic
PSA	Pressure-sensitive adhesive	RFI	Radio-frequency interference
PSF	Point spread function	RFP	Request for proposal
PSI	Primary skin irritation	RFQ	Request for quotation
PSP	Postsynaptic potential	RH	Relative humidity
PSR	Proton spin resonance	RHE	Reversible hydrogen electrode
PSS	Progressive systemic sclerosis	RIA	Radioimmunoassay
PT	Plasma thromboplastin	RM	Repetition maximum; Right masseter
PTB	Patellar tendon bearing orthosis	RMR	Resting metabolic rate
PTC	Plasma thromboplastin component; Positive temperature coefficient; Pressurized personal transfer capsule	RMS	Root mean square
PTCA	Percutaneous transluminal coronary angioplasty	RN	Radionuclide
PTFE	Polytetrafluoroethylene	RNCA	Radionuclide cineangiogram
PTT	Partial thromboplastin time	ROI	Regions of interest
PUL	Percutaneous ultrasonic lithotripsy	ROM	Range of motion; Read only memory
		RP	Retinitis pigmentosa
		RPA	Right pulmonary artery
		RPP	Rate pressure product
		RPT	Rapid pull-through technique
		RPV	Right pulmonary veins
		RQ	Respiratory quotient

RR	Recovery room	SEBS	Surgical isolation barrier system
RRT	Recovery room time; Right posterior temporalis	SID	Source to image reception distance
RT	Reaction time	SIMFU	Scanned intensity modulated focused ultrasound
RTD	Resistance temperature device	SIMS	Secondary ion mass spectroscopy; System for isometric muscle strength
RTT	Revised token test	SISI	Short increment sensitivity index
r.v.	Random variable	SL	Surgical lithotomy
RV	Residual volume; Right ventricle	SLD	Sublethal damage
RVH	Right ventricular hypertrophy	SLE	Systemic lupus erythemotodes
RVOT	Right ventricular outflow tract	SMA	Sequential multiple analyzer
RZ	Return-to-zero	SMAC	Sequential multiple analyzer with computer
SA	Sinoatrial; Specific absorption	SMR	Sensorimotor
SACH	Solid-ankle-cushion-heel	S/N	Signal-to-noise
SAD	Source-axis distance; Statistical Analysis System	S:N/D	Signal-to-noise ratio per unit dose
SAINT	System analysis of integrated network of tasks	SNP	Sodium nitroprusside
SAL	Sterility assurance level; Surface averaged lead	SNR	Signal-to-noise ratio
SALT	Systematic analysis of language transcripts	SOA	Sources of artifact
SAMI	Socially acceptable monitoring instrument	SOAP	Subjective, objective, assessment, plan
SAP	Systemic arterial pressure	SOBP	Spread-out Bragg peak
SAR	Scatter-air ratio; Specific absorption rate	SP	Skin potential
SARA	System for anesthetic and respiratory gas analysis	SPECT	Single photon emission computed tomography
SBE	Subbacterial endocarditis	SPL	Sound pressure level
SBR	Styrene-butadiene rubbers	SPRINT	Single photon ring tomograph
SC	Stratum corneum; Subcommittees	SPRT	Standard platinum resistance thermometer
SCAP	Right scapula	SPSS	Statistical Package for the Social Sciences
SCE	Saturated calomel electrode; Sister chromatid exchange	SQUID	Superconducting quantum interference device
SCI	Spinal cord injury	SQV	Square wave voltammetry
SCRAD	Sub-Committee on Radiation Dosimetry	SR	Polysulfide rubbers
SCS	Spinal cord stimulation	SRT	Speech reception threshold
SCUBA	Self-contained underwater breathing apparatus	SS	Stainless steel
SD	Standard deviation	SSB	Single strand breaks
SDA	Stepwise discriminant analysis	SSD	Source-to-skin distance; Source-to-surface distance
SDS	Sodium dodecyl sulfate	SSE	Stainless steel electrode
S&E	Safety and effectiveness	SSEP	Somatosensory evoked potential
SE	Standard error	SSG	Solid state generator
SEC	Size exclusion chromatography	SSP	Skin stretch potential
SEM	Scanning electron microscope; Standard error of the mean	SSS	Sick sinus syndrome
SEP	Somatosensory evoked potential	STD	Source-tray distance
SEXAFS	Surface extended X-ray absorption fine structure	STI	Systolic time intervals
SF	Surviving fraction	STP	Standard temperature and pressure
SFD	Source-film distance	STPD	Standard temperature pressure dry
SFH	Stroma-free hemoglobin	SV	Stroke volume
SFTR	Sagittal frontal transverse rotational	SVC	Superior vena cava
SG	Silica gel	SW	Standing wave
SGF	Silica gel fraction	TAA	Tumor-associated antigens
SGG	Spark gap generator	TAC	Time-averaged concentration
SGOT	Serum glutamic oxaloacetic transaminase	TAD	Transverse abdominal diameter
SGP	Strain gage plethysmography; Stress-generated potential	TAG	Technical Advisory Group
SHE	Standard hydrogen electrode	TAH	Total artificial heart
SI	Le Système International d'Unités	TAR	Tissue-air ratio
		TC	Technical Committees
		TCA	Tricarboxylic acid cycle
		TCD	Thermal conductivity detector
		TCES	Transcutaneous cranial electrical stimulation

TCP	Tricalcium phosphate	UHMWPE	Ultra high molecular weight polyethylene
TDD	Telecommunication devices for the deaf	UL	Underwriters Laboratory
TDM	Therapeutic drug monitoring	ULF	Ultralow frequency
TE	Test electrode; Thermoplastic elastomers	ULTI	Ultralow temperature isotropic
TEAM	Technology evaluation and acquisition methods	UMN	Upper motor neuron
TEM	Transmission electron microscope; Transverse electric and magnetic mode; Transverse electromagnetic mode	UO	Urinary output
TENS	Transcutaneous electrical nerve stimulation	UPTD	Unit pulmonary oxygen toxicity doses
TEP	Tracheoesophageal puncture	UR	Unconditioned response
TEPA	Triethylenephosphoramidate	US	Ultrasound; Unconditioned stimulus
TF	Transmission factor	USNC	United States National Committee
TFE	Tetrafluorethylene	USP	United States Pharmacopeia
TI	Totally implantable	UTS	Ultimate tensile strength
TICCIT	Time-shared Interaction Computer-Controlled Information Television	UV	Ultraviolet; Umbilical vessel
TLC	Thin-layer chromatography; Total lung capacity	UVR	Ultraviolet radiation
TLD	Thermoluminescent dosimetry	V/F	Voltage-to-frequency
TMJ	Temporomandibular joint	VA	Veterans Administration
TMR	Tissue maximum ratio; Topical magnetic resonance	VAS	Visual analog scale
TNF	Tumor necrosis factor	VBA	Vaginal blood volume in arousal
TOF	Train-of-four	VC	Vital capacity
TP	Thermal performance	VCO	Voltage-controlled oscillator
TPC	Temperature pressure correction	VDT	Video display terminal
TPD	Triphasic dissociation	VECG	Vectorelectrocardiography
TPG	Transvalvular pressure gradient	VEP	Visually evoked potential
TPN	Total parenteral nutrition	VF	Ventricular fibrillation
TR	Temperature rise	VOP	Venous occlusion plethysmography
tRNA	Transfer RNA	VP	Ventriculoperitoneal
TSH	Thyroid stimulating hormone	VPA	Vaginal pressure pulse in arousal
TSS	Toxic shock syndrome	VPB	Ventricular premature beat
TTD	Telephone devices for the deaf	VPR	Volume pressure response
TTI	Tension time index	VSD	Ventricular septal defect
TTR	Transition temperature range	VSWR	Voltage standing wave ratio
TTV	Trimming tip version	VT	Ventricular tachycardia
TTY	Teletypewriter	VTG	Vacuum tube generator
TUR	Transurethral resection	VTS	Viewscan text system
TURP	Transurethral resections of the prostate	VV	Variable version
TV	Television; Tidal volume; Tricuspid valve	WAIS-R	Weschler Adult Intelligence Scale-Revised
TVER	Transscleral visual evoked response	WAK	Wearable artificial kidney
TW	Traveling wave	WAML	Wide-angle mobility light
TxB ₂	Thromboxane B ²	WBAR	Whole-body autoradiography
TZ	Transformation zone	WBC	White blood cell
UES	Upper esophageal sphincter	WG	Working Groups
UP	Urea-formaldehyde	WHO	World Health Organization; Wrist hand orthosis
UffIS	University Hospital Information System	WLF	Williams-Landel-Ferry
UHMW	Ultra high molecular weight	WMR	Work metabolic rate
		w/o	Weight percent
		WORM	Write once, read many
		WPW	Wolff-Parkinson-White
		XPS	X-ray photon spectroscopy
		XR	Xeroradiograph
		YAG	Yttrium aluminum garnet
		ZPL	Zero pressure level

CONVERSION FACTORS AND UNIT SYMBOLS

SI UNITS (ADOPTED 1960)

A new system of metric measurement, the International System of Units (abbreviated SI), is being implemented throughout the world. This system is a modernized version of the MKSA (meter, kilogram, second, ampere) system, and its details are published and controlled by an international treaty organization (The International Bureau of Weights and Measures).

SI units are divided into three classes:

Base Units	
length	meter [†] (m)
mass [‡]	kilogram (kg)
time	second (s)
electric current	ampere (A)
thermodynamic temperature§	kelvin (K)
amount of substance	mole (mol)
luminous intensity	candela (cd)
Supplementary Units	
plane angle	radian (rad)
solid angle	steradian (sr)

Derived Units and Other Acceptable Units

These units are formed by combining base units, supplementary units, and other derived units. Those derived units having special names and symbols are marked with an asterisk (*) in the list below:

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
*absorbed dose	gray	Gy	J/kg
acceleration	meter per second squared	m/s ²	
*activity (of ionizing radiation source)	becquerel	Bq	1/s
area	square kilometer	km ²	
	square hectometer	hm ²	ha (hectare)
	square meter	m ²	

[†]The spellings “metre” and “litre” are preferred by American Society for Testing and Materials (ASTM); however, “-er” will be used in the Encyclopedia.

[‡]“Weight” is the commonly used term for “mass.”

§Wide use is made of “Celsius temperature” (*t*) defined $t = T - T_0$ where *T* is the thermodynamic temperature, expressed in kelvins, and $T_0 = 273.15$ K by definition. A temperature interval may be expressed in degrees Celsius as well as in kelvins.

<i>Quantity equivalent</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable</i>
* capacitance	farad	F	C/V
concentration (of amount of substance)	mole per cubic meter	mol/m ³	
* conductance	siemens	S	A/V
current density	ampere per square meter	A/m ²	
density, mass density	kilogram per cubic meter	kg/m ³	g/L; mg/cm ³
dipole moment (quantity)	coulomb meter	C·m	
* electric charge, quantity of electricity	coulomb	C	A·s
electric charge density	coulomb per cubic meter	C/m ³	
electric field strength	volt per meter	V/m	
electric flux density	coulomb per square meter	C/m ²	
* electric potential, potential difference, electromotive force	volt	V	W/A
* electric resistance	ohm	Ω	V/A
* energy, work, quantity of heat	megajoule	MJ	
	kilojoule	kJ	
	joule	J	N·m
	electron volt [†]	eV [†]	
	kilowatt hour [†]	kW·h [†]	
energy density	joule per cubic meter	J/m ³	
* force	kilonewton	kN	
	newton	N	kg·m/s ²
* frequency	megahertz	MHz	
	hertz	Hz	1/s
heat capacity, entropy	joule per kelvin	J/K	
heat capacity (specific), specific entropy	joule per kilogram kelvin	J/(kg·K)	
heat transfer coefficient	watt per square meter kelvin	W/(m ² ·K)	
* illuminance	lux	lx	lm/m ²
* inductance	henry	H	Wb/A
linear density	kilogram per meter	kg/m	
luminance	candela per square meter	cd/m ²	
* luminous flux	lumen	lm	cd·sr
magnetic field strength	ampere per meter	A/m	
* magnetic flux	weber	Wb	V·s
* magnetic flux density	tesla	T	Wb/m ²
molar energy	joule per mole	J/mol	
molar entropy, molar heat capacity	joule per mole kelvin	J/(mol·K)	
moment of force, torque	newton meter	N·m	
momentum	kilogram meter per second	kg·m/s	
permeability	henry per meter	H/m	
permittivity	farad per meter	F/m	
* power, heat flow rate, radiant flux	kilowatt	kW	
	watt	W	J/s
power density, heat flux density, irradiance	watt per square meter	W/m ²	
* pressure, stress	megapascal	MPa	
	kilopascal	kPa	
	pascal	Pa	N/m ²
sound level	decibel	dB	
specific energy	joule per kilogram	J/kg	
specific volume	cubic meter per kilogram	m ³ /kg	
surface tension	newton per meter	N/m	
thermal conductivity	watt per meter kelvin	W/(m·K)	
velocity	meter per second	m/s	
	kilometer per hour	km/h	
viscosity, dynamic	pascal second	Pa·s	
	millipascal second	mPa·s	

[†]This non-SI unit is recognized as having to be retained because of practical importance or use in specialized fields.

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
viscosity, kinematic	square meter per second	m ² /s	
	square millimeter per second	mm ² /s	
	cubic meter	m ³	
	cubic decimeter	dm ³	L(liter)
	cubic centimeter	cm ³	mL
wave number	1 per meter	m ⁻¹	
	1 per centimeter	cm ⁻¹	

In addition, there are 16 prefixes used to indicate order of magnitude, as follows:

<i>Multiplication factor</i>	<i>Prefix</i>	<i>Symbol</i>	<i>Note</i>
10 ¹⁸	exa	E	
10 ¹⁵	peta	P	
10 ¹²	tera	T	
10 ⁹	giga	G	
10 ⁸	mega	M	
10 ³	kilo	k	
10 ²	hecto	h ^a	^a Although hecto, deka, deci, and centi are SI prefixes, their use should be avoided except for SI unit-multiples for area and volume and nontechnical use of centimeter, as for body and clothing measurement.
10	deka	da ^a	
10 ⁻¹	deci	d ^a	
10 ⁻²	centi	c ^a	
10 ⁻³	milli	m	
10 ⁻⁶	micro	μ	
10 ⁻⁹	nano	n	
10 ⁻¹²	pico	p	
10 ⁻¹⁵	femto	f	
10 ⁻¹⁸	atto	a	

For a complete description of SI and its use the reader is referred to ASTM E 380.

CONVERSION FACTORS TO SI UNITS

A representative list of conversion factors from non-SI to SI units is presented herewith. Factors are given to four significant figures. Exact relationships are followed by a dagger (†). A more complete list is given in ASTM E 380-76 and ANSI Z210.1-1976.

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
acre	square meter (m ²)	4.047 × 10 ³
angstrom	meter (m)	1.0 × 10 ^{-10†}
are	square meter (m ²)	1.0 × 10 ^{2†}
astronomical unit	meter (m)	1.496 × 10 ¹¹
atmosphere	pascal (Pa)	1.013 × 10 ⁵
bar	pascal (Pa)	1.0 × 10 ^{5†}
barrel (42 U.S. liquid gallons)	cubic meter (m ³)	0.1590
Btu (International Table)	joule (J)	1.055 × 10 ³
Btu (mean)	joule (J)	1.056 × 10 ³
Bt (thermochemical)	joule (J)	1.054 × 10 ³
bushel	cubic meter (m ³)	3.524 × 10 ⁻²
calorie (International Table)	joule (J)	4.187
calorie (mean)	joule (J)	4.190
calorie (thermochemical)	joule (J)	4.184 [†]
centimeters of water (39.2 °F)	pascal (Pa)	98.07
centipoise	pascal second (Pa·s)	1.0 × 10 ^{-3†}
centistokes	square millimeter per second (mm ² /s)	1.0 [†]

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
cfm (cubic foot per minute)	cubic meter per second (m ³ /s)	4.72 × 10 ⁻⁴
cubic inch	cubic meter (m ³)	1.639 × 10 ⁻⁴
cubic foot	cubic meter (m ³)	2.832 × 10 ⁻²
cubic yard	cubic meter (m ³)	0.7646
curie	becquerel (Bq)	3.70 × 10 ^{10†}
debye	coulomb-meter (C·m)	3.336 × 10 ⁻³⁰
degree (angle)	radian (rad)	1.745 × 10 ⁻²
denier (international)	kilogram per meter (kg/m)	1.111 × 10 ⁻⁷
	tex	0.1111
dram (apothecaries')	kilogram (kg)	3.888 × 10 ⁻³
dram (avoirdupois)	kilogram (kg)	1.772 × 10 ⁻³
dram (U.S. fluid)	cubic meter (m ³)	3.697 × 10 ⁻⁶
dyne	newton(N)	1.0 × 10 ^{-6†}
dyne/cm	newton per meter (N/m)	1.00 × 10 ^{-3†}
electron volt	joule (J)	1.602 × 10 ⁻¹⁹
erg	joule (J)	1.0 × 10 ^{-7†}
fathom	meter (m)	1.829
fluid ounce (U.S.)	cubic meter (m ³)	2.957 × 10 ⁻⁵
foot	meter (m)	0.3048†
foot-pound force	joule (J)	1.356
foot-pound force	newton meter (N·m)	1.356
foot-pound force per second	watt(W)	1.356
footcandle	lux (lx)	10.76
furlong	meter (m)	2.012 × 10 ²
gal	meter per second squared (m/s ²)	1.0 × 10 ^{-2†}
gallon (U.S. dry)	cubic meter (m ³)	4.405 × 10 ⁻³
gallon (U.S. liquid)	cubic meter (m ³)	3.785 × 10 ⁻³
gilbert	ampere (A)	0.7958
gill (U.S.)	cubic meter (m ³)	1.183 × 10 ⁻⁴
grad	radian	1.571 × 10 ⁻²
grain	kilogram (kg)	6.480 × 10 ⁻⁵
gram force per denier	newton per tex (N/tex)	8.826 × 10 ⁻²
hectare	square meter (m ²)	1.0 × 10 ^{4†}
horsepower (550 ft·lbf/s)	watt(W)	7.457 × 10 ²
horsepower (boiler)	watt(W)	9.810 × 10 ³
horsepower (electric)	watt(W)	7.46 × 10 ^{2†}
hundredweight (long)	kilogram (kg)	50.80
hundredweight (short)	kilogram (kg)	45.36
inch	meter (m)	2.54 × 10 ^{-2†}
inch of mercury (32 °F)	pascal (Pa)	3.386 × 10 ³
inch of water (39.2 °F)	pascal (Pa)	2.491 × 10 ²
kilogram force	newton (N)	9.807
kilopond	newton (N)	9.807
kilopond-meter	newton-meter (N·m)	9.807
kilopond-meter per second	watt (W)	9.807
kilopond-meter per min	watt(W)	0.1635
kilowatt hour	megajoule (MJ)	3.6†
kip	newton (N)	4.448 × 10 ²
knot international	meter per second (m/s)	0.5144
lambert	candela per square meter (cd/m ²)	3.183 × 10 ³
league (British nautical)	meter (m)	5.559 × 10 ²
league (statute)	meter (m)	4.828 × 10 ³
light year	meter (m)	9.461 × 10 ¹⁵
liter (for fluids only)	cubic meter (m ³)	1.0 × 10 ^{-3†}
maxwell	weber (Wb)	1.0 × 10 ^{-8†}
micron	meter (m)	1.0 × 10 ^{-6†}
mil	meter (m)	2.54 × 10 ^{-5†}
mile (U.S. nautical)	meter (m)	1.852 × 10 ^{3†}
mile (statute)	meter (m)	1.609 × 10 ³
mile per hour	meter per second (m/s)	0.4470

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
millibar	pascal (Pa)	1.0×10^2
millimeter of mercury (0 °C)	pascal (Pa)	$1.333 \times 10^{2\dagger}$
millimeter of water (39.2 °F)	pascal (Pa)	9.807
minute (angular)	radian	2.909×10^{-4}
myriagram	kilogram (kg)	10
myriameter	kilometer (km)	10
oersted	ampere per meter (A/m)	79.58
ounce (avoirdupois)	kilogram (kg)	2.835×10^{-2}
ounce (troy)	kilogram (kg)	3.110×10^{-2}
ounce (U.S. fluid)	cubic meter (m ³)	2.957×10^{-5}
ounce-force	newton (N)	0.2780
peck (U.S.)	cubic meter (m ³)	8.810×10^{-3}
pennyweight	kilogram (kg)	1.555×10^{-3}
pint (U.S. dry)	cubic meter (m ³)	5.506×10^{-4}
pint (U.S. liquid)	cubic meter (m ³)	4.732×10^{-4}
poise (absolute viscosity)	pascal second (Pa·s)	0.10 [†]
pound (avoirdupois)	kilogram (kg)	0.4536
pound (troy)	kilogram (kg)	0.3732
poundal	newton (N)	0.1383

INTRODUCTION

The use of reliable, high performance miniature sensors in the medical field is of growing importance for patient health monitoring. Batch sensor fabrication, as this has been introduced by Integrated Circuit (IC) manufacturing, is an efficient way to produce silicon sensors with desirable characteristics. Since microsensors combine small size with electrical and mechanical principles of operation they constitute together with microactuators what is usually called Microelectromechanical Systems (MEMS). These components are mainly made from silicon and other related materials to explore existing know-how and infrastructure of silicon technology. All of the above factors have allowed for fast growth of the microsensor field during the last years. This article focuses on physical microsensors used in the medical field that are based on the capacitive approach.

Historically, silicon piezoresistive devices were first introduced in the early 1960s to monitor pressure related variations (1). Piezoresistive silicon sensors take advantage of the piezoresistance effect observed in Si and Ge crystals (2). During this phenomenon, the value of a resistor realized from these semiconductors changes when mechanical strain is applied.

Piezoresistive devices have since then been investigated and used with catheters or as implantable units to monitor blood pressure variations (3,4). Such devices are already present in the market (5,6). Problems related to the nature of the piezoresistance effect include the relatively important temperature sensitivity of piezoresistive sensors that have to be compensated for with rather sophisticated electronics as well as the increased power consumption when compared to capacitive devices (7). These drawbacks of piezoresistive devices have accelerated the investigation of other device options for pressure measurements. It was in the 1980s that research on capacitive sensors began.

THE CAPACITIVE APPROACH

The capacitive approach is based on the parallel plate capacitor principle. In that structure the capacitance between two parallel electrodes is given by

$$C = \epsilon_r \epsilon_0 \frac{A}{d} \quad (1)$$

where ϵ_r , ϵ_0 is the relative and vacuum permittivity constant, respectively, A is the plate surface area, and d is the plate distance.

When an applied external force acts in a way to change the distance between the two electrodes, the displacement is detected as a capacitance change. In many applications when a micromechanical structure is realized to detect a capacitance change, one of the two electrodes remains fixed and the other is flexible (Fig. 1a). The flexible electrode that is rigidly supported on its edges deflects so it does not remain parallel to the fixed electrode (Fig. 1b). In that case, the previous simple expression is modified and the capacitance is given by

$$C = \epsilon_r \epsilon_0 \int_A \left(\frac{1}{d - w(x,y)} \right) \quad (2)$$

where $w(x,y)$ is the displacement of the flexible electrode.

Since the measured capacitance depends on the distance between the two electrodes, it can be used to calculate

Figure 1. An example of a capacitive sensor is a pressure sensor. In parts a, the thin sensor diaphragm remains parallel to the fixed electrode and in part b, the diaphragm deflects under applied pressure resulting in capacitance change.

the value of the stimulus modifying the interelectrode spacing. Different approaches for capacitive micro devices have appeared that make use of the above principle.

One major application in the medical field for capacitive transducers is pressure measurement. First explorative research of capacitive microdevices made using silicon technology was initiated in the early 1980s (8–11). These initial studies have demonstrated that capacitive devices exhibit superior properties from their piezoresistive competitors in terms of pressure sensitivity, scalability, manufacturing simplicity, as well as process variation tolerance.

APPLICATIONS IN THE MEDICAL FIELD

The manufacturing advantages of micromachined silicon sensors have made them very attractive in the field of minimally invasive therapy. Catheters used in this field need to penetrate into small blood vessels putting stringent requirements on sensor size, which should be one-half of the size of the vessel to be accessed. In small vessels, catheters usually have a diameter of 2 mm, while the smallest catheter at the moment has a diameter of 0.36 mm (12). Miniaturization, therefore, of both sensor and packaging size drives this kind of application. Capacitive devices within the above size requirements have been demonstrated in silicon (13) and are mainly competing with fiber optic pressure sensors (14), or a free hanging strain gauge (15).

Catheters, however, are unsuitable for long-term monitoring of blood pressure. With AAA (abdominal aortas aneurism) and CHF (congestive heart failure) being the major cardiovascular diseases in our days, an implantable pressure monitoring system that would tailor treatment medication by measuring blood pressure appears very attractive. These implantable applications will require a miniature batteryless telemetric sensor able to communicate with an external handheld unit. In such applications, power consumption becomes an additional issue and capacitive devices offer a clear advantage over piezoresistive ones. These types of systems have been under investigation (16,17) and have already demonstrated good performance.

Capacitive pressure sensors have also been successfully applied in the following areas. (1) Intraocular pressure monitoring (10,18). Glaucoma is, for example, a serious disease characterized by an increased pressure in the eye that may result in blindness. In that case, a sensitive capacitive device has been developed for remote sensing of eye pressure (normally 10–20 mmHg 1.33–2.66 kPa above atmospheric pressure, but much increased in glaucoma). (2) Intracranial pressure monitoring (19), as well as for clinical assessment of prosthetic socket fit (20) and pressure distribution in artificial joints (21). Intracranial pressure monitoring is an implant used in the treatment of patients with trauma of the head as well as in neurological patients.

Although pressure is the field where capacitive sensors have been applied more extensively, there are also other applications under development in the medical field. Accelerometers, for example, are used for measuring inclination

of body segments and activity of daily living, with application in patient rehabilitation (22), but also register the kind of movements that occur in healthy persons during normal standing (23,24). Physical activity as well as energy expenditure as these can be followed by accelerometers proves to be useful information for personal status monitoring. An accelerometer design includes the fabrication of a proof mass that is displaced in proportion with acceleration. The use of capacitance to measure that displacement significantly improves sensitivity.

Recently, ultrasound imaging technology has also exploited the advantages of capacitive sensors for both transmission and detection purposes (25). Such capacitive devices can be batch fabricated to form a transducer array with array elements that can be as small as 50 μm diameter. Ultrasound devices are made of a thin flexible electrode facing a rigid electrode. For transmission purposes, the membranes are driven into vibration by the electrostatic force exerted between the two electrodes. For reception, the membrane vibration is excited by an impinging acoustic wave that is converted by the capacitive device to electrical signal. This as well as other efforts (26,27) are driven from the need to obtain in the future high resolution images within the body using three-dimensional 3D echographic probes.

Miniature capacitive transducers, known in low frequency applications as condenser microphones, are used in hearing aids and have been reported from different research groups (28,29). In their work, Rombach et al. developed a low noise capacitive microphone with higher sensitivity and broader bandwidth than those used in traditional hearing aids. This device consists of two backplates with an intermediate membrane made of a low stress silicon-rich nitride and B^+ polysilicon multilayer. Pedersen et al., on the other hand, presented an integrated capacitive microphone based on polyimide technology and realized by postprocessing on a CMOS wafer at low processing temperatures.

Capacitive sensors have also been used as humidity sensors for the diagnosis of pulmonary diseases. In this device, a chemically absorbing layer (usually a polymer) is placed between the parallel electrodes of a capacitor. Then, humidity is detected as a change in capacitance because of the dielectric constant change as water molecules are absorbed in the polymer. In a similar configuration, hydrogel has been used between the electrodes of a capacitive sensor to measure body analytes from the capacitance variation occurring due to the swelling of the polymer (30).

FABRICATION TECHNOLOGIES FOR CAPACITIVE SENSORS

Silicon is widely accepted as the material of choice for microsensor fabrication. Known for its good mechanical properties, high mechanical strength, and light weight it's an ideal material for physical sensors (31). More importantly, the existing know-how from IC manufacturing made the use of silicon technology for transducers quite straightforward during the last decades.

This section describes the main silicon technologies that are used for the fabrication of capacitive devices. Most of

the capacitive devices used in medical technology, namely, pressure sensors, accelerometers, and ultrasound sensors, have been developed using two major technology platforms.

Bulk Micromachining Technologies

Bulk micromachining has historically been developed first. It consists of engineering a silicon wafer by a series of lithographic processes followed by wet or dry etching, in order to form thin membranes or other free standing structures that can move upon an external stimulation. In bulk micromachining, the micromechanical silicon structures are fabricated by selectively removing whole sections, or in some cases, all but a small part of the silicon wafer. Thus the structures fabricated in this way are made of single-crystal silicon and have excellent mechanical properties. In bulk micromachining, processing may take place in either the front or the back side of the silicon wafer.

Wet etching of silicon is based on a chemical reaction of silicon with a base solution (KOH) in order to remove silicon material and form the intended 3D structure. Dry etching is a physicochemical process that was initially developed for the etching of thin films. During the last decade, however, this technique has also been used for the removal of thick Si material (32).

The above techniques combined with others usually used in IC manufacturing, like ion implantation, thermal processing, and thin-film (metal or silicon insulator) deposition, constitute the backbones of capacitive sensor fabrication. A detailed description of these processes is beyond the scope of this article and can be found elsewhere (33).

Apart from these processing technologies it is necessary in many applications to use other specific processes. For example, in pressure sensor fabrication it is always desirable to have a reference pressure enclosed in the sensor body. This requires a reliable technology for sealing a cavity with known pressure. For that reason, bulk micromachining techniques are combined with technologies usually referred to as bonding technologies. Two are the most established technologies in this area: anodic bonding and fusion bonding, in chronological order of their discovery and application. Anodic bonding is achieved between silicon and a glass substrate at medium temperature ($\sim 400^\circ\text{C}$) under the application of a direct current (dc) voltage across the two substrates (34). Prior to contact of the two substrates, their surfaces are adequately cleaned to remove any particle that can inhibit their good contact. Bulk micromachining combined with anodic bonding has been successfully used for the realization of medical capacitive pressure sensors by a couple of research groups (35,36). In the process developed at the University of Michigan, boron etch-stop techniques and silicon-glass anodic bonding is used to fabricate a capacitive pressure sensor. In this process, KOH is used to initially form a recess in the surface of a silicon wafer, followed by a deep boron diffusion to define the rim of the transducer, and a shallow diffusion defining the eventual thickness of the diaphragm. The completed silicon wafer is finally electrostatically bonded to a glass wafer. The silicon wafer is then dissolved in EDP etchant, leaving only the silicon

transducer islands bonded to the glass. In this way, a thin silicon membrane structure over a sealed cavity is fabricated that exhibits high pressure sensitivity adequate for use in blood pressure monitoring.

A more recently discovered technique that has been applied for sealing of a pressure reference cavity is fusion bonding. This technique does not require the application of a voltage across the bonded substrate. Instead, it includes a high temperature heat treatment. So after a thorough wafer cleaning and drying process of two silicon wafers that renders their surface hydrophilic, they are brought into contact at room temperature. The two wafers are initially drawn together at room temperature by van der Waals forces developed between the hydrogen atoms of water molecules covering their surfaces. This initial attraction is commonly known as prebonding. Prebonding follows a high temperature heat treatment that during which a hydrogen atom is removed transforming the hydrogen bonds to covalent bonds between oxygen atoms thus increasing the bonding strength (37). The temperature necessary to achieve high strength bonding is $> 800^\circ\text{C}$. A successful example of this technology together with bulk micromachining is applied for the realization of a capacitive-type pressure sensor for blood pressure monitoring developed by Goustouridis et al. (13). This simple process results in robust capacitive sensors with low parasitics (Fig. 2). It involves two silicon wafers that are silicon fusion bonded to form the final 3D structure, and a thick oxide in between in which a sealed cavity is formed. The sensor diaphragm is formed by creating a heavily boron-doped region in the cavity bottom. After bonding, the wafer stack is first mechanically ground and then etched in EDP etchant to leave the sensor diaphragm on top of the cavity thus creating the pressure sensor. The sealed cavities are then metalized and packaged. Figure 3 depicts the complete pressure sensing element as it appears after the metallization step.

Hydrophobic bonding is also applied when we need to bond two bare silicon surfaces without a SiO_2 layer on the surface. This technique requires an HF final step to remove any oxide layer from the surface. In hydrophobic bonding, the water molecules necessary to complete the prebonding step are substituted from the HF molecules, while the rest of the bonding process is similar to the hydrophilic one.

More recently, plasma activated bonding (38) or other low temperature bonding ($< 400^\circ\text{C}$) using spin on glass (SOG) (39) have been applied. These techniques are more appropriate for wafer level packaging and have to be more developed in the future for use in sensor fabrication.

Recently, wafer bonding has also been used for demonstration of capacitive ultrasound devices (25), as well as of capacitive accelerometers (40).

Surface Micromachining and SOI Technologies

Surface micromachining technologies have been developed with the primary goal of cointegrating the electronic and mechanical parts on the same silicon chip. Since the active and passive layers of a surface micromachined structure are realized using the same conductive and insulating thin-film layers as in IC manufacturing, it is possible by appropriately designing the mask sequence to realize both

Figure 2. Fabrication of capacitive sensors using bulk micromachining and silicon fusion bonding. Two wafers are used for this purpose. (a) Each wafer is processed independently before the bonding; (b) after the bonding process the two wafers are permanently stacked together; (c) selective wet etching releases the boron doped silicon diaphragms; (d) metallization is performed for electrical connects of the membrane and the substrate.

components in parallel by adding a few mask levels after the completion of the electronic circuit. This particular feature is behind the drive for the development of this technology.

In the case of surface micromachining, all of the processing takes place only on the surface of the front side of the silicon wafer. The micromechanical structures fabricated in this manner are made out of polycrystalline silicon deposited by low pressure chemical vapor deposition (LPCVD) techniques over a sacrificial layer. The sacrificial layer is a deposited oxide, usually phosphorsilicate glass (PSG). This layer is subsequently removed by an HF solution through narrow access channels to release the poly-

Figure 3. This figure illustrates the final capacitive pressure sensor structure (not to scale).

silicon structure (Fig. 4). Sealing of the channels is necessary and it is realized by a deposition step. With surface micromachining, it is possible to fabricate far smaller microelectromechanical devices than with bulk micromachining. Depositing processes allow for very good control over the dimensions of the deposited materials.

Surface micromachining is a very important technology with a demonstrated potential. Problems related to stiction of membrane structures on the substrate during aqueous removal of sacrificial layers have been resolved by the application of other etching and drying techniques like gas-phase etching or freeze-drying techniques using cyclohexane (41). A typical process sequence developed (42) for capacitive ultrasound transducers is shown in Fig. 5.

There is continuing discussion on the advantages–disadvantages of the cointegration of sensors with electronics. Although it is considered that surface micromachining can result in a higher packing density, and consequently smaller and cheaper components, it appears that yield issues still need to be overcome until this technology can be definitively adopted in preference to hybrid fabrication technologies.

A recent variation of the two technologies employs silicon-on-insulator (SOI) technology with some unique features. The SOI technology offers the possibility of using crystalline silicon as the active part of a capacitive-type structure with more predictable mechanical behavior than the polysilicon film used in surface micromachining. In fact, the internal stresses (either compressive or tensile) developed during the growth of the polysilicon film, which evolved during subsequent thermal treatment because of change of the grain size, is a source of potential uncertainties for the behavior of these films.

Silicon-on-insulator is a mature technology and nowadays can offer crystalline silicon structures of varying thicknesses over a variety of SiO₂ buried layer thicknesses. This has become possible after the discovery of wafer bonding technology, which enables the development of back-etch-silicon-on-insulator (BESOI) structures.

Thin as well as thick silicon structures allow for capacitive pressure sensors development, ultrasound capacitive sensors using rather thin membranes of some micron thickness as well as capacitive-type accelerometers, where

Figure 4. Typical surface micro-machining process. (a) Deposition of the sacrificial layer (silicon oxide) and etch channels formation, (b) deposition of silicon nitride ring, (c) deposition of polysilicon film, (d) removal of the sacrificial layer by HF in wet or vapor form, (e) sealing of the device with deposited silicon oxide.

Si structures exceed some hundreds of micrometers. The introduction of deep reactive ion etching (DRIE) in silicon processing especially during the last few years, has enabled the vertical anisotropic etching of Si at the rate of several microns per minute, and the fabrication of thick proof masses on BESOI or glass structures for capacitive accelerometers (43). This accelerometer uses a silicon proof mass of 0.5 mg with 120 μm thickness formed by DRIE and measures in plane (x or y axis) acceleration. It uses a sense gap of only 2 μm between sense fingers and the electrodes (Fig. 6). As the proof mask moves under acceleration, the distance between sense fingers and fixed electrodes change, which consequently modifies the capacitance.

Finally, a different but similar approach results in capacitive-like pressure sensors based on a field effect transistor (44). In this case, the usual dielectric of a MOS-FET is replaced by a vacuum cavity. The external pressure variations deflect the gate electrode, and consequently influence the capacitive coupling of the flexible membrane (gate) with the channel thus modifying the current flow in the device. Although these devices present an attractive design, there have not seen any new developments.

OPERATION ISSUES OF CAPACITIVE SENSORS

As introduced in the first paragraph a capacitive sensor is an equivalent parallel plate capacitor with clamped edges where the diaphragm deforms during the application of a differential pressure across the two sides in the case of capacitive pressure devices.

In the normal operation mode of a capacitive pressure sensor, the diaphragm does not contact the substrate electrode. The capacitance response of a typical pressure sensor is shown in Fig. 7. The output capacitance is nonlinear because of its inverse relationship with the electrode gap d_0-w (eq. 2), which is a function of pressure, P . This non-linearity becomes more significant for large membrane

deflections. At the point when the sensor diaphragm touches the cavity bottom (Fig. 7), the behavior of the sensor changes and enters “touch mode” operation (45). In this operating region, linearity increases and the sensor capacitance is dominated by the area touching the cavity bottom, since the gap there is replaced from the very thin and high dielectric constant SiO₂ layer of the bottom electrode.

Sensitivity of the Capacitive Sensor

Because of the nonlinearity of the response, the sensitivity of a capacitive sensor is not constant. For example, the sensitivity of the capacitive pressure sensor for blood pressure monitoring (defined as $1/C_0(\Delta C/\Delta P)$ with the response shown in Fig. 7 is 1.5 fF/mmHg for the low pressure range and increases to > 18 fF/mmHg for the upper part of the measurement range (> 200 mmHg, 26.66 kPa). In the touch mode operation region, (> 300 mmHg, 39.99 kPa) the sensor has a nearly linear response with a sensitivity of 12 fF/mmHg.

Temperature variation, although not a critical issue for medical application (because of the small variation of the body temperature), can affect the accuracy of the measurements. The temperature influence on the capacitive sensor response is due to either the mismatch of thermal expansion of dissimilar materials used in the fabrication process (usually Si and SiO₂), or to gas expansion in case gas is trapped in a sealed cavity of the sensor. It can of course be due to both of the above reasons. In the case of a sealed cavity, the temperature influence, because of the expansion of the gas trapped inside the cavity, can be eliminated if the cavity is sealed in vacuum. On the other hand, the effect of the different thermal expansions of the materials used is always a problem that requires appropriate design in order to reduce or even eliminate the effect. In the cases of capacitive devices fabricated with surface micromachining,

Figure 5. Surface micromachining process sequence for the fabrication of capacitive ultrasonic transducers as taken from X. Jin et al. (42).

Figure 6. Comb-shaped accelerometer structure fabricated using a combination of processes like bonding silicon with glass substrate and Deep Reactive Ion Etching (43).

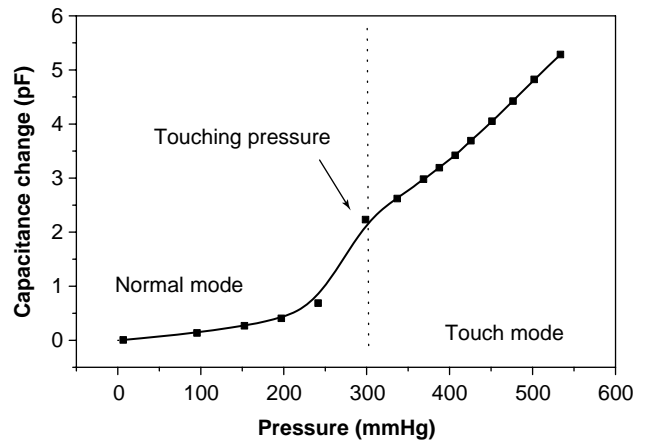

Figure 7. Typical response of a capacitive pressure sensor with 325 μm OD circular diaphragm. The diaphragm touches the cavity bottom at 300 mmHg ($\sim 40\text{ kPa}$). A pressure sensor must be designed to operate either for lower values than 300 mmHg or for higher pressure values. Otherwise an hysteresis phenomenon can be observed.

or by using anodic bonding of silicon with a glass substrate, the influence of temperature becomes more complicated.

Figure 8 shows the influence of temperature on the response of a capacitive pressure sensor, not sealed in a vacuum. The variation of the distance between the curves with temperature represents the temperature coefficient of the pressure sensitivity (TCS) while the slope of the lower curve is the temperature coefficient of zero pressure offset (TCO). The TCS is defined as $\Delta S/S\Delta T$, where S is the pressure sensitivity defined as $\Delta C/C_0\Delta P$ and TCO is defined as $\Delta C/C_0\Delta T$.

This simple configuration of a parallel plate capacitor is used mainly in pressure sensors and ultrasound imaging devices. Accelerometers are usually designed with comb-shaped electrodes that result in increased linearity and sensitivity (40,43).

Figure 8. Temperature variation of a capacitive pressure sensor in the range 0–400 mmHg ($\sim 53.3\text{ kPa}$). The effect is due mainly to trapped gas expansion inside the cavity.

CAPACITIVE SENSOR ELECTRONIC INTERFACES

Although capacitive sensors offer advantages with respect to high sensitivity and low power operation, they also present difficulties in the design of electronic interfaces to convert capacitance changes into electrical signals. Parasitic capacitances often dominate system performance by reducing sensitivity and increasing nonlinearity (46). Therefore, it becomes absolutely essential for sensor systems incorporating capacitive sensors to either integrate the MEMS component with the electronic interface or place the two chips at close proximity to each other to reduce parasitics. At the same time, it is important that the electronic interface is designed to suppress the remaining parasitic capacitances and provide for a large zero capacitance range. A good starting point for the study of capacitance measurement circuits may be found in Ref. 47, where a number of basic circuits are discussed.

Depending on the technological steps used to fabricate the sensor, several parasitic capacitances $C_{p1,2}$ and conductances G_p may be present in the device and increase in importance as devices get smaller and the sensing capacitance C_s gets in the pF range. These parasitic effects may originate from various sources depending on the fabrication process used (i.e., stray capacitances of metal lines and connecting pads in parallel with the sensing capacitance or leakage resistors). Further variations may also be observed, due to technological reasons, between batches of the same sensor. In Fig. 9, a simple electrical model of a typical capacitive sensor, including parasitic effects, is shown. The spread in sensor characteristics (e.g., zero capacitance, sensitivity) resulting from these effects puts a great strain in the design of electronic interfaces for capacitive sensors. For this reason, most of the capacitive interfaces to date have been designed by taking into consideration the particular sensor and application that they are going to be used for. The design is a trade-off between power consumption, interface accuracy, and resolution, or even die size in some applications in the medical field.

A number of architectures have been proposed to date to convert capacitive changes into electrical signal. Some are built around a relaxation oscillator (46,48), others use switch capacitor techniques to convert capacitance changes

Figure 9. Simple electrical model of a capacitive sensor. Parasitic capacitances is designated by $C_{p1,2}$, conductances by G_p and the sensing capacitance by C_s .

into voltage, and others interface the sensor directly into a sigma-delta modulator. A few attempts to develop a generic interface have also been reported (49,50). However, the power consumed is too high for remote sensing applications.

Van Der Goes and Meijer (49) presented a universal transducer interface for the read out of capacitors, platinum resistors, thermistors, resistive bridges, and potentiometers. The circuit uses the three signal technique in which the sensor signal E_x , a reference signal E_{ref} , and the offset E_{off} of the whole interface are measured in an identical way to achieve continuous autocalibration of offset and gain. The two port measurement technique is used to eliminate sensor parasitic capacitance. In this technique, a testing voltage, V , is forced on one capacitor electrode while current I is sensed on the other (51). The current I then depends only on the applied voltage and sensing capacitance. However, the technique is not energy efficient, since it requires four measurement cycles and three external voltage sources to determine the sensor capacitance.

Yazdi et al. (50) also developed a standardized switch capacitor interface for capacitive sensors, as shown in Fig. 10. This interface is capable of interfacing through a standard bus with a microcontroller that collects sensor data through the interface, calibrates data, and either stores or transmits it wirelessly or through a serial port. The readout circuit utilizes a low noise front-end charge integrator to read out the difference between the sensor capacitance and a reference capacitor. An input multiplexer allows for interfacing with up to six capacitive sensors. Finally, the chip can be digitally programmed to operate with one of three external or internal reference laser trimmable capacitors.

Bracke et al. (52) reports on a low power generic switched capacitor interface for capacitive sensors. The circuit uses a special clocking scheme, in which the analog sensor circuit block is clocked at a low 8 kHz frequency, while the sigma-delta modulator is clocked at 128 kHz. The technique ultimately reduces power consumption to 90 μ W on the ON-state.

CAPACITIVE ELECTRONIC INTERFACES FOR IMPLANTABLE APPLICATIONS

In medical applications, where the diagnostic device is to be implanted inside the human body, only limited power is available for the electronic circuits and sensor. In such cases, power can only be found via a battery implanted together with the sensing system or through passive telemetry. In passive telemetry, energy may be harvested from a remote electromagnetic field transmitted outside the body. The same field may also be used to receive control data and transmit sensor data to a data logger. In both cases, minimizing power consumption is essential.

A simple low power interface for biomedical applications could be realized by using a simple relaxation oscillator (46,48). A capacitance-to-frequency modulated output was first proposed by Hanneborg et al. (46). This circuit delivers a digital pulse trail with frequency dependent on the sensor

Figure 10. Circuit blocks of the capacitive electronic interface as described by W. Bracke et al. (50).

capacitance. The circuit consists of two current sources: a switch and a Schmitt trigger. The unknown capacitance is periodically charged and discharged by flipping the switch between current I_+ and I_- (Fig. 11).

An implementation of this type of capacitance-to-frequency converter is presented in Fig. 12. The circuit converts capacitance at its input into a frequency signal that can be readily fed to a digital microcontroller for processing. Either a capacitive sensor or a reference may be

Figure 11. Block diagram of the capacitive to frequency converter proposed by Hanneborg et al. (46). The circuit consists of two current sources, a switch and a Schmitt trigger.

switched in, and the frequency delivered at the circuit output is dependant on the input capacitance according to

$$f = \frac{I_0}{2C_x V_h} \tag{3}$$

where I_0 is the current by which the sensor capacitance C_x is charged or discharged, and V_h is the hysteresis of the Schmitt trigger. The parameter V_c is a control signal that allows for switching between the unknown sensor capacitance C_x and a reference capacitor C_{ref} . The output frequency when the reference is selected is independent of pressure, thus compensation of temperature and long-term drifts are possible by taking the ratio of the reference frequency and sensor frequency, F_{ref}/F_{sens} .

The response of a pressure measuring system based on this circuit realized in $1.2\ \mu\text{m}$ of CMOS technology and a capacitive pressure sensor (53) is shown in Fig. 13. It operates at 4 V and draws $20\ \mu\text{A}$ of average current. The system exhibits a sensitivity of 36 Hz/mmHg and is able to resolve pressure changes of 5 mmHg (0.66 kPa). A photograph of this system is shown in Fig. 14.

In medical science, however, there is often the need for long-term monitoring of vital life parameters. A good example is abdominal aortic aneurysm (AAA), which is a ballooning of the abdominal aorta. Patients who suffer from this condition need to undergo a procedure during which a stent graft is inserted. After the operation, however, it is possible that the aneurysmal sac is not completely isolated, leading to recurrent pressurization of the sac, a complication that, if left undetected, may lead to rupture of the sac and patient death. Long-term, postoperation monitoring of the patients is therefore necessary.

Early efforts for systems for the monitoring of blood pressure (54) used miniature active transmitters to transfer measured data and were battery powered, which limited

Figure 12. Schematic of Schmitt-trigger based oscillator used as a capacitive interface.

Figure 13. Frequency response of a pressure measuring system consisting of the simple circuit of Fig. 12 and a capacitive pressure sensor in the range 0–300 mmHg (~40 kPa).

Figure 14. A photograph of a hybrid pressure measuring system consisting of a capacitive sensor and associated signal conditioning electronic circuit.

their lifetime. An alternative approach to power these modules is through induction coupling, while the same radio frequency (RF) field can be used to transfer data out of the implanted module (55). The implanted circuit should be virtually immune to supply fluctuations arising from random misalignment of the implanted and the external coil. A new circuit was developed based on the previous architecture, but in which each circuit block was redesigned.

The block diagram of the passive telemetry system is depicted in Fig. 15. It consists of an external control unit (the base unit) and an implantable transponder. Wireless communication can then be established between the two units, based on an absorption modulation mechanism. The transponder receives power and external control data

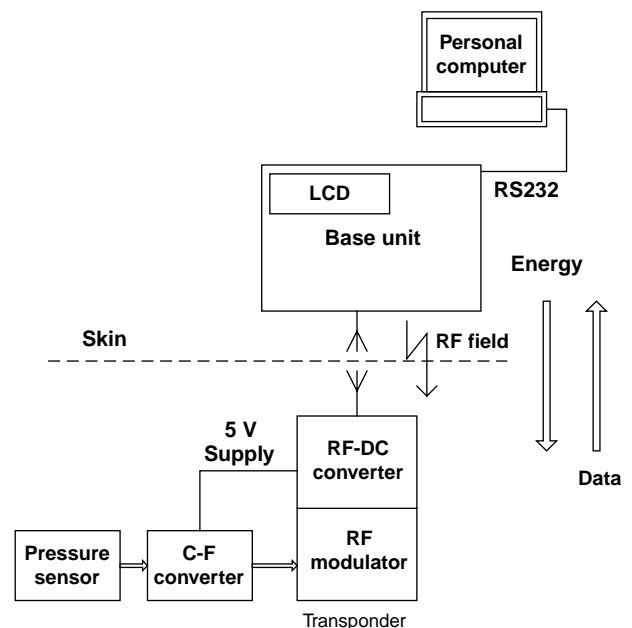

Figure 15. Block diagram of passive telemetry system.

Figure 16. Transponder electronics.

through an RF field, while it can transmit data by modulating the absorption rate. The base unit, on the other hand, demodulates the transmitted data and processes it through a microcontroller to convert the signal into an eight bit unsigned byte array. The resulting byte can then be sent to a PC through a serial output.

The block diagram of the transponder electronics is shown in Fig. 16. The improved capacitance-to-frequency circuit is used to interface a capacitive pressure sensor. The circuit consists of two basic blocks: a bandgap reference voltage generator and an oscillator. In order to achieve independence of the output frequency from the received power, this time the oscillator operates on an internally stabilized voltage generated from a bandgap reference. Voltage regulation is a critical part of telemetric systems as the induced power, and thus the voltage output, of the RF/dc converter in the transponder can greatly fluctuate in an actual implanted system because the relative position changes of the two antennas. In addition, to further immune the system from supply fluctuations a current mode comparator is used in the oscillator.

The bandgap reference voltage circuit is capable of operating at a low power supply as it operates on an internally regulated voltage VREG (56). This same node is also used for the supply of the oscillator circuit after the contributions of the extra branches of the oscillator are accounted for.

The oscillator itself is designed around a current mode comparator that results in an output frequency independent of power supply fluctuations and with small temperature drift. Triggering levels of this oscillator are defined by two currents: I_h and I_1 . The period of the output pulse can then be shown to be equal to

$$T = \frac{2C_x}{I_0} (V_{\text{bias}} - V_{TN})(\sqrt{n} - 1) \quad (4)$$

where n stands for the ratio of I_h to I_1 , and V_t is the threshold voltage. By taking the inverse of eq. 4 and substituting for I_0 , we obtain

$$f = \frac{k \frac{W_0}{L_0} (V_{\text{bias}} - V_{TN})}{2C_x(\sqrt{n} - 1)} \quad (5)$$

Equation 5 implies that the output frequency is independent of the supply voltage and is dependent on temperature through the mobility term in k and the threshold voltage V_t . Note also that the bias voltage V_{bias} is chosen to be equal to the bandgap reference voltage produced from the previous stage, and is thus considered independent of voltage and temperature variations.

The C/F converter was designed and fabricated in $0.8 \mu\text{m}$ CMOS technology. A hybrid pressure measuring system composed of a capacitive pressure sensor (16) and the C/F chip. The system remains operational for a supply voltage down to 2.7 V and exhibiting high immunity to voltage variations from 3.7 to 5.5V (Fig. 17). Simulated pressure pulses as those present in the aorta were measured using passive telemetry (Fig. 18).

CONCLUSIONS

Capacitive microsensors are in progressively increasing use in medical applications because of their advantages, such as small size, high sensitivity, and low power consumption. Silicon is the material of choice for these devices, which are finding applications for measuring pressure and

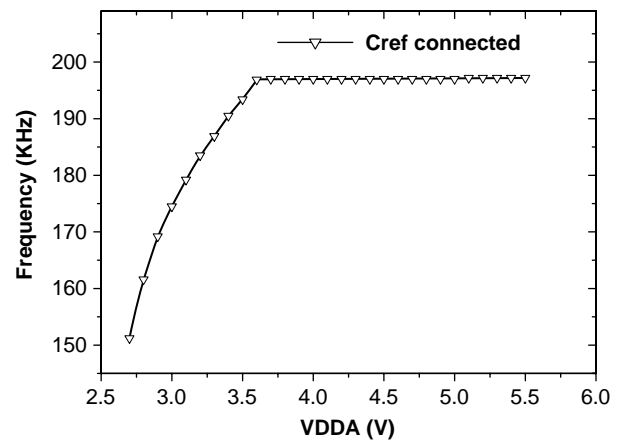

Figure 17. Pressure measuring system frequency output.

acceleration, but also in ultrasound imaging and microphones and for monitoring body analytes. Actually, although most of the existing devices are not integrated together with signal conditioning electronic circuits on the same chip, in the future it is expected that there will be an increasing integration scheme driven by the need of higher level miniaturization. Because of their low power consumption advantage, capacitive microsensors are of interest as implantable monitoring devices. An attractive application appears to be a miniaturized telemetry system that combines techniques for wireless power and data transfer to a capacitive sensor integrated with signal conditioning electronics.

CARDIAC OUTPUT, FICK TECHNIQUE FOR

STEVEN C. FADDY
University of Sydney
Darlinghurst, Australia

INTRODUCTION

Cardiac output (CO) is an important measurement in many medical investigations. It is the amount of blood pumped by the ventricles of the heart and can be defined as the product of stroke volume (SV) and heart rate (HR), where stroke volume is the amount of blood expelled by the ventricle with each contraction and the HR is the number of contractions per minute:

$$CO = SV \times HR$$

Cardiac output gives an indication of ventricular function and is also used in the calculation of a number of flow-dependent parameters, such as cardiac index, systemic vascular resistance, pulmonary vascular resistance, valve areas, and intracardiac shunt ratios.

The Fick technique is the gold standard in CO measurement. It relies on direct measurement of oxygen consumption and expenditure to derive the rate of blood flow throughout the individual.

HISTORY

In 1870, the German physiologist, Adolf Fick (1829–1901), described a novel method of determining cardiac output based on diffusion of respiratory gases in the lungs. This came after almost 30 years of work by Fick and numerous others, who reasoned that diffusion was one of the most essential events within the living organism. In 1855, Fick had published his findings relating to diffusion of gas across a fluid membrane. These became known as Fick's law of diffusion and stated that the rate of diffusion of a gas is proportional to the partial pressures of the gas on either side of the membrane, the area across which diffusion is taking place and the distance over which diffusion must take place. As an aside, Fick also invented contact lenses in 1887.

The 1870 publication by Adolf Fick stated: "It is astonishing that no one has arrived at the following obvious method by which [the amount of blood ejected by the ventricle of the heart with each systole] may be determined directly, at least in animals. One measures how much oxygen an animal absorbs from the air in a given time, and how much carbon dioxide it gives off. During the experiment one obtains a sample of arterial and venous blood; in both the oxygen and carbon dioxide content are measured. The

difference in oxygen content tells how much oxygen each cubic centimeter of blood takes up in its passage through the lungs. As one knows the total quantity of oxygen absorbed in a given time one can calculate how many cubic centimeters of blood passed through the lungs in this time. Or if one divides by the number of heart beats during this time one can calculate how many cubic centimeters of blood are ejected with each beat of heart. The corresponding calculation with the quantities of carbon dioxide gives a determination of the same value, which controls the first (1).”

In simplest terms, cardiac output can be calculated as a ratio of the amount of oxygen consumed through breathing and the rate in which oxygen is taken up by the tissues.

Cardiac Output

$$= \text{Oxygen consumption} / \text{Arteriovenous oxygen difference}$$

It was not until the 1930s that quantitative measurement of the components allowed confirmation of the Fick equation as a means of calculating cardiac output.

PHYSIOLOGY OF THE FICK TECHNIQUE

Oxygen Consumption (VO_2)

The first step in calculating CO by the Fick technique is to determine the amount of oxygen consumed by the individual over a period of time. This is best done in the resting state so that there is constant oxygen consumption over the collection period. The traditional method is collection of expired gases in a Douglas bag over a period of ~ 3 min. Then, from the volume of expired gas, the oxygen content of the expired gas and the oxygen content of the inspired room air, it is possible to calculate the amount of oxygen taken up by the individual.

Subtracting the oxygen content of expired gas from that of the inspired room air ($\%v/v$ or $\text{mL of O}_2 \cdot 100 \text{ mL}^{-1}$ of the gas) gives the oxygen difference between the inspired and expired gases, expressed in $\text{mL of O}_2 \cdot 100 \text{ mL}^{-1}$ of expired gas. Applying a factor of 10 gives this figure as milliliters of O_2 per liter of expired gas, which are the units used later in the calculation. Dividing the total volume of expired gas by the collection time gives the minute ventilatory rate, expressed in liters per minute $\text{L} \cdot \text{min}^{-1}$.

The product of the O_2 difference ($\text{mL} \cdot \text{L}^{-1}$) and the minute volume ($\text{L} \cdot \text{min}^{-1}$) is the oxygen consumption (VO_2) expressed in milliliters of oxygen absorbed per minute.

$$\text{VO}_2 = (\text{O}_{2\text{Room air}} - \text{O}_{2\text{expired}}) \times (\text{volume}/\text{time})$$

Example: Inspired $\text{O}_2 = 21.0 \text{ mL} \cdot 100 \text{ mL}^{-1}$ room air
 Expired $\text{O}_2 = 16.7 \text{ mL} \cdot 100 \text{ mL}^{-1}$ expired gas
 O_2 difference = $21.0 - 16.7 = 4.3 \text{ mL} \cdot 100 \text{ mL}^{-1}$
 Total volume expired = 26.1 L
 Collection time = 3 min
 Minute volume = $26.1 \text{ L} \cdot 3 \text{ min}^{-1} = 8.7 \text{ L} \cdot \text{min}^{-1}$
 Therefore,
 O_2 consumption = $(4.3 \times 10) \text{ mL} \cdot \text{L}^{-1} \times$
 $8.7 \text{ L} \cdot \text{min}^{-1} = 374 \text{ mL} \cdot \text{min}^{-1}$

An alternative to the Douglas bag method is the use of a metabolic rate meter with a hood or facemask, a variable-speed blower and a servocontrol loop with an oxygen sensor. This method employs essentially the same principle as the Douglas bag method, but gives a real-time measurement of VO_2 . The variable-speed blower maintains a flow of room air through the hood or facemask past the patient into a polarographic oxygen sensor (gold and silver-silver chloride electrode), varying the flow in order to keep the oxygen concentration at the measuring electrode constant. By keeping the oxygen concentration at the measuring electrode constant, the only variable is the flow rate through the system. Under steady-state conditions, this is the only variable determining the oxygen consumption (VO_2).

Although this method provides a real-time measurement of VO_2 , thus excluding the need for collection of a Douglas bag, it is still rather time and labor intensive. In addition, it has been suggested that it is difficult to obtain reproducible results and the method gives consistently lower results than the Douglas bag technique.

Arteriovenous Difference

As with oxygen consumption, measurement of oxygen uptake by the body involves measuring blood oxygen content before and after entering the lungs. The arteriovenous oxygen difference (AV_{diff}) is the difference between the content of oxygen (ctO_2) in the oxygenated arterial blood leaving the lungs and the deoxygenated venous blood returning to the lungs (mL O_2 per 100 mL of blood). The AV_{diff} represents the volume of oxygen delivered to meet the body's metabolic demands. Again, this figure is multiplied by 10 to give the AV_{diff} in units of mL O_2 per liter of blood.

$$\text{AV}_{\text{diff}} = \text{ctO}_{2(\text{Arterial})} - \text{ctO}_{2(\text{Venous})}$$

Example: Arterial O_2 content = $19.5 \text{ mL} \cdot \text{dL}^{-1}$ blood
 Venous O_2 content = $13.2 \text{ mL} \cdot \text{dL}^{-1}$ blood
 $\text{AV}_{\text{diff}} = 19.5 - 13.2 = 6.3 \text{ mL} \cdot \text{dL}^{-1} = 63 \text{ mL} \cdot \text{L}^{-1}$

Typically, a sample from the main pulmonary artery is used for venous blood and a sample from the left ventricle or aorta is used for arterial blood oxygen content measurements.

Cardiac Output

The rate at which oxygen is taken up by the lungs and the rate at which it is taken up by the body is now known from the above calculations. The ratio of these two figures gives the cardiac output. The examples above show that the lungs take up 374 mL of oxygen each minute and that the blood takes up 63 mL of oxygen for each liter that passes through the lungs. How many lots of 63 mL (1 L aliquots of blood) must pass through the lungs to take up 374 mL of oxygen each minute? The answer is 5.9 L of blood must pass through the lungs each minute in order to absorb this amount of inspired oxygen.

Example: $\text{VO}_2 = 374 \text{ mL} \cdot \text{min}^{-1}$
 $\text{AV}_{\text{diff}} = 63 \text{ mL} \cdot \text{L}^{-1}$
 $\text{CO} = 374/63 = 5.9 \text{ L} \cdot \text{min}^{-1}$

PRACTICAL CONSIDERATIONS FOR USING THE FICK TECHNIQUE

Oxygen Consumption

The measured volume of a gas is affected in part by the ambient temperature and atmospheric pressure in which it is collected. Obviously, these will vary from day to day, leading to a potential source of variation in the calculation of oxygen consumption, and ultimately, cardiac output. The combined gas law (a combination of Boyle's and Charles' law) describes the relationship of pressure, temperature, and volume in a gas. This law can be used to correct measured gas volumes to standard temperature and pressure (STP). This means that the measured volume of gas is standardised to 273 K and 760 mmHg (101.32 kPa).

As well as correcting for variations in atmospheric pressure, it is also necessary to correct for water vapor pressure. Dalton's law tells us that the pressure of a gas mixture is equal to the partial pressures of all of the components of the mixture. Water vapor is present in the atmosphere and in exhaled gas and its partial pressure contributes to the total atmospheric pressure. Water vapor exerts a constant pressure at a given temperature, regardless of the atmospheric pressure. Water vapor pressure is 47 mmHg (6.26 kPa) at normal body temperature and 17.5 mmHg (2.33 kPa) 20 °C. Before correcting for STP it is necessary to subtract the water vapor pressure from the total atmospheric pressure to obtain the dry gas pressure at the ambient temperature. This is known as 'standard temperature and pressure, dry' (STPD), which is used for the correction.

Example : Atmospheric pressure = 762 mmHg (6.26 kPa)
 Ambient temperature = 23 °C
 Water vapor pressure at
 23 °C = 21 mmHg (2.79 kPa)
 Dry gas pressure = 762 – 21 mmHg
 = 741 mmHg (98.79 kPa)
 STPD correction factor for 741 mmHg and
 23 °C = 0.8991 {from standard tables}
 Volume of expired gas = 9.68 L · min⁻¹
 STPD corrected volume = 9.68 × 0.8991
 = 8.7 L · min⁻¹

By standardizing to STPD, we have removed the effect of water vapor pressure, ambient pressure, and temperature on the volume measurement and, hence, potential sources of day to day variation in measurement of the cardiac output.

Arteriovenous Oxygen Difference

Although many current generation analyzers can calculate oxygen content (ctO₂), earlier models did not. It may be necessary to manually calculate oxygen content from the hemoglobin level (Hb) and oxygen saturation of a sample. Hemoglobin is able to carry 1.36 mL of oxygen per gram of hemoglobin. Therefore, by multiplying the hemoglobin

level by 1.36 it is possible to calculate the oxygen carrying capacity of the individual. Simply stated, this is the maximum amount of oxygen that can be carried by 100 mL of the individual's blood and is dependent on the hemoglobin level. Some textbooks have quoted the constant as 1.34 and others add a value of 0.03 to account for oxygen dissolved in plasma, but 1.36 is the generally accepted constant for calculation of oxygen carrying capacity.

$$\text{Oxygen carrying capacity} = \text{Hgb} \times 1.36 \text{ mL} \cdot \text{dL}^{-1}$$

If the total amount of oxygen that the blood is capable of carrying and the saturation of the sample is known, it is possible to calculate the oxygen content of that sample.

$$\text{ctO}_2 = \text{oxygen carrying capacity} \times \% \text{ saturation}$$

The arteriovenous oxygen difference is the difference in oxygen content between arterial and venous blood.

Example : Hb = 14.5 g · dL⁻¹

$$\begin{aligned} \text{Oxygen carrying capacity} &= 14.5 \times 1.36 \\ &= 19.72 \text{ mL} \cdot \text{dL}^{-1} \end{aligned}$$

$$\text{Arterial saturation} = 98.9\%$$

$$\begin{aligned} \text{Arterial oxygen content} &= 19.72 \times 98.9\% \\ &= 19.5 \text{ mL} \cdot \text{dL}^{-1} \end{aligned}$$

$$\text{Venous saturation} = 66.9\%$$

$$\begin{aligned} \text{Venous oxygen content} &= 19.72 \times 66.9\% \\ &= 13.2 \text{ mL} \cdot \text{dL}^{-1} \end{aligned}$$

Therefore,

$$\text{AV}_{\text{diff}} = 19.5 - 13.2 = 6.3 \text{ mL} \cdot \text{dL}^{-1} = 63 \text{ mL} \cdot \text{L}^{-1}$$

In this example, each liter of blood leaving the lungs delivers 63 mL of oxygen to the tissues.

Figure 1 shows a complete example of CO measurement using the Fick technique.

ASSUMPTIONS WHEN USING THE FICK TECHNIQUE FOR CARDIAC OUTPUT

Absence of Intracardiac Shunt

The method of calculating cardiac output described above uses the amount of oxygen absorbed by the blood as it travels through the lungs. We then assume that the amount of blood pumped by the right ventricle through the lungs is equal to the amount pumped by the left ventricle through the systemic vessels since the cardiovascular system is a closed system. This assumption does not always hold true and it is sometimes necessary to alter the calculation.

The term shunt describes the condition where a communication exists between the left- and right-sided chambers of the heart. If this condition results in shunting of blood between the venous and arterial circulation, the assumption becomes invalid because some blood is being recirculated through part of the circuit and the two ventricles are pumping unequal volumes. If an intracardiac shunt is known or suspected, it is necessary to collect blood samples at different points than the standard arterial and pulmonary artery sites. Calculation of cardiac output and

A. Standard Temperature and Pressure

Atmospheric pressure = 762 mmHg
 Ambient temperature = 23°C
 Water vapor pressure at 23°C = 21 mmHg
 Dry gas pressure = 762 – 21 mmHg = 741 mmHg
 STPD correction factor for
 741 mmHg and 23°C = **0.8991**

B. Volume measurement

Total volume expired = 28.14 L
 Collection time = 3 min
 Minute volume = 28.14 L ÷ 3 min = **9.68 L·min⁻¹**

C. Oxygen Difference

Inspired O₂ = 21.0 mL / 100 mL⁻¹
 Expired O₂ = 16.7 mL / 100 mL⁻¹
 O₂ difference = 21.0 – 16.7 = **4.3 mL / 100 mL⁻¹**

D. Oxygen Consumption

O₂ consumption = (4.3 × 10) mL·L⁻¹ × 8.7 L·min⁻¹ = **374 mL·min⁻¹**

E. Arteriovenous O₂ Difference

Arterial O₂ content = 19.5 mL·dL⁻¹ blood
 Venous O₂ content = 13.2 mL·dL⁻¹ blood
 AV_{diff} = 19.5 – 13.2 = 6.3 mL·dL⁻¹ = **63 mL·L⁻¹**

F. Cardiac Output

VO₂ = 374 mL·min⁻¹
 AV_{diff} = 63 mL·L⁻¹
 Cardiac output = 374 / 63 = **5.9 L·min⁻¹**

STP corrected volume
 0.8991 × 9.68 L·min⁻¹ = **8.7 L·min⁻¹**

Figure 1. Example of cardiac output measurement using the Fick technique. The arrows indicate how the various parameters discussed in the text are interrelated in the various calculations.

shunt ratios in the presence of an intracardiac shunt is discussed later in this article.

Collection of True Arterial Sample

In a normal heart, it is not easy to gain access to the pulmonary veins to collect an arterial sample as the blood leaves the lungs. As a result, left ventricular or aortic blood is used to measure arterial oxygen content. This method ignores the small amount of venous admixture from bronchial and thebesian venous drainage into the left atrium.

Direct Measurement of Oxygen Consumption

Owing to the time- and labor-intensive methods of measurement of oxygen consumption (VO₂), there is often a

temptation to use an estimate of oxygen consumption rather than direct measurement. Standard formulas and nomograms are used to estimate VO₂ from height, weight, age, and sex. The body surface area (BSA) is calculated from height and weight and expressed in units of square meters (m²).

$$BSA = 0.007184 \times \text{weight}^{0.425} \times \text{height}^{0.725}$$

Age, sex, and basal metabolic rate are used to determine heat production from standard nomograms. Finally, heat production and BSA are used to estimate the oxygen consumption.

$$VO_2 = [BSA \times \text{Heat Production}] / 291.72$$

This method estimates the basal oxygen consumption at rest. It does not make allowances for any pathological

conditions, including those being investigated, that may affect the resting oxygen consumption. Studies comparing measured and estimated VO_2 have shown that estimating VO_2 from the various available formulas can lead to large and unpredictable errors in both VO_2 and cardiac output values (2,3). The practice of estimating VO_2 is strongly discouraged.

DETECTION AND ASSESSMENT OF INTRACARDIAC SHUNTS

Earlier in this article it was seen how the oxygen content of blood entering and leaving the lungs was used to calculate the cardiac output. It was assumed that blood flowing through the lungs is equal to blood flowing through the systemic circulation (since the cardiovascular system is a closed circuit). Several conditions may result in blood being recirculated between the left and right sides of the heart, leading to unequal flow in the pulmonary and systemic circulation. These conditions include atrial septal defects, patent foramen ovale, ventricular septal defects, and patent ductus arteriosus. Patent foramen ovale has been estimated to be present in 27.3% of the population (4), but the presence of a defect does not necessarily result in intracardiac shunting.

A communication between the left- and right-sided chambers of the heart can result in blood being shunted from right to left (venous blood being mixed into the arterial circulation), left to right (arterial blood being mixed into the pulmonary circulation), or as a bidirectional shunt (blood moves back and forth across the communication at different stages of the cardiac cycle). Although the method of calculating cardiac output remains essentially the same, the sites of blood collection are different in cases where intracardiac shunting exists. The following passages describe the methods for calculating systemic and pulmonary flow in the presence of different intracardiac shunts.

Left-to-Right Shunt

In a left-to-right shunt, arterial blood is pushed across the defect into the pulmonary circulation. This will artificially elevate the oxygen saturation and oxygen content in the pulmonary artery. To avoid error in the calculation of systemic cardiac output in the presence of a left-to-right shunt, it is necessary to collect the venous blood sample in the chamber immediately proximal to the shunt. In the case of atrial defects, blood is collected from both the inferior and superior vena cavae. Oxygen content (ctO_2) from these sites is used in the calculation of mixed venous oxygen content (MVO_2). The individual values are weighted and averaged according to the relatively higher flow from the superior vena cava and the absence of coronary sinus blood in the measurements. The generally accepted formula used for estimation of mixed venous oxygen content is

$$\text{MVO}_2 = [3 \times \text{ctO}_{2(\text{SVC})} + \text{ctO}_{2(\text{IVC})}] / 4$$

MVO_2 becomes the venous component of the arteriovenous difference calculation and cardiac output (systemic flow, Q_s) is calculated as described earlier.

It is also possible to calculate pulmonary flow (Q_p) by using the pulmonary artery oxygen content as the venous component (blood entering the lungs) and left ventricular or aortic oxygen content as the arterial component (blood leaving the lungs). The pulmonary flow is equal to the systemic flow returning to the heart plus the volume being recirculated from the left-sided chambers via the shunt. This is reflected in the CO calculation. Because of the recirculated arterial blood, the venous oxygen content in the pulmonary artery will be elevated, leading to a decrease in the arteriovenous difference and, hence, a higher pulmonary flow.

Right-to-Left Shunt

The opposite occurs in a right-to-left shunt. Venous blood is mixed into the arterial circulation leading to a decrease in systemic arterial oxygen saturation. The calculation of systemic flow (Q_s) uses the arterial and venous (pulmonary artery) samples as usual. The calculation of pulmonary flow (Q_p) requires a sample to be taken after the blood leaves the lungs, but proximal to the shunt. In a right-to-left shunt it is necessary to sample blood from the pulmonary veins. In practical terms, this requires the catheter to pass from the right atrium across the defect to the left atrium and then into a pulmonary vein. Pulmonary vein oxygen content becomes the arterial component of the arteriovenous difference and pulmonary flow is calculated as usual.

In the presence of a right-to-left shunt, systemic flow is equal to the pulmonary flow leaving the lungs plus the amount that passes across the shunt directly from the right-sided chambers. Sampling in the left ventricle or aorta distal to the shunt will therefore give a lower arterial oxygen content than would be measured in the pulmonary veins, leading to an decrease in the arteriovenous difference and, hence, a higher systemic flow compared to the pulmonary flow.

A right-to-left shunt should be suspected in any patient who has an arterial oxygen saturation less than 95%. Investigation of these patients should include assessment for the presence of a bidirectional shunt.

Bidirectional Shunt

The presence of a bidirectional shunt complicates the calculation of pulmonary and systemic flow. Neither of the methods described above is suitable since both assume shunting in only one direction. The systemic blood flow (SBF) is calculated using oxygen contents sampled at the sites where blood enters and leaves the systemic circulation (arterial and mixed venous sites, respectively). Pulmonary blood flow (PBF) is calculated using sampling sites where blood enters and leaves the lungs (pulmonary artery and pulmonary vein, respectively). Finally, effective blood flow (EBF) is calculated using samples taken where the blood enters the heart and leaves the lungs (mixed venous and pulmonary vein oxygen contents). The mixed venous oxygen values should be the same as the pulmonary artery sample if no shunts are present. Similarly, the pulmonary vein should be the same as the left ventricular or aortic

$VO_2 = 201 \text{ mL}\cdot\text{min}^{-1}$ $Hb = 13.9 \text{ g}\cdot\text{dL}^{-1}$ Oxygen carrying capacity = $13.9 \times 1.36 = 18.9 \text{ mL}\cdot\text{dL}^{-1}$		
Site	Saturation %	ctO ₂ mL·dL ⁻¹
Arterial		
Pulmonary vein (PV)	94.1	17.8
Radial artery (RArt)	83.0	15.7
Venous		
Superior vena cava (SVC)	58.6	11.1
Inferior vena cava (IVC)	61.0	11.6
Right atrium (RA)	68.8	13.0
Pulmonary artery (PA)	63.4	12.0
Mixed venous (MV) = (3 × SVC + IVC)/4	59.2	11.2
Pressure measurements		
Mean Pulmonary Artery pressure = 43 mmHg (5.73 kPa)		
Mean Left Atrial pressure = 4 mmHg (0.53 kPa)		

$$PBF = \frac{VO_2}{ctO_{2(PV)} - ctO_{2(PA)}} = \frac{201}{17.8 - 12.0} = 3.5 \text{ L}\cdot\text{min}^{-1}$$

$$SBF = \frac{VO_2}{ctO_{2(RArt)} - ctO_{2(MV)}} = \frac{201}{15.7 - 11.2} = 4.5 \text{ L}\cdot\text{min}^{-1}$$

$$EBF = \frac{VO_2}{ctO_{2(PV)} - ctO_{2(MV)}} = \frac{201}{17.8 - 11.2} = 3.0 \text{ L}\cdot\text{min}^{-1}$$

$$\text{Left-to-right shunt} = PBF - EBF = 3.5 - 3.0 = 0.5 \text{ L}\cdot\text{min}^{-1}$$

$$\text{Right-to-left shunt} = SBF - EBF = 4.5 - 3.0 = 1.5 \text{ L}\cdot\text{min}^{-1}$$

$$PVR = \frac{80 \times (PA_m - LA_m)}{Q_p} = \frac{80 \times (43 - 4)}{3.5} = 891 \text{ dyn}\cdot\text{s}\cdot\text{cm}^{-5}$$

sample in the absence of any shunts. Therefore, by sampling at these sites, the pulmonary (and hence, systemic) flow that would normally occur if no shunts were present is being calculated

$$SBF = VO_2/[ctO_{2(Art)} - ctO_{2(MV)}]$$

$$PBF = VO_2/[ctO_{2(Pvein)} - ctO_{2(Part)}]$$

$$EBF = VO_2/[ctO_{2(Pvein)} - ctO_{2(MV)}]$$

Since the systemic flow (SBF), pulmonary flow (PBF), and the flow that would occur in the absence of any shunts (EBF) is known, the size of the shunts can also be calculated

$$\text{Right to left} = SBF - EBF$$

$$\text{Left to right} = PBF - EBF$$

Figure 2. Bidirectional shunt calculation in a 55 year old woman with Eisenmenger’s syndrome secondary to an atrial septal defect (ASD). Note the predominantly right-to-left shunt due to increased pulmonary vascular resistance. These results show little deterioration compared to measurements taken six months earlier [$Q_p = 3.7 \text{ L}\cdot\text{min}^{-1}$, mean PA pressure = 39 mmHg (5.19 kPa) and $PVR = 800 \text{ dyn}\cdot\text{s}\cdot\text{cm}^{-5}$].

Figure 2 shows calculations for a bidirectional shunt based on the principles discussed above. Note the changes in oxygen saturation and content as blood passes the atrial defect. In the left heart, oxygen saturation decreases as blood passes from pulmonary veins to the left ventricle due to mixing of deoxygenated blood being shunted across the defect. Conversely, oxygen saturation in the right heart increases as blood passes from the vena cavae (mixed venous) to pulmonary artery due to oxygenated blood being shunted across the defect from the left atrium.

Pulmonary–Systemic Flow Ratio

An alternative to calculating flow across a defect is to calculate the pulmonary/systemic flow ratio (P/S ratio). This value is a ratio of the pulmonary flow relative to

the systemic flow. Calculation of the P/S ratio does not involve calculation of actual flows, so it is not necessary to collect expired gases to calculate the VO_2 . The P/S ratio is calculated using only the oxygen content (or saturation) from arterial, pulmonary artery, mixed venous, and pulmonary vein samples.

The AV_{diff} for the pulmonary component is calculated by subtracting mixed venous oxygen content from systemic arterial oxygen content. The systemic AV_{diff} is calculated by subtracting the pulmonary artery oxygen content from the pulmonary vein oxygen content. If a pulmonary vein sample is not possible, use an estimate of 98% unless the arterial saturation is higher. Using arterial oxygen content to estimate the pulmonary vein content will assume that there is no right-to-left shunt. The P/S ratio (or P:S ratio) is the calculated by dividing the pulmonary component by the systemic component.

The P/S ratio is the proportion of flow through the pulmonary circulation relative to the systemic circulation. Therefore, a value > 1.0 indicates left-to-right shunting. An arbitrary value of between 1.5 and 2.0 is often used to determine the need for definitive treatment to correct the defect, in order to avoid late sequelae from prolonged pulmonary vascular overload. A P/S flow ratio < 1 indicates right-to-left shunting and may be a sign of irreversible pulmonary vascular disease.

Example: $Hb = 14.5 \text{ g} \cdot \text{dL}^{-1}$

$$\text{Oxygen carrying capacity} = 19.72 \text{ mL} \cdot \text{dL}^{-1}$$

$$\text{Arterial oxygen content} = 98.9\%$$

$$ctO_{2(\text{Art})} = 19.5 \text{ mL} \cdot \text{dL}^{-1}$$

$$\text{Pulmonary artery oxygen content} = 66.9\%$$

$$ctO_{2(\text{PA})} = 13.2 \text{ mL} \cdot \text{dL}^{-1}$$

$$\text{Mixed venous oxygen content} = 63.1\%$$

$$ctO_{2(\text{MV})} = 12.4 \text{ mL} \cdot \text{dL}^{-1}$$

$$\begin{aligned} \text{Pulmonary: } ctO_{2(\text{Art})} - ctO_{2(\text{MV})} &= 19.5 - 12.4 \\ &= 7.1 \text{ mL} \cdot \text{dL}^{-1} \end{aligned}$$

$$\begin{aligned} \text{Systemic: } ctO_{2(\text{PV})} - ctO_{2(\text{PA})} &= 19.5 - 13.2 \\ &= 6.3 \text{ mL} \cdot \text{dL}^{-1} \end{aligned}$$

$$\text{P/S ratio} : 7.1/6.3 = 1.13$$

FLOW-DEPENDENT PARAMETERS

A number of frequently used parameters in cardiovascular medicine are dependent on knowing systemic or pulmonary flow. Calculation of these parameters, and the effect that the cardiac output has on each, is discussed. Table 1 lists expected normal ranges for a number of common flow-dependent parameters.

Cardiac Index

Cardiac output is often corrected for patient's size, based on body surface area (BSA). Cardiac index (CI) is calculated by dividing the cardiac output by the body surface area.

$$CI = CO/BSA \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$$

Table 1. Expected Ranges for Common Flow-Dependent Parameters

Cardiac Output	$= \frac{\text{Oxygen consumption}}{\text{Arteriovenous oxygen difference}}$
V_{O_2}	$= \frac{BSA \times \text{Heat Production}}{291.72}$
M V_{O_2}	$= \frac{3 \times ctO_{2(\text{SVC})} + ctO_{2(\text{IVC})}}{4}$
SBF	$= \frac{VO_2}{ctO_{2(\text{Art})} - ctO_{2(\text{MV})}}$
PBF	$= \frac{VO_2}{ctO_{2(\text{P vein})} - ctO_{2(\text{P art})}}$
EBF	$= \frac{VO_2}{ctO_{2(\text{P vein})} - ctO_{2(\text{MV})}}$
CI	$= \frac{CO}{BSA} \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$
Area	$= \frac{\left\{ \frac{CO}{(\text{SEP} \times \text{HR})} \right\}}{(44.3 \times \sqrt{\text{gradient}})}$
Area	$= \frac{\text{Cardiac output}}{\sqrt{\text{Gradient}}}$
Area	$= \frac{(CO \times \text{DFP} \times \text{HR})}{37.7 \times \sqrt{\text{gradient}}}$
SVR	$= \frac{80 \times (A_{0m} - RA_m)}{Q_s}$
PVR	$= \frac{80 \times (PA_m - LA_m)}{Q_p}$
CO	$= \frac{V_{CO_2}}{ctCO_{2(\text{Ven})} - ctCO_{2(\text{Art})}}$
CO	$= \frac{\Delta V_{CO_2}}{\Delta ctCO_{2(\text{Art})}}$
CO	$= \frac{\Delta V_{CO_2}}{S \times \Delta ETCO_2}$

Some believe cardiac index is a more useful parameter than cardiac index because it accounts for the patient's size. A large person (as approximated by BSA) would be expected to have a higher cardiac output while a low cardiac output in a smaller person may not necessarily be indicative of a poorly functioning ventricle. Many authors only express cardiac output in terms of cardiac index for this reason.

Valve Areas

Basic fluid dynamic principles state that a fluid exerts pressure equally in all directions. Therefore, when the valves of the heart are open they should allow equalisation of pressure in the two chambers that they separate. Sometimes the valves of the heart become stiff, thickened or do not open properly, inhibiting flow through the valve. This is referred to as valve stenosis. A result of this process is a pressure gradient, a difference in pressure on either side of the valve. Take an example of aortic valve stenosis. When

the left ventricle contracts, it is pushing against an obstruction. The systolic pressure will be higher in the ventricle than in the aorta. The difference in pressure is referred to as a pressure gradient (expressed in mmHg) and can be measured during cardiac catheterisation. The pressure gradient across a valve is often used to determine the severity of a valve stenosis. However, the main parameter that should be considered is the cross-sectional area of the valve. A pressure gradient of 20 mmHg (2.66 kPa) is often considered an indication of mild aortic stenosis. However, in the presence of low cardiac output, it is necessary to have quite a narrow valve orifice to achieve this gradient. Conversely, a less severe stenosis could achieve a gradient of 50 mmHg (6.66 kPa) in a patient with a high cardiac output.

Both the cardiac output and mean pressure gradient are used in the calculation of valve area. The Gorlin formula is used for calculating valve area of the aortic or pulmonary valve:

$$\text{Area} = \left[\frac{\text{CO}}{\text{SEP} \times \text{HR}} \right] / (44.3 \times \sqrt{\text{gradient}})$$

where HR is the heart rate and SEP is the systolic ejection period (since gradients in these valves are measured during systole). However, a shorter formula is often used as an approximation:

$$\text{Area} = \text{Cardiac output} / \sqrt{\text{Gradient}}$$

Taking the example of aortic stenosis, a mean gradient of 20 mmHg (2.66 kPa) in a patient with a normal cardiac output of $4.5 \text{ L} \cdot \text{min}^{-1}$ would give a valve area of $4.5 / \sqrt{20} = 1.00 \text{ cm}^2$. In a patient with a low cardiac output of $3.1 \text{ L} \cdot \text{min}^{-1}$, the valve area ($3.1 / \sqrt{20} = 0.69 \text{ cm}^2$) would be much smaller to achieve this gradient. Similarly, our patient with a mean gradient of 50 mmHg (6.66 kPa) would not have such a severe narrowing if a high cardiac output (e.g., $7.1 \text{ L} \cdot \text{min}^{-1}$) is present ($7.1 / \sqrt{50} = 1.00 \text{ cm}^2$).

The Gorlin formula for calculating mitral or tricuspid valve area is slightly different:

$$\text{Area} = (\text{CO} \times \text{DFP} \times \text{HR}) / (37.7 \times \sqrt{\text{gradient}})$$

where DFP is the diastolic filling period (since gradients in these valves are measured during diastole).

Vascular Resistance

Measurements of vascular resistance are based on principles of fluid dynamics where resistance is defined as the decrease in pressure between two points in a vascular segment divided by the flow through that segment. While this simplification does not account for pulsatile flow, calculation of vascular resistance in this way is useful in a number of clinical settings.

In the past, Wood units ($\text{mmHg} \cdot \text{L} \cdot \text{min}^{-1}$) were used to express vascular resistance. Today, vascular resistance is more commonly expressed in absolute resistance units ($\text{dyn} \cdot \text{s} \cdot \text{cm}^{-5}$), which are derived from the mean pressure gradient ($\text{dyn} \cdot \text{cm}^{-2}$) divided by the mean flow ($\text{cm}^3 \cdot \text{s}^{-1}$). A constant of 80 is used to convert values from traditional units (mmHg and $\text{L} \cdot \text{min}^{-1}$) to absolute resistance units.

Systemic vascular resistance (SVR) is therefore defined as the difference in pressure between blood entering the systemic circulation (mean aortic pressure) and blood leav-

ing the systemic circulation (mean right atrial pressure) divided by the systemic blood flow:

$$\text{SVR} = [80 \times (\text{AO}_m - \text{RA}_m) / \text{Q}_s]$$

Similarly, pulmonary vascular resistance (PVR) is defined as the difference between mean pulmonary artery pressure and mean left atrial pressure divided by the pulmonary flow:

$$\text{PVR} = [80 \times (\text{PA}_m - \text{LA}_m) / \text{Q}_p]$$

In the absence of intracardiac shunting both SVR and PVR can be calculated using the standard cardiac output measurement. If intrapulmonary shunting is present, systemic and pulmonary flow must be individually calculated for use in the SVR and PVR calculations, respectively.

There are a number of causes of increased systemic or pulmonary vascular resistance, some reversible and some permanent. The use of serial cardiac output and pressure measurements during drug challenges can assist in identifying management strategies that may be helpful in reducing vascular resistance.

VARIATIONS OF THE FICK METHOD

The Fick principle can be applied to any gas involved in diffusion, including carbon dioxide. Such variations to the classic Fick formula are often referred to as the indirect Fick principle.

By measuring the difference between inspired and expired CO_2 and the minute ventilation volume we can calculate CO_2 production (VCO_2). Arteriovenous CO_2 difference is calculated from the measured values of arterial and venous carbon dioxide content (ctCO_2). The ratio of VCO_2 and the arteriovenous CO_2 difference gives the cardiac output.

Earlier in this article it was seen how the oxygen content (ctO_2) of blood is calculated from the amount of hemoglobin and oxygen saturation of the sample, since nearly all of the oxygen is bound to hemoglobin. A relatively smaller proportion of CO_2 is bound to hemoglobin. About 70% is transported in the blood as bicarbonate. Only 23% is bound to hemoglobin and 7% is transported as dissolved CO_2 . Therefore, the calculation of CO_2 content is not dependent on hemoglobin level.

Carbon dioxide content (ctCO_2) is calculated from the formula:

$$\text{ctCO}_2 = 11.02 \times \text{PCO}_2^{0.396}$$

Thus, if we have partial CO_2 pressure of arterial (PaCO_2) and venous (PvCO_2) samples, we can calculate the arteriovenous carbon dioxide difference as

$$\text{ctCO}_{2(\text{Ven})} - \text{ctCO}_{2(\text{Art})} = 11.02(\text{PvCO}_2^{0.396} - \text{PaCO}_2^{0.396})$$

Then cardiac output is calculated with the formula:

$$\text{CO} = \text{VCO}_2 / (\text{ctCO}_{2(\text{Ven})} - \text{ctCO}_{2(\text{Art})})$$

There are some advantages to using the carbon dioxide method. When a patient is receiving high concentrations of supplemental oxygen, analysis of inspired and expired

oxygen will give a small difference between two relatively large values. Even a small error in the estimation of either value will yield an inaccurate $\dot{V}O_2$. Additionally, some oxygen analysers (e.g., paramagnetic analyzers) have poor accuracy at high oxygen concentrations. Measurement of cardiac output in patients receiving high concentrations of supplemental oxygen may be erroneous and the Fick principle using carbon dioxide may prove more accurate.

Applying the Fick principle to carbon dioxide involves the same steps as using oxygen for the calculation. There is still the requirement for analysis of expired gases, as well as collection and analysis of arterial and mixed venous blood samples. However, there are a number of ways of estimating, rather than directly measuring, the various parameters necessary to calculate cardiac output using the Fick CO_2 technique.

Infrared (IR) light absorption sensors in the breathing circuit can measure inspired and expired CO_2 content. Alternatively, an assumption can be made about the content of CO_2 in the inhaled gas (especially if the patient is being ventilated with 100% oxygen) and only expired CO_2 needs to be measured. Along with an airflow sensor (e.g., as a differential pressure pneumotachometer), these measurements can provide real-time estimation of $\dot{V}CO_2$.

There is a logarithmic relationship between cardiac output and end-tidal CO_2 ($ETCO_2$). At normal or high cardiac output the respiratory rate determines the amount of CO_2 that is eliminated by the lungs with each breath. If it is assumed that CO_2 exchange at the alveolar–arterial membrane reaches equilibrium, then $ETCO_2$ can be used to estimate $PaCO_2$. In this way, it is possible to estimate cardiac output without subjecting the patient to unnecessarily invasive procedures.

The critically ill patient presents a number of challenges. These patients are usually intubated and manually ventilated with high concentrations of inspired oxygen. While many will have arterial lines for blood pressure monitoring, those that do not are exposed to added risk of morbidity if arterial access is necessary to determine cardiac output. In addition, placement of a pulmonary artery catheter for the measurement of mixed venous gas tension exposes the patient to significant risk of sepsis, pneumothorax, thrombosis, or pulmonary artery rupture. However, cardiac output is often vital in determining end-organ perfusion.

Recently, a system for noninvasive measurement of cardiac output using the Fick principle and carbon dioxide was developed for use with ventilated patients in the intensive care unit, based on the estimations described above. A number of assumptions allow this system to be used without the need for arterial or mixed venous blood samples. The technique involves measuring changes in carbon dioxide production and arterial CO_2 content between normal breathing conditions and under rebreathing conditions with 10–15% CO_2 and a reservoir with a volume 1.5 times the tidal volume. Carbon dioxide production ($\dot{V}CO_2$) is calculated from the minute ventilation and expired CO_2 content under normal breathing conditions. Arterial CO_2 content [$ctCO_{2(Art)}$] is estimated from the end-tidal CO_2 ($ETCO_2$) with adjustments for the slope of the CO_2 dissociation curve and degree of dead space ventilation.

During partial rebreathing, carbon dioxide elimination from the blood is reduced, but $ETCO_2$ increases and reaches a plateau within a few breaths. Studies conducted in anaesthetised dogs have showed that during a brief period of CO_2 rebreathing there is a change in $PaCO_2$ and in calculated $\dot{V}CO_2$, but little or no change in venous carbon dioxide content ($ctCO_{2(Ven)}$) (5). It is believed that this finding is due to the quantity of CO_2 stores in the body being large and new equilibrium levels not being attained for 20–30 min. This finding becomes highly important in the noninvasive estimation of cardiac output. Any change in the arteriovenous CO_2 difference during the brief rebreathing period can be attributed to changes in the arterial CO_2 component alone.

If it is assumed that the cardiac output and $ctCO_{2(Ven)}$ remain constant during normal breathing (N) rebreathing (R):

$$\begin{aligned} CO &= \dot{V}CO_{2(N)} / (ctCO_{2(Ven)(N)} - ctCO_{2(Art)(N)}) \\ &= \dot{V}CO_{2(R)} / (ctCO_{2(Ven)(R)} - ctCO_{2(Art)(R)}) \end{aligned}$$

From basic algebra it is known that

$$X = A/B = C/D = (A - C)/(B - D)$$

Then,

$$\begin{aligned} CO &= (\dot{V}CO_{2(N)} - \dot{V}CO_{2(R)}) / [(ctCO_{2(Ven)(N)} - ctCO_{2(Art)(N)}) \\ &\quad - (ctCO_{2(Ven)(R)} - ctCO_{2(Art)(R)})] \end{aligned}$$

Rearranging this equation:

$$\begin{aligned} CO &= (\dot{V}CO_{2(N)} - \dot{V}CO_{2(R)}) / [(ctCO_{2(Ven)(N)} - ctCO_{2(Ven)(R)}) \\ &\quad - (ctCO_{2(Art)(N)} - ctCO_{2(Art)(R)})] \end{aligned}$$

Since it has been assumed that $ctCO_{2(Ven)}$ does not change during rebreathing ($ctCO_{2(Ven)(N)}$ is equal to $ctCO_{2(Ven)(R)}$), these values cancel each other out and the equation becomes:

$$CO = (\dot{V}CO_{2(N)} - \dot{V}CO_{2(R)}) / (ctCO_{2(Art)(R)} - ctCO_{2(Art)(N)})$$

In other words, cardiac output is equal to the change in $\dot{V}O_2$ divided by the change in arterial CO_2 content between the normal and rebreathing states:

$$CO = \Delta \dot{V}CO_2 / \Delta ctCO_{2(Art)}$$

As $ctCO_{2(Art)}$ is estimated from $ETCO_2$ and the slope (S) of the CO_2 dissociation curve:

$$CO = \Delta \dot{V}CO_2 / S \times \Delta ETCO_2$$

This method of cardiac output estimation gives a measure of the pulmonary capillary blood flow (Q_{PCBF}). Changes in $\dot{V}CO_2$ and $ETCO_2$ only reflect the blood flow that participates in gas exchange. An intrapulmonary shunt occurs when venous blood passes through unventilated areas of the lungs and moves into the arterial circulation without taking up oxygen or releasing carbon dioxide. A large intrapulmonary shunt will not be reflected in the changes seen in $\dot{V}CO_2$ and $ETCO_2$. Therefore, it is necessary to estimate the degree of shunting and correct the cardiac output estimation accordingly. For example, if only 80% of pulmonary blood flow is participating in gas exchange, the Q_{PCBF} estimated

by this method will be 80% of the total cardiac output. The shunting fraction is calculated using the arterial oxygen saturation (SaO_2 , from a pulse oximeter), the fraction of inspired oxygen (FiO_2), arterial oxygen tension (PaO_2) and standard isoshunt tables. The requirement of an arterial blood gas sample for PaO_2 means that this method is not truly noninvasive.

As mentioned previously, this noninvasive method involves a number of assumptions. In summary, these assumptions are the CO_2 exchange at the alveolar-arterial membrane reaches equilibrium. Therefore, $ETCO_2$ is equal to $PaCO_2$; cardiac output remains constant during rebreathing; venous CO_2 content does not change during a brief period of rebreathing; and there is little or no intrapulmonary shunting.

SUMMARY

The Fick method remains the gold standard of cardiac output measurement. While technically challenging, it relies on direct measurement of oxygen consumption and uptake to determine the rate of blood flow through the lungs and around the body. Accurate measurement of cardiac output is necessary for the estimation of several important parameters and assessment of complex congenital cardiac conditions. Variations of the classical Fick principle allow estimation of cardiac output in patients who might otherwise be unsuitable.

INTRODUCTION

Cardiac output is defined as the volume of blood pumped by the left or right ventricle per unit of time and is normally expressed in $L \cdot \text{min}^{-1}$ (1). For the average 70 kg adult male, the cardiac output is $\sim 5 L \cdot \text{min}^{-1}$, however, exercise can cause this figure to increase as much as six times the resting value in well-trained athletes (2). Knowledge of cardiac function is an important tool for determining the hemodynamic status of an individual whether he/she is a trained athlete or a patient in a critical care setting. Accurate direct measurement of cardiac output is a rather difficult task since to obtain a direct measurement would require collecting and measuring all of the blood pumped from the heart into the aortic outflow tract. It is necessary, therefore, to develop indirect methods for the measurement of cardiac output that would provide equivalent accuracies. The Fick (2) and other indicator dilution methods (3) are two of the invasive procedures that provide good reasonable results. More recently, echo cardiography and other noninvasive techniques have been gaining in popularity, yet the Fick and Indicator Dilution methods remain the “Gold Standards” against which all other methods are compared because of their accuracy, safety, reproducibility, and relative simplicity (1).

The Fick principle (4) is based on the fact that the amount of an indicator taken up (or released) by an organ is the product of its blood flow and the difference in concentration of the substance between the organ’s arterial and venous blood. Cardiac output can be determined by dividing the amount of oxygen consumed by the arterial-venous oxygen difference (AVO_2 difference). The theory behind this procedure is explained more fully below.

The indicator dilution method became widely accepted after Hamilton, in 1948, demonstrated that this technique agreed with the Fick method. In the indicator dilution method (5) an indicator (dye, thermal, saline) is injected into the venous blood and its concentration is measured continuously in the arterial blood as it passes through the circulatory system. The cardiac output is determined by analyzing the resulting time-dependent concentration curve.

INDICATOR DILUTION METHOD FUNDAMENTAL EQUATIONS

Figure 1. Simple mixing chamber.

Consider the simple mixing chamber shown in Fig. 1, where Q is the constant volumetric flow rate into and out of the chamber, m_i is the mass of indicator injected into the inflow stream, $C(t)$ is the concentration of indicator in the chamber at any instant, and m_L is the mass of indicator that leaves the chamber due to diffusion to the wall and/or metabolism. The differential mass of indicator that leaves the chamber at point 2 per differential time is given by

$$dm_2 = C(t)Qdt$$

where $C(t)$ at point 2 is the same as the concentration of indicator in the mixing chamber assuming complete mixing in the chamber. The total mass of indicator that leaves the chamber is determined by integrating the above equation with the result shown below.

$$m_2 = Q \int_0^{\infty} C(t)dt$$

The differential mass of indicator that leaves the chamber due to diffusion to the chamber wall and/or metabolism is proportional to the concentration of indicator, $C(t)$, and the surface area of the chamber, A .

$$dm_L = C(t)ADdt$$

where D is the proportionality constant for diffusion and/or metabolism.

The total mass of indicator leaving the chamber due to diffusion is

$$m_L = AD \int_0^{\infty} C(t)dt$$

The total mass of indicator leaving the chamber is equal to the mass of indicator entering the chamber minus the mass loss of indicator due to diffusion

$$m_2 = m_i - m_L$$

which leads to

$$Q \int_0^{\infty} C(t)dt = m_i - AD \int_0^{\infty} C(t)dt$$

and subsequently to the equation for volumetric flow rate

$$Q = \frac{m_i}{\int_0^{\infty} C(t)dt} - AD$$

The integral of $C(t)dt$ is determined from the area under the indicator dilution curve. Note that if the area of the

chamber wall is large and/or the diffusion coefficient is large, then the flow rate will be overestimated unless the diffusion is taken into account. In practice, the effect of diffusion is taken into account by a multiplying calibration factor (K) as shown in equation 1.

$$Q = \frac{m_i}{\int_0^{\infty} C(t)dt} K \quad (1)$$

This is the familiar Stewart–Hamilton equation for calculating cardiac output from the indicator dilution curve (6).

INDICATOR DILUTION CURVE FUNDAMENTAL EQUATIONS

The equations for the indicator dilution curve are determined by the indicator mass flow rate conservation, which states that the mass flow rate of indicator into the mixing chamber must equal the mass flow rate of indicator out of the mixing chamber plus the mass rate of removal by diffusion plus the rate of change of indicator stored in the chamber.

$$C_i Q = C(t)Q + C(t)AD + V \frac{dC(t)}{dt}$$

The parameter V is the volume of the chamber and complete mixing is assumed so that the concentration of indicator leaving the container at point 2 is equal to the concentration of indicator in the chamber at any instant.

Rearranging this equation results in the first-order differential equation

$$\left(\frac{V}{Q + AD} \right) \frac{dC(t)}{dt} + C(t) = \frac{Q}{Q + AD} C_i$$

which has a time constant of

$$\tau = \frac{V}{Q + AD}$$

After the injection of the indicator is complete, the concentration of indicator flowing into the chamber becomes zero resulting in the following equation during the washout phase.

$$\tau \frac{dC(t)}{dt} + C(t) = 0$$

The solution to this equation is

$$C(t) = C(t_1)e^{-[(t-t_1)/\tau]}$$

where $C(t_1)$ is the indicator concentration at time t_1 on the washout part of the indicator dilution curve.

Taking the natural log of this equation results in

$$\ln C(t) = \ln C(t_1) - [(t - t_1)/\tau]$$

This shows that if the indicator dilution curve is plotted as natural log of C versus t , then the curve will become a straight line during the washout phase and the slope of the curve is the negative reciprocal of the system time constant.

Rearranging this equation yields

$$\tau = \frac{t_1 - t_2}{\ln C(t_2) - \ln C(t_1)}$$

where $C(t_1)$ and $C(t_2)$ are indicator concentrations at time t_1 and t_2 , respectively, all located on the washout part of the indicator dilution curve.

This equation can be rearranged to the following:

$$\tau = -C(t_1) / \left(\frac{dC}{dt} \right)_{t_1}$$

The total area under the indicator dilution curve from t_1 to infinity is given by

$$\int_{t_1}^{\infty} C(t) dt = \tau C(t_1) \int_{t_1}^{\infty} e^{-[(t-t_1)/\tau]} d\left(\frac{t-t_1}{\tau}\right)$$

which results in the equation for the remaining area under the curve.

$$\int_{t_1}^{\infty} C(t) dt = C(t_1) \tau = \frac{(t_1 - t_2)}{\ln C(t_2) - \ln C(t_1)} C(t_1) \quad (2)$$

This equation can be rearranged to the following:

$$\int_{t_1}^{\infty} C(t) dt = \frac{-[C(t_1)]^2}{[C(t)/dt]_{t_1}} \quad (3)$$

APPLICATION OF THE INDICATOR DILUTION EQUATIONS AND RECIRCULATION

The following results are from a computer simulation in which 6 mg of indicator are injected into the right atrium of an average male with indicator concentrations being read from the radial artery. The volumes used by the simulation for the chambers involved are shown in Figure 2.

Figure 2. Schematic of simulation system.

Q is cardiac output ($6 \text{ L} \cdot \text{min}^{-1}$)

1 is the right atrium ($V1 = 100 \text{ mL}$)

2 is the right ventricle ($V2 = 100 \text{ mL}$)

3 is the pulmonary circulatory system ($V3 = 600 \text{ mL}$)

4 is the left atrium ($V4 = 100 \text{ mL}$)

5 is the left ventricle ($V5 = 100 \text{ mL}$)

6 is the systemic artery volume from the left ventricle to the radial artery ($V6 = 100 \text{ mL}$)

The total circulatory system volume is taken to be 6 L.

The diffusion coefficient D is taken to be zero in the simulation. The resulting indicator dilution curve as measured in the radial artery is shown in Fig. 3.

The dashed line beginning at $\sim 22 \text{ s}$ shows what the curve would do if there were no recirculation of the indicator through the circulatory system back to the right atrium. The solid line shows the actual curve with recirculation.

Figure 3. Indicator dilution curve.

The area under the indicator dilution curve can not be determined directly from the dilution curve. The dilution curve is plotted on a semilog graph in Fig. 4.

During the washout phase, the concentration curve approaches a straight line (dashed line) before the recirculation distorts the plot (solid line). This indicates that the system is behaving as a first-order decay, and we can use equation 2 to determine the area under the curve from any chosen time on the straight-line portion of the curve to infinity.

In this simulation, the area under the indicator dilution curve that would occur if there were no recirculation from 0 to 40 s is found to be $59.8 \text{ mg} \cdot \text{s} \cdot \text{L}^{-1}$, which results in a calculated cardiac output of $6.02 \text{ L} \cdot \text{min}^{-1}$.

With recirculation we determine the area under the curve from 0 to 15 s to be $47.387 \text{ mg} \cdot \text{s} \cdot \text{L}^{-1}$ and use equation 2 to calculate the area from 15 s to infinity.

For example, use the concentrations at 15 and 20 s that are in the straight-line portion of the semilog plot.

$$C_{t=15} = 2.096 \text{ mg} \cdot \text{L}^{-1} \quad C_{t=20} = 0.908 \text{ mg} \cdot \text{L}^{-1}$$

Equation 2 gives the area from 15 s to infinity as $12.528 \text{ mg} \cdot \text{s} \cdot \text{L}^{-1}$ so the total area from 0 to infinity is calculated to be $59.915 \text{ mg} \cdot \text{s} \cdot \text{L}^{-1}$. Now using equation 1, the cardiac output is found to be $6.01 \text{ L} \cdot \text{min}^{-1}$.

Using equation 3 at 15 s yields the same result.

Figure 4. Semilog plot of indicator dilution curve.

FICK PRINCIPLE

If the indicator is supplied to the mixing chamber shown in Fig. 1 at a steady rate until steady state is reached, then the concentration of indicator in the stream leaving the chamber will be constant and is given by the equation

$$m_{f_2} = C_2 Q$$

where m_{f_2} is the mass flow rate of indicator flowing out of the chamber.

Under steady flow conditions the mass flow rate of indicator into the chamber in the inflow stream plus the mass flow rate of indicator entering the chamber by injection will be equal to the mass flow rate of indicator flowing out of the chamber in the outflow stream.

$$m_{f_1} + m_{f_i} = m_{f_2}$$

In terms of inflow and outflow concentration of indicator, this equation is

$$C_1 Q + m_{f_i} = C_2 Q$$

Solving for Q yields the equation on which the Fick method is based.

$$Q = \frac{m_{f_i}}{C_2 - C_1}$$

In practice, the indicator used in the measurement of cardiac output by the Fick method is oxygen so that m_{f_i} is the consumption rate of oxygen in the lungs, C_1 is the concentration of oxygen in the venous blood, and C_2 is the concentration of oxygen in the arterial blood.

THERMAL DILUTION METHOD FUNDAMENTAL EQUATIONS

For thermal dilution measurement of cardiac output, a warm or cold injectate is injected into the right atrium and the temperature of blood in the pulmonary artery is measured by a thermistor as shown in Fig. 5. A warm injectate would need to be considerably warmer than the blood that might be hot enough to denature proteins (60°C). If it were not very warm, the poor signal/noise ratio would render the method unusable. Therefore cold injectate is the only practical thermal indicator (7,8).

A bolus of cold fluid is injected into the right atrium and the resulting temperature is recorded from the pulmonary artery. Conservation of energy requires that the total thermal energy entering the system during the procedure must be equal to the total thermal energy that leaves the system as the system returns to normal temperatures.

The thermal energy carried across a boundary by a differential volume of fluid is given by

$$dE = \rho C_P T(t) Q dt$$

where ρ is the density of the fluid, C_P is the specific heat of the fluid, $T(t)$ is the temperature of the fluid at any instant, Q is the volumetric flow rate of fluid crossing the boundary, and dt is the differential time.

Figure 5. Catheter in place for thermal dilution measurement.

The total thermal energy that crosses a boundary for a constant volumetric flow rate with constant thermal properties is

$$E = \rho C_P Q \int_0^\infty T(t) dt$$

The total thermal energy that enters the system is a combination of energy carried into the system by blood flow and the thermal energy carried into the system by the injectate, where the subscript b refers to blood and subscript i refers to injectate.

$$E_i = \rho_b Q C_{P_b} \int_0^\infty T_b dt + \rho_i C_{P_i} V_i T_i$$

The total thermal energy that leaves the system is a combination of the energy carried out of the system by blood flow and thermal energy loss to the walls of the atrium and ventricle.

$$E_o = \rho_b Q C_{P_b} \int_0^\infty T(t) dt + \rho_i C_{P_i} V_i T_b + hA \int_0^\infty (T - T_b) dt$$

where $T(t)$ is the temperature recorded by the thermistor at any instant, h is the thermal convection coefficient, and A is the internal surface area of the right atrium and right ventricle.

Using these equations in the thermal energy conservation equation

$$E_i = E_o$$

and rearranging gives

$$\rho_b C_{P_b} Q \int_0^\infty (T(t) - T_b) dt = \rho_i C_{P_i} V_i (T_i - T_b) - hA \int_0^\infty (T(t) - T_b) dt$$

Solving for Q yields the thermal dilution equation for volumetric flow rate.

$$Q = \frac{\rho_i C_{P_i} V_i (T_i - T_b)}{\rho_b C_{P_b} \int_0^\infty (T(t) - T_b) dt} - \frac{hA}{\rho_b C_{P_b}}$$

The term on the right represents the heat loss to the walls of the atrium and ventricle. In practice, there would be an additional heat loss in the catheter. The heat losses are normally accounted for by a correction term (K) that is a function of the catheter type being used as shown below.

$$Q = \frac{\rho_i C_{V_i}}{\rho_b C_{V_b}} \frac{V_i (T_i - T_b)}{\int_0^{\infty} (T(t) - T_b) dt} K$$

The thermal dilution method has the advantage that recirculation is not a problem due to the large surface available in the circulation to bring the injectate temperature to body temperature. A disadvantage is that the injection site and the sensing site must be close together to avoid large heat losses and the absence of total mixing in the ventricle can cause inaccuracies.

INTRODUCTION

The amount of blood pumped by the heart each minute, the cardiac output, provides a measure of the body's

potential for supplying oxygen and nutrients and is relevant to assessing the condition of the heart. Taken together with various pressures, it is a key clinical indication of the heart's ability to meet the body's needs and an indirect indication of the status of those needs. In the clinical setting, measurement of cardiac output is required to guide drug therapy aimed at manipulating the function of the cardiac muscle (inotropic drugs) and the state of the systemic and pulmonary vascular resistance (vasoconstrictor and vasodilator drugs). Combined with ultrasound velocity data, cardiac output allows precise assessment of the status of mitral and aortic valve stenosis and regurgitation.

G. N. Stewart articulated the basic principle of indicator-dilution measurement of cardiac output in a landmark paper in 1897 (1). Stewart stated that if a substance was introduced at a constant rate into the flowing bloodstream and allowed to mingle with the blood, then the measured steady-state concentration of that substance downstream of the site of introduction would be inversely proportional to the flow rate (cardiac output). Of greater practical importance was his additional observation that if a small amount of the substance was introduced rapidly, then the cardiac output could still be computed. To do that one would divide the average rate at which the substance is introduced (total amount divided by measurement time) by the average concentration. Stewart called this technique the "sudden injection" method. In the late 1920s, W. F. Hamilton and his colleagues further investigated Stewart's sudden injection method (2,3). They found that the concentration curve from timed samples did not simply return to baseline, but exhibited a secondary rise. This was attributed to fast physiologic recirculation of an unknown amount of the indicator. To eliminate the influence of any recirculating indicator on measurement calculation, they proposed extrapolating the original down slope of concentration to zero using an exponential function. This method proved successful in validation studies both in mechanical models and animal experiments, and the sudden injection method with exponential extrapolation is commonly referred to as the Stewart-Hamilton method.

Various indicators have been used to measure cardiac output with the Stewart-Hamilton method, notably saline (detected by its effect on electrical conductivity) and optical dye (detected by its effect on optical absorption), but G. Fegler's proposal in the mid-1950s that heat could be used has proved the most convenient, although initially controversial (4,5). His earliest report "was received with polite incredulity" (6). Fegler rapidly injected a small amount of cold Ringer's solution into the vena cava and recorded the transient decrease in temperature in the aortic arch and in the right ventricle. He computed both left and right heart outputs from these data.

Concerns were voiced regarding the ability to quantify this "negative" indicator, the stability of the baseline temperature, and the background noise (6). These are all valid concerns, but concerns that have been successfully addressed with clinical technology. Current practice is to introduce a small bolus of cold solution into the right atrium (via a venous catheter) and to measure the

consequent transient temperature decrease in the pulmonary artery. With the advent of balloon-flotation pulmonary-artery pressure measurement catheterization techniques in the late 1960s (7), small thermistor sensors could be readily placed in the pulmonary artery, and the thermal dilution measurement became clinically accepted even as validation experiments progressed. The pulmonary-artery catheters provide important hemodynamic pressure information and, for that reason alone, are placed in many patients.

Swan and Ganz are credited with developing and popularizing the pulmonary-artery pressure catheter containing a thermistor and injection port for thermal dilution (8), and these catheters are commonly called Swan–Ganz catheters, although Swan–Ganz, strictly speaking, is a registered trademark of Edwards Life-sciences Corporation. The instrumentation required to process the temperature signal and determine cardiac output is modest, fitting into either a small, battery-operated instrument easily used at the patient's bedside, or into a module component of a bedside workstation in the ICU or operating room, making the method easy and convenient. The additional "invasion" of a thermistor is negligible, and the additional value of cardiac output measurements is great. And since the indicator is a physiologically innocuous solution, thermal dilution measurement of cardiac output has become an important part of clinical care. Today, bolus thermal dilution cardiac output is considered the gold standard against which other methods are compared.

THEORY

Principle of Indicator Dilution

The basic principle of indicator dilution is quite simple: If the concentration of a uniformly dispersed indicator in an unknown volume is measured, then the unknown volume can be simply determined by dividing that concentration into the total amount of indicator. If the volume is flowing past a sensor, then the volume in any given period of time will equal the amount of indicator in that period of time divided by the concentration. If the rate at which the indicator is flowing past the sensor is controlled and known, then the amount of indicator in a period of time is also known and the volume flow rate can be determined. Alternatively, if the total amount of indicator over a larger period of time is known, such as when a bolus is introduced all at once, then average flow rates can be determined. Each approach has strengths and weaknesses in technique, necessary assumptions, and equipment. We focus on the popular bolus technique but, particularly with thermal techniques, the theory can be extended.

In the case of thermal dilution, the indicator is introduced into the right atrium and its concentration is measured in the pulmonary artery. We assume that all of the indicator introduced, an amount I , eventually passes into the pulmonary artery at some rate $i(t)$. If we assume no indicator recirculates, we may write this

as

$$I = \int_0^{\infty} i(t) dt \quad (1)$$

$$= \int_0^{\infty} F(t)c(t)dt \quad (2)$$

where F is volumetric flow and c is concentration. When the flow is constant, F can be moved out of the integral and we can solve for F as

$$F = \frac{I}{\int_0^{\infty} c(t)dt} \quad (3)$$

Several assumptions have been made in arriving at this equation. Equation 1 is a statement of conservation and requires that all indicators pass the sensor exactly once. Equation 2 requires that the concentration in the pulmonary artery be uniform across the area where the concentration is being measured, and equation 3 requires that the flow rate be constant. All but the first requirement can be satisfied for the pulmonary artery catheter-based measurements if we consider the right heart to be a perfect mixing chamber, with a competent valve at the outflow, and a pumping rate that is constant over the integration time. The mixing chamber guarantees that the blood will be equivalently labeled at its outflow so that each flow stream is representative of the total, and the valve guarantees that the concentration changes in a stepwise fashion in all flow streams, which allows legitimate averaging of pulsatile variations in flow. A rigorous proof can be found in Perl et al. (9) and the assumptions and necessary conditions are discussed in Trautman and Newbower (10). Each of these articles contains numerous relevant references.

Heat as an Indicator: "Thermal" Dilution

In thermal dilution, the indicator is caloric, introduced as a known volume of a cold physiologic solution whose concentration is measured via the induced temperature change. The relationship between temperature and the concentration of heat in a solution, the amount of heat in a unit volume, involves the specific heat and density of the solution. When two solutions at different temperatures, such as the indicator and blood, are mixed, the temperature of the mixture may be predicted by

$$T = \frac{T_1 C_p m_1 + T_2 C_p m_2}{C_p m_1 + C_p m_2} \quad (4)$$

where C_p and m are, respectively, the specific heat and mass of the solutions. If we take the first solution to be the indicator solution and the second to be the blood, then the difference in temperature due to the indicator will be predicted by

$$T - T_2 = \frac{(T_1 - T_2)C_p m_1}{C_p m_1 + C_p m_2} \quad (5)$$

A very good assumption, at least prior to significant heat exchange with tissue, is that the indicator solution and the temperature transient travel together. In this case,

equation 5 holds for all instances of time, and the mass concentration of the indicator solution may be predicted from the temperature transient by

$$c(t) = \frac{[T(t) - T_2]\rho_1}{T(t) - T_2 - (C_{p1}\rho_1/C_{p2}\rho_2)[T(t) - T_1]} \quad (6)$$

where ρ is the density of the solution. The amount of indicator is equal to the volume of the physiologic solution V times its density ρ_1 (giving its mass) and equation 3 becomes

$$F = \frac{V\rho_1}{\int_0^\infty c(t) dt} \quad (7)$$

$$F = \frac{V\rho_1}{\int_0^\infty \frac{[T(t) - T_2]\rho_1}{T(t) - T_2 - (C_{p1}\rho_1/C_{p2}\rho_2)[T(t) - T_1]} dt} \quad (8)$$

Equation 8 forms the basis for the thermal dilution method for measuring cardiac output. This equation may be easily programmed, but it generally has been approximated to simplify implementation. The most common approximation is based on the assumption that the indicator solution has no effect on the thermal properties of the blood. In this case, the increment in the amount of heat leaving the heart due to the indicator is equal to

$$H = \rho_2 C_{p2} F \int_0^\infty [T(t) - T_2] dt \quad (9)$$

This is equivalent to equation 2 and requires the same assumptions. The amount of heat added in a certain volume of an indicator solution is equal to

$$H = \rho_1 C_{p1} V (T_1 - T_2) \quad (10)$$

Equating equations 9 and 10 leads to the simpler formula for flow:

$$F = \left(\frac{C_{p1}\rho_1}{C_{p2}\rho_2} \right) \frac{V[T_1 - T_2]}{\int_0^\infty [T(t) - T_2] dt} \quad (11)$$

Equations 8 and 11 are equivalent only when cool blood is used as the indicator. Equation 11 is simpler than equation 8 and can be implemented in an analog circuit. However, it is based on the implausible condition that the indicator solution carries heat (or cold) into the blood and then is either transported completely apart from the thermal transient or has no thermal effect on the blood. Fortunately, the practical difference between flow estimates based on these two equations is small. The ratio of thermal properties for a dextrose-in-water (D5W) indicator solution is approximately equal to 1.08, and for a normal (0.9%) saline solution it is approximately equal to 1.10. Since the expected temperature transient is 0.5–1.0 °C, the expected difference between equations 8 and 11 is only 1–2% for these indicators.

If the indicator is not introduced as a finite bolus, then the conservation statement of equations 1 and 2 needs to be generalized and other assumptions made. The product of flow rate and concentration at the outflow of the mixing chamber will still be equal to the amount of indicator

passing by, but its relationship to the input indicator can be more complex. A simple example is where the indicator is infused at a constant rate in which case, absent recirculation, the flow rate will be inversely proportional to measured concentration. If the infusion rate is not constant then the transient response of the heart system needs to be considered.

Heat can be introduced by direct energy transfer, such as from an electrical heater. In this case, the volume factor in the numerator of equation 11 is not relevant and must be replaced by a measure of the amount of heat introduced. It is, however, impractical to introduce a large bolus (impulse) of heat comparable to the 750 W of 10 mL of iced saline: The surface temperature would be dangerously high. Instead, the heater is pulsed at low power, the resulting temperature changes measured with a fast-response thermistor, and sophisticated signal processing used to extract the dilution signal from the baseline. Such techniques have the potential to measure cardiac output continuously and were introduced in the early 1980s (11). Catheters with heating elements (10 cm long filaments in the right ventricle) have been produced since the early 1990s (12). The surface temperature and thus the amount of heat that can be introduced are limited by physiological concerns (4–7 °C), and therefore the technique is sensitive to background thermal noise. The heater is typically pulsed, and the accuracy is dependent on processing the correlation between the heating waveform and the measured temperature response (11–13). These techniques are entering clinical use as a companion to bolus thermal dilution, but are not considered here.

Necessary Conditions

For the preceding development, we assumed that the flow is constant; the volume and temperature of the solution are known, the indicator does not recirculate, and perfect mixing occurs somewhere between injection and sampling. Little can be done to control the variation of flow; it is flow that is being measured. (In those situations where flow is *not* constant, it can be shown that the computed result will be a concentration-weighted average of the true cardiac output over the period of measurement.) The other assumptions are usually reasonable, although in practice it is difficult to have an accurate measure of the volume or temperature of the injected solution since heat will exchange with all material contacting the solution. There is also a lost volume in the dead space of the catheter used to introduce the solution, and it is impossible to eliminate the physiologic recirculation of indicator. In addition, the integrals must be truncated to permit a practical measurement. These and other practical issues are covered next.

Notably absent from these formulas is the time response of the thermal sensor. Although not intuitively appealing, it can be shown that this response is of little importance as long as the curve does not become distorted by the effects of noise and recirculating indicator. The area under the thermal curve is preserved even with slow-responding thermal sensors. The operator should, however, be aware that the thermal curve obtained with a slow thermistor is not necessarily a high fidelity representation of the

temperature transient. The observed or recorded temperature curve will be smoothed and filtered over time.

PRACTICAL APPLICATION OF THE THEORY

The practical application of thermal dilution theory is simple; all that is typically necessary to measure cardiac output is to reset the “cardiac output computer,” inject 2–10 mL of an ice-cold or room temperature solution into the catheter port, and wait for the answer to appear on the computer. The thermal sensor is contained on a special pulmonary artery catheter that also provides the injection lumen into the right atrium. The temperature curve may be recorded to reassure the operator that a reasonable signal was obtained. Typical curves for various flow rates are shown in Fig. 1.

When the computer is reset, it samples the baseline temperature, integrates the processed temperature curve until recirculation is detected or assumed, and calculates the cardiac output assuming predefined conditions. It applies a correction for the portion of the curve that is lost by the truncation of the integral (to avoid influence of recirculation). The predefined conditions include the volume and temperature of the injectate, the thermal characteristics of the fluids, and a correction factor that corrects for the physical properties of the particular injection catheter employed. Most computers make approximations and apply corrections. The most common are listed below.

Thermal Properties of Blood Are Approximately Constant

The thermal properties of blood vary with hematocrit. However, the convenience of assuming a normal hematocrit—and thus not requiring knowledge of the actual hematocrit and entering it—far outweighs the importance of the potential error. The specific heat-density product for erythrocytes is $\sim 3.52 \text{ J}\cdot\text{K}^{-1}\cdot\text{mL}^{-1}$, and for plasma it is $\sim 4.03 \text{ J}\cdot\text{K}^{-1}\cdot\text{mL}^{-1}$ (14). Therefore, for blood with a hematocrit of 40% this product is $3.83 \text{ J}\cdot\text{K}^{-1}\cdot\text{mL}^{-1}$, with a hematocrit of 30% it would be $3.88 \text{ J}\cdot\text{K}^{-1}\cdot\text{mL}^{-1}$, and with 50% it would be $3.78 \text{ J}\cdot\text{K}^{-1}\cdot\text{mL}^{-1}$. Thus, the nominal value assumed for blood could be in error by 1–2% causing an error in the cardiac output measurement of the same value.

Indicator Does not Affect Thermal Properties of Blood

The specific heat-density product for normal (0.9%) saline is $\sim 4.19 \text{ J}\cdot\text{K}^{-1}\cdot\text{mL}^{-1}$, and that for 5% dextrose-in-water is

$\sim 4.11 \text{ J}\cdot\text{K}^{-1}\cdot\text{mL}^{-1}$ (15). These are significantly different from the nominal $3.81 \text{ J}\cdot\text{K}^{-1}\cdot\text{mL}^{-1}$ for blood. The thermal properties of the indicator-blood mixture will thus vary with the level of dilution. However, most computers assume that the indicator does not affect the thermal properties of blood. This assumption leads to the simpler equation [Eq. 11] derived above. Cardiac output computers using this approximation can be expected to overestimate the cardiac output by 1–2%.

Heat Loss Is Predictable

When the syringe containing the cold solution is taken from the ice bath it immediately begins to warm. The solution warms further as it is injected through caloric exchange with the walls of the catheter. Only a negligible amount of heat is gained during manipulation of the syringe before injection. However, the exchange with the walls of the catheter can account for several percentages with a 0°C solution (16). In addition to those conductive losses of indicator, a significant amount of solution is left in the catheter after the injection has been terminated. The typical dead space volume is 0.9 mL so that only 91% of the solution is injected into the bloodstream. However, the solution that filled the dead space prior to injection is pushed into the blood stream and, if not at blood temperature, can add to the effective indicator volume. In addition, some of the “cold” left in the dead space after injection can leak through the catheter wall and add to the injectate.

Empirical studies have shown that the combination of these losses and gains can be grouped into a single correction factor, multiplying the total indicator volume. This correction factor varies only a few percentages with catheter insertion length and other mechanical factors (17). The correction factor does depend on the temperature and volume of the injected solution and on the design of the catheter. Catheter manufacturers generally provide, with their package inserts, a table of values for the correction factor or “computation constant” under various typical conditions. This factor is determined by measuring the average temperature of the injectate, as it emerges from the injectate, lumen of the catheter, while the appropriate length of catheter is immersed in a 37°C bath. The amount of injectate that emerges is a reasonably constant fraction of the amount introduced.

Devices can be used to measure the temperature of the injected solution as it enters the injection catheter. This reduces the need for precisely controlling the initial temperature of the solution and reduces errors due to warming of the solution during handling. These devices do not improve knowledge about the unknown heat loss during injection. Catheters have also been fabricated with thermistors in the distal port of the injection lumen, to measure true injectate temperature. These catheters demonstrate better reproducibility particularly with room temperature injectates, but have yet to win clinical acceptance due to cost and complexity. Note also that the rate at which the indicator is introduced must be controlled and consistent to allow inferring amount of heat from temperature.

Figure 1. Typical thermal dilution curves, taken at different flows and superimposed to illustrate variations in shape and area.

Decay of Dilution Signal Is Exponential

Recirculation of the thermal indicator is relatively small in humans since there is ample opportunity for exchange with the tissue beds. In smaller animals, recirculation is more apparent. In either case, the decay of the temperature signal measured in the pulmonary artery approximates an exponential (the result of the mixing chamber) and, once truncated, the true but obscured curve can be mathematically extrapolated with reasonable accuracy. The relatively small amount of curve area being estimated limits the significance of errors in extrapolation. Some cardiac output computers actually fit an exponential to the uncorrupted curve and use the parameters of fit to extrapolate the curve, while most assume that curves generally have the same shape and integrate to a fraction of the peak temperature and multiply this area by a constant. Either method appears to result in a reliable measure of cardiac output. Certain pathologies can alter the shape of the thermal dilution curve and reduce the effectiveness of these extrapolation procedures.

Baseline Temperature Is Constant

The baseline temperature is not constant, varying with the respiratory cycle and subject to the fluid infusions from other sources (i.e., intravenous fluid administrations). In addition, the heart itself generates heat that can be observed as very small pulsatile variations in temperature in the pulmonary artery. Fortunately, these variations and the baseline shifts are usually small compared to the ~ 0.5 – 1.0°C dilution signal. Cardiac output computers thus assume that the baseline acquired prior to the arrival of the dilution signal remains constant during the course of the measurement. (Note that shifts in baseline can adversely affect the extrapolation procedure used to reduce the effects of recirculation.)

Flow Rate Is Constant Throughout the Integral

Cardiac output can vary by as much as 10–20% over the respiratory cycle. Since thermal dilution measurement integrals typically average only 5–10 s of the cardiac output, the measured cardiac output could vary by as much as 10–15% depending on where in the cycle the injection is made. There is really nothing the computer can do about this without information about the phases of the respiratory cycle. Cardiac arrhythmias, which can result from the cold injection, can cause dramatic errors in the measured output. The clinical practice of averaging several separate cardiac output determinations helps to average out some of the potential variation from both of these sources. See section on *Measurement Performance* for more discussion on accuracy and reproducibility.

EQUIPMENT

The thermal dilution method for cardiac output measurement is popular because it is easily performed with a minimum of equipment and little additional invasion of the patient. The basic equipment consists of a pulmonary artery catheter to position a thermistor or other

temperature-sensitive element in the pulmonary artery, a means for making thermal indicator (usually saline) injections into the right atrium (usually a syringe), typically through a separate lumen in the catheter, a source of measured volumes of a cold solution, and an electronic instrument to determine the blood temperature from the thermistor signal, to determine and integrate the dilution signal, and to compute a final result. Each of these elements is described separately.

Pulmonary Artery Catheters

The pulmonary artery (PA) catheter generally contains several lumens (channels) that terminate at measured distances from the tip. A balloon, located at or near the tip, is inflated during catheter insertion to carry the tip through the heart and into the pulmonary artery (flow directed). One lumen terminates at the tip and is used to measure the pressure during catheter insertion to follow its position relative to the heart; later it measures pulmonary artery pressure and, intermittently, pulmonary capillary wedge pressure (with the balloon inflated). A second lumen typically terminates in the right atrium and is used to monitor right atrial pressure (central venous pressure). Indicator solutions are injected either through the right atrial port or through a second atrial lumen intended for drug infusion. Catheters can have several additional lumens (e.g., atrial and RV pacing wires) and sensors (e.g., mixed venous oxygen saturation). The pulmonary artery catheter provides important hemodynamic information and may be inserted in patients for that purpose alone.

For use with thermal dilution, the pulmonary artery catheter is augmented by adding a thermistor proximal to (before) the balloon (typically, 4 cm from the tip). A thermal dilution catheter is illustrated in place in Fig. 2. The

Figure 2. A pulmonary artery catheter in place in the right heart. The balloon, shown inflated here for wedge pressure measurement, normally remains deflated during pressure monitoring and cardiac output measurements. The cold injectate enters the bloodstream through the injection port, and the temperature transient is sensed by the thermistor.

thermistor typically is encapsulated in glass and coated with epoxy to fully insulate it electrically from the blood. The relatively slow time response of this encapsulated sensor does not affect the accuracy of the measurement since the area under a temperature curve is preserved. Wires connecting the thermistor are contained in a separate lumen. The thermistor wires terminate in an external connector that typically contains an electrical resistance used to standardize the response of the thermistor. Thus the catheter contains one-half of a Wheatstone bridge. The overall length is ~ 100 cm, with distance marks every 10 cm to guide insertion. The typical size is 7–8.5 Fr although pediatric catheters may be 5–6 Fr. (One French is equal to one millimeter in circumference.)

Edwards Lifesciences was the original commercial manufacturer of the thermal dilution catheter, basing it on a concept acquired from Swan and Ganz, researchers involved with validation experiments. Their Swan–Ganz catheter was introduced in 1971. Since that time several manufacturers (e.g., Instrumentation Laboratories, Cobe, Abbott, Arrow) produce thermal dilution catheters, disposable items selling for $\sim \$50$ – 80 each, although catheters with heating filaments and multiple sensors can cost $\$200$ and up. A thermal dilution catheter is shown in Fig. 3.

Pulmonary artery catheters are not without clinical complications. The threat of infection is always present. Clots can form on the poly vinyl chloride (PVC) catheter surface, but this complication has been mostly eliminated with anticoagulant coatings. Unfortunately, there are patients who have severe reaction to heparin (i.e., heparin induced thrombosis) and in these patients heparin-coated catheters need to be avoided. The catheter can become knotted in the right heart, a complication that requires a trip to the cardiac catheterization laboratory to resolve.

Most dangerous is the rare complication of the catheter tip puncturing the pulmonary artery. In normal use, the balloon is temporarily inflated, the balloon wedges into a branch of the pulmonary artery, flow through that branch of the pulmonary circulation is stopped and the pressure measured from the distal lumen will approximate the left atrial pressure. It is critical that nurses and physicians understand the waveforms associated with “permanent wedge” position to avoid pulmonary rupture. This complication is almost always associated with erosion of the

pulmonary artery from a catheter permanently in the wedge position or with inflating a catheter that is in the distal pulmonary arterial position.

The balloon is an important feature of pulmonary artery catheters since it plays a key role in the acquisition of pressure information in addition to facilitating placement of the catheter. Balloons are generally made from latex and designed to inflate beyond the tip of the catheter while not occluding the distal pressure lumen. This shields the tip reducing the tip trauma to the pulmonary artery. Manufacturers attach the balloon to the base catheter in a way that minimizes rough surfaces and overall size of the catheter while being durable. Latex-free balloon catheters are available for use in patients with latex allergies, but are expensive and have limited functionality, usually having only a single right atrial port. The non-latex balloon is also not as durable and measurements of wedge pressure must be kept to a minimum.

The size and material of the catheters can vary among manufacturers and models, both of which can affect their stiffness and thus the ease of insertion, and the size of the dead space in the injection lumen and, thus, the heat loss correction factor. The injection port may be larger in some catheters, reducing injection effort. The frequency response of the pressure measurement lumens may be different due to attention to details of fluid mechanics. Personal preference, reliability, and economic concerns are also clearly important in purchase decisions. Some catheters offer other capabilities such as continuous cardiac output measurements based on advanced signal processing algorithms, mixed venous oximetry, and the ability to electrically pace right atrium and ventricle.

Cold Solution

The indicator solution is typically an isotonic saline or dextrose solution cooled to 0°C by placing the bottle or prefilled capped syringes in an ice bath. This makes the injected indicator $\sim 37^\circ\text{C}$ cooler than body temperature. This 10 mL of 37°C difference injected in 2 s represents extraction of thermal energy from the bloodstream at a rate of ~ 750 W. Cold indicator is most useful in the operating room where patient temperatures can vary rapidly and dramatically. In the non-OR setting, or in operative patients where normothermia is expected, room-temperature solutions are frequently used because they are more convenient, but the variable room temperature must be monitored by the computer. The injected energy is reduced by a factor of ~ 3 , reducing the signal-to-noise ratio and, thus, expected measurement performance. Most cardiac output computers provide a temperature probe to measure the actual temperature of the bath or of the room, which is presumably the temperature of the injectate. Manufacturers also produce an optional temperature-measuring probe that attaches to the injection port on the thermal dilution catheter and measures the temperature of the injectate as it enters the catheter. This further reduces concern about the actual room or bath temperature. Some catheters also have thermistors at the injection port itself.

The ice bath is the subject of some unproved concerns regarding infection. Undesirable organisms could remain

Figure 3. A Swan–Ganz pulmonary artery catheter produced by Edwards Lifesciences. The various lumens are accessed through individual Luer-Lok connectors fanning out from an external divider on the main catheter. The electrical connector for the thermistor wires is also connected to the main catheter at the same point. (Photograph courtesy of Edwards Lifesciences Corporation, Irvine, CA.)

Figure 4. A closed injection system for cold injectate, by Edwards Lifesciences. A cooling coil rests in a Styrofoam ice bucket, the syringe serves as a piston pump to draw up a known volume of pre-cooled injectate from the coil and to force it into the injection lumen of the catheter. The closed system reduces the risk of nosocomial contamination associated with traditional injectate delivery methods. CO-Set+ System improves reproducibility and accuracy through its in-line temperature probe and volume-limited syringe. (Photograph courtesy of Edwards Lifesciences, Irvine, CA.)

or grow in the capped syringes when left in the bath for long periods of time. A cleaner alternative to the ice bath is offered by a closed injectate system with a cooling coil, offered as an optional accessory by some manufacturers. One such device is shown in Fig. 4. The coil sits in an ice bath keeping the solution cold. The syringe is used to draw up solution and then immediately introduce it into the catheter port. Fig. 5 shows the complete system.

Although these solutions are generally benign, in some circumstances, such as in small pediatric patients, there is a risk of volume overload from frequent measurements. In these situations, smaller volumes are used (e.g., 3 mL) and fewer measurements are made.

Cardiac Output Computers

When thermal dilution measurements were first introduced in the early 1970s, manufacturers produced catheters with nonstandardized thermistors. Each manufacturer then produced a computer to mate with its catheter. In addition to generic differences in thermistor types, each individual thermistor of a given type can have a different temperature response requiring the operator to enter a calibration constant, idiosyncratic to the specific catheter, its thermistor response, and even the patient's blood temperature. In current products, the thermistor connector contains an electrical resistance selected to match the particular thermistor and complete a half Wheatstone bridge with a standard response. The value of the resistance in this circuit is chosen such that the voltage response of the half bridge will be the same for all thermistors of a given family and also will be linear near 37 °C. The nearly linear range is ~ 20 °C. With these catheters, the catheter is

Figure 5. Basic thermal dilution system, with computer, syringe, catheter, and source of cold injectate, in this case from a closed system. (Courtesy of Edwards Lifesciences, Irvine, CA.)

merely connected to the computer's electronics, and the pulmonary artery blood temperature and the cardiac output can be measured. The electronic circuitry used to measure the thermal response is electrically isolated, since the thermistor is in the conductive bloodstream quite close to the heart and insulation failures can conceivably occur. Since the catheter functions as half of a Wheatstone bridge, the electronics merely mimic the other half of the bridge circuit, excite the bridge with a low level of current, and amplify the voltage difference proportional to temperature change.

When the operator signals that a measurement is to be made, the baseline temperature is acquired and the indicator concentration is computed (or approximated) and integrated. When the "end of curve" criterion is reached, the integration is stopped, the integral is adjusted for area lost by truncation, and the final area is inverted and multiplied by the appropriate constants for the measurement conditions. This constant is entered in the computer and only changed when conditions change. Cardiac output computers differ both in the method they use to truncate the integration and in the options they offer, such as, syringe size, injectate temperature, and integration into bedside systems.

Calibration of Equipment

Each catheter is individually calibrated by the manufacturer to give a standard response (as described previously), and the heat loss correction factor is determined also by the manufacturer for the particular catheter model for a variety of measurement conditions. No operator calibrations are necessary or practical.

In certain research settings (e.g., custom-made catheters), it is desirable to add the calibration resistor to the catheter. The value of the resistance is given by

$$R = R_0(\beta - 2T_0)/(\beta + 2T_0) \quad (12)$$

where R_0 is the thermistor resistance at 37 °C, T_0 is 310 K, and β is the characteristic temperature (a gain constant) for the thermistor, equal to 3500 K for those used in thermal dilution catheters compatible with the Edwards Lifesciences standard.

Example Equipment

Most cardiac output computers are fully integrated into hemodynamic monitoring systems. The cardiac output component is usually part of the temperature-sensing module. Data from the measurements are acquired into the system's data recording and analysis packages and automated calculations of systemic and pulmonary vascular resistances are obtained.

In the typical computer, the preamplifier is fully isolated and uses a conservative $7 \mu\text{A}$ to sense the thermistor resistance. When a new cardiac output is desired, the operator presses a button and rapidly injects the cold solution. The dilution curve is typically shown as it is measured and the result is displayed once the curve has finished. Analog and digital outputs may be provided for integrating into a larger measurement or workstation system. In a typical computer the temperature difference is integrated from baseline up to its peak, then down to 30% of the peak value, and multiplied by 1.22. This integral is then inverted and multiplied by the computation constant provided by the catheter manufacturer. The computation constant is the product of all constants (e.g., the ratio of thermal constants, the injectate volume, $60 \text{ s}\cdot\text{min}^{-1}$, and $0.001 \text{ L}\cdot\text{mL}^{-1}$) and the catheter heat-loss correction factor (e.g., 0.825). Although the method for extrapolating the integral appears overly simple, it is quite effective. As pointed out earlier, the dilution curve has a consistent shape, and amount of area obscured by recirculation is small and comes relatively late in time (in humans). Some computers use more elaborate methods.

A typical computer and display is shown in Fig. 6. This example from Philips Medical Systems integrates into the monitoring system and computes several derived values as well as displaying hemodynamic information.

MEASUREMENT PERFORMANCE

Direct measurement of cardiac output is quite difficult given the location of the measurement site and the necessity

Figure 6. A modern cardiac output computer, integrated into a monitoring system, by Philips Medical Systems. The thermal dilution curve is displayed for inspection, and the cardiac indices can be automatically computed from the cardiac output and body parameters entered by the clinician. (Photograph courtesy of Philips Medical Systems, Andover, MA.)

to divert flow in some manner. The performance of thermal dilution measurements of cardiac output has been assessed in a number of less direct ways. Validation studies have been performed in mechanical flow models to assure that the measurement theory is sound in practice (and to determine the heat-loss corrections appropriate to specific catheters). Simultaneous thermal dilution and dye-dilution measurements, and also thermal dilution and direct Fick measurements, have been performed in animals and humans. Comparisons have also been made with electromagnetic flowmeters in animal preparations. All of these methods have shown thermal dilution to be effective for measuring cardiac output and as accurate as these other methods. In addition, an important consideration in the clinic is the reproducibility of the measurement over time and from operator to operator. Clinical studies of this sort have shown thermal dilution to be reliable and it is now considered the gold standard against which other measurements are compared.

It is interesting to note that the dye-dilution method was the incumbent standard, using indicators, such as indocyanine green dye measured by withdrawing blood from an artery through an optical sensor. This technique measures somewhat different flows—left-heart output rather than right-heart output, for example—and is subject to other issues of physiology and technique, such as greater recirculation and accumulation of indicator. Nevertheless, dye-dilution was clinically useful and thermal dilution was shown to be better and more convenient. By the early 1980s, thermal dilution was the technique of choice.

Accuracy

The accuracy of thermal dilution is degraded by the various assumptions and approximations discussed previously. Thus, even in the absence of physiologic noise, this measurement can only be expected to be within 2–7% of the true value without other measurements and specific corrections relevant only to a research setting. This accuracy is, however, well within a clinically acceptable range and is no worse than that of other methods. In his first trials with this technique, Fegler compared thermal dilution with standard direct Fick measurements in animals, finding a discrepancy of $< 7\%$. Early validation studies with thermal dilution catheters were performed by Ganz and colleagues in the early 1970s (8,17,18). In addition to supporting the overall accuracy of thermal dilution, they determined that the sensitivity of the result to mechanical and technique-dependent factors, such as catheter insertion length and speed of injection, was within 3%. This they considered to be biologically insignificant (17).

Others have since obtained good correlation with simultaneous dye dilution and other methods for measuring flow, if not slopes of identity. It is interesting to note that since the dye concentration is usually measured in a systemic artery, dye dilution will provide a measurement of left heart output that is $\sim 4\%$ higher than the right heart output measured by thermal dilution, due to the bronchial circulation bypassing the right heart. In addition, all of these reference methods have some of their own

uncertainty in calibration, and conclusions are thus necessarily limited.

Exploration of the heat loss during injection has yielded interesting information on variability (16,19,20) but has not quantified the systematic loss to the point of accurate prediction of total injected heat (cold). The *in vitro* studies of effective losses and determination of correction constants provide adequate foundation for an accurate measurement.

Reproducibility

Cardiac output need not be known to great accuracy (within 10% is quite adequate) as long as the measurements are reproducible and can be used to track therapies. The reproducibility (variance) of the measurement with 10 mL of iced solution is generally accepted to be in the range of 10–15%. This is higher with room temperature solutions, and with smaller volumes (21). The reproducibility can be improved by 20–40% with a thermistor sensing the injectate temperature at the injection port in the right atrium. (20,22)

Some factors that can affect the reproducibility of this measurement derive from physiology and some from technique.

Physiology. As noted previously, the cardiac output can be expected to vary over the respiratory cycle, particularly with positive-pressure-assisted ventilation. This is shown quite succinctly in a careful study in animals by Jansen et al. (23) where the injection was made at random, but at known phases of the ventilation cycle. When plotted sequentially in time, the results span a range of $\pm 15\%$ and appear randomly distributed. When ordered according to the phase of the ventilator, the cardiac output result varies cyclically over the course of ventilation. Therefore, a determination of cardiac output using an arbitrary injection time could differ from another determination at another arbitrary time by as much as 30% due, presumably, to real physiologic variations, with flow modulated by intrathoracic and intra-abdominal pressure. Some contribution of baseline drift and thermal noise cannot be discounted by this study.

Clinically, the baseline temperature is usually assumed to be constant during the period of the measurement. Yet blood temperature varies by as much as 0.1°C over the ventilatory cycle due to differential blood return from the upper and lower extremities. This fluctuation in baseline temperature is typically small compared with the $\sim 1^\circ\text{C}$ thermal dilution signal obtained with 0°C injectate, but extends over significant time. It is more significant with room temperature injectates and with heated-filament (continuous cardiac output) signals. The magnitude of the baseline drift can be much greater, particularly with patient movement. Of note, intravenous fluid infusions will affect the blood temperature enormously, particularly during flushes of the lines. The heat output from the heart itself returns into the right atrium from the coronary veins in synchrony with the heartbeat. These pulsations in temperature are less pronounced, being smoothed by the mixing volume in the right ventricle, and cause little practical difficulty.

Since the indicator is introduced immediately upstream of the heart, the solution can, conceivably, transit the heart in a single beat (or very few beats) if the ejection fraction is high. (Thermal dilution curves obtained with fast-response thermistors can be used to determine the ejection fraction by quantifying this washout time when the injection is made directly into the ventricle.) Therefore, these few beats must be representative of the average output for the measurement to be useful. An arrhythmia at the time of injection, occasionally caused by the injection, can lead to a single very large ejection with a very good ejection fraction. In this situation, the measured output will be much larger than the true average cardiac output. The method is not in error, but the measured output is not the steady-state output. Therefore, if arrhythmias are suspected, the measurement should be discarded or a very large variation in results anticipated.

Certain pathologies can affect thermal dilution cardiac output measurements. Tricuspid regurgitation will increase the effective mixing volume for the indicator, thus increasing the extent and decreasing the magnitude of the thermal transient. However, it is important to note that TR does not invalidate the fundamental physical principles upon which the measurement is based. If the computer can wait long enough, the CO measurement in the face of TR should be accurate. In order to be sure this is the case, the practitioner must watch the thermal dilution curve as it evolves on the monitor screen.

Very low ejection fractions can have a similar effect. Although the basic assumptions underlying the measurement remain intact, the curve can be distorted to an extent that makes the practical measurement unreliable. More serious problems are caused by an incompetent pulmonic valve. This valve is necessary to minimize the nonlinear averaging effects of the pulsatile flow, and any flow reversal at the thermistor can lead to multiple re-measurement of the thermal transient. Either of these effects degrades the cardiac output determination.

Technique. Thermal dilution measurements are reasonably insensitive to variations in operator technique. As noted above, the injectate will not warm significantly as the syringe is handled briefly prior to injection. And if this is a concern, probes can be used which measure the temperature of the injectate as it is injected. The content of the injection catheter dead space must be considered to achieve a high level of reproducibility. If multiple measurements are made over a short period of time, that is, to average several serial determinations, sufficient time must be allowed for the residual injectate to return to blood temperature. A couple of minutes appears sufficient to warm the dead space as well as to allow the blood temperature to return to a stable baseline. One strategy is to discard the first measurement, using it merely to fill the dead space with a cool solution. Another strategy for assuring a consistent effect from the dead space is to withdraw blood immediately following the injection. The potential for blood clotting, however, limits the applicability of this procedure. As noted earlier, some catheters can measure the temperature of the injectate at the point of injection (20,22) thus minimizing these effects.

In summary, judicious choice of the time of injection can improve reproducibility. Attention should be paid to the phase of ventilation, to changes in any concomitant intravenous fluid infusions, and to any concurrent cardiac arrhythmias. The temperature curve can be recorded from most cardiac output computers. This curve, and the prior baseline, can give the knowledgeable operator evidence on which to judge the validity of a particular result. Recall, however, that the time course of the thermal curve is not necessarily the same as the time course of the thermal transient in the flow stream. Most clinicians use a single measurement to guide therapy although in many settings, such as in studies, it is still common practice to use the average of three serial cardiac output determinations or to discard the outlier and average the remaining two.

Ease of Use

The ease and robustness of thermal dilution measurements of cardiac output are probably responsible for its clinical popularity. The equipment is straightforward to operate, and specialized technicians are not needed to acquire reliable data. The right heart catheters may be placed for other clinical reasons without fluoroscopy. When a measurement of cardiac output is indicated, all that is necessary is to attach a computer and inject cold solution.

FUTURE DEVELOPMENTS

This measurement is simple, fundamentally inexpensive, and has remained popular for several decades. It is, however, moderately invasive. If the need for the pressure information from the pulmonary artery catheters was reduced or supplanted, the ease of making a thermal dilution measurement would diminish. There are liabilities and contraindications associated with pulmonary artery catheters and the injection of cold solutions, and this measurement is not always prescribed in critical care. Use of PA catheters is falling somewhat as other methods of assessing cardiac filling and function become more widely available, such as ultrasound-based measurements and central venous lines. However, several million pulmonary artery catheters are used each year in North America and their widespread use is likely to continue. It is interesting that many surgeons who must manage their patients via phone consultations rely heavily on PA catheter measurements, especially when the ICU team does not include experienced physicians.

Indicator-dilution measurements of the sort described in this article are fundamentally intermittent. In many cases, a continuous measurement would be favored. Continuous cardiac output measurement with the heated filament paired with advanced signal processing is becoming popular, and other techniques such as analyzing pulse contours are also becoming more accepted. Thermal dilution with 10 mL of iced solution is the standard against which these techniques are compared, and periodically calibrated (13).

Catheters will continue to improve, with better clot resistance, materials, additional lumens, heating elements and sensing elements as measurements demand. Cardiac output is integrated into measurement systems forming

part of derived parameters and important correlations, a trend that will continue to follow medical instrumentation and healthcare information technology in general. And as the reliability of the measurements increases with experience and technology, the long-promised closed-loop therapies may become a reality.

CARDIOPULMONARY RESUSCITATION

EDWARD GRAYDEN
Mayo Health Center
Albertlea, Minnesota

INTRODUCTION

Cardiopulmonary resuscitation (CPR) may be defined as the emergency restoration of vital functions in a person who has undergone a life-threatening event. The term “cardiopulmonary resuscitation” is actually misleading since the goal of all CPR is to return the victim to appropriate cerebral function; cardiopulmonary resuscitation is the vehicle by which the rescuer attempts to reach this goal. The process of resuscitation may be viewed as a continuum where at one end of the spectrum psychomotor skills of CPR may be initiated by a lay bystander who might be the first rescuer on the scene of an accident, witness to someone choking on food at a restaurant, or perhaps is present when a family member succumbs to a heart attack. Cardiopulmonary resuscitation may also be viewed in a more general and organizational sense to encompass the entire process of the emergency response to victims. The education and training of the public and first responders in basic life support, such as policeman and firefighters, is the cornerstone in an attempt to reduce sudden death through lifesaving skills. Training in basic life support focuses on providing the rescuer with the ability to recognize emergencies, activate the Emergency Medical System (EMS, 911), maintain an airway, provide effective rescue breathing and cardiac circulation. American Heart Association sponsored programs also focus on prevention of risk through education of the public regarding the etiologies of coronary artery disease, myocardial infarction (heart attack), and cerebrovascular disease (stroke). Information presented through these programs attempts to modify lifestyle patterns and behaviors, such as smoking, known to cause or exacerbate these events. The new focus in community emergency response is in the training of laypersons in the use of the Automatic External Defibrillator

(AED). Documentation of successful resuscitation in communities with high proportions of the public trained in CPR and use of an AED reach 49% in out-of-hospital victims known to have suffered ventricular fibrillation (a terminal cardiac dysrhythmia that is a common endpoint in the progression toward death) (1,2). Currently, there has been significant progress made in making these automatic defibrillators present in communities and in public places, such as shopping centers, sporting event facilities and mass transportation. The American Heart Association “ABCs” of CPR (airway, breathing, circulation) have now been supplanted with the “ABCDs” (airway, breathing, circulation, defibrillation). The progression of CPR continues into Advanced Cardiac Life Support (ACLS) supervised by a physician and consists of BLS as well as sophisticated adjuncts to provide oxygenation and ventilation, intravenous access with administration of drugs that support circulation, monitoring of cardiac rhythms with rapid interpretation of dysrhythmias and subsequent maneuvers to terminate or suppress these harmful cardiac electrical abnormalities, and postresuscitation care.

This article will first review the history of CPR followed by a detailed analysis of the pulmonary and cardiac physiology relevant to the application of these resuscitative functions. An overview of Emergency Cardiac Care (ECC) will be undertaken to enlighten the reader about the organizational process guiding CPR. The actual mechanism of BLS and ACLS will be then addressed with a brief overview of defibrillators. Finally, the salient points of this article will be summarized and future directions of resuscitation will be explored.

HISTORICAL PERSPECTIVE

Restoration of life to the dying has been a common action from antiquity to the present time. Ancient attempts at artificial respiration have been described by the prophet Elisha in the Bible (3). Galen was able to observe the inflation of a dead animal’s lungs in the second century, but there has been no recording of this significant finding applied to early attempts at resuscitation (4). Resuscitation methods during this time were futile—such as applying hot materials to the abdomen or whipping the victim; animal bladders were expanded with smoke and then the outlets of these bladders placed into the dying person’s rectum (5). Centuries later Paracelsus, a Swiss physician (1493–1591), first reported the use of a fireplace bellows to ventilate a dying patient. In 1740, the Paris Academy of Sciences recommended the instillation of air into a victim through a mouth-to-mouth technique and within 4 years Tossach used this method successfully to revive a person (4). Ironically, this technique was lost, only to be rediscovered some 200 years later. During the eighteenth century, multiple new attempts at artificial respiration occurred. The “Inversion Method” practiced in Europe and America was used for drowning whereby the victim was hung upside-down in an effort to drain water from the lungs and many successful attempts have been recorded for this maneuver. The “Barrel Method” as well as the “Trotting

Horse Method” were also used at this time consisting of rotating the prone drowning victim over a barrel that alternated chest compression (expiration) and chest relaxation (inspiration) or placing the drowned individual prone on a horse, with the bouncing incurred during the trot inducing the same rhythmic compression and relaxation (5). The realization that alternating compression and relaxation of the chest could induce expiration and inhalation, respectively, led to direct manual efforts by the rescuer. DeHaen in 1783 first described a chest compression, arm-lift combination (6). Leroy reported the first use of the supine victim ventilation position ~1830 and later in this century (~1860–1870s) Silvester’s, Howard’s, and Schafer’s prone methods of manual compression became popular and persisted into the twentieth century. The familiar Schafer–Emerson–Ivy ventilation method of scapular compression combined with pelvic-lift emerged in the United States at the beginning of this century.

The efficacy of these various methods of manual artificial respiration was resolved in the 1950s by Gordon, who performed experiments upon fresh corpses prior to rigor mortis and then on volunteers who underwent general anesthesia and paralysis by curare. Ventilatory volumes were measured and the “push–pull” maneuvers that caused active inspiration and expiration were at least twice as effective as the Schafer method or other procedures that only produced either active inspiration or expiration (7–9). The Holger–Nielsen method (prone back-pressure, arm-lift) for resuscitation became the standard of care.

At the time of these scientific studies attempting to clarify manual methods of artificial respirations, Elam elected to evaluate the physiology of mouth-to-mouth ventilation. As an anesthesiologist, Elam had serendipitously performed mouth-to-mouth ventilation to paralyzed polio patients, for as long as several hours. Though mouth-to-mouth or mouth-to-nose ventilation had been known to have been practiced by midwives for the newborn, the question posed by this physician was, “What was the mechanism involved in the success of exhaled-air ventilation?” (10). The answers to this question came from a series of experiments where volunteers allowed themselves to be paralyzed while awake, and then ventilated by mouth-to-mouth, mouth-to-mask, or mouth-to-endotracheal tube by Elam and his colleagues until the paralyzing agent was allowed to wear off. Blood gas values were analyzed and the conclusion was that normal physiological parameters could be maintained by exhaled-air ventilation (11). This landmark study brought forth the subsequent challenge to the current back-pressure, arm-lift mode of artificial ventilation. In an effort to answer the question of which form of artificial oxygenation and ventilation would prove superior, a series of controlled experiments was then conducted by Elam and Safar. The various lung volumes with blood gas analysis for the back-pressure, arm-lift was compared with mouth-to-mouth ventilations. These two methods were used on awake, paralyzed volunteers and patients without any mask, endotracheal tubes or adjunctive airway support! These experiments also investigated the mechanisms of soft tissue airway obstruction and the effectiveness of head-tilt and jaw-thrust in maintaining the airway in rescue breathing (the jaw-thrust was first

described in Germany by Esmarch and Heiberg in the nineteenth century). The data and conclusions of these studies were published and within one year a dramatic change was made within the American and International Red Cross, global medical associations and the Armed Forces. Modern resuscitation through mouth-to-mouth oxygenation and ventilation was born through these landmark investigations (12–20). “Airway, Breathing” of the “ABCs” for current CPR principles had been founded.

The advent of electrical energy production in the eighteenth century made possible the first recorded successful defibrillation by Squires in 1775; a landmark publication came later in 1809 when Burns hypothesized that effective resuscitation would occur with the combination of artificial ventilation and electric shock (6). Even though a primitive “shock instrument” was fabricated by Aldini (6) in the 1830s, there did not appear to be any significant research into electrical cardiac excitation until much later in the century. The miraculous discovery of anesthesia in the 1840s unfortunately led to catastrophic complications. Documentation of the first case of cardiac arrest was reported in 1848 when a child died under chloroform anesthesia while having a superficial procedure completed (21). As this type of complication became more commonplace, research began to focus upon cardiac physiology and mechanisms to restore the normal heart rhythm and function. Open-chest cardiac compression was first reported by Schiff in 1847 during unsuccessful attempts to circulate blood in dogs and 2 years later Niehans reported an emergency attempt at open cardiac compression in a patient who arrested during an induction of general anesthesia using chloroform. Cardiac contractions reoccurred for a brief time prior to the patient’s death (21). Interestingly, in 1847 Boehm reported the first study of closed-chest cardiac compressions in cats (22). The chest was compressed with a rhythmic motion and a cardiac pressure was sustained. In the next 10 years, Koenig and Maass reported eight successful closed-chest cardiac compressions in humans (23) secondary to anesthetic-initiated cardiac standstill; one of these resuscitations lasted for more than 1 h (24). Unfortunately, the open-thorax mode of direct cardiac massage was to be the predominant form of attempted circulatory support for the next 60 years despite these reports.

Alternating current, brought forth by the investigations of Tesla, was first reported by Prevost and Batelli to stop dog heart fibrillation in 1899 (25). Intense research into terminal cardiac dysrhythmias and electrical termination of these lethal rhythms was started in the United States by Kouwenhoven, a professor of electrical engineering, in 1928. The funding for this project was undertaken by the Consolidated Edison Company because of the numerous fatalities induced by electrocution of its employees. Termination of ventricular fibrillation through electrical countershock was confirmed and the effects of both alternating and direct current were investigated in the dog open heart model. By 1933, this group had described the principles necessary for successful open heart alternating current (ac) defibrillation (26). In 1939, the Russians Gurvich and Yuniev were the first to describe successful external defibrillation and reported that direct current

(dc) countershock was superior to ac generated currents. They reported that a capacitor discharge applied to the exterior of the dog's chest would stimulate a cardiac rhythm if only applied no later than 1.5 min after the induction of ventricular fibrillation; however, they noted that the time to successful defibrillation could be extended to as long as 8 min by the application of external chest compressions. There was no description as to how these chest compressions were done (27). Unfortunately, their report was not available to western researchers until 1947 and substantiation of the benefits of dc versus ac would not be made for a number of years.

The research of Kouwenhoven at the Johns Hopkins Hospital continued in defibrillation experiments and in 1958 Knickerbocker, a research fellow, made an astute observation; during a defibrillation experiment he noted a pressure wave form being generated by the application of external electrodes on the dog's thorax (28). During a later, but similar study, Knickerbocker had a dog unexpectedly start to fibrillate and since defibrillation electrodes were not immediately available, he employed the same type of pressure upon the dog's sternum that he had found to generate a systolic pressure. After ~5 min of chest compression, the animal was successfully defibrillated into a normal sinus rhythm. A surgeon, Dr. James Isaacs, who was also conducting experiments in the same laboratory, became aware of this incident and had the foresight to encourage new research by this group into the generation of circulatory blood pressures by external cardiac massage (29). During these subsequent studies, arterial-venous pressure gradients were found to be generated and carotid artery flow was documented. Data that was reproducible indicated that if chest compressions were initiated within 1 min of ventricular fibrillation and continued for as long as 20 min, dogs could be resuscitated by defibrillation and appeared to have no deficits in central nervous system function. Further experimentation on dogs led to the conclusion that the optimum location for chest compressions was on the distal one-third of the sternum with a force of between 35 and 45 newtons (30). Even though postmortem studies revealed numerous injuries, such as rib fractures to these animals, the life-saving benefits were very apparent. Soon the practicality of closed-chest compressions became evident when Kouwenhoven and Isaacs made these laboratory observations available to the surgical staff and, in the same year, a 2-year old child was successfully resuscitated in the operating room at Johns Hopkins Hospital. An organized approach directed at patient resuscitation followed, resulting in 118 cases of successful restoration of life by chest compression following documented ventricular dysrhythmia (31).

Further collaboration at this time by Safar, Elam, and Kouwenhoven resulted in the basic tenets of modern CPR. Since external cardiac chest compressions were found not to produce adequate tidal volumes from airway obstruction (32), control of the airway confirmed by head-tilt data became the "A" in the "ABCs" of CPR. Exhaled air ventilation would become the "B" for rescue breathing. The addition of cardiac compressions, the "C" in the rudiments of basic cardiopulmonary resuscitation was then combined to produce what is now the standard protocol of care in basic

life support. The final studies determined what ratio for breathing and chest compressions would be used; one rescuer CPR utilized 2 breaths for every 15 compressions while the addition of a second rescuer could increase the ratio to 1 ventilation per 5 chest compressions (33).

While the first open chest defibrillation in an operating room was reported by Beck at Case Western University in 1947, Zoll reported the first successful closed-chest or external defibrillation in humans (34). This early defibrillator utilized 60 Hz ac current of 1.5 A at a range of 120–150 V. A 6:1 isolation step-up transformer converted the 120-V line current to a range of 0–720 V with the duration of current set at 0.15 s by a condenser-relay circuit. The machine was capable of producing 12,000 W during this time interval. The copper electrodes were 7.5 cm in diameter. This paper described the successful countershock for terminating ventricular fibrillation in four patients. The advent of external cardiac defibrillation would now usher in modern cardiopulmonary resuscitation when conjoined with airway manipulation, rescue breathing, and closed cardiac chest compressions.

The historical evolution for understanding the mechanisms of cardiopulmonary resuscitation has been paradoxical; the physiology of rescue breathing appears to have been well understood versus the mechanisms of cardiac flow due to chest compressions. Positive pressure ventilation, of which mouth-to-mouth resuscitation is an example, utilizes different mechanical principles to expand the lungs versus normal breathing, but the gas exchange once in the alveoli is very similar. The action of chest compressions, however, has remained controversial. After the serendipitous finding of increased blood pressure upon application of defibrillator paddles, Kouwenhoven hypothesized that sternum compression of the heart against the spine forced blood out of the ventricles (28), but no hemodynamic studies supported this claim. Further research demonstrated an increased venous pressure equal to arterial pressure during chest compression that brought into question whether the heart ejected blood in the normal manner (35). A study 1 year later actually measured cardiac output in patients being resuscitated utilizing external cardiac compressions. The ejected blood was found to have flows approximately one-quarter of normal even though systolic blood pressures appeared to be adequate (36). An investigation of actual intravascular pressures during external cardiac compressions determined that left atrial (venous) pressure was very close to arterial pressure, which argued against a projectile expulsion of blood by the heart. The hypothesis of this study was that the requisite flow needed for organ perfusion was driven by the action of the cardiac valves. This action was thought to account for the arterial-venous pressure gradient to sustain oxygen delivery (37). The cardiac compression–cardiac flow hypothesis was further contested with a series of studies generated by the observation that coughing by patients sustained blood pressure. Reports of successful resuscitation in documented ventricular fibrillation by coughing led to research that compared arterial pressures produced by chest compressions to that produced by cough. The conclusion was that improved hemodynamic parameters occurred with coughing CPR (38). Further interest into these mechanisms was

induced by a number of reports whereby trauma patients with a flail chest were not able to be resuscitated through closed-chest compressions; a flail chest results when the thoracic cage is compromised during rib fracture. Direct cardiac compression should be easier to produce since the ribs offer no resistance. Evidence appeared to support increased intrathoracic pressure rather than direct cardiac compression as the mechanism producing blood flow (39,40). Echocardiography was also utilized in several studies where CPR was initiated in humans; the cardiac valves were visualized and noted to be in the open position. Additionally, the left ventricle did not appear to be compressed, again lending credence to the "thoracic pump" theory of blood flow (41,42). Unfortunately, this theory could not account for coronary circulation blood flow or as to the mechanism of blood flow during disruption of intrathoracic pressure, such as when a pneumothorax (collapsed lung) occurs. Subsequent research utilizing very sophisticated instrumentation determined that, indeed, pressure gradients were generated with chest compressions in animals relative to aortic and thoracic venous vessels, data not supported by the thoracic pump theory. Contrast dye echocardiography demonstrated typical opening and closure of the mitral valve with projection of the contrast being propelled throughout the heart and then into the aorta (43,44). The momentum changed with these studies in elucidating the exact mechanism for blood flow, resupporting the cardiac compression hypothesis. What is currently hypothesized today is that both mechanisms seem to operate relative to resuscitation-generated cardiac ejection of blood. The key to understanding this paradox is that chest compressions involve two forces: compression and release of pressure upon the sternum. Compression of the heart forces blood through the atria and ventricles with flow generated, as evidenced by arterial and venous pressure gradients. Release of sternum pressure appears to augment venous return, supporting the thoracic pump theory. Therefore, it appears at this time that the current literature supports both mechanisms in CPR generated blood flow (45).

PULMONARY PHYSIOLOGY

Pulmonary function provides for the oxygenation of tissues and the removal of carbon dioxide from cell metabolism; human's survival is dependent on this function. It is by no coincidence that the first two actions of cardiopulmonary resuscitation, airway establishment and then rescue breathing, must be accomplished prior to chest compressions. Resuscitation is hopeless unless oxygenation and ventilation can be established. It is easiest to appreciate pulmonary function as a progression of air transport from the airway into the lungs, with an overview of lung mechanics and the molecular basis for oxygen and carbon dioxide transport.

After a volume of air is breathed through the oral or nasal passages, this inspired gas passes to the lungs by way of the trachea, bronchi, and bronchioles. Muscular tone in the soft palate and pharynx maintain this anatomical area of the airway. The trachea is supported by numerous

cartilaginous rings. At the bronchiole and alveolar level, transpulmonary pressures are responsible for patency. Cardiopulmonary resuscitation of the unconscious victim demands that the first action taken by the rescuer is to make sure that the airway is open. The usual cause is obstruction of the airway by the tongue or soft tissues. Maneuvers to open the airway are the first line treatment in CPR when a person is found to be unresponsive.

The lungs function by expanding through a negative pressure pump mechanism causing inspiration of air by two mechanisms. The diaphragm, a large muscle located at the lung bases, contracts increasing the subatmospheric pressure and thus producing a pressure gradient relative to ambient air. Movement of the rib cage acts in conjunction with the diaphragm, as lung expansion occurs during elevation of the ribs. Normally, the ribs are positioned in a superior-inferior dimension; as the thoracic cage is raised, the ribs move in an anterior-posterior direction, increasing the intrathoracic lung compartment by ~20%. The lung expansion through this mechanism also acts to produce a subatmospheric gradient, drawing air into the lungs. This occurs because the lung volumes increase at a more rapid rate than gas flow through the airway. As energy is utilized to cause this expansion, expiration during normal breathing is simply the result of the elastic recoil of the lungs and air is expelled, as now the pressure gradient reverses. During episodes of rapid oxygen metabolism, the work of breathing increases and thus the rapidity of chest wall movement requires a forceful expiration. The abdominal musculature functions in this manner to compress the diaphragm. It should be apparent that pressure-volume relationships establish the adequacy of lung mechanics. Transmural pressures, that is, the difference between the interior of the lung minus the lung exterior (or the pleural space, which separates the lung from the chest wall), define the various lung volumes as well as being a measure of elastic forces on the lung (the force tending to cause lung collapse). The slope of the P - V curve at any point represents the lung compliance; in the normal adult lung this averages 200 mL of air/cm of water, that is, when transpulmonary pressure increases by 1 cm of water, the lungs expand by 200 mL. Lung compliance is not only affected by the elastic force of the lung tissue, but also by the forces generated by surface tension in lung and pleural fluids. This surface tension elastic force is reduced in the lung by surfactant, a complex molecule primarily composed of phospholipids, which has hydrophilic and hydrophobic moieties.

When a rescuer determines that a person is unconscious and begins CPR, the airway is first opened and then rescue breathing is attempted. As mouth-to-mouth ventilations are instituted, now the lungs are expanded by positive pressure, quite different than the previously described normal mechanism. The intraalveolar as well as intrapleural pressure will rise above atmospheric pressure. The diaphragm is progressively pushed toward the abdomen in contradistinction to this muscle's upward or cephalad movement with contraction. Upon expiration, the intrapleural pressure, which is positive, decreases to subatmospheric pressure upon end-expiration and the diaphragm also moves away from the abdomen. When

Figure 1. The dynamic lung volumes that can be measured by simple spirometry are the tidal volume, inspiratory reserve volume, expiratory reserve volume, inspiratory capacity, and vital capacity. The static lung volumes are the residual volume, functional residual capacity, and total lung capacity. Reprinted from *Anesthesiology*, 4th ed., Benumof: *Respiratory Physiology and Respiratory Function During Anesthesia*, p. 590, 1981, with permission from Elsevier Science.

positive pressure ventilation is employed in other clinical settings, such as with ventilator therapy, a constant concern is that with any damage to the lungs, gases will be propelled into the pleural space. If there is no egress of these gases, a ball-valve mechanism ensues, and the increasing positive pressure in this pleural space will compress the lung, causing hypoxemia and death (pneumothorax).

The lungs are subdivided into four static volumes and four capacities (Fig. 1). A capacity is the combination of two or more lung volumes; capacities are helpful in describing the pulmonary function and disease processes. A device called a spirometer, invented in 1846 by Hutchinson for amusement purposes, is used for these measurements (46). The original machine was a watertight bell emersed in a water tank and connected by tubing to the patient's airway. As this bell moves with inhalation or exhalation, an attached writing instrument marks these volumes on a chart. The current spirometers utilize a bellows or piston with electronic circuitry. All measurements are representative of the average adult man. These volumes and capacities are 20–25% less in women.

1. **Tidal Volume:** The volume of air either inspired or expired with a normal breath; This is ~500 mL; these are minimum volumes that are typically attempted in rescue breathing.
2. **Inspiratory Reserve Volume:** This is the maximum volume of air that can be inspired after a normal tidal volume; it is ~3000 mL.
3. **Expiratory Reserve Volume:** The maximum volume of air that can be ejected after expelling the tidal volume; it is ~1100 mL.
4. **Residual Volume:** The volume of air remaining in the lungs after a maximal expiration; this volume is ~1200 mL.

The four lung capacities consist of the following:

1. **Inspiratory Capacity–Tidal Volume plus Inspiratory Reserve Volume:** This volume represents the

maximum amount of air that can be inspired after a normal expiration and represents ~3500 mL.

2. **Functional Residual Capacity–Expiratory Reserve Volume plus Residual Volume:** The volume of air in the lungs after a normal expiration; ~2300 mL.
3. **Vital Capacity–Inspiratory Reserve Volume plus Tidal Volume plus Expiratory Reserve Volume:** This volume is the maximum amount of air that can be expelled after a maximum inspiration and is ~4600 mL.
4. **Total Lung Capacity–Vital Capacity plus Residual Volume:** The maximum volume of air that can be expired after greatest possible inspiration.

The minute respiratory volume is equal to the tidal volume as a product of the respiratory rate. Since the normal tidal volume is ~500 mL and the normal respiratory rate is ~12–15 breaths/min, the minute respiratory volume is ~6–7.5 L/min. The inspired and expired volumes are not quite equal since the volume of oxygen absorbed through the alveoli is slightly greater than the volume of carbon dioxide that is expired. Only the inspired air that reaches the alveoli can participate in oxygenating the blood. There is a portion of a normal inspiration that does not reach the alveoli and this volume of gas is referred to as dead space ventilation. Anatomic dead space refers to the volume of gas from the nose, mouth, and trachea to the respiratory bronchioles. This volume averages ~2.2 mL/kg. Thus in a normal tidal volume of 500 mL, only 350 mL of air and thus 72 mL of oxygen, is available for gas exchange.

The tidal volume and the respiratory rate have a profound effect upon the total alveolar ventilation. This fact has been reflected in the revisions of CPR literature over the years. Suppose patients all have the same total minute ventilation of 5000 mL. The first patient has only a small tidal volume of 150 mL and is breathing 33 times/min, producing a minute ventilation of ~5000 mL. Recall that not all of the air in a breath reaches the alveoli; dead space is ~150 mL. The total dead space ventilation would be equivalent to the total minute ventilation. The actual alveolar ventilation would be zero. This patient will become hypoxic very quickly. The second patient has a tidal volume of 250 mL and is breathing at a rate of 20 times/min. The total minute ventilation will be again 5000 mL. The alveolar ventilation will be 2000 mL. The third patient has a tidal volume of 500 mL and a breathing rate of 10 times/min; again the total minute ventilation is 5000 mL, but in this case the actual alveolar ventilation is 3500 mL. The conclusion that should be drawn from these examples is that the efficiency of ventilation is greater when the tidal volume is increased versus the equivalent change in respiratory rate relative to total alveolar ventilation.

The composition of air that one breathes changes significantly from the atmosphere to the alveolus. At sea level, nitrogen produces a partial pressure of ~597 mmHg and composes ~78% of room air. Oxygen has a partial pressure of 159 mmHg and represents almost 21% of the total for atmospheric gas. Carbon dioxide and water make up the remaining partial pressures and percentages. Once the air is humidified by the nasal and oral airways, water vapor

comprises 47 mmHg and increases to ~6% of the mixture with a corresponding reduction for nitrogen and oxygen. The alveolar air has a reduction in both nitrogen (569 mmHg, 75%) and oxygen (104 mmHg and 13%). In the clinical setting, the alveolar oxygen tension is an extremely useful measurement to evaluate the variables in pulmonary mechanics and gas exchange. The ideal alveolar gas equation is useful approximation and is expressed as follows:

$$PA_{O_2} = [(P_B - P_{H_2O})(F_1O_2)] - \frac{PA_{CO_2}}{R} + F$$

Where PA_{O_2} is the partial pressure of oxygen in the alveoli; P_B is the barometric pressure; P_{H_2O} is the partial pressure of the water vapor in the alveoli at 37 °C; F_1O_2 is the partial pressure of oxygen; PA_{CO_2} is the partial pressure of alveolar carbon dioxide; R is the ratio between the volume of carbon dioxide diffusing from the pulmonary blood to the alveoli and the oxygen diffusing from alveoli into pulmonary blood. Approximately 200 mL/min of carbon dioxide versus 250 mL of oxygen exchange, so the ratio 0.8. F is a small correction factor that can be ignored clinically. Therefore, for example, suppose that a patient has been medicated with opioids after a painful operation and the alveolar partial pressure rises to 65 mmHg since these drugs reduce the respiratory sensitivity to carbon dioxide. The barometric pressure is 760 mmHg.

Therefore,

$$PA_{O_2} = [(760 - 47)](0.21) - \frac{65}{0.8}$$

$$PA_{O_2} = 68 \text{ mmHg}$$

These figures have a profound influence upon oxygenation in resuscitation. A simplified example will enlighten the reader; from the previous review of lung volumes, the total lung capacity is ~5000 mL. If roughly 20% of the atmosphere is oxygen, then 20% of the total lung volume, 1000 cm³, will contain oxygen. As mentioned earlier, the basal metabolic rate for oxygen consumption is ~250 mL/min. Therefore, the quotient of the 1000 cm³ relative to the oxygen consumption of 250 mL/min yields 4 min until hypoxia ensues from lack of oxygen. This is reason why time is so critical for the rescuer; unfortunately, the brain is the most oxygen-sensitive organ in the body and cerebral function diminishes rapidly after this critical four minutes. In ACLS, supplemental oxygen is immediately made available to the victim. Given the previous example, if 100% oxygen is administered without entrainment of room air (and nitrogen), now the total lung volume of oxygen would be 5000 cm³. At the same basal metabolic rate for oxygen utilization, 250 mL/min, theoretically the patient could remain apneic for 20 min before hypoxia would ensue! Practically, this does not occur because of the metabolic byproduct of carbon dioxide diffusing into the alveoli as well as the tremendously increased energy requirements caused by the ventricular dysrhythmias; however, the point to be made here is how the atmospheric composition of gases can easily be altered by the addition of supple-

mental oxygen to improve the mortality and morbidity of cardiopulmonary resuscitation.

Alveolar ventilation is the ultimate endpoint with respect to lung mechanics. Air must be transmitted throughout the respiratory passages until oxygen can be absorbed by the blood. As a person inspires a normal tidal volume, the contained oxygen reaches the terminal bronchioles. Interestingly there is no organized flow of gas from this point to the alveoli; the oxygen traverses the respiratory bronchiole and alveolar duct into the alveolus for gas exchange by simple diffusion. Once the oxygen reaches the alveolar membrane, the diffusing capacity, which averages 21 mL/min per mmHg, causes the 250 mL of oxygen to traverse the respiratory membrane since the driving oxygen pressure difference is ~12 mmHg. The basic metabolic rate for oxygen utilization is equal to 250 mL/min. Therefore, during quiet respiration, with normal tidal volumes, oxygen intake is appropriate for oxygen utilization. When physical work or exercise increases the metabolic requirements for oxygen, the diffusing capacity can increase threefold in a young healthy adult male. The egress of carbon dioxide through the alveolar membrane is also crucial for survival. The diffusing capacity has never been measured accurately for carbon dioxide due to the rapidity with which this gas passes from red blood cell to alveolus; however, since the diffusion coefficient of carbon dioxide is ~20 times that of oxygen, a range of between 400 and 1200 mL/min per mmHg would be expected for this gas.

OXYGEN AND CARBON DIOXIDE TRANSPORT

Once oxygen diffuses through the alveolar membrane and enters the venous pulmonary blood, it is primarily carried in combination with hemoglobin encased in the red blood cells and secondarily in solution. Hemoglobin is a tetramer molecule consisting of four amino acid polypeptide chains and four heme groups. The globin, or protein portion, consists of two pairs of identical alpha chains and, in the adult hemoglobin, two beta chains. The locus for the alpha chains is located on chromosome 16. The alpha chain is always present; however, there may be some variety in the non-alpha chain. Fetal hemoglobin, for example, has two gamma chains, which increases the hemoglobin binding of oxygen, increasing the efficiency of maternal oxygen transport across the placenta. The four heme moieties are located in the center of each globin molecule. Heme is synthesized from glycine and succinyl coenzyme A to form a tetrapyrrole ring. Subsequent enzymatic reactions produce a protoporphyrin and, finally, ferrous iron is inserted into the center of this ring as a function of mitochondrial synthesis. Since there are four heme-combining sites in each hemoglobin molecule, a maximum of four oxygen molecules can attach to the receptors. When all four receptor sites are combined with oxygen, the hemoglobin has a 100% saturation. If only three molecules of oxygen are bound, the hemoglobin is 75%, and so forth. Oxyhemoglobin is hemoglobin that has oxygen bound to the heme sites (HbO₂); unbound hemoglobin is termed "reduced hemoglobin" or "deoxyhemoglobin" (Hb). The key principle to

Figure 2. The oxygen-hemoglobin dissociation curve. Four different ordinates are shown as a function of oxygen partial pressure (the abscissa). In order from right to left, they are: saturation (%), O_2 content (mL of $O_2/0.1$ L) of blood; deoxygen (O_2) supply to the peripheral tissues (mL/min); and O_2 available to the peripheral tissues (mL/min), which is the O_2 supply minus ~ 200 mL/min that cannot be extracted below a partial pressure of 20 mmHg. Three points are shown on the curve: *a*, normal arterial; *v*, normal mixed venous; and P_{50} , the partial pressure (27 mmHg) at which hemoglobin is 50% saturated. Reprinted from Anesthesiology, 4th ed., Benumof: Respiratory Physiology and Respiratory Function During Anesthesia, p. 596, 1981, with permission from Elsevier Science.

understand is that oxygen binding to hemoglobin is directly related to the partial pressure of oxygen. As the inhaled air reaches the alveoli and participates in gas exchange, hemoglobin becomes fully saturated with oxygen relative to the partial pressure at the alveolar membrane. Oxygen delivery and unbinding occurs at the tissue partial pressure. The initial binding of the first oxygen molecule to hemoglobin facilitates the further binding of the second molecule, and in turn, these first two molecules facilitate further binding of the third oxygen molecule. This interaction occurs until the fourth oxygen molecule is bound, and this characteristic of changing oxygen affinity of hemoglobin is reflected in a sigmoid curve when the percent saturation of hemoglobin is plotted against the partial pressure of oxygen (Fig. 2).

The curve has a steep and flat portion. The steep slope of the curve reflects the rapid combination of oxygen with hemoglobin as the partial pressure increases. Beyond ~ 60 mmHg, the curve flattens, reflecting very low increases in saturation relative to increases in oxygen partial pressures. The clinical significance of this flat portion of the curve can be observed by noting that a fall from 100 to 60 mmHg only decreases the oxygen saturation from near ~ 100 –90%. This zone of the curve provides for a safe range of minimal saturation and decreases relative to great decreases in partial pressure during oxygen loading. Furthermore, increasing the partial pressure beyond 100 mmHg of O_2 does not really oxygenate the blood to any

significant degree; since the hemoglobin is fully saturated, only the dissolved plasma oxygen will increase.

Another significant property of hemoglobin is the fact that the oxygen affinity of this molecule changes with intracellular pH (Bohr effect). As the end product of metabolism, carbon dioxide is present at the tissue level and is converted to a weak acid by the red blood cell catalyst, carbonic anhydrase. This weak acid ionizes to hydrogen ion and lowers the intracellular pH, which decreases the oxygen affinity of hemoglobin, and thus facilitates the unloading of oxygen at the tissue level where it is precisely needed. Since reduced hemoglobin is a weaker acid than hemoglobin, the hydrogen ions are bound and thus deoxyhemoglobin returns to the lungs, where the reverse situation occurs. Carbon dioxide is reconverted in the red blood cell, and with the diffusion of this CO_2 into the alveoli, the pH rises and the affinity of hemoglobin increases for oxygen.

PULMONARY CIRCULATION

Pulmonary blood flow begins with ejection of venous blood from the right ventricle into the pulmonary arteries. Successive arterial branching occurs so that at the level of the alveolar circulation the capillaries lie in intimate contact with the alveoli allowing for a very efficient and exceedingly large surface area for gas exchange. Since the pulmonary arterial pressure is only 20% or so of the systemic circulation, with a mean pressure of ~ 18 mmHg, these arterioles do not require significant amounts of smooth muscle. Thus the walls of these vessels are extremely thin, allowing for the diffusion of oxygen and carbon dioxide. This characteristic makes these capillaries very susceptible to distortion relative to alveolar pressure. Since the arterial pressure is so low, alveolar pressure may at times exceed pulmonary capillary pressure and this transmural pressure will cause these tiny vessels to collapse. In the upright lung, this situation occurs where pulmonary blood flow pressure is minimal, that is, at the superior aspect of the lungs. This pressure gradient scenario may be observed in Fig. 3.

In *zone 1*, where pulmonary pressure can fall below alveolar pressure, the potential exists for no flow to occur in the capillary. Any situation that decreases systemic blood pressure and thus pulmonary blood flow such as hemorrhage, or increases alveolar transmural pressure, such as might positive pressure ventilation encountered in rescue breathing, might cause this change. The alveolar pressure exceeds pulmonary arterial pressure and, in turn, pulmonary venous pressure.

In *zone 2*, the pulmonary arterial pressure increases due to the elevated hydrostatic pressure as a function of position relative to the column of blood. The alveolar pressure exceeds pulmonary arterial pressure in this zone; however, the pulmonary venous pressure relative to alveolar pressure is low and thus the gradient in this zone is the difference between arterial and alveolar pressure. The analogy to this unique lung region has been described as the vascular waterfall effect (47). The elevation of the river above the dam is described as pulmonary arterial pressure

Figure 3. The Four Zones of the Lung. Schematic diagram showing distribution of blood flow in the upright lung. In zone 1, alveolar pressure (P_A) exceeds pulmonary artery pressure (P_{pa}), and no flow occurs because the intraalveolar vessels are collapsed by the compressing alveolar pressure. In zone 2, arterial pressure exceeds alveolar pressure, but alveolar pressure exceeds venous pressure (P_{pv}). Flow in zone 2 is determined by the arterial–alveolar pressure difference ($P_{pa} - P_A$) and has been likened to an upstream river waterfall over a dam. Since P_{pa} increases down zone 2 and P_A remains constant, the perfusion pressure increases, and flow steadily increases down the zone. In zone 3, pulmonary venous pressure exceeds alveolar pressure, and flow is determined by the arterial–venous pressure difference ($P_{pa} - P_{pv}$), which is constant down this portion of the lung. However, the transmural pressure across the wall of the vessel increases down this zone so that the caliber of the vessels increases (resistance decreases), and therefore flow increases. Finally, in zone 4 pulmonary interstitial pressure becomes positive and exceeds both pulmonary venous pressure and alveolar pressure. Consequently, flow in zone 4 is determined by the arterial interstitial pressure difference ($P_{pa} - P_{ISF}$). Reprinted from Anesthesiology 4th ed., Benumof: Respiratory Physiology and Respiratory Function During Anesthesia, p. 578, 1981, with permission of Elsevier Science. Diagram modified and reprinted with permission from West JB: Ventilation/Blood Flow and Gas Exchange, 4th ed., Blackwell Scientific Publishers, Oxford, 1970.

and the dam height analogous to alveolar pressure. The downstream river is equivalent to pulmonary venous pressure. Pulmonary blood flow is relative only to the difference between the height of the river upstream and the elevation of the dam. The distance that the water falls over the dam is immaterial to flow rate. Since the alveolar pressure tends to remain constant throughout this zone, but the pulmonary alveolar pressure increases secondary to the gravity, flow increases linearly. *Zone 2* circulation is unique in that ventilation and cardiac changes may alter flow dynamics, shifting these relationships into a momentary *zone 1* or *3* picture.

The dynamics in *zone 3* are straightforward. Here pulmonary venous pressure exceeds alveolar pressure and blood flow is governed by the arterial–venous gradient, which occurs in the systemic circulation. Blood flow never ceases and all capillaries remain patent, with the

additional feature of decreasing alveolar pressure maximizing vessel diameters and decreasing pulmonary vascular resistance. The rate of pleural pressure rises as a function of the transmural pressure gradient between lung apex and base; this pressure does not increase as rapidly as the pulmonary artery–venous difference that optimizes blood flow.

Zone 4 is ordinarily not present in normal lung physiology. Some pathological process is required to increase fluid pressure between cells where pulmonary venous and alveolar pressure is exceeded. Conditions such as iatrogenic fluid overload, pulmonary embolism, high levels of negative pleural pressure encountered with airway obstruction in a spontaneously breathing patient, or thoracostomy maneuvers causing profound negative pleural pressures (48,49) may cause this situation. Pulmonary arterial pressures exceed interstitial pressures, which, in turn exceeds venous and alveolar pressures. Since interstitial pressures are greater than venous pressures, regional blood flow is decreased relative to *zone 3*, and flow is governed by the pulmonary arterial-to-interstitial gradient.

In conclusion, it should be evident that both alveolar ventilation and pulmonary blood flow have a variable distribution throughout the lung. The lung base not only receives more blood flow than the apex but, because the compliance of the basal alveoli is greater than the apical alveoli, the lung base receives a greater amount of the tidal volume. Since the blood flow gradient is steeper than the ventilation gradient, the base is relatively overperfused and thus hypoventilated; the reverse situation occurs in the apex where the lung is overventilated and hypoperfused. These conditions have a profound effect upon end-organ oxygen transport. The first scenario refers to physiologic shunt blood flow; should absolutely no ventilation occur, a true shunt occurs. Decreased ventilation relative to perfusion increases alveolar carbon dioxide and thus, as seen in the alveolar gas equation, alveolar oxygen concentration will decrease. The oxygen content of the systemic arterial blood is decreased and thus oxygen transport to the tissue results in hypoxemia. A ventilated alveoli that is not perfused, as in *zone 1*, does not participate in gas exchange. Alveolar carbon dioxide decreases and alveolar oxygen increases due to the absence of blood flow. This situation is termed “alveolar dead space ventilation”. The composition of alveolar gas is essentially equal to atmospheric gas. The extremes of alveolar dead space ventilation and shunt are ends of a continuum in lung ventilation and perfusion dynamics. Ventilation and perfusion ratios will vary throughout the lung both on an anatomical and physiological basis. The total effective gas exchange can thus be seen as the complex interplay between lung mechanics, ventilation, perfusion, and molecular interactions.

CARDIAC PHYSIOLOGY

The heart is an extremely efficient pump, which results in the progressive pulsatile ejection of blood to the organs. The heart is composed of four chambers: two atria and two ventricles. As blood enters the right atrium from the large veins, passive flow continues into the right ventricle. The right atrium then contracts, forcefully ejecting

the remaining 25% of this blood into the right ventricle. After a delay, this right ventricular blood flow is directed into the pulmonary arteries. A progressive reduction in vessel size results in a capillary meshwork intimately in contact with the alveoli whereby the gas exchange mechanisms function. Pulmonary venous blood, now oxygenated and devoid of carbon dioxide, enters the left atrium. This blood is pumped to the left ventricle, and into the systemic circulation where the cycle is continuously repeated.

Cardiac muscle has some similarities to skeletal muscles, but also some very significant differences as well. Cardiac muscle is arranged in a striated latticework with actin and myosin filaments, which lie adjacent to one another and contract in the same manner as skeletal muscle. However, cell membranes separate these fibers yet allow ionic diffusion between these membranes or *intercalated disks*. Thus during a chemical depolarization resulting in an action potential, unimpeded progression of this electrical current flows with minimal resistance throughout the heart. The *intercalated disks* allow for the heart to actually act as two separate systems. The two atria are electrically excited as a unit, as are the ventricles. The anatomical division of atria and ventricles by nonconducting fibrous tissue does not allow conduction to occur between the atrial and muscle in an unorganized manner. A very specialized conduction system ensures that atria and ventricles are depolarized in a progressive manner.

The atrioventricular valves close during ventricular contraction (systole) preventing the backflow of blood into the atria. The tricuspid valve lies between the right atrium and right ventricle; the mitral valve is located between the left atrium and left ventricle. As blood is ejected out of the right and left ventricles, the semilunar valves open; the pulmonary and aortic valves, respectively, then close during cardiac relaxation (diastole) to prevent blood from returning from the pulmonary and systemic circulation. Note that the first arterial branches off the aorta are the coronary arteries.

The specialized conducting system of the heart that produces a progressive, rhythmical contraction of atria and ventricles has several components. The sinus node provides the genesis for cardiac depolarization. This specialized cardiac muscle is located in the right atrium just below and lateral to the superior vena caval ostium. This strip of tissue, ~ 15 mm long, connects directly to the atrial musculature. Generation of action potentials in the sinus node progresses directly to the entire atria causing a unified contraction of all muscle fibers at once. The resting membrane potential of the sinus node fibers is ca. -60 mV compared with the ca. -90 mV for cardiac muscle. This difference in the sinus node electronegativity is due to the fact that sodium ions with their positive charge progressively "leak" intracellularly. A progressive rise in threshold voltage occurs until ca. -40 mV; opening of the rapid sodium channels at this point then produces the initial cardiac depolarization. The sustained contraction of the cardiac muscles is due to the secondary influx of calcium ions, followed by the influx of potassium ions, which exchange with the outward diffusion of the sodium ions.

Figure 4. Rhythmical sinus node action potential compared with ventricular muscle fiber. Reprinted from *Textbook of Medical Physiology*, 10th ed., Guyton and Hall, p. 108, 2000, with permission from Elsevier Science.

This last ion counterexchange of potassium for sodium limits the induced hyperpolarization of the cell allowing repolarization. This phenomenon of "leaky" sodium channels produces the rhythmic excitation, which initiates the cardiac cycle. The rate of this sinus node depolarization is controlled by the autonomic nervous system through the interaction of the para-sympathetic (acetylcholine) and sympathetic (norepinephrine) fibers. Generally, the length of time for this activation is on the order of 10 ms. Drugs utilized in ACLS, such as atropine and epinephrine, affect the firing interval of the sinus node.

Once the atrial muscle fibers are activated, the action potentials cause a generalized contraction of all of these fibers at once, again due to the unique anatomy of the cardiac musculature. Activation of the left atrium occurs through the specialized fibers termed the "anterior interatrial band". The anterior, middle, and posterior internodal pathways transmit the pacemaker impulses to the atrioventricular node in ~ 0.03 s. The AV node is essentially a junction box that has two unique features; a delay in the pacemaker action potential occurs here, which affords a delay in ventricular contraction so that the blood is allowed to empty from the atria to both ventricles and normally action potentials can only travel in one direction. This atrioventricular node is positioned in the right atrial posterior wall just behind the tricuspid valve. The delay in the ventricular depolarizing impulse is ~ 0.13 s.

The final pathway for the activation of the ventricles occurs through the Purkinje fibers, which terminate in the left and right bundle branches. These branches run in the ventricular septum separating the right and left ventricle and then terminate into progressively smaller branches throughout the ventricular muscle. The Purkinje fibers act in contradistinction to the AV node; action potentials are transmitted at a velocity 100-fold allowing rapid excitation and contraction of both ventricles. Transit through the Purkinje fibers is only ~ 0.03 s with the same approximate time necessary for complete ventricular muscle activation.

The electrical activity described in Fig. 5 can be measured at the skin such that electrical potentials are recorded as the ECG. A normal ECG consists of several

Figure 5. A normal electrocardiogram (ECG) cycle with wave segments and intervals. Reprinted from *Anesthesiology*, 5th Edition, Hillel and Thys: *Electrophysiology*, p. 1232, 2000, by permission from Elsevier Science.

waves of depolarization and repolarization. The P wave is produced from the summed action potentials generated during atrial depolarization. It is upright and, after returning to baseline, a pause is observed reflecting the progressive depolarization through the AV node. This P–R interval (actually the P–Q interval, but often the Q-wave is not visualized) begins at the initiation of the P wave and ends at the beginning of the QRS complex. The normal duration of the P–R interval is ~ 0.12 – 0.21 s or three to five of the small squares on the ECG graph paper. During the P–R interval atrial depolarization occurs as well as the electrical activity generated in the AV node. The QRS complex, which consists of a Q wave, R wave, and S wave, represents the electrical activity causing ventricular depolarization. The Q wave is seen as a negative deflection from the baseline, which is followed by the large positively deflected R wave. The S wave follows the R wave and, like the Q wave, has a negative deflection. Often the Q wave and S wave may not be observed in the complex. The normal QRS duration is usually no > 0.10 s or 2.5 of the small ECG squares. The S–T segment begins at the end of the S wave (commonly termed the “J point”) and ends at the onset of the T wave. This interval is usually isoelectric, but can have a normal variance of ca. -0.5 to $+2.0$ in the precordial leads (see below). The normal duration is < 0.12 s and ~ 2.5 ECG squares. The T wave is a repolarization wave and reflects potentials generated with ventricular recovery. This wave usually has a positive deflection of ~ 0.5 mV, but often is not observed because of decreased amplitude. The T wave represents a continuum of absolute to a relative refractory period of ventricular depolarization. It is important to note that the electrical activity observed in the electrocardiogram represents electrical activation of the atrial and ventricular muscles and not the actual contractions themselves. A standardized method for recording ECGs consists of graph paper upon that positivity is reflected with upward deflections and negativity, downward deflections. Ten small divisions represent 1 mV. The large vertical lines represent 0.20 s with the smallest intervals representing 0.04 s. These voltages recorded at the skin are very small relative to the actual potentials of ~ 110 mV at the heart. Proximity of the recording electrodes

as well as angular direction from the heart then will affect the size and shape of the ECG, respectively.

The standard electrocardiogram utilizes 12 leads (electrodes) to view the electrical activity of the heart. Six standard limb leads are combined with six chest (precordial) leads. Initial resuscitation events that require dysrhythmia interpretation usually view the bipolar leads I, II, III. These leads utilize two electrodes, one positive and one negative, to monitor the heart and record potential differences. Electrodes are applied through an adherent conductive gel to the left shoulder, right shoulder and left leg essentially forming a triangle (Einthoven’s triangle, Fig. 6). The ground lead is usually placed on the right leg. Lines that bisect the sides of the triangle have their origin at the heart, the center of the triangle, which is the zero axis of each side. In lead I, the left shoulder is connected to the positive electrode and the right shoulder electrode is negative; the recording is the potential difference between the left shoulder and right shoulder. In lead II, which is the most common limb lead to be monitored, the negative electrode is placed on the right shoulder and the positive terminal to the left leg. Depolarization in the heart follows this same electrical vector as lead II and thus optimizes P wave height and shape as well as QRS morphology. Lead III places the positive terminal on the left leg and the negative terminal on the left arm. These three leads are very similar to one another in that the P, Q, and T waves are positive. They are excellent for dysrhythmia interpretation; since electrical activity from atria to ventricles is displayed, waveform and time related changes are very apparent, both to the diagnostician and computer (such as in an automatic external defibrillator).

CARDIAC ARREST DYSRHYTHMIAS

The previous section presented information relevant to understanding and interpreting the normal ECG. This

Figure 6. Einthoven’s triangle.

Figure 7. The fatal rhythm of ventricular fibrillation.

primer of basic electrocardiography will enable the reader to now have some ability to differentiate the lethal rhythms that cardiopulmonary resuscitation demands for optimizing treatment.

The fatal dysrhythmia of ventricular fibrillation (Fig. 7) is a common endpoint in cardiac arrest. There are no QRS complexes, P waves or T waves that are identifiable. Scientific evidence over the years has conclusively established that only early defibrillation has any hope of restoring a normal sinus rhythm to the heart and subsequent survival. The fibrillating heart has no ability to eject blood since there is no coordination of heart muscle and no progressive flow of blood from atria to ventricles to systemic circulation. Cardiac depolarization and repolarization within the ventricular muscle occurs in a chaotic manner; ventricular muscle is activated in an unorganized fashion. This electrical activity sustains a vicious cycle of reexcitation, never allowing the return of normal cardiac function. The ventricles neither relax nor contract and in this ventricular fibrillating state consume massive amount of energy. Since there is no ejection of blood, unconsciousness from lack of cerebral blood flow occurs within seconds and death ensues from hypoxia.

After a normal cardiac sequence there is a refractory period (as mentioned previously with the beginning of the T wave, which is at the end of the cardiac cycle), whereby this cardiac impulse cannot reexcite the heart until a new electrical stimulus is generated from the sinoatrial node. However, the underlying etiology of ventricular fibrillation appears to be due to electrical reentry or "circus movements", where the normal termination of depolarization does not occur. These abnormal electrical pathways may be generated in several ways: a shortened refractory period, decreased depolarization velocities, or increased distance for the normal electrical impulse to travel. Recall that the progression of depolarization takes place only in one direction and essentially travels almost in a circle with excitation of the ventricles. If this normal impulse reaches cardiac muscle that has already been depolarized, the refractory time will not allow another depolarization. Stimulation of cardiac muscle will not occur until the entire myocardium is ready to be energized as one unit. Suppose that one of the three abnormal conditions were present; any ventricular muscle that was not refractory could be stimulated to contract in an unorganized manner. In a clinical setting, many individuals have hypertension and develop enlarged hearts. A large ventricular muscle mass

would create an increased distance for the normal electrical impulse to follow, thus creating the potential for a "circus movement" to initiate reexcitation of muscle fiber. Rates of depolarization from the sinoatrial node through the AV node may result from blockade of this specialized system from a variety of causes. Electrolyte imbalance, as well as coronary artery disease, are common factors in inducing conduction block. Alterations in the sympathetic nervous system as well as drugs may act in sensitizing the heart, allowing more rapid conduction of impulses and increased susceptibility to fibrillation. Once the ventricular muscle begins this chaotic activity, a chain reaction phenomena begins: conduction velocities throughout the heart decrease, allowing even more time for reentrant depolarizations to occur and the actual muscle refractory time is decreased, increasing the opportunity for these impulses to propagate this dysrhythmia.

The cornerstone of cardiopulmonary resuscitation is early defibrillation. The previous American Heart Association mnemonic of CPR, the "ABCs", which consisted of Airway, Breathing, Circulation, has been changed to "ABCDs" to include defibrillation. After one shock, 60% of all victims succumbing to ventricular fibrillation will survive; after two shocks, 80% survive; after three shocks, 90% will be successfully resuscitated (48). Electrical countershock utilizing high-voltage current can inhibit defibrillation by instantaneously depolarizing all cardiac muscle tissue. The myocardium then is totally refractory to any reentry currents. The electrocardiogram will typically record asystole, or no evidence of electrical activity, from the heart for several seconds. Resumption of the normal cardiac pacemaker will resume, and organized contraction should reoccur. Time is of the essence, since as a heart continues in fibrillation, the rapid utilization of high-energy phosphates depletes this "fuel" for resumption of normal cardiac activity. It is obvious that delay in defibrillation induces a state whereby even successful technique in countershock will be not be able to sustain a normal cardiac rhythm due to the lack of substrate for myocardial energy consumption. The underlying philosophy of cardiopulmonary resuscitation now is early access to defibrillation for the victim.

Pulseless ventricular tachycardia (Fig. 8) is the other malignant dysrhythmia that requires immediate external countershock. Unlike ventricular fibrillation, the electrocardiogram displays a rapid regular rhythm with a widened and abnormal appearing QRS complex. Usually,

Figure 8. Ventricular tachycardia.

the rate is very rapid, with a range of ~ 100 – 250 beats/min, contrasted to the normal sinus rhythm rate of 60 – 100 beats/min. Three or more of these bizarre appearing complexes define this dysrhythmia. Usually, the P wave and T wave are obscured and thus the P–R interval cannot be measured. This rapid rate does not allow adequate filling of the ventricles, and causes a ventricular lack synchrony with the atria; the result is dramatic loss of cardiac output and blood pressure. Since there is no effective cardiac output and these dysrhythmias degenerate into ventricular fibrillation, external countershock is mandated. The sinus node functions normally in VT, whereby the atria are properly depolarized. There can be a retrograde depolarization of the atria from the ventricles in some instances of ventricular tachycardia and there will be a definite P wave associated with the abnormal QRS complex. Usually, these retrograde P waves have a negative (downsloping) peak. Another unusual feature of this dysrhythmia is that at certain time intervals the atria may be able to initiate an impulse completely through the AV node and Purkinje system at the instant where the ventricular-initiated depolarizations leave the conduction system vulnerable. The result is termed a “capture beat”. If this normally conducted impulse occurs at the same time that a ventricular depolarization is generated, a fusion beat is generated, which appears as a cross between the normal- and ventricular-originated complex. This dysrhythmia may either be paroxysmal or sustained and the shape of these QRS waves either monomorphic or polymorphic. Degeneration into ventricular fibrillation is a common course; for this reason countershock is required. The mechanism for pulseless ventricular tachycardia is hypothesized to be a

reently depolarizing current due to delayed conduction. The site of occurrence for this aberrant mechanism would localize to the Purkinje system and ventricles.

An unusual form of ventricular tachycardia (Fig. 9) is termed “Torsade de Pointes” or twisting of points (49). Notice the QRS morphology viewing the rhythm strip from left to right. On first appearance, this dysrhythmia appears to be ventricular tachycardia. The QRS complexes are wide (versus the normal narrow QRS shape), but constantly changing in shape and amplitude yet there appears to be a rhythmic oscillation about the baseline. The depolarization wave appears to twist around the central axis or helix. This dysrhythmia is triggered by electrical potentials that either occur before or after the normal spontaneous depolarization of the heart or is associated with a prolonged QT interval. Should this dysrhythmia be associated with no evidence of effective blood flow, immediate countershock would be the treatment of choice after the “ABCs” of CPR have been accomplished. However, if Torsade de Pointes is misdiagnosed as ventricular tachycardia and a pulse is present, the potential exists for the wrong treatment and lethal results. This dysrhythmia usually occurs when there is an underlying prolongation of the QT interval. Since many of the antiarrhythmic agents will prolong this interval, it should be apparent that selection of one of these drugs to terminate a misdiagnosed ventricular fibrillation when Torsade is present has the potential to produce a nontreatable dysrhythmia. Antidepressants, antipsychotics, and electrolyte abnormalities (particularly hypokalemia and hypomagnesemia) will produce the underlying QT prolongation that serves as the catalyst for Torsade

Figure 9. Torsade de Pointes.

Figure 10. Asystole.

to appear (50). Strategies for treating this rhythm are to correct the factors providing the substrate for dysrhythmia; magnesium supplementation, and correction of all electrolyte abnormalities as well as what is termed “overdrive pacing” to externally pace the heart to rates of between 100 and 120 beats/min (51).

Asystole (Fig. 10) is the terminal arrhythmia that represents a dying heart. Observation of the above example shows the absence of electrical activity (flat line), but occasionally P waves, or what is termed “ventricular escape beats”, may be present. Usually, the presence of asystole means death for the victim, so rescuers are taught to view this rhythm in more than one lead since fine ventricular fibrillation may actually be the abnormal rhythm rather than asystole. This distinction is extremely important since VF needs to be immediately treated with defibrillation, whereas in asystole the possible causes need to be identified, and defibrillation is contraindicated for resuscitation. Why not shock the heart that is in asystole? The answer lies in the fact that rarely a victim may experience high levels of parasympathetic nerve input to the heart. This parasympathetic stimulation can produce complete cessation of the atrial and ventricular pacemaker. Defibrillation also produces an intense parasympathetic nerve discharge, which, in this specific situation could terminate any chances for the heart to recover normal pacing function (52). Evidence substantiates that defibrillation for asystole does not improve the survival rates in out-of-hospital arrest scenarios (53). There have been rare occasions reported in the literature where victims have positively responded to transcutaneous cardiac pacing for which many defibrillators now have this

capability. The heart is stimulated externally to produce an effective cardiac output. The caveat is that this maneuver can only be effective if there are only several minutes of asystole. A specific situation that lends itself to transcutaneous pacing is the asystole that occurs after defibrillation. This witnessed arrhythmia occurs immediately after some countershock attempts and thus there can be a window of < 1 min for pacing to be initiated. There may be certain types of patients who also might respond to asystolic pacing, such as those with Stokes–Adams–Morgagni syndrome, where intermittent atrio-ventricular block produces asystole or the hypoxia initiated P wave asystole (54).

The last terminal rhythm group that occurs frequently in resuscitation efforts is pulseless electrical activity (PEA). Observe the rhythm strip in Fig. 11; this is an example of a normal sinus rhythm. At first, one would question why a normal ECG would be included in emergency cardiac care and treatment. The key to understanding pulseless electrical activity is that the rhythm may appear to be entirely normal; however, upon further physical assessment of the victim, no pulse is detectable. Historically, cardiologists have referred to this state as electromechanical dissociation, where the normal atrial and ventricular depolarization progresses without any myocardial muscle contraction. Recent scientific evidence utilizing echocardiography and invasive pressure monitoring catheters have found that minute myofibril contractions do occur with depolarization; however, there is not enough effective projectile pressure generated to produce any external signs of perfusion, thus the term pseudoelectromechanical dissociation has been proposed (55,56).

Figure 11. Pulseless electrical activity.

Other rhythms are also included in this group; ventricular escape rhythms, postdefibrillation rhythms, and bradysystolic rhythms have different QRS morphology than the normal sinus rhythm; however, the same underlying problem of no pulse and no organ perfusion is the defining issue. The key to resuscitation of the victim in PEA is to quickly recognize and treat the underlying problem that has created this scenario. Since there is no perfusing rhythm it should be obvious that the "ABC" basics must be immediately made available to the victim while the differential diagnosis prioritized to the specific situation is reviewed.

There have been a number of mnemonic memory aids suggested to recall the most common conditions provoking pulseless electrical activity. Two common lists are the '5 Hs' and '5Ts' and the "MATCH-HHH-ED" (57,58).

- Hypovolemia; Hypoxia; Hydrogen ion excess (acidosis).
- Hyper or Hypokalemia (excess or loss of potassium ions).
- Hypothermia; "Tablets" (referring to medications or drug overdose).
- Tamponade (blood trapped around the heart chamber).
- Tension pneumothorax (trapped air causing lung over-inflation and resultant loss of cardiac perfusion).
- Thrombosis (secondary to myocardial infarction) and Thrombosis (secondary to pulmonary embolism).
- M—Myocardial injury or infarction
- A—Acidosis
- T—Tension pneumothorax
- C—Cardiac tamponade
- H—Hypothermia
- H—Hypo or Hyperkalemia
- H—Hypoxia
- H—Hypovolemia
- E—Embolism
- D—Drug overdose or chemical toxins.

The most common cause of PEA is hypovolemia: inadequate intravascular fluid volume. These fluid volume losses may be real, such as in acute hemorrhage or relative, wherein the capacitance vessels (veins) vasodilate, leaving inadequate vascular blood and fluids to compensate. A classic evolution to pulseless electrical activity would ensue from hemorrhage, producing normal electrical complexes, with progression to a tachycardia where the heart rate increases to compensate for pressure loss. Peak pressure for each cardiac ejection of blood (systolic pressure) would decrease, but increased constriction of the circulatory vessels would increase (diastolic pressure). As the blood pressure continues to drop to extremely low levels secondary to the hemorrhage, the sinus tachycardia continues. At this point, the astute clinician would consider this cause for PEA and immediately give the victim intravascular fluid followed by blood products to stabilize the victim. It is obvious that the definitive treatment in this case would be surgery; the goal of the resuscitative response is to maintain perfusion and oxygen delivery to the tissues. Time again is critical since without effective

cardiac flow, perfusion of the myocardium is nonexistent and hypoxia develops quickly. Progression toward ventricular fibrillation, asystole, and death are the end result. An example of relative hypovolemia is septic shock. In this situation, a bacterial infection produces endotoxins, which causes the resistance vessels to dilate. There is normal circulating blood volume, but increased vessel capacitance resulting in a progressive blood pressure drop. Due to the underlying pathology, the vessels are unable to adequately constrict and the evolution to cardiac dysfunction secondary to poor or absent coronary perfusion occurs, eventually producing the terminal rhythms of ventricular fibrillation and asystole. Treatment in this scenario consists of increasing the fluid volume as well as to utilize drugs that act to constrict the blood vessels.

Each one of the other conditions mentioned above that can cause pulseless electrical activity also has an immediate treatment response, after the appropriate steps in basic life support have been met. Thus while the victim is being oxygenated and ventilated, and perfusion accomplished through chest compressions, the clinician is rapidly focusing upon the conditions that would be most causative and then initiating treatment. In hypoxia, treatment consists of supplemental oxygen and adequate mechanical ventilation of the lungs. In cardiac tamponade or tension pneumothorax, needle decompression of the pericardial sac or lung is the required emergency management. Electrolyte imbalances require immediate infusion or neutralization of the ion. A preexisting acidosis might require exogenous sodium bicarbonate. An acute myocardial infarction (heart attack) causing PEA would need supplemental oxygen, pain management, fluid resuscitation and immediate infusion of coronary artery thrombolytics. Pulseless electrical activity is always associated with an underlying clinical condition that, when identified and treated early, has the potential to be reversed and thus effective perfusion restored to the victim.

MECHANISMS FOR COMMUNITY CPR

The American Heart Association is a volunteer organization that has as its goal the reduction of mortality and morbidity secondary to cardiovascular and cerebrovascular disease. The AHA established a scientific mission in 1963 to evaluate and promulgate standards of CPR. In 1971, the Emergency Cardiac Care Committee was founded. Since the first conference on CPR in 1966 sponsored by the National Academy of Sciences and the National Research Council, guidelines for CPR have been based upon the available scientific evidence. Since this time there have been six conferences, the last in 2000 consisting of resuscitation experts worldwide. All aspects of CPR have been evaluated, including the actual access for emergency care in the community, education of the layperson, and delivery of basic CPR and ACLS. "Emergency Cardiovascular Care" is the term used to describe the organized response to life-threatening emergencies for the adult, pediatric, and neonatal victim. Other ECC provisions for care include educating the layperson to recognize the signs and symptoms of myocardial ischemia and infarction, stroke, activation of the EMS system (911) as well as early

implementation of basic life support, defibrillation, and advanced cardiac life support with immediate victim transfer to the hospital. The goal of ECC is to save lives and this also includes educating the public regarding cardiovascular risk and how to maintain healthy lifestyles. The cornerstone of all emergency care is the layperson. Effective emergency care can only occur with public awareness of these events as well as prompt administration of CPR and use of the automatic external defibrillator. Once the EMS system has become involved with the victim, progression of care is dictated by a physician and ACLS protocol. The optimization of oxygenation and ventilation through supplemental oxygen and adjunctive respiratory devices, electrocardiographic monitoring with rhythm assessment and treatment, establishment of intravenous access for appropriate medications and post-resuscitation management are all elements of ACLS.

The American Heart Association "Chain of Survival" is a crucial concept to be understood in the context of CPR and is taught to the layperson in the basic lifesaving courses. There are four critical links in this chain that require specific actions on the part of the public. In the event of an emergency the first link involves activating the emergency medical services system. Obviously, the layperson must be able to recognize that a true emergency exists, and this underscores the efforts by the community organizations to educate the public regarding signs and symptoms of heart attack, stroke, and loss of the airway. The key is unresponsiveness; anyone found unconscious should initiate the first link by way of immediately involving EMS through calling 911. Once an emergency medical dispatcher is contacted, immediate aid in the form of paramedics is sent to the scene. The dispatcher is also taught how to aid the layperson in how to provide basic CPR, which is the second link in the chain. Only until the EMS personnel arrive and begin managing care for the victim does the dispatcher terminate the call. In some communities, "enhanced 911" is available in which a computer will provide the dispatcher with the address from which the call is made in case communication is difficult or there is a premature telephone disconnection. This second link of CPR is the most critical phase in the Chain of Survival since the rescuer provides oxygen to the victim and, if needed, circulates this oxygen by chest compressions to the brain, heart, and vital organs. If bystander CPR is initiated within 4 min after a victim collapses, the odds of survival, after discharge from the hospital, are doubled (59).

The third link in the chain is early defibrillation, either by the public use of the automated external defibrillator or by the paramedic on the scene. Early access to defibrillation for the victim of cardiac arrest will significantly improve the chance for survival: each minute of delay for defibrillation for the victim in ventricular fibrillation decreases the chance of survival by 7–10%, and if defibrillation is provided within the first 5 min, chance of survival is 50% (60). Unfortunately, if >12 min of delay from collapse to initial resuscitation is encountered, the survival rate only ranges between 2 and 5%, and intact neurological function is compromised (61).

Recently, gambling casinos have implemented access for defibrillators and for victims who received a shock

within 3 min had a 74% survival rate since a low response time of between 2 and 3 min was documented (62). Since time to defibrillation is so critical, automatic external defibrillators have been made much more accessible to the public. These devices can now be found in large gathering places such as stadiums, golf courses, airports and airplanes, shopping malls, large grocery stores, and other facilities where people in great numbers tend to congregate. So important is the early access to defibrillation that a great majority of states have enacted legislation to encourage use of these devices. The Cardiac Arrest Survival Act provides legal immunity for the layperson and the public business or corporate entity that uses or provides an automatic external defibrillator for resuscitation, which is essentially an expansion of the "Good Samaritan" type legislation. This immunity should encourage active participation by the public for involvement in victim resuscitation. Public access defibrillation has been described as the second most significant advance, compared to CPR, in the pre-hospital rescue scenario.

The final fourth link in the Chain of Survival is early ACLS by highly trained paramedical personnel. Emergency medical technicians expand (EMTs) incorporate basic CPR with interpreting cardiac dysrhythmias and, if required, defibrillation. Emergency medical technicians expand the immediate life-saving care by providing supplemental oxygen, intubation and control of the airway, gaining intravenous access and administering pharmacologic medications while in contact with a physician. This process occurs at the scene, and once the victim is stabilized, advanced cardiac life support continues through transport to the hospital emergency room. The most significant impact of early ACLS is to prevent the catastrophic progression of lack of oxygenation and cardiac arrest rather than to treat the terminal conditions inherent in this process.

The rescuer, whether a lay person of EMT, who begins CPR in the "field" must continue BLS (63) until one of the following events occurs:

1. The victim begins to show signs of spontaneous ventilation and perfusion.
2. Care is transferred to another qualified BLS responder, EMT, or ALS medical providers; or to a physician who makes the determination that resuscitation should be terminated.
3. The rescuer cannot continue resuscitation due to exhaustion or to hazards that may jeopardize the rescuer's life or the lives of others in the team.
4. An authentic no-CPR order is presented to the responders.

The determination to discontinue resuscitation depends on a stepwise evaluation of the efforts made during BLS and ACLS. A review of the process should ensure that each step in the resuscitation has been carried out in a flawless manner. Successful ventilation and intubation, intravenous access and the administration of appropriate medications as well as countershock should be achieved according to ACLS protocol. Electrocardiography evaluation should render a conclusion of no reversibility for the underlying agonal rhythm. Recently, the determination of end-tidal

carbon dioxide has been advocated as a potential predictor of death (64). During resuscitation end-tidal carbon dioxide reflects the adequacy of cardiac output generated during chest compressions. This study suggested that after standard ACLS protocols had been followed for 20 min, a persistent end-tidal carbon dioxide level of 10 mmHg or less predicted nonsurvival in the victim with electrical activity, but without a pulse.

CARDIOVASCULAR DISEASE

Every year ~500,000 people are hospitalized for treatment of chest pain secondary to cardiac origin and 1.5 million victims will experience a heart attack (65,66).

Some 500,000 people a year who have a myocardial infarction (heart attack) will die from this insult and ~225,000 of these deaths will occur within the first hour after symptoms and prior to reaching a hospital (67,68). In 17% of the victims, chest pain is the first and only symptom (67). It is again significant that time to intervention for the patient experiencing a myocardial infarction is crucial to survival; treatment must be undertaken within the first several hours after the symptoms occur (70,71). Early treatment underscores the necessity for rapid recognition of a cardiac event, followed by rapid CPR, defibrillation, ACLS and transport to the hospital.

The most common cause of a heart attack is ischemic atherosclerotic disease. The essential pathophysiology is the narrowing of the coronary artery lumens by deposits of fat-substrate such as cholesterol and lipids, which eventually retain calcium. The actual process of the accumulation of these plaques occurs very slowly, but has been demonstrated to begin at an early age. This same process affects the cerebral arteries as well and is the etiology for an ischemic stroke. As the coronary artery lumen narrows, a dynamic situation develops where blood flow and thus oxygen supply will not meet with increased demand for oxygen by the cardiac muscle fibers. Typically the coronary artery will have a circumference reduction of 70% for symptoms to occur. This condition of ischemia will produce a characteristic constellation of transient symptoms, referred to as angina pectoris. Chest pain is the most common sign of an acute cardiac ischemic event, occurring in 70–80% of the population (72). This pain appears to have several different components: transmission of dull, poorly localized pain occurs through the sympathetic visceral nerve fibers; a somatic pain generator produces the sharp and dermatomal aspects; and psychological input gives rise to the sense of impending doom (73,74). This cerebral input to the event may significantly exacerbate the ischemia since activation of sympathetic nervous system will increase heart rate and contractile force, further tipping the scale toward more energy consumption and thus oxygen demand.

Paradoxically, the majority of episodes of an acute coronary event (angina and or infarction) occur during periods of rest or mild to moderate exercise; profound physical exercise is associated with the minority of events (75). The victim will experience an intense, dull, crushing pressure sensation in the chest, most commonly behind the

breastbone (retrosternally) and/or pain in the back, arms, shoulders, or mandible. Often nausea, vomiting, sweating, and shortness of breath (dyspnea) may accompany the pain. There appears to be a circadian rhythm regarding the occurrence of angina and the progression to infarction. Two daily peaks in incidence have been noted with the first pattern beginning from awakening to about noon, and the second peak occurring in the early evening (76,77). There are atypical presentations to unstable angina or myocardial infarction that will delay access for the victim. This subset of the population may have only vague, mild discomfort, which can be confused with a myriad of medical complaints. Diabetics, women, and the elderly all have a higher incidence of nonclassical presentations for cardiovascular ischemia (78,79). Diabetics are prone to neurological dysfunction and thus may have no sensation of the pain associated with angina. A retrospective review found that 30% of first heart attacks in men and 50% of first infarctions in women did not present with classical signs and symptoms and were clinically not recognized (80). When oxygen demand decreases, such as when the physical activity is discontinued, the decreased oxygen supply secondary to the narrowed lumen will be adequate and the symptoms will usually resolve. Progression of the disease, however, results in a much more severe mechanism for ischemia. The plaque is predisposed to rupture and when this occurs, activation of the coagulation system releases mediators that form a clot or thrombus over the plaque, which can further limit blood flow, or catastrophically, stop all blood flow completely. If the partial occlusion from the thrombus is severe enough, what is termed “unstable angina” develops. Though there have been many definitions of unstable angina, the main characteristic is that this type of angina occurs at rest and is progressive or prolonged in nature. Nocturnal angina, again with the victim at rest, would be classified as unstable angina. The heart is consuming the least amount of oxygen yet there is a lack of supply due to lumen reduction from the plaque. Clot enlargement provides the mechanism for dislodgement of particles or emboli, which then travel downstream, lodging in the microvasculature and these individuals are at a very high risk for progression to irreversible cardiac damage.

Complete occlusion of the coronary artery results in a myocardial infarction. Deprivation of oxygen results in the death of cardiac myofibrils and induces irritability in the cardiac conduction system, setting the stage for the initiation of lethal dysrhythmias such as ventricular fibrillation. Where and how severe the damage is to the heart depends on what coronary artery has the occlusion. If the left main coronary artery has an acute total obstruction, mortality is very high since no blood flow will occur through the two distal branches, the left anterior descending and circumflex arteries. Blood flow will be blocked to the entire left ventricle, the septum between the left and right ventricle, and the bundle branches. Even if the patient receives timely CPR, and clot lysis, a significant amount of heart may be destroyed resulting in scar tissue and a drastic reduction in blood flow, resulting in what is termed “congestive heart failure”. If the thrombus were to lodge and occlude the right coronary artery, hypoxia would occur in

the AV node, right ventricle, and in the majority of individuals, the posterior and inferior aspect of the left ventricle.

The continuum of acute cardiac injury, from unstable angina to myocardial infarction typically presents with characteristic electrocardiographic signs. Recall what the normal elements are to the ECG. During episodes of unstable angina where cardiac muscle demand for oxygen exceeds supply, ischemic changes to the ECG are seen as S-T segment depression, defined as \geq to a 1 mm change from baseline on the standard graphpaper or changes in the T waves. When this S-T segment depression is down-sloping, this is a sensitive sign of ischemia. The T waves may appear inverted or enlarged and symmetrical. When actual occlusion of the artery occurs, myocardial injury to tissues ensues and both muscle contraction and conduction are decreased from normal. The ECG change characteristic of injury is S-T segment elevation in contradistinction to changes of ischemia. When there is ≥ 1 mm above baseline for the S-T segment elevation, significant cardiac injury has occurred. This group of patients who exhibit S-T segment elevation on the ECG in two contiguous leads may be salvaged through reperfusion therapy. Restoration of blood flow and the course of injury is very dependent on early administration of thrombolytics or percutaneous transluminal coronary angioplasty (PTCA). The greatest improvement in mortality and morbidity occurs when reperfusion therapy is administered within the first 3 h after onset of symptoms (81,82). Conjoined with early CPR and defibrillation, reperfusion therapy stands as one of the greatest advances in acute coronary syndromes. Current regimens include the fibrinolytics streptokinase and alteplase, as well as numerous other similar agents that act by inducing fibrinolysis through interactions with tissue plasminogen activator. The PTCA is a mechanical procedure whereby a catheter is guided through the coronary arteries into the area of stenosis, and then a balloon is inflated to expand the vessel. This procedure is restrictive in that only specialized centers have the capability to utilize this regimen, although it may be superior to thrombolytics.

Myocardial infarction defines the actual death of cardiac tissue. This is the end result of the process of ischemia with myocardial cell injury. The infarcted tissue area, again representative for the specific coronary artery occluded, will exhibit characteristics associated with loss of cellular life. Intracellular contents are released after loss of cell wall integrity. Some of these enzymes, such as creatine phosphokinase and the troponins, can be measured in the bloodstream to confirm infarction. The classic ECG changes for myocardial infarction are the presence of abnormal Q waves. When a Q wave is or ≥ 1 mm in width and the height is $>25\%$ of the R wave height, the diagnosis can be made. An abnormal Q wave reveals the existence of dead cardiac tissue, but does not reveal anything about when the infarction happened. The assumption can be made for a recent infarction if the Q wave is associated with S-T segment changes and/or T wave changes. A non-Q wave infarction can also occur: There is myocardial cell wall dissolution with the release of cardiac enzymes, but only accompanied by S-T segment changes or T wave abnormalities. There is a lower mortality rate for non-Q wave heart attacks, but, unfortunately, an increased incidence of future reinfarction or

death (83,84). Fibrinolytics are contraindicated in patients with non-Q wave infarction since the clot occlusion may be paradoxically aggravated by release of thrombin, which further activates platelets (85).

Prehospital intervention for the victim suffering an acute cardiac event is based upon the "Chain of Survival". Once the signs and symptoms of a heart attack are recognized, early access to the emergency medical system is imperative. A common problem encountered is denial either from the victim or the rescuer, which impedes response time. Once the EMS personnel arrive at the scene a pertinent medical history is obtained and physical examination completed. A complete 12 lead ECG is obtained and then transmitted to the physician who is dictating care. Oxygen is the first line treatment for anyone complaining of chest pain. It should be recalled that supplemental oxygen substantially increases the oxygen tension in the blood and significantly improves tissue oxygenation. A critical blood flow restriction may be palliated by improving oxygen supply in this manner. The administration of the drug nitroglycerin is quickly administered for the victim symptomatic for angina in conjunction with oxygen. Nitroglycerin is delivered sublingually for rapid absorption into the bloodstream. Nitroglycerin is effective in relieving the symptoms of angina in several ways: relaxation of venous smooth muscle occurs due to binding of specific vascular receptors. As relaxation of the venous capacitance vessels occurs, venous return to the heart is decreased, thereby relieving ventricular wall tension, which ultimately decreases ventricular work and oxygen consumption. The nitrates also dilate the large coronary arteries as well as increasing blood flow through collateral vessels, which improves ischemic blood flow (86,87). Aspirin is the third drug that should be administered immediately by either the BLS provider or EMT when symptoms suggest a cardiac event (and the victim is not allergic to aspirin). A regular tablet of aspirin (325 mg), when ingested, will cause an immediate anticlotting mechanism by way of platelet inhibition. There is evidence that suggests aspirin decreases coronary artery reocclusion and future coronary symptoms, with reduction of death and furthermore, the effects of aspirin appear to be additive to fibrinolysis (88). The fourth drug that is administered during episodes of chest pain secondary to unstable angina or myocardial infarction is morphine. Although morphine is a narcotic analgesic, it produces beneficial hemodynamic effects in addition to profound pain relief. Morphine causes decreased vascular tone in the venous capacitance vessels, thus reducing myocardial wall tension, much like nitroglycerin. The mechanism, however, is different in that the action appears to be mediated through central nervous system reductions in sympathetic tone (89). A convenient mnemonic has been utilized, "MONA", for recall of these four immediate effective therapies for pre-hospital treatment of the acute coronary syndrome.

CEREBROVASCULAR DISEASE

There has been a concerted effort in the Emergency Cardiovascular Care system to improve pre-hospital recognition of

the warning signs of stroke and provide rapid access to the Emergency Medical System. Public awareness of the issues regarding a "brain attack" has lagged relative to the exposure and education afforded cardiovascular disease. Stroke ranks third behind heart disease and cancer for morbidity in the United States; 500,000 Americans a year suffer from a cerebrovascular accident and 125,000 of these victims will die (90). Until recently, stroke victims were only offered supportive and rehabilitative therapy for the complications experienced if they survived the initial insult. However, advances in fibrinolytic therapy, as in treatment of cardiovascular disease, dramatically improves outcome for the patient who has experienced an ischemic stroke (91). Fibrinolytic treatment reduces stroke disability and significantly improves quality of life after hospital discharge (92,93). The caveat is that the cerebrovascular accident must be recognized and treatment initiated in a timely manner; fibrinolytics need to be provided within 3 h after the onset of an ischemic stroke (94). Thus there is a narrow window of opportunity to limit cerebral damage, which underscores how important the role is for the public in providing immediate access to the EMS system for the victim.

The underlying cause for an ischemic stroke is comparable to the etiology for myocardial infarction. There is a disruption to cerebral blood flow due to the presence of an occlusive clot. The oxygen supply to the particular area of the brain supplied by the blocked artery does not meet the tissue demand and the same process of ischemia, injury, and cell death will occur. The thrombus, which occludes the vessel, is the end result of atherosclerotic changes to the artery. However, due to the unique anatomical positions of the cerebral arterial system, a blood clot formed elsewhere in the body can embolize to disrupt blood flow to the brain. Approximately 75–85% of all strokes are of this type, and defined as ischemic, and furthermore can be classified as to the arterial system that is affected. The two major arterial conduits to the brain are the carotid arteries and vertebral arteries, which affect the cerebral hemispheres or brain stem–cerebellum, respectively. Typically, a person who is at risk will develop what is termed "a transient ischemic attack" (TIA) prior to a full-blown stroke. Essentially, a TIA is a reversible mini-stroke that may affect specific brain function or eyesight and will last anywhere from minutes to hours (95). The TIA is a harbinger of a future "brain attack" much like unstable angina will forecast a heart attack. About 5% of those persons presenting with a TIA will end up with a stroke in 1 month; the risk will increase to ~12% after 1 year and an extra 5%/year thereafter (96). Fortunately, the symptoms from a TIA will bring the patient into the medical system for evaluation whereby treatment regimens clearly reduce risk for ischemic stroke. The surgical procedure of carotid endarterectomy in which the carotid artery plaque is removed has been proven very beneficial for patients that have had a recent TIA and a >70% stenosis of the carotid artery (97). In those individuals who are not operable candidates, aspirin and the specific platelet inhibitor types of drugs have been shown to be successful in preventing subsequent stroke in patients presenting with TIA (98).

The minority of acute strokes are due to hemorrhage of cerebral artery. The bleeding may occur in the subarach-

noid space, which is in the superficial exterior aspect of the brain, or in the brain tissue itself, defined as an intracerebral hemorrhage. The common etiology to a subarachnoid hemorrhage is an aneurysm where the arterial wall weakens, and eventually a disruption occurs (99). In the case of a hemorrhage into the brain tissue itself, high blood pressure appears to be the major causative factor (100). While there are similar signs and symptoms in both types of stroke, there are also distinct differences in findings, which aids in the diagnosis. In general, the presentation for a subarachnoid hemorrhagic stroke is more severe with a very common complaint of an extremely painful headache, which tends to be global, and may have radiation of pain into the face or neck. This headache is often accompanied by mental status changes, nausea, vomiting, photophobia, or cardiac dysrhythmias. In a minority of patients, a prodromal episode of these symptoms may be caused by leakage of the aneurysm offering a warning sign (101). While the victim suffering from an intracerebral hemorrhage may also present with a severe headache, these patients tend to have a greater neurological insult with significantly depressed mental status function. The signs and symptoms of an ischemic versus a hemorrhagic stroke overlap and diagnosis may be difficult based upon the medical history and physical findings. Since radiological imaging offers the greatest aid in differentiating these two types of cerebrovascular accidents, time is very critical to clinch the diagnosis to offer the appropriate treatment. Fibrinolytics would obviously be a catastrophic therapy in the mistaken treatment of what appears to be an ischemic stroke when the etiology is a ruptured blood vessel that requires surgery.

The American Heart Association "Chain of Survival" that has been implemented and associated with cerebrovascular disease has been applied to the pre-hospital care of the stroke victim. Early recognition of a stroke and activation of the EMS system are paramount in initial therapy, which is often problematic, since, unlike a heart attack, stroke may be difficult to detect. While early defibrillation is not ordinarily indicated for the stroke victim, the possibility always exists that coincidental lethal dysrhythmias may be present during the initial presentation (102). The last link in the chain is early hospital care. The common theme regarding out-of-hospital management for cardiac or stroke victims is rapid entry for the victim into advanced life saving. The '7-D' mnemonic has been recommended as an aid for care in the stroke patient: Detection; Dispatch; Delivery; Door; Data; Decision; Drug (103). Early detection, with an accurate recall of the initial signs of a stroke are critical to care and must be accomplished by the immediate family member or layperson, with immediate access to "Dispatch", the EMS personnel. An important point to emphasize is that the majority of strokes occur at home (104). Paramedics who arrive at the scene must confirm a rapid, tentative diagnosis through focused medical history and physical examination, and then "Deliver" the patient rapidly to the hospital. Once the patient is through the Emergency Department "Door" the medical history and physical examination are further refined along with radiography (computerized tomography). A "Decision" is made regarding whether fibrinolytic therapy is

indicated for an ischemic stroke and the “Drug” treatment is initiated. The drug therapy must be initiated within 3 h after the onset of an ischemic stroke.

The changes in mental status and/or sensorimotor function in a cerebrovascular accident may range from minor, almost unrecognizable changes, to loss of consciousness and seizures. A person may exhibit grades of confusion, with a progression to stupor or coma where the airway is obtunded and basic life support is required. Comprehension of language often occurs with inappropriate responses to simple questions. Physical manifestations are often present unilaterally. Paralysis in either the face, upper, or lower extremity may range from slight weakness to frank inability to exercise any muscular control. Since the face is always exposed, muscle weakness is exhibited by loss of tone and sagging of the muscles in facial expression. Difficulty writing (aphasia) or speaking (dysarthria) occurs due to loss of appropriate motor input from the brain. Loss of sensation is another common sign of a stroke (or a TIA). Visual disturbances, including blindness are much more obvious and usually involve only one eye. If the location of the ischemia is in the vertebrobasilar arterial system, centers of the brain controlling coordination are involved and signs such as gait disturbances (gait ataxia) are common. The dilemma of pre-hospital rapid neurological assessment to evaluate the possible stroke victim when the presentation is varied has been improved by several instruments. The Cincinnati Pre-hospital Stroke Scale (104) is very effective in identifying the stroke victim. Three physical findings are assessed: facial droop; arm drift; and speech. Abnormal features in any one category is very predictive for cerebrovascular accident. The Los Angeles Pre-hospital Stroke Screen also is extremely useful for assessment. Six criteria are first evaluated in the medical history: (1) age > 45 years, (2) absent history of seizures or epilepsy, (3) no history of motor loss, (5) serum glucose not < 60 g/dL nor > 400 g/dL, and (6) asymmetry in any one of the three categories of facial musculature, grip strength, and arm strength. If all criteria are positive, there is a 97% chance of an acute stroke (105). These tests have streamlined the response time and have allowed the hospital emergency room to prepare for rapid definitive diagnosis.

THE “ABCs” OF ADULT CPR

The evolution of the current basics of life-support has resulted in a streamlined set of actions that has standardized the initial care for the victim, whether accomplished by a public bystander or emergency room physician. Assessment of the victim always precedes a physical maneuver on the part of the rescuer; constant appraisal of the effectiveness of CPR and the response of the victim is a core principle in American Heart Association Basic Life Support tactics. The initial steps of resuscitation are never bypassed; for example, if the airway is not established, the single rescuer would never start chest compressions, or begin intravenous access. The stepwise process in the algorithm ensures that an orderly process occurs in a situation where chaos and a high degree of emotional

turmoil exist for the rescuer. Since there are some basic differences in how resuscitation is administered to the adult versus a child, anyone 8 years or older is considered an adult.

When one encounters a potential victim, the first assessment is to determine unresponsiveness. “Shake and shout” has been a common first action to determine that the victim is really unconscious (there no doubt has been a number of resuscitations initiated upon someone who was sleeping, assuming unconsciousness)! Once there is no doubt that a true emergency exists, the rescuer sends another member of the group to activate the EMS system by phoning 911 and to obtain an AED. If the rescuer is alone, he or she must leave the victim momentarily to call 911 and get the AED; these automated defibrillators have a standardized placement near a telephone. After accessing the EMS and obtaining a defibrillator, the rescuer places the victim in the supine position, and kneels at the head (the left side is suggested when utilizing an AED). The “ABCs” of CPR now are initiated.

A = Airway

The unconscious person has a generalized relaxation of all muscles and in the throat this causes the tongue to move in a posterior direction, occluding the airway. Since the tongue is attached to the mandible, manipulating the jaw and head will retract anteriorly. Two methods are utilized to open the airway; the “head-tilt and chin-lift” or the “jaw-thrust” maneuvers. Tilting the head backward by placing one hand on the forehead and raising the chin with the two fingers of the other hand is the most commonly used technique. An important feature of this technique is to make sure that the fingers are placed on the inferior surface of the mandibular bone and not the soft tissue under the tongue, as the later placement will worsen airway compromise. In a situation where a neck injury is suspected with possible spinal cord compromise, extension of the head is contraindicated; the jaw-thrust is utilized to open the airway. The head is held in the neutral position while applying forward pressure with both hands at the angle of the jaw, just below the ears. In this way, there is no change in head position. At this point inspection of the mouth is important to remove any secretions, vomitus or foreign bodies that may be an impediment to air exchange. Once the airway is opened, the rescuer “looks, listens, and feels” for breathing by placing his or her cheek and ear close to the victim’s mouth. The chest is examined for movement while feeling and listening for air passage. In the case of a partial obstruction of the airway, the victim will tend to make high-pitched “crowing” noises that may be accompanied by cyanosis of the skin (due to unoxxygenated hemoglobin). Instead of the chest expanding with an inspiration, retraction of thorax or lung compartment will occur. It is imperative that the airway be opened and maintained in this situation since ineffective ventilations will invariably lead to hypoxia.

B = Breathing

Once it is ascertained that the victim is not breathing (this should occur within ~10 s), the rescuer places his mouth

around the victim's mouth and pinches the nose shut with one hand while maintaining chin-lift with the other hand. Two long, extended breaths are given, each ~ 2 s, with the goal of providing ventilation to the lungs while minimizing the egress of air into the stomach. Since during unconsciousness there is a relaxation of all muscles, the lower esophageal sphincter will relax and thus any air that enters the stomach may force gastric contents into the esophagus and then into the trachea. Aspiration of these highly acidic stomach contents into the lungs may occur. The complex interplay between rescuer, positive pressure ventilation, peak airway pressure, tidal volume, and inspiratory flow rate has had a considerable degree of scientific evaluation (106–109). The consensus supports a tidal volume of between 800 and 1000 mL to maintain adequate oxygenation when only room air is provided in the rescue breathing. This volume is slightly less than the 1992 ECC Guidelines of a rescue tidal volume of 800–1200 mL. A slow prolonged breath over 2 s decreases peak positive pressure and thus entry of air into the stomach while providing the optimum tidal volume. When supplemental oxygen is available, evidence has confirmed that a tidal volume of 500 mL provides effective oxygenation and ventilation in the unintubated patient as long as the inspired oxygen fraction is $>40\%$ (110,111). Once rescue breathing is commenced, one should assess effectiveness by noting whether the chest rises with each breath. If there is no change or the rescuer observes that significant effort is required to minimally expand the chest, the airway step has not been optimized and the rescuer has to reopen the airway with additional head extension and chin-lift (or jaw-thrust if a head or neck injury is suspected). If readjustment of the airway does not provide the ability to ventilate, a foreign body lodged in the airway should be suspected and the rescuer should proceed through the algorithm specific for dealing with this issue. Victims with dentures may prove difficult to ventilate; generally dentures should be left in place since it is easier for the rescuer to form a seal around the mouth. However, loose dentures may be aspirated and should be removed if their retention is inadequate. In the case where the rescuer cannot maintain an adequate seal, or if the mouth is unavailable for airway exchange secondary to trauma, mouth-to-nose breathing should be attempted (112). A deep breath should be inhaled by the rescuer prior to respiratory exchange since this maneuver optimizes the maximum amount of oxygen made available for each tidal volume (113). Should the victim only require oxygenation and ventilation, rescue breathing provides one breath every 5 s or 12 breaths/min (114).

There is always the concern regarding exposure to an infectious organism when performing rescue breathing. At this point in time, there has not been any evidence documenting the transmission of human immunodeficiency virus (HIV), hepatitis, or tuberculosis when mouth-to-mouth resuscitation has been instituted in an emergency (115). However, reluctance upon the part of any lay rescue person to perform this action is understandable and there is no moral or legal duty to do so. Barrier devices have been developed that prevent intimate contact with the victim and there are two basic types: face shields and masks. This adjunctive equipment has been made available in the

healthcare environments due to the requirements of the Occupational Health and Safety Administration. The face shield has a flexible plastic covering with a one way circular valve that, when placed over the victim, separates the rescuer from contact and from exhaled gases. Mouth-to-mask rescue ventilation provides a better seal and further distance from the victim's mouth than the face shield, which is advantageous should vomiting occur. Some of these masks have a port where supplemental oxygen can be provided and entrained with the rescue breathing. A flow rate of 10 L/min through one of these masks will increase the inspired concentration of oxygen to at least 40% (116). When supplemental oxygen is supplied in this manner, smaller tidal volumes, on the order of 400–600 mL, will maintain oxygenation while decreasing the risk of gastric insufflation (117).

C = Circulation

After delivery of two rescue breaths, the next step in basic CPR is to assess for signs of circulation. For many years the layperson was taught to feel for the presence or absence of a carotid pulse. Research in the 1990s found numerous pitfalls with the pulse check that appeared to have a negative impact on survival and, since 2000, this task is not taught to the lay responder anymore. Significant time delays in trying to determine if a pulse was present delayed time to defibrillation and thus survival (118). The accuracy of the pulse test revealed a sensitivity of only 55% and a specificity of 90% and overall the accuracy was 65% (119). At this time, the lay rescuer is instructed to look for signs of perfusion, such as movement, breathing, or coughing and if unsure, to begin chest compressions.

Correct positioning of the hands and compression skills are easily learned by the layperson. A simplified method for hand placement has been taught for several years and consists of placing the heel of one hand over the center of the breastbone (sternum) between the nipples and then interlocking the fingers of the remaining hand over the first, so that pressure will be transmitted through the heels of both hands. Effective compressions are generated by positioning the rescuer's shoulders over the hands and sternum and depressing the sternum from 1.5 to 2 in. Release after compression must be complete without taking the hands off the chest to prevent "bouncing". Chest compressions should be similar in action to that of a piston in a reciprocating engine with half of the cycle spent in compression and the other half spent in relaxation. The effectiveness of this ratio has been documented with regard to both cerebral and coronary perfusion pressures (120). The recommended rate for chest compressions is 100/min, which has been substantiated by numerous studies (121,122).

The single rescuer initiates chest compressions after providing the victim with two rescue breaths and assessing for signs of effective cardiac blood flow. A ratio of 15 compressions followed by 2 rescue breaths continues for four cycles and then the victim is reassessed for spontaneous circulation. Chest compressions should be resumed within 10 s after noting no signs of perfusion and the 15:2 cycle continued with an interruption for assessment of vital signs in several minutes, followed by the same ratio.

When additional responders are present during resuscitation of a cardiac arrest victim, immediate activation of the EMS system must be accomplished and a defibrillator brought to the scene, if these actions have not already been completed by the lone rescuer. The second rescuer should then assess the adequacy of ventilations and chest compressions and reassess for signs of a pulse and breathing within 10 s while CPR is halted. Though it is not expected that the layperson be able to engage in two-person resuscitation, the process is included here for completeness. Medical professionals as well as the paramedical caregivers should all be able to demonstrate this skill. The compressor is positioned in the normal manner, at the side of the victim. The second rescuer is stationed at the victim's head, maintaining the airway, monitoring for effective compression by carotid artery pulse check, and providing rescue breaths. Previous scientific guidelines utilized a compression:ventilation ratio of 5:2 (123), which has now been changed in light of recent scientific evidence. Currently, a ratio of 15 compressions to 2 ventilations is recommended for both one and two rescuer CPR (124–126) since it appears that improved survival occurs as a result of the higher rate in spite of a decreased number of ventilations. The effectiveness of chest compressions relative to coronary perfusion pressure (the difference between aortic diastolic pressure and the left ventricular end-diastolic pressure) suggests that, as the number of compressions increases, so does the perfusion pressure; therefore, 15 chest compressions improves and sustains blood pressure more effectively than the previous recommendation of 5 compressions to 2 ventilations. The pauses with the previously recommended 5:2 compression:ventilation scheme had more drops in cerebral and coronary perfusion and therefore decreased oxygen delivery compared to the new scheme. Therefore, whether a one- or a two-rescuer resuscitation occurs, the preferred compression/ventilation ratio is 15:2. When advanced life support is initiated and the patient is intubated (a breathing tube placed through the mouth and into the trachea) there is no pausing for ventilations; chest compressions continue at 100/min and ventilations are provided at a rate of 12 times a minute (127).

Despite the fact that there has never been evidence to suggest that transmission of disease occurs through mouth-to-mouth exchange of air or secretions, studies have demonstrated a lack of enthusiasm upon the part of both the layperson and professional rescuers to perform this maneuver on strangers (128,129). Current guidelines, as of 2001, now indicate that if the rescuer is unable to perform mouth-to-mouth ventilations, chest compressions should be started for the victim (130). The Cerebral Resuscitation Group of Belgium concluded that there was no difference in outcome for the victim if chest compressions were or were not accompanied by mouth-to-mouth rescue breathing (124). Since any resuscitation attempt utilizing chest compressions without ventilation may provide a better outcome for the victim than no action at all, education regarding this tactic in resuscitation has been made available to the lay responder. While it appears contrary to basic physiological principles that resuscitation could be successful without providing oxygen to the blood, evidence suggests that agonal breathing mechanisms are able to

maintain adequate PaO_2 and $PaCO_2$ during CPR without rescue breathing (131). The etiology for this paradox appears to be due to the decreased perfusion from chest compressions; since the cardiac output is only one-fourth that of normal, ventilation perfusion mismatch does not occur due to low rates of blood flow through the lungs. In essence there is a decreased requirement for oxygen; any excess ventilation is wasted due to this decreased perfusion and the lack of oxygen transport by the available red blood cells (132,133). This form of CPR is only recommended for the public rescuer since paramedical personnel should always have adjunctive airway devices available for resuscitation.

AIRWAY OBSTRUCTION

The tongue is the most common cause of airway obstruction and basic life support addresses this issue with various maneuvers to open the airway thus allowing either spontaneous respirations to resume or mouth-to-mouth ventilations to be initiated for the victim. Foreign body airway obstruction is the cause of ~3000 deaths a year (134).

In perspective, there are 198 deaths per 100,000 persons for coronary artery disease, 16.5 deaths per 100,000 individuals for motor vehicle accidents, and 1.2 deaths per 100,000 due to foreign body obstruction (135). The "cafe coronary" (where choking was mistaken for an acute coronary event) appears to be the most common cause of choking in adults since this emergency usually happens during eating and meat seems to be the culprit for most occurrences (136). A foreign body lodged in the airway can either completely occlude or partially occlude any segment of the respiratory passages. The key to distinguishing these two scenarios is that the victim is able to continue to breathe, albeit with difficulty, during a partial obstruction, and therefore the rescuer should not attempt any rescue attempt that potentially could convert a partial to a complete obstruction. As in all basic life support, it is crucial to activate the emergency medical system to get assistance. When a victim begins to make high pitched "crowing" sounds, cannot speak, or becomes cyanotic, hypoxia quickly ensues and this person needs immediate aid. The public is taught the universal choking sign where the neck is clutched with both hands. The first question to ask the choking victim if, in fact, he or she is unable to breathe and if they can speak. The next immediate step is the Heimlich maneuver (137), which should be attempted in anyone between the ages of one and adulthood. This action is not indicated in infants <1 year old (138). Forceful external elevation of the diaphragm utilizes the remaining volume of air in the lungs to expel a foreign body. Placement of the hands is very important to minimize injury to the internal organs; when the victim is standing or sitting the rescuer wraps both arms around the victim's body and clenches the hand to make a fist. This fist, with the thumb compressed against the abdominal skin is placed above the umbilicus and below the xiphoid process (the distal end of the breastbone). A rapid thrust is made in a superior-posterior direction and continued until either the foreign object is displaced or the person becomes unconscious.

Once unconscious the EMS system must be activated by calling 911 and CPR is initiated for the victim. In this circumstance, after the airway is opened, mouth-to-mouth ventilation may be possible due to the muscle relaxation that occurs with unconsciousness, converting a complete obstruction to a partial obstruction, thus allowing rescue breaths to provide oxygenation to the blood. When opening the airway and during subsequent ventilations, the only change in basic CPR is to open the mouth and look for the presence of the offending obstruction, and if visible, grasp the object with the fingers and remove it (139). Blind finger sweeps are prohibited since injury can easily occur to the soft tissues of the mouth and throat. The initiation of chest compressions may also create enough intrathoracic pressure to expel the foreign object (140,141). The recommended maneuver for the obese or pregnant patient is to utilize chest thrust since the increased abdominal girth in either type of victim makes the Heimlich procedure difficult in terms of finding landmarks and avoiding injury, especially to the fetus. The victim is grasped from behind and the arms encircle the chest, just under the armpits, with the fist placed upon the breastbone. Again the thumb of the first hand is placed next to the skin overlying the breastbone and the second hand is then placed over the first, and with the hands interlocked, rapid compressions are performed in a posterior manner.

Once the foreign body is expelled from the unconscious victim, the basic "ABCs" are initiated as in any life-support situation. "Look, listen, and feel" for signs of breathing and if no excursion of air is present, the two rescue breaths are immediately provided for the victim. The next action in the sequence is to observe signs of adequate circulation, and if none are present, chest compressions are initiated and an AED is attached to the patient (142).

THE AUTOMATIC EXTERNAL DEFIBRILLATOR

The key issue in cardiopulmonary resuscitation is rapid initiation of the "Chain of Survival" and the length of time between victim collapse and defibrillation. Public access defibrillation (PAD) has the capability of significantly improving survival rates from cardiac arrest, in some cases to almost 50% (143). Since ventricular fibrillation has the highest frequency of occurrence in cardiac arrest and can only be terminated by countershock, it is clear that early defibrillation is will dramatically improve survival rates. The ECC guidelines of 2000 have a goal defibrillation within five minutes of the EMS activation (911 call).

The first automated cardiac resuscitator was described by Diack et al. in 1979 (144). This 19 lb battery-powered and most importantly, portable device sensed respiratory rate and the ECG. Ventricular fibrillation and asystole could be diagnosed. An oropharyngeal airway utilized a transducer to detect respiratory pressure as well as an electrode, which was applied to the base of the tongue. An electrode was placed over the chest wall (xiphoid area), which completed the electrical circuit for defibrillation. After initial trials in animals, the device was used at St. Vincent Hospital, Portland, Oregon on a 49-year-old male

who arrived to the ED in ventricular fibrillation. The patient had failed to respond to CPR, chest defibrillation and medications. The patient was actually seizing from massive doses of lidocaine injected to decrease the automaticity of cardiac condition. The automatic resuscitator converted this lethal rhythm with one 335 J shock via the tongue-epigastric pathway.

There are actually no fully automatic external defibrillators available to the public; this is a misnomer since some actions are required upon the rescuer for the device to work. Once the AED is attached to the patient by adhesive pads and turned on, electronic evaluation occurs of the victim's underlying rhythm, and if a lethal dysrhythmia is evident, the AED will advise the rescuer to activate the "shock" button. These devices first record and then interpret the ECG. Narrow range bandwidth amplifiers first filter out various artifacts such as powerline transmission, high or low frequency radio transmissions, and extraneous "noise" that occurs from poor connections. Successive segments of the filtered ECG are then analyzed through a mathematical algorithm with each segment further tested in a sequential matter. The specifics of these algorithms are not made public due to the competitive nature of the various companies manufacturing these devices, but, essentially the rate, amplitude, waveform, frequency, and baseline variability of the ECG are analyzed and mathematical integration results to identify the rhythm that would or would not be treatable by defibrillation. The accuracy of these devices is extremely high after extensive testing both *in vitro* and *in vivo* to an early skeptical audience of medical personnel. The rare errors encountered with AED function appears to be related to movement of the patient, such as when the patient is being ventilated or repositioned during the analysis mode. Agonal respirations by the victim also create movement artifact that will interfere with rhythm analysis. The errors have generally been of omission in that dysrhythmias that would benefit from defibrillation have not been recognized, such as very coarse or fine ventricular fibrillation (145).

Since the first biphasic waveform was used in an AED in 1996 there has been a progression toward utilizing this new technology in future defibrillators. The current monophasic waveform devices deliver current that is unipolar and either damped sinusoidal or truncated relative to the rate at which the pulsed current decreases to zero. The biphasic defibrillators utilize a biphasic wave form of which each are exactly opposite in polarities. Optimum defibrillation is a balance between producing enough current to terminate VF without extensive damage to the heart. When a monophasic defibrillator is used during CPR, 200 J of energy is recommended for the first shock, with two succeeding shocks of between 200 and 300 J suggested in the AHA VF algorithm. These increases in energy with each shock have been demonstrated to optimize defibrillation success while minimizing tissue damage (146,147). Numerous studies have confirmed that biphasic waveform energy utilizing shocks as low as 115–130 J were as effective in terminating VF as the monophasic 200 J shock (148,149). The current scientific evidence supports conclusions that low-energy biphasic waveforms have at

least the equivalent effectiveness as the monophasic waveforms in defibrillating VF; it appears that biphasic waveform defibrillation will be the standard of care in the future.

Operation of the various AEDs is very straightforward and, although there are different models, the devices have very similar controls and functions. Once the AED is brought to the scene of a victim that is not breathing and has no effective pulse, it should be positioned at the victim's left side for easier electrode placement and to allow the "ABCs" of CPR to continue without interruption on the victim's right side. The machine is turned on, and then a series of prompts by an electronic voice guide the rescuer through the remaining steps. The electrodes are next placed on the skin, with the right pad positioned just under the right collar bone (clavicle) and the left pad placed lateral to the left nipple. The third step requires that everyone involved in the resuscitation desist from any contact with the victim while the AED analyzes the rhythm. This is extremely important in that any movement generated by the rescuers will induce an artifact error. Depending on the particular device, some AEDs will automatically analyze while some machines require manual selection by the operator. If VF or VT is present, an electronic voice will indicate that a shock should be delivered; everyone should clear the victim and there should be no one in contact with the body. Once the operator is sure that everyone is clear of the victim, the "shock" button is depressed and the victim's body will exhibit the generalized musculature contracture observed with a defibrillating current. Cardiopulmonary resuscitation is not resumed since the AED must again be ready to deliver another shock after analyzing the postshock rhythm. In this way, three shocks are successively delivered before resumption of "airway, breathing, and chest compressions". If the "no shock indicated" message is transmitted to the rescuers, either there is now a pulsatile, perfusing rhythm, or there is a lethal dysrhythmia that would not improve survival with a defibrillating shock (such as asystole). If signs of circulation become present, then rescue breathing should continue, unless of course the victim also has a recurrence of adequate ventilations (150).

There are some specific circumstances that must be considered with the use of an AED. Children that are <8 years of age or victims weighing <25 kg may not benefit from the current AED since the energy delivered in the monophasic devices are in excess of the recommended 2:4 J/kg. Though it appears that VF can be detected accurately in children, there is insufficient evidence that the algorithms devised for the adult cardiac arrest patient will always determine an arrest rhythm that will benefit from defibrillation, particularly with regard to pediatric tachy-arrhythmias (151,152). However, in the pediatric arrest patient the potential benefit greatly outweighs the risk of AED-individual injury, and therefore this device should be readily available for early application. Another special situation occurs when the victim has been in the water. Even when the victim has been removed from water, there is the risk of induced shock to the rescuer from the moisture present on the victim's body. The other concern, which has the most

potential for occurrence, is that the shock would not be conducted along the appropriate pathway from the electrodes, instead bypassing the heart by the water present upon the skin. The third issue regarding AEDs is that many older victims may have a pulse generator present for cardiac rate control or for internal defibrillation. These devices are usually implanted in the superficial tissues of the chest and appear as an elevated, hard lump, which may or may not be easily observed, depending on the obesity of the patient. What can be observed is the scar from implantation; avoidance of pad placement over the implanted device would mitigate any interference for the AED to detect and provide a defibrillating shock. The last situation that may be encountered is the medication patches, which many patients utilize for a variety of conditions. Pad placement over these patches could significantly decrease the energy delivered to the heart; the recommended procedure is to remove the medication patch and wipe the medication away from the skin prior to pad placement (153).

The AED has the potential to be a strategic intervention to increase out-of-hospital survival in the cardiac arrest patient. Public access defibrillation will continue to be more available due to the efficacy already demonstrated in the previously mentioned studies as well as progressive legislation. The continued technology to produce smaller devices at less cost will undoubtedly increase access both in public places and into the homes of those individuals at risk for sudden cardiac death.

PEDIATRIC AND INFANT CARDIOPULMONARY RESUSCITATION

There are significant differences in the etiology for cardiac arrest in the adult compared to children. In adults, a terminal dysrhythmia is usually caused by progression of coronary artery disease where an acute hypoxic event produces hypoxia, injury, and then disruption of organized depolarization of myofibrils. Children are entirely different in that a hypoxic pulmonary event is the usual cause of the progression of a normal sinus rhythm to an extremely slow heart rate (bradycardia) and then to asystole. The majority of these arrests occur from foreign body obstruction, drowning, trauma, or Sudden Infant Death Syndrome (SIDS), poisoning, asthma, or pneumonia (154). This is where the American Heart Association CPR algorithm for the child is different than that of the adult. Since respiratory failure is such a significant etiology for cardiac arrest, the rescuer is instructed to provide CPR first then "phone fast" rather than the adult rescue scenario where activation of the EMS system (phone first) occurs prior to CPR. The remaining steps in the "ABCs" of life support are similar to the adult. Once unresponsiveness is determined for the victim and the rescuer shouts for help, the child should be placed supine, being careful to move the entire body as one if a head or neck injury is suspected. The airway is opened with the "head-tilt, chin-lift" as in the adult, or the "jaw-thrust maneuver" if there is suspicion for head or neck trauma. After opening the airway and inspecting the mouth for a foreign body, "look, listen,

and feel” for the passage of air by the victim within the time frame of no more than ten seconds. If the assessment reveals lack of adequate ventilation, two slow rescue breaths with an adequate pause between them to allow for exhalation are delivered to the victim; the endpoint for tidal volume is a visible rise in the thoracic chest wall. As in the adult, if no air enters the lungs, the most common cause is an inadequate airway lumen secondary to either tongue obstruction or a foreign body. Repositioning of the head should be immediately attempted, and if the rescuer can still not ventilate, entry into the foreign body obstruction algorithm should be the next action undertaken. Should the rescuer provide effective ventilation for the two initial breaths and signs of circulation exist, a rate of 20 breaths/min is recommended for an infant (< 1 year of age) and for the child (1–8 years of age.) If no movement, spontaneous breathing, or other signs of circulation exist, chest compressions should be started within 10 s. The depth for compressions in an infant or child should be about one-third to one-half of the total distance from the child’s anterior chest wall to the back, and at a rate of 100 times/min. In a child (1–8 years of age), the use of only one hand is recommended, with placement between the nipple line and the bottom of the breastbone (sternum.) As in the adult, the heel of the hand is used. A ratio of five compressions to one ventilation is recommended, with reassessment of the child after 20 cycles of compressions and ventilations have occurred. Chest compressions in an infant (< 1 year of age) are similar except that chest compressions are accomplished with two fingers to a depth of one-third to one-half the distance from the anterior chest to the back. The location for compression is one finger-width below an imagined line between the nipples. The rate is 100 times/min and the compression to ventilation ratio is 5:1, as in the child. Reassessment for signs of circulation and spontaneous ventilations should occur after ~ 1 min or 20 cycles of compressions and ventilations (155).

Foreign body obstruction is treated in a similar manner to the adult in a child between 1–8 years of age when assessment by the responder indicates a severe or complete airway occlusion. After immediate activation of the EMS system, the Heimlich maneuver is instituted with the same adult landmarks where the rescuer’s fists are placed above the umbilicus, being careful to stay away from the inferior aspect of the breastbone, where the xiphoid process is located. Should the child become unresponsive from respiratory arrest, CPR should be initiated, with the initial airway assessment focused upon looking for the foreign object, and, if visible, removing it. Two rescue breaths should be initiated and then chest compressions begun. As in the adult, chest compressions may cause the foreign object to be dislodged where it can be extricated. The infant (under the age of 1 year) is treated quite differently when foreign body aspiration is suspected, since concerns have been raised regarding intraabdominal injury and the Heimlich maneuver (156,157). The infant is cradled with one hand and arm, turned prone, and then five back blows are delivered between the shoulder blades (scapulae) using the heel of the hand. Immediately the victim is turned supine and cradled with the opposite hand and arm. Up to

five chest-thrusts are delivered in the same location for chest compressions. This scheme is alternated until either the obstruction is dislodged or the infant becomes unconscious. Once unresponsive, the next action, as in the adult and child, is to look in the airway and determine if the obstruction can be removed. Cardiopulmonary resuscitation is then initiated and activation of the EMS system undertaken (158).

CONCLUSION

Cardiopulmonary resuscitation has made gigantic strides since the scientific community integrated the rudiments of airway maintenance, rescue breathing and external chest compressions in the 1960s. Once these procedures were developed, the foresight by healthcare professionals to implement CPR in the community and educate the public in the early 1970s has contributed greatly to the success of this program. Currently, the strategy is to simplify the training for Basic Life Support as well as to increase the number of lay responders. Since 1973 > 40 million people have learned the basic life-saving skills taught in CPR classes (156). The recognition that emergency cardiac care should not only provide an organized structure for resuscitation, but also to incorporate education in the prevention of risk factors for coronary artery disease, stroke, and pediatric mortality has the capability of dramatically reducing future morbidity and death. For example, ~ 30% of the deaths from atherosclerotic vascular disease are attributable to smoking, and in those individuals who quit smoking, the death rate declines to almost near normal (160,161). Risk factors, such as smoking, that can be changed by providing both education and interventional guidelines, are a continual focus for organizations like the American Heart Association to address at the present and in the future. As previously mentioned, public access for the automated defibrillator has the potential to greatly reduce deaths in the prehospital arrest scenario. As the time element for CPR and defibrillation has been proven to be so critical for reducing morbidity and mortality from cardiac arrest, those communities that have incorporated aggressive public and paramedical training for these two modalities have reported an almost 50% resuscitation rate for victims documented to have had ventricular fibrillation (1,2). The proliferation of AEDs both in public gathering places and into the home, certainly has the capability to improve these statistics. The continued focus upon rapid recognition of stroke victims in lay responder courses will make a dramatic improvement in rapid treatment and neurological salvage for these individuals. It has been stated that the community will be “the ultimate coronary care unit”(162) since the majority of cardiac arrests occur in the out-of-hospital setting and, therefore, public involvement is crucial to survival. The expectation for the future is that the public “coronary care unit” will be expanded to include a “neurological care unit” as well. The challenge for the future will be to continue to expand the public awareness and involvement in these programs as new scientific evidence continues to guide the evolution of cardiopulmonary resuscitation.

HISTORICAL EVENTS IN CPR

Antiquity	Prophet Elisha describes attempts to revive the dead.
Second century	Galen observed the inflation of a dead animal's lungs.
Middle Ages	Hot materials to the abdomen, whipping, rectal smoke.
Paracelsus, sixteenth century	Fireplace bellows ventilated a patient.
Tossach 1744	First recorded mouth-to-mouth resuscitation.
Squires, 1775	First successful defibrillation.
DeHaen, 1783	Chest compression, arm lift technique.
Leroy, 1830	First description of supine ventilation.
Schiff, 1847	Open chest cardiac compression.
Silvester; Howard, twentieth century	Alternating arm position ventilation; back, abdominal and chest pressure, respectively.
Koenig; Maass, 1850s	Reports of eight successful closed-chest cardiac compressions in humans.
Holger-Nielson, twenty-first century	Prone back pressure, arm-lift.
Gurvich; Yuniev, 1939	First successful external defibrillation by a device.
Kouwenhoven, Knickerbocker, Isaacs, 1950s	Defibrillation experiments coupled with chest compressions.
Elam, 1960s	Physiology of rescue breathing.
Elam, Safar, Kouwenhoven, 1960s	Principles of modern CPR.
Zoll, 1956	First successful external defibrillation in humans.

INTRODUCTION

Synovial or diarthrodial joints are created to enable the movement between bones. Articular cartilage on the end of articulating bone, therefore, must accomplish two functions: (1) absorb, distribute, and transmit mechanical loading, and (2) create a low friction and wear surface for movement over decades of mammalian life. Three cartilage phenotypes exist: hyaline cartilage, fibrocartilage, and elastic cartilage. In the older literature, articular cartilage is often referred to as hyaline cartilage due to its glassy appearance; this appearance is derived from its high proteoglycan content. Indeed, articular cartilage has the highest proteoglycan content of all biological tissues, while, at the same time, it has the lowest cellular content. The chondrocytes not only secrete and control collagen and proteoglycan contents in the extracellular matrix, but also are responsible for regulating the elaborate molecular architecture of these macromolecules and their ultrastructural organization (1-3). Throughout life, the healthy chondrocytes under normal conditions secrete and elaborate sufficient amounts of the extracellular matrix macromolecules and completely encase themselves in an environment that possesses truly remarkable biomechanical mechanisms that protect them against the mechanical insults associated with joint loading, and thus survive for long periods of time under normal health conditions (4-6).

Cartilage in a small number of joints in humans, such as the knee meniscus, temporo-mandibular joint, and intervertebral discs, is fibrocartilage. The intervertebral disc, besides its complex macromolecular architectural and ultrastructural organization, also has a complex macrostructural organization; the latter is manifested in the

macro-layering of the outer rings of collagen-rich annulus fibrosis and an inner core of a proteoglycan-rich "kidney-shaped" nucleus pulposus. The cells of these fibrocartilaginous tissues are fibroblasts and chondrocytes, some of which are called fibrochondrocytes. Whereas the genotype and phenotype of cartilage cells determine the biochemical and molecular properties of cartilage, the mechanical properties of articular cartilage are largely dependent on the constituents of extracellular matrix (3). This divergence in the determination of biological and mechanical properties is attributed to the scarce cellularity in adult cartilage, with chondrocytes that account for only less than 10% of the adult cartilage volume (4,7). Comprehensive reviews of hyaline and fibrocartilage can be found elsewhere (1,3,8).

An average human takes approximately 2 million steps per year. The joints in the lower limbs, therefore, can undergo 1-4 million cyclic loads from physical activities (9,10). These loads can peak 4-5 times body weight (11,12), and can cause both macro- and micro-structural changes in articular cartilage that may ultimately lead to degenerative diseases such as osteoarthritis (4,7,13-15). Arthritis, which encompasses more than 100 diseases and conditions, is recognized as among the leading causes of physical disability worldwide (16). Thus, investigation of the properties of normal and arthritic cartilage is essential not only for the understanding of the etiology of arthritis (6), but also devising possible approaches toward the tissue engineering of cartilage and meniscus for clinical treatment modalities (17).

ARTICULAR CARTILAGE AND MENISCUS: COMPOSITION AND STRUCTURE

Chondrocytes and fibrochondrocytes are responsible for the morphogenesis, matrix synthesis, and maintenance of articular cartilage and meniscus as functional tissues. However, these cells only account for approximately 10% of the total cartilage volume in adults (3,7,18,19). Chondrocytes receive nutrients and shed metabolic waste products largely from convective transport and diffusion, either from/to the synovial fluid or from subchondral bone. In the adult, articular cartilage is generally aneural and avascular. Vasculature is present only in the periphery of mature meniscus (20).

Hyaline Cartilage and Articular Cartilage

Hyaline cartilage is present on the articulating surfaces of the bones in most, but not all, synovial joints. Articular cartilage serves to bear and distribute load and contribute to joint lubrication. It serves these different purposes through varying the amount of water relative to the amounts of Type I collagen and proteoglycans and the molecular and ultrastructural organizations of these structural molecules. Healthy articular cartilage appears smooth, bluish white, glistening, and intact. Osteoarthritic articular cartilage appears dull and coarse and may have tears and frays. Hyaline cartilage is also present in the growth plate at the metaphyseal region of long bones and in the cranial base and serves to enable longitudinal bone growth by endochondral ossification (21-23). A review of

growth plate cartilage is beyond the scope of this chapter, but can be found elsewhere (24–26).

Articular cartilage has two immiscible phases—a solid phase and a fluid phase. Small electrolytes such as Na^+ and Cl^- are dissolved in the fluid phase and are freely mobile by diffusion and convection through the porous-permeable solid phase. The fluid and solid phases have been modeled in the now classic biphasic theory developed by Mow et al. (27). Normal fluid component ranges from 75 to 80% by wet weight, and the remaining 20 to 25% of the organic matrix forms solid material with complex material properties (3,18,19). Up to 65% of the solid ECM by dry weight is made of collagen, whereas proteoglycans constitute up to 25%; other glycoproteins, chondrocytes, and lipids can generally make up 10% (3,28,29). Collagen fibers are classified on the basis of their amino acid composition and molecular structure. Although an assortment of collagens exist in both hyaline cartilage and fibrocartilage, Type II collagen is most prevalent in articular cartilage, whereas Type I collagen is most common in the meniscus (3,30). The collagen fibers are assembled as tight triple-helical structures made from three polypeptide alpha-chains. The triple helices are then arranged as tropocollagen molecules, which are wound in a helical manner to form larger collagen fibers that are, in turn, are organized into a strong cohesive collagen network (3,31,32). This arrangement allows for considerable tensile stiffness and strength (33–38). The collagen also serves to restrain the swelling pressure created from the surrounding embedded proteoglycans (2,18,19,39). Proteoglycans (PGs) are hydrophilic macromolecules with numerous glycosaminoglycans (chondroitin and keratin sulfates) attached to a protein core; the protein core of this bottle-brush-shaped molecular is, in turn, attached to a hyaluronan (mw: molecular weight $\sim 0.5 \times 10^6$) resulting in a supra-macromolecule with an approximate molecular weight ranging from $(200 \text{ to } 300) \times 10^6$ (3,29,40–42). These enormous, negatively charged molecules are trapped in the fine porous meshwork of collagen by frictional and electrostatic forces and by steric exclusion; thus, in the ECM, PGs function largely to generate osmotic pressure (2,39) and to resist the compressive stresses of articulation acting on the cartilaginous surface. Although various PGs exist in cartilage, the one that constitutes up to 80–90% of the total PGs in cartilage is aggrecan (3). As the name implies, aggrecan facilitates the formation of large aggregates. Like collagen,

aggrecan, as with all PGs, maintains a structure that is directly correlated with its function. The general structure of PGs occurs through noncovalent bonding of aggrecans to the hyaluronan via link proteins, thus securing firm linkages. Attached to the protein core are the glycosaminoglycan side chains (GAGs) that are vital for biological and biomechanical functions of the tissues; indeed, they are hallmarks of chondrogenic activity in tissue engineering. These GAGs bear the necessary physical properties that ultimately confer onto these tissues their hydrophilic tendencies and compressive load-carriage abilities (3,18,19). The presence of large numbers of sulfate and carboxyl groups on the GAGs gives rise to a high negative-charge density in the ECM (2). This anionic nature attracts positively charged ions, creating an osmotic pressure, known as Donnan osmotic pressure, that favors tissue hydration (3,39,43). The fixed-negative charges also create intense repulsive forces of the GAGs against each other. This expansion force of the PG molecules causes tensile stresses to be developed within the surrounding collagen network surrounding the PGs. This swelling pressure thus resists the compressive forces against the cartilage without volume loss.

Articular cartilage is organized into three layers or zones (3,44) as shown in Fig. 1. The superficial zone forms the articular surface, whereas the deep zone is anchored to calcified cartilage and subchondral bone; both zones have well-defined collagen architectures. An intermediate zone exists in between with a random collagen fiber ultrastructural organization. These layered structural arrangements have long been hypothesized to be important in cartilage function (45–47). The overall thickness of articular cartilage, including the three zones, varies between joints, age, individuals, and species from less than a millimeter to a few millimeters, with the thickest being measured at the retro-surface of the human patella and femoral trochlea (3,13,48).

The superficial zone has the highest collagen, water content, and chondrocyte density, but the lowest proteoglycan content among all three zones (2,49–51). The abundant collagen fibrils are aligned parallel to the articular surface and provide the superficial zone with substantial tensile strength in an orthotropic manner (37,38,52,53). The chondrocytes in this zone are flattened and are apparently polarized to be parallel to the surface (Fig. 2a) (7,54). Recently, intricate 3D images have been taken to

Figure 1. Layered structure of cartilage collagen network showing three distinct regions (3).

view the discoid-shaped cells as they are maintained in this layer. Methods have ranged from digital volumetric imaging (55) to atomic force microscopy (56).

The intermediate, or middle, zone is generally the thickest amongst the three uncalcified zones of articular cartilage. Collagen fibrils, although less dense, have a greater diameter than the superficial zone, but appear to be more randomly oriented (47,57). The intermediate zone also has the highest proteoglycan content (3). Chondrocytes are more rounded, although cell density is not as high as in the superficial zone (3,58) (Fig. 2b).

The deep zone is relatively thin and the collagen are intertwined to form larger fiber bundles, and, from this zone, they insert perpendicularly into the calcified zone, and thus anchor the uncalcified tissue to the bony ends as required by joint articulation. This organization allows the bundles to firmly anchor the articular cartilage to the underlying subchondral bone. In general, chondrocyte density decreases from the middle zone to the deep zone, where they are similarly aligned as the collagen bundles, arranging into columns perpendicular to the uncalcified-calcified cartilage intersurface (3,55).

Several recent studies have investigated the pericellular matrix (PCM) and the interterritorial matrix (ITM) of chondrocytes. Using algorithms to account for fluid flow and differences in the relative stiffness between the PCM, the ITM, and the chondrocyte, different elastic moduli between PCM and ITM have been found to have a significant effect on chondrocyte's mechanical environment (59). Gradient distributions of charges and material densities relative to chondrocyte surface are important in cartilage fluid flow dynamics and deformation behavior (60). Using micropipette isolation of chondrocytes and nuclei, chondrocyte nuclei have been found to be stiffer than intact chondrocytes (59,61,62). Cultured chondrocytes are able to elaborate a PCM rich in Type VI collagen; however, intact chondron pellets accumulate significantly more

Figure 3. A representative height map of the PCM and ITM chondrocytes obtained through force mode of atomic force microscopy. Qualitatively, the ITM showed greater peak and valley contours than the topographic contour of the PCM (a). (b) presents the average Young's moduli of the PCM and ITM attained via nanoindentation. The average Young's modulus of the ITM (636.1 ± 124.91 kPa) was significantly greater than the PCM (265.1 ± 52.76 kPa) ($p < 0.01$) ($N = 19$) (64).

proteoglycans and Type II collagen than chondrocytes without a native PCM (63). Following a few weeks of accumulation of the ITM and PCM by isolated chondrocytes, a rapid increase in compressive stiffness occurs in both the chondron and the chondrocyte pellets (63). Using atomic force microscopy (AFM), the ITM is found to be stiffer to nanoindentation than the PCM (Figs. 3a and 3b) (64).

Meniscus and Fibrocartilage

The meniscus in the knee joint is a fibrocartilage. The two menisci (lateral and medial) in each knee joint are crescent or semi-lunar shaped and are attached to the joint capsule. The triangular cross section of the meniscus tapers radially inward from the periphery, and the center of the meniscus is thin and unattached. Thus, the cross section of the meniscus is wedge-shaped. The central region is a vascular and has more proteoglycans, hence more hyaline in appearance. The anterior and posterior horns of the meniscus form the tips of the crescents. The anterior horn of the lateral meniscus is attached to the tibia in front of the intercondylar eminence, partially blending with the

anterior cruciate ligament. The posterior horn is attached to the tibia near the intercondylar eminence as well as to the femur via the meniscofemoral ligament. The anterior and posterior horns of the medial meniscus are attached to the tibia near their respective intercondylar fossae. The anterior horns of the lateral and medial menisci are connected by the transverse ligament. The thick peripheral borders and associated horns of the meniscus are vascularized by blood supply predominantly from the genicular arteries surrounding the joint. The thinner central portions of the meniscus are aneural and avascular, a region very much like hyaline cartilage (20). The meniscus is lubricated with synovial fluid (65), probably by the same lubrication mechanisms known to exist in articular cartilage (66). Fibrocartilage is found in a small number of other joints. The disk of the temporomandibular joint (TMJ) and the intervertebral disks are both composed of fibrocartilage, although they are drastically different structures with different distributions of cartilage and PGs and ultrastructural organization.

The fibrocartilagenous structure of the meniscus differs from that of hyaline cartilage in many ways. The cells of the meniscus are sometimes called fibrochondrocytes, although it is probable that some cells are more like fibroblasts, whereas others are more like chondrocytes (65,67). The peripheral two-thirds of the meniscus are primarily composed of a randomly oriented mesh-like, coarse, collagen fibrillar matrix (68–71). In deeper portions, large rope-like collagen fiber bundles are arranged circumferentially, retaining the overall semi-lunar shape of the meniscus and providing tensile strength. Smaller fibers are also found radially and connect to the larger circumferential collagen fiber bundles (72). As mentioned above, the inner portion of the meniscus resembles that of hyaline cartilage, containing a higher percentage of proteoglycans enmeshed within a randomly arranged collagen fibrillar matrix (71,73,74).

The function of the meniscus is to enhance higher congruity of the articulating surfaces of the distal femur and proximal tibia, to accommodate the range of motion, in addition to the same functions of load bearing and load distribution to that of articular cartilage (20). The previous assumption that the menisci are functionless, evolutionary remains of leg muscles is erroneous and that meniscectomy (a common clinical procedure) is indeed a common procedure in animal models to study the etiology of osteoarthritis (75–78).

CARTILAGE AND MENISCUS: MECHANICAL PROPERTIES

Articular cartilage and meniscus are both important load-bearing tissues and vital to the maintenance of normal joint functions (3,18,19). Articular cartilage can absorb mechanical shock of joint motion and spread the applied load onto the subchondral bone. It also contributes to the lubrication mechanism and provides a surface with low friction, enabling repetitive gliding motion between articulating surfaces (7,66). The meniscus of the knee has important biomechanical functions such as load transmission at the otherwise highly incongruent tibiofemoral

articulation, shock absorption, joint congruity, and stability (18,19). The salient biomechanical functions of articular cartilage and meniscus are dependent on their biological structure, composition, and the intrinsic material properties of the ECM. The knowledge of their material properties such as tensile, compressive, and shear moduli is essential to understand not only their biomechanical functions, but also in the tissue engineering of articular cartilage and meniscus to produce in a biomimetic manner artificial-biological replacements (17,79).

Tensile Properties

When cartilage is tensed, the tensile stress-strain behavior is nonlinear. A typical nonlinear stress-strain (σ - ϵ) curve for cartilage, meniscus, and other soft tissues is depicted in Fig. 4 (3). For small deformations, a 'toe-region' is seen in the stress-strain curve, in which the collagen fibrils will primarily realign in the direction of the externally applied force instead of being stretched (elongation per unit length). For larger deformations, the collagen fibrils are stretched, and a larger tensile stress is generated within the collagen fibers (e.g., 35–38,52,53,80–83). In this linear region, the stress is proportional to the applied strain, and their ratio is known as Young's modulus in tension, or tensile modulus. This tensile modulus is a measure of the stiffness of the collagen-PG solid matrix and is primarily dependent on the density of collagen fibrils, fibril diameter, and type or amount of collagen cross-linking (3,18,19,52). Beyond the linear region, the cartilage strip will rupture abruptly, and the tensile failure stress is a measure of the strength of the collagen fibrillar network.

In general, the tensile modulus of articular cartilage will be in a range of 1–30 MPa, which is much larger than the compressive modulus of cartilage (~ 0.5 MPa), which is known as tension-compression nonlinear property of the

Figure 4. Typical stress-strain curve for articular cartilage and meniscus in a uniaxial and uniform strain rate experiment. The toe region is marked by an increasing slope, whereas the linear region appears to be a straight line (3).

cartilage (84–86). The tensile properties are also known to vary with location, depth, and orientation of test specimens of cartilage and meniscus. Hultkrantz (45) demonstrated the anisotropic organization of the collagen network by puncturing holes in the surface of articular cartilage with a round pin. He found that round puncture holes will form elongated splits, analogous to splits formed in lumber when a large round awl pierces it. The split-line patterns were, to him, evidence of collagen fiber orientation, which is still an enigma today because electron microscopy has not found such surface collagen anisotropy. (Nevertheless, the pattern of split lines is similar to Langer lines formed in the skin in a similar manner.) Much later, Woo et al. (38), Kempson et al. (52), and Roth and Mow (37) showed that the tensile strength and stiffness of the samples cut parallel to the split-line direction were higher than those cut perpendicular to it. The cartilage strips from high weight-bearing areas of human knee joints exhibit larger tensile modulus than those from low weight-bearing areas (53,82) because high weight-bearing areas generally have a relatively higher proteoglycan content. The adult human femoral articular cartilage exhibits a gradual decrease in tensile strength and stiffness as the distance from the articular surface increases (36,81), while this functional dependence was not observed for young bovine humeral joints (38). A dependency of cartilage tensile properties with skeletal maturation was found by Roth and Mow (37). These investigators found that, with the closing of the growth plate (indicative of skeletal maturity), the strength and stiffness of cartilage are much less than those properties of immature cartilage (open-physis). The effects of age on the tensile properties of adult cartilage were extensively studied by Kempson (81), and the results showed that the tensile modulus decreases with age, and that the modulus of the hip cartilage decreases more markedly than that of ankle cartilage. This finding may explain the relatively high occurrence of osteoarthritis in the hip compared with the ankle. Like articular cartilage, the tensile properties of meniscus vary with respect to the location (anterior, central, and posterior) and specimen orientation relative to the predominant collagen fiber direction (circumferential and radial) (18,19,74). Specimens from the posterior half of the medial meniscus have been shown to be significantly less stiff and less strong in tension than specimens from all other regions (87). This experimental result agrees with the ultrastructural findings using polarized light; in the posterior half of the medial meniscus, collagen fiber bundles have significantly reduced circumferential organization (87).

Numerous experiments have shown that the tensile modulus is correlated with the collagen content or the ratio of collagen content to proteoglycan content in articular cartilage (e.g., 82). The tensile modulus of articular cartilage decreases to only 1% after disruption of collagen cross-linking by elastase (88). In contrast, no significant correlations have been found between the tensile property of the cartilage and proteoglycan content (36,89). These findings indicate that collagen content, organization, and cross-linking play significant roles in generating high tensile modulus of articular cartilage. For meniscus, although the tensile properties show significant regional

and directional variations, little difference appeared in the biochemical composition with site, and no significant correlation exists between tensile property and chemical contents (74). The variation of tensile properties seems to reflect local differences in collagen ultrastructure and fiber bundle direction as described above.

Compressive Properties

The compressive behavior of cartilage and meniscus has been extensively studied under various configurations, such as confined compression, unconfined compression, and indentation (see Fig. 5). Most of the earliest studies (e.g., 90–94) used the indentation technique to determine the mechanical property of articular cartilage and modeled the cartilage to be a single-phase, elastic body with the assumption of the Poisson's ratio ranging between 0.4 and 0.5 (e.g., 91–96). However, this single-phase elastic model cannot describe the time-dependent viscoelastic behavior of the tissue nor the role played by cartilage's major component (i.e., water). Cartilage and meniscus exhibit a viscoelastic creep in response to a constant load (i.e., its deformation will increase with time). Conversely, if a constant displacement is applied, the force response will decrease gradually with time to a constant value (i.e., a stress-relaxation will be observed).

These viscoelastic behaviors derive from the friction of water flowing through solid matrix (27,97), as well as the flow-independent intrinsic energy dissipation inside the macromolecular solid matrix during mechanical loading (98–101). As mentioned, articular cartilage and meniscus can be regarded as biphasic materials: a fluid phase composed of water and electrolytes, and a solid phase mainly composed of collagen and proteoglycans (27). The solid matrix is considered as being porous and permeable. Water resides in the microscopic pores and flows through the matrix during joint loading. Under a slow ramp loading, the observed viscoelastic behaviors are usually dominated by the large drag forces generated by the flow of interstitial fluid through the porous-permeable solid matrix, and therefore, the flow-independent intrinsic energy dissipation is negligible. However, osteoarthritic cartilage has higher permeability and lower ECM stiffness; in such tissues, the intrinsic viscoelastic behavior becomes the dominating component governing their mechanical behaviors.

The transient behavior of the tissue under compression is primarily determined by the mechanism of fluid pressurization because of high friction between solid and fluid phases, which is also known as flow-dependent viscoelastic behavior (27). Figure 6 (3) shows the stress-relaxation behavior of a tissue specimen under confined compression. In this experiment, before time t_0 , the tissue is compressed with a constant rate, and the interstitial fluid inside the tissue will be pushed out through upper porous platen. As a result of the distributive fluid drag force, a larger deformation can be seen at the downstream side (Fig. 6a and 6b). During the relaxation phase (after t_0), no fluid exudation occurs, but the fluid needs to redistribute inside the tissue before the equilibrium is reached (Figs. 6c, 6d, and 6e). Although the velocity of fluid flow is very low, the friction force, or the drag force, could be very large because the pore

Figure 5. Schema of three configurations frequently used to study the compressive properties of articular cartilage. (a) In the confined compression configuration, a load is applied to the cartilage sample via a rigid porous permeable platen. The side walls are assumed to be smooth, impermeable, and rigid, thereby preventing lateral expansion and fluid flow. (b) In the unconfined compression configuration, the cartilage sample is compressed between two rigid, smooth, and impermeable platens. The lateral side allows fluid flow. (c) In the indentation configuration, the cartilage is compressed via a rigid porous permeable indenter. The porous indenter allows the fluid exudation to occur freely into the indenter tip and, therefore, creep of the cartilage layer.

size inside the tissue is very small (~ 50–65 nm for articular cartilage), and the permeability of the tissue is as low as 10^{-15} N·s/m⁴. Therefore, the generated fluid pressure can be remarkably high inside the tissue during the transient state, which also means that chondrocytes encased within the ECM will normally be bathed in a highly

Figure 6. A schematic representation of fluid exudation and redistribution within cartilage during a rate-controlled confined compression stress-relaxation test (lower left). The horizontal bars in the upper figures indicate the distribution of strain in the tissue. The lower graph (right) shows the stress response during the compression phase (O, A, B) and relaxation phase (B, C, D, E) (3).

pressurized fluid. It has been estimated that this fluid pressure could be 30 times more than the elastic stress generated in the solid matrix of articular cartilage (3). Considering that the equilibration process usually takes several hours, no real equilibrium state occurs in joints under physiological conditions because the joints are moving virtually at all times, even during sleep. Thus, the mechanism for fluid pressurization is likely to be the major physiological load-supporting mechanism in diarthroidal joints, and it plays an important role in shielding the solid matrix from large compressive stresses during the joint function (7).

At equilibrium, the fluid flow stops, no fluid pressure gradient exists inside the tissue, and the applied load is entirely supported by the solid matrix of the tissue. Thus, the compressive property can be obtained from the relations between stress and strain. It has been found that the equilibrium strain is proportional to the applied load. Typically, the equilibrium aggregate modulus (27) for normal articular cartilage ranges from 0.4 to 1.5 MPa, whereas the average equilibrium aggregate modulus for the meniscus is about 0.4 MPa. Table 1 shows the equilibrium aggregate moduli of lateral condyle and patellar groove cartilage and meniscus, showing considerable variation among the species and tissue location (3).

Tissue mechanical properties are highly dependent on their composition and structure. It has been shown that the equilibrium aggregate modulus for human articular cartilage correlates in an inverse manner with water content and in a direct manner with PG content (27,102,103). The highly loaded regions of articular cartilage generally have larger compressive modulus and greater PG content (53,104,105). In contrast, no correlation is found between the compressive stiffness and collagen content. Removal of PGs from articular cartilage samples dramatically decreases the compressive modulus, whereas trypsin

digestion of collagen fibrils has little effect on compressive modulus (80,106).

The biphasic theory has been the most successful model for the compressive viscoelastic behaviors of cartilage and meniscus under various conditions (27). This theory assumes that (1) the solid matrix and interstitial fluid are immiscible and incompressible; (2) viscous dissipation is due to the fluid flow between water and the porous-permeable solid matrix; and (3) the frictional drag is proportional to the relative velocity and can be affected by ECM compression. This biphasic theory further assumes that the solid matrix experiences infinitesimal strain and that the stress-strain relations can be described by the generalized Hooke’s law. Despite its simplification, as biological models typically are, the isotropic form of the linear biphasic theory has been shown to provide an accurate description of the compressive creep and stress relaxation behavior of these tissues. In particular, a numerical algorithm based on this biphasic theory was developed and accurately predicted the aggregate modulus, Poisson’s ratio, and permeability of articular cartilage from the indentation creep experiment (13,100,107). The biphasic theory has also been extended by employing higher levels of tissue complexities, including material inhomogeneities (108–110), material symmetries (33,34,85,86,111), and matrix viscoelasticities (33,34,84,98–100).

Shear Properties

The intrinsic viscoelastic properties of the solid matrix of cartilage and meniscus can only be determined in a *pure* shear experiment and under small strain conditions. In pure shear, the kinematics of deformation does not permit volumetric change, and hence, no interstitial fluid flow is possible when no pressure gradients are applied. Under these three conditions, the tissue deforms without change in volume, and therefore, the interstitial fluid pressure and fluid flow are minimal. As a result, the flow-dependent viscoelastic properties are excluded, and the measured physical parameters will be independent on the friction or drag force between fluid phase and solid phase, which often occurs in compressive configurations, thus directly reflecting the intrinsic viscoelastic property of solid matrix. This flow-independent viscoelastic behavior of the collagen-PG matrix derives from the internal friction between collagen and PG molecules (3,101).

The first shear properties measurement was reported by Hayes and Mockros (112), and later, nonlinear viscoelastic and fatigue properties of bovine articular cartilage were

investigated (113,114). However, all these tests were performed in a simple shear configuration, and dynamic shear properties of these studies were reported at frequencies (e.g., 20–1000 Hz) much higher than the physiological range (e.g., 1 Hz). Pure shear tests of articular cartilage and meniscus have been performed under transient, equilibrium, and dynamic conditions to characterize the intrinsic or flow-independent viscoelastic behavior (e.g., (101,115–117)). When a circular cartilage specimen is subject to a sudden change of angular displacement, the shear stress will increase instantaneously, followed by a rapid decay before equilibrium is reached. The quasilinear viscoelastic theory (118) has been shown to provide an excellent description of this intrinsic stress-relaxation behavior of normal human patellar cartilage (116). The equilibrium shear modulus for normal human, bovine, and canine articular cartilage has been found to vary in a range of 0.05–0.25 MPa. Values for the magnitude of the dynamic shear modulus $|G^*|$ of normal cartilage are in the range of 0.2–20 MPa and vary with both the frequency and magnitude of the normal stress. The phase shift angle (δ) for cartilage lies between 9° and 20° over a frequency range of 0.01 Hz to 20 Hz (101). Please note that δ is a measure of matrix dissipation, with a loss angle of 0° corresponding to a perfectly elastic material, and 90° to a perfectly dissipative material. The viscoelasticity of meniscus in response to shear is qualitatively similar to that exhibited by articular cartilage, although the magnitudes of the material coefficients of these tissues are significantly different. Meniscus shear properties exhibit an orthotropic symmetry (i.e., the three planes of symmetry defined by its fibrous architecture dominate the shear properties of the meniscus). The equilibrium shear moduli are 36.8 kPa, 29.8 kPa, and 21.4 kPa in the circumferential, axial, and radial directions, respectively (18,19,119). These shear modulus values are ten times less than those observed for articular cartilage. For dynamic tests, the magnitude of the complex shear modulus $|G^*|$ and phase shift angle δ for circumferential, axial, and radial specimens reflect orthotropic collagen fiber organizational symmetry as well (Fig. 7) (3).

The collagen network plays an active mechanical role in contributing to the shear stiffness and energy storage in cartilage (101). Conceptually, the role played by collagen when the specimen is in shear may be visualized as shown in Fig. 8 (101). The tension in the diagonally oriented collagen acts to increase the shear stiffness of the solid matrix. This effect is confirmed by the experimental result that $|G^*|$ is directly and significantly related to the collagen content of articular cartilage and also by the fact that

Figure 7. The magnitude of dynamic shear modulus $|G^*|$ and $\tan \delta$ for meniscal specimens with normal vectors oriented circumferentially, axially, and radially at 1 rad/s (3).

cartilage has a relatively small loss angle and large shear modulus (101) compared with that of PG solutions at physiological concentrations (107,120,121). The depletion of the PG content has been shown to decrease the dynamic shear modulus up to 55% (101,122), which is considered as a result of the decrease of tensile stress inside the collagen fibrils due to the decrease of PG swelling pressure.

Swelling Properties

Swelling in articular cartilage derives from the presence of negatively charged groups (SO_3^- and COO^-) along the GAG chains of PG molecules. For normal and degenerative femoral head cartilage, the fixed-charge density (FCD) ranges from 0.04 to 0.18 mEq/g wet tissue at physiological pH (2,123). These fixed charges will require a high concentration of counter-ions (Na^+) to maintain electroneutrality, and the concentration, along with that of co-ions (Cl^-), is governed by the Donnan equilibrium ion distribu-

Figure 8. A scheme representation of cartilage in pure shear. The tensile stress inside collagen fibrils provides shear stiffness (101).

tion law (124). This excess of freely mobile ions will introduce an imbalance of ion concentration between the fluid compartment inside the tissue and the bathing fluid outside the tissue, giving rise to a higher pressure in the interstitial fluid than the ambient pressure in the external bath, known as the Donnan osmotic pressure. This osmotic pressure decreases with FCD and has a range of 0.1 to 0.25 MPa for normal articular cartilage. With the increase of the external saline concentration, the osmotic pressure will decrease. For the very large external saline concentration (e.g., 2 M), the osmotic pressure is considered to be extremely small, or zero.

This osmotic pressure causes the tissue to swell, as measured by both weight change (2,123) and dimensional change (125,126). These latter experimental results show that the swelling of articular cartilage is inhomogeneous and anisotropic. The swelling ability increases with depth, with the largest dimensional change for the deep zone and almost no change for the superficial layer. The magnitude of swelling is the largest in the thickness direction and the smallest in the split-line direction. In articular cartilage, the osmotic pressure is restrained by the surrounding collagen network. Therefore, residual stress or pre-stress exists inside the solid matrix even before external load is applied. Articular cartilage will warp or curl toward its articular surface upon its removal from the subchondral bone, and the curvature or the extent of curling will decrease with the increase of external saline concentration (126). It has been hypothesized that this curling is caused by the combination effects of swelling pressure and inhomogeneity inside the tissue (126–129). Recently, a three-layer orthotropic model based on triphasic theory (39) has been developed to describe the curling behavior of cartilage strip by considering its layered structure that includes depth-dependent collagen fibril orientation and chemical content distributions (128). The predicted curvature change with external saline concentration agrees well with previously published experimental results. This model has also suggested that the large stiffness of the superficial layer and high swelling pressures play key functional roles in the development of pre-stress in cartilage and in its curling behavior.

Quantification of morphological changes has been extensively used to study changes in cartilage swelling with osteoarthritis (OA) (44). With OA, compositional and microstructural changes will occur, which includes the fibrillation of the superficial zone of articular cartilage, the decrease of the PG concentration, and the imbibitions of water; these items are the earliest indicators of the OA degeneration of cartilage (18,19,29,102). The elevated water content or swelling has been shown to be very sensitive to collagen fibrillation. Experimental results also suggest that the water content of the tissue increases after digestion with collagenase (82,83,101). Physically, collagen fibrillation decreases the stiffness of the solid matrix, specifically the elastic bulk modulus, which allows the tissue to imbibe more water (52,104).

Triphasic Mixture Theory

To account for the swelling behavior, Donnan osmotic effects, ion transport, and electrical potentials inside the

tissue, Lai et al. (39) developed the triphasic theory to incorporate the effects of negatively charged groups on the PGs of solid matrix. In this theory, the electrolytes (mainly Na^+ and Cl^-) within the interstitial fluid are considered as a separate phase, and the solid phase is charged. This triphasic theory was further extended to account for multiple species of ions in the tissue (130). Note that Huyghe and Janssen (131) developed an equivalent theory, named the quadriphasic theory, in which ion species Na^+ and Cl^- were treated as two separate phases.

Using the triphasic theory, the electrokinetic coefficients such as electrical conductivity has also been derived in terms of the physical parameters of charged tissues (39,130,132–134). Furthermore, a theoretical analysis (134,135) showed that the electrical potential inside the tissue comes from two competing sources: a diffusion potential deriving from the FCD inhomogeneity and a streaming potential resulting from the fluid flow within a charged material. These two sources of electrical potential have different polarity and compete against each other. Within the physiological range of material properties of articular cartilage, the polarity of electrical potential inside the tissue depends on the stiffness of the tissue. For softer tissues (such as OA tissue), the diffusion potential tends to dominate, whereas the streaming potential tends to dominate for stiffer tissues (such as normal tissue).

Numerical methods, such as finite difference and finite element formulations, have been developed to demonstrate the contributions of the FCD in mechano-electrochemical (MEC) behaviors of charged, hydrated soft tissues (43,134,136,137). These studies showed that higher FCD decreases the characteristic time (gel time) and causes the tissue to reach equilibrium in a shorter amount of time, and showed that the osmotic effects can contribute up to 50% of the equilibrium confined compression stiffness (136) and about 30% in unconfined compression (43). With the finite element formulation, Lu et al. (138) successfully correlated the predicted FCD with the biochemical measurements, while simultaneously measuring the apparent mechanical properties from the indentation creep experiment.

Recently, the triphasic formulations have been linearized, and the analytic solutions for the MEC response of the tissue under unconfined compression have been obtained both for transient state and at equilibrium (139). With a regular perturbation, simple relations have been derived to describe how the apparent properties, such as Young's modulus and Poisson's ratio, change with the fixed negative-charge density (FCD) at equilibrium (139,140). These relations actually are applicable to various testing configurations, even for steady permeation, and they indicate the correspondence of mechanical properties between an elastic body and a charged triphasic material such as articular cartilage and meniscus (139–142).

CARTILAGE WEAR AND DEGENERATION

Cartilage wear and degeneration have been extensively studied due to their significant roles in physically debilitating diseases such as osteoarthritis and rheumatoid

arthritis (1). Two types of wear occur in synovial joints: fatigue wear and interfacial wear (66). Fatigue wear is independent of the lubrication within the joint and is caused by functional activities such as cyclic, repetitive loading. A balance is presumably maintained under the normal physiological condition whereby tissue turnover is maintained by cells in various components of the synovial joint. A number of factors may contribute to cartilage wear and degeneration. Collagen fibers can be severed by excessive functional activities, leading to a compromise in tensile strength. The normally tight collagen fiber bundles can be unwound and loosened (47,143). When inflammatory cytokines are released, proteoglycans are lost rapidly, leading to a breakdown of the ECM (144–146). Fibrillated cartilage from osteoarthritic patients shows an increase of apoptotic chondrocytes deeper than in the normal articular cartilage, which generally has apoptotic cells only near the surface (145,147). Collective loss of chondrocyte and ECM may lead to microcracks and fissures, which may further grow with functional loading. Thus, fatigue wear of cartilage is a mechanism dependent on biological synthesis and mechanical loading (5).

Interfacial wear can result from physical contact loading of articulating surfaces. Interfacial wear has been categorized into two classes: adhesive and abrasive wear (66). Adhesive wear is more common and occurs when a junction is created when the two solids are in contact. As the opposing surfaces continue to move past the junction, fragments from the weaker surface may be torn off and adhere to the stronger material. The concept is analogous to rubber skid marks left on a road from a braking car. The car is able to move past the formed junction only by having elements of the weaker material, the rubber tire, come off and adhere to the stronger material, which is, in this case, the road. Abrasive wear occurs when a harder material comes into contact with a softer material. No junction is formed. While in contact and rubbing against each other, the harder material cuts or plows into the softer material. The harder material can be either one of the opposing surfaces or loose particles caught between two softer opposing surfaces, cutting into both of them (66).

Pain, stiffness, swelling, and reduced range of motion are the common phenotypic characteristics of osteoarthritis. Typically, clinical diagnosis is only made after significant cartilage deterioration. A number of methods have been formed to monitor the development of osteoarthritis. Radiography has been the conventional method for both diagnosis and monitoring. The topographical variation in degenerative cartilage has been used in designing an arthroscopic indentation instrument in which osteoarthritis could be diagnosed *in vivo* and possibly treated before the diminishing qualities of the disease (148). Other manners that have been proposed for detection are chondrocalcin measurement (149) and knee wear particle analysis, which is derived from the concept of abrasive wear (150).

CURRENT CARTILAGE REPAIR STRATEGIES

Cartilage's poor capacity for self-regeneration is well known. The poor regenerative capacity of cartilage has

been contrasted to bone, because bone readily regenerates (unless it is a critical size bone defect) and has a relatively rich blood supply (151). A lack of angiogenesis has been cited as the primary cause for cartilage's poor capacity for regeneration. However, normal cartilage is avascular. Vascular supply to cartilage likely will turn it into bone. Thus, a lack of vascularization is not the direct cause for cartilage's poor regenerative capacity (152).

The regenerative ability of cartilage in response to injury also depends on factors such as joint loading, the degree of injury, the location of injury, and whether it is cartilage lesion alone or osteochondral lesion (153,154). Cartilage responds differently to slowly or rapidly applied loads. For example, loading causes fluid movement in the matrix and may serve to counteract the deformation and to distribute the loads throughout the tissue. However, rapid compressive loading may not allow the fluid to infuse matrix, thus transferring excessive loading to the cells and the ECM macromolecules. Should excessive force be sustained, the chondrocytes and ECM molecules may undergo rupture or degradation. Another factor in determining the cartilage's regenerative capability is the chondrocytes' intrinsic ability to replenish the supply of matrix molecules, as well as the approaches to remove degraded materials (17,153,155).

Articular cartilage injuries can be classified as follows: (1) cartilage matrix and cell injuries without substantial tissue defects; (2) defects, fissures, or ruptures in articular cartilage only; and (3) osteochondral lesions. The first category of cartilage injuries without substantial tissue defects, nonetheless, is associated with a decreased concentration of matrix macromolecules such as PGs and collagen. Albeit without tissue-level defects, loss of PGs and collagen results in a decrease in mechanical strength. Unless repaired, even the first category of cartilage injuries can lead to more substantial defects as described in the second and third categories (153,155).

The second category of articular cartilage injuries is localized within cartilage. They include focused mechanical disruption of the matrix including fissures, tears, incisions, or interruption of the integrity of articular surface. Chondrocytes not only attempt to replace the loss of matrix macromolecules but also proliferate to fill the voids created during injury (153,156). However, the rates of chondrocyte proliferation and matrix synthesis may not be sufficiently high to match the rate of cartilage degradation. As articular cartilage has no nerve supply, except at the very periphery, even substantial cartilage lesions may not elicit pain. A few types of synovial joint injuries likely exist that elicit pain, such as osteochondral injuries, synovial membrane injuries, and injuries to the periphery of articular cartilage. These injuries are usually not repaired by the articular chondrocytes (4).

The third category is osteochondral injuries that involve both articular cartilage and subchondral bone and elicit inflammatory responses such as an influx of blood-borne cells, platelets, and cytokines. Hemorrhaging or fibrin clot formation may occur and later develop into a fibrous mass. The influx of cytokines may induce migration of progenitor cells, although no guarantee exists that these progenitor cells, likely mesenchymal stem cells that are capable of

differentiating into all connective tissue lineage cells, will differentiate into chondrocytes. In fact, osteochondral lesions are likely repaired, if repairable, by fibrocartilage or fibrous tissue instead of hyaline cartilage (154), and rarely possess the complex zonal structures of native articular cartilage (153,157). The mechanical strength of fibrocartilage is approximately one-third of the strength of native hyaline articular cartilage, and thus may not be able to fulfill the weight-bearing and load-bearing functions of normal articular cartilage. Over time, osteochondral lesions may undergo further degradation, leading to the exposure of subchondral bone, which results in osteoarthritis and can lead to joint immobility.

Current clinical treatments for articular cartilage injuries have several deficiencies. Depending on the degree of injury and whether the defect is partial- or full-thickness, the treatments generally involve surgical irrigation, debridement, and tissue augmentation. Partial thickness injuries of the articular cartilage involving clefts and fissures, often in the early stages of osteoarthritis, are most commonly treated with arthroscopic surgery such as lavage or debridement. Arthroscopic lavage involves the irrigation of the joint, whereas debridement is the arthroscopic removal of damaged tissue. By performing these treatments either alone or in combination, a decrease in joint pain usually results. However, lavage or debridement treatments rarely induce the repair process of cartilage (155,157).

Full-thickness injuries refer to lesions in both articular cartilage and subchondral bone. Although a large number of treatments are empirical, several procedures have taken the advantage to simulate the native repair process. Arthroscopic treatments such as abrasion arthroplasty, Pridie drilling, and microfracture are commonly used, and all include the further perforation of the subchondral bone to induce bleeding and further fibrous tissue formation. Abrasion arthroplasty and microfracture are used in conjunction with debridement to reduce the amount of damaged tissue within the joint. The outcome of these treatments is variable, largely because the healing and repair process within the articular surface are somewhat unpredictable. Furthermore, factors such as the patient's age, postoperative activity level, and overall health also affect the outcome (158).

Recently, soft tissue grafts such as the transplantation of the periosteum or perichondrium have been used clinically to repair the articular surface for cylindrical, full-thickness defects. The rationale for using periosteum is its observed chondrogenic potential during development and fracture repair (159). The periosteum consists of a fibrous and cambial layer. The cambial layer contains precursor cells that are capable of differentiating into osteoblasts and perhaps chondrocytes. The process of periosteum transplantation involves the creation of a defect spanning the full thickness of articular cartilage and penetrating the subchondral bone, and then placement of the periosteum graft within the defect. However, much debate has occurred as to which layer of the periosteum should lay adjacent to the bone and which layer should face the articular surface, as the cambial layer can form cartilage, whereas the fibrous layer forms fibrous tissue. Larger full-thickness defects are generally repaired using allogenic or autogenic

osteochondral tissue plugs, called mosaicplasty, excised from nonload-bearing regions of the joint and inserted into the full-thickness defect. Reports exist of fibrous tissue formation and chondrocyte death at the interface between the plug and surrounding tissue, which may lead to further degeneration of the joint. Furthermore, donor site morbidity remains a drawback of the periosteum graft or mosaicplasty (160).

For substantial osteochondral lesions, total joint replacement using metallic condyle and plastic socket is most commonly in practice. Current modalities of total joint replacements suffer from drawbacks such as donor site morbidity, pathogen transmission, wear and tear, and a limited life span (161). Secondary surgeries are necessary in 10–15% of the cases and suffer from substantial difficulties such as scar tissue formation and loss of host tissue (162). More importantly, current total joint replacement therapies fail to yield biological regeneration.

CURRENT MENISCAL REPAIR STRATEGIES

Prior to the recognition of the importance of the meniscus in the biomechanics of the knee joint in the 1970s, the preferred treatment for meniscal injury such as tear was total excision of the meniscus or open meniscectomy. Despite some reports of temporary relief of symptoms, the long-term outcome of excision or meniscectomy was poor. In the 1980s, understanding of the material properties and biomechanical roles of the meniscus led to more conservative treatments for meniscal tears. Furthermore, the development of arthroscopy enabled more accurate diagnosis of meniscal tears and, subsequently, more precise surgical treatment that has substantially reduced the amount of damage to the surrounding tissue in comparison with open-joint surgery (163).

Partial-thickness split tears and small (< 5 mm) full-thickness split tears, vertically or obliquely, are usually left alone and without surgical intervention. The inner wall of the meniscus must be stable during probing, which is commonly performed arthroscopically during diagnosis. Follow-up arthroscopic examinations are often necessary to monitor tissue healing. These injuries are usually associated with ligament tears such as the anterior cruciate ligament (ACL). Ligament tears in conjunction with meniscal tears drastically reduce the stability of the knee and can lead to further meniscal damage.

Meniscal injuries that require surgical repair or excision are large defects with compromised vascular supply, large meniscal deformations, or damage to the peripheral or circumferential collagen fibers. In need of excision, it is preferable to leave a partial meniscus intact as opposed to full meniscectomy. The surgical approaches are either open-joint surgeries or arthroscopic surgery to suture tears within the meniscus (163).

TISSUE ENGINEERING OF ARTICULAR CARTILAGE AND MENISCUS

The rapidly evolving field of tissue engineering has promised to deliver biological replacements of damaged

articular cartilage and meniscus. In comparison with current treatment modalities, tissue engineering represents a shift in the paradigm. Whereas current treatment modalities improve articular cartilage and meniscal injuries by increments, the end goal of tissue engineering is to generate or regenerate articular cartilage and meniscus.

Previous investigations of the structural, biochemical, and mechanical properties of articular cartilage and meniscus serve as the necessary foundation and have set the stage for the tissue engineering of these structures. For example, a commonly stated long-term goal of a biochemical study to investigate the PG distribution in various zones of articular cartilage was to improve the treatment of cartilage defects in arthritis, which was all too familiar for a published study or a grant proposal decades ago.

To tissue-engineer articular cartilage or meniscus, one has the conceptual liberty of selecting cell sources, scaffolds, or growth factors. Another essential choice is whether mechanical stress is to be applied to the tissue-engineered articular cartilage or meniscus prior to or after *in vivo* implantation. Thus, the initial stage of tissue engineering of articular cartilage and meniscus is an optimization process of cells, scaffolds, growth factors, or mechanical stimulus.

Cells Capable of Generating Articular Cartilage and Meniscus

Articular chondrocytes are the obvious choices for articular cartilage regeneration (164–166). From the standpoint of scientific discovery, articular cartilage or meniscal regeneration from articular chondrocytes or meniscal fibrochondrocytes has revealed a wealth of information (e.g., 167–169). From the standpoint of alignment with eventual therapeutic regeneration of synovial joint condyle in arthritis patients, the selection of articular chondrocytes is problematic. The essential problem at this time is that articular chondrocytes are not very expandable *ex vivo*. Thus, relatively large donor site defects are necessary to harvest a large amount of tissue(s) from the patient in order to obtain sufficient numbers of articular chondrocytes or meniscal fibrochondrocytes for healing substantial articular cartilage or meniscal defects. In contrast, mesenchymal stem cells, whose natural progeny includes both chondrocytes and fibrochondrocytes, can be obtained in small quantities (e.g., a few cc of bone marrow content) (170) or from other connective tissue sources such as adipose tissue (170,171), readily expanded *ex vivo* in cell culture and reliably differentiated into chondrocytes cells (170,172). Embryonic stem cells may turn out to be a viable cell source for synovial joint regeneration, especially in consideration of the recent demonstration of the differentiation of embryonic stem cells into osteogenic cells (173,174). Embryonic stem cells are likely to be of greater significance in synovial joint condyle regeneration if the isolation and expansion of adult MSCs encounter substantial difficulties. However, thus far, it does not appear to be the case for synovial joint condyle regeneration (172). Chondrogenic and osteogenic cells derived from MSCs appear to be the logical choices at this time for exploring clinically applicable approaches toward regenerating the synovial joint condyle (152,172,175–180).

Biomaterial Scaffolds Are often Necessary for the Engineering of Structural Tissues such as Articular Cartilage and Meniscus

The optimal scaffolds for articular cartilage and meniscal regeneration are yet to be determined. An increasing number of meritorious studies have reported a wide range of natural and synthetic polymers for articular cartilage regeneration. Many of the tested synthetic polymers are biocompatible and biodegradable, two desirable features for cartilage regeneration (181). A model scaffold should allow effective diffusion of essential nutrients and metabolic wastes, given that chondrocytes and fibrochondrocytes both rely on diffusion for survival.

For cartilage regeneration, natural and synthetic polymers may need to simulate the extracellular matrix environment of chondrocytes that are created by Type II collagen and PGs in a highly aqueous matrix. Several hydrogels simulate cartilage matrix to various degrees, such as alginate, hyaluronate, chitosan, and polyethylene glycol-based polymers (175,176,181–183). The organization of chondrocyte phenotypes in various zones of articular cartilage may also need to be simulated, as demonstrated in recent reports by encapsulating articular chondrocytes from various zones of bovine articular cartilage into different hydrogel layers (184–186). The water content and diffusion properties of hydrogels mimic an ECM to allow tissue-forming cells to obtain systemic nutrients (187). The initial viscous liquid form of several hydrogel materials provides a unique capability to form complicated shapes while maintaining uniform cell distributions. For examples, an aqueous-derived silk scaffold also encompasses hydrogel-type properties and has been shown to support chondrogenesis (188). Pellet culture is a practice devoid of scaffolds that takes advantage of the dense, avascular, and aneural condition of cartilage. This system is done simply by centrifuging chondrocytes or MSCs into a pellet and incubating them in desired conditions. Although pellets do not provide efficient shape retention, they do bestow valuable information *in vitro* as models for chondrogenic MSC differentiation. Despite various levels of reported success with *in vitro* models, cell-hydrogel interactions need to be better understood, along with optimization of hydrogel composition, cross-linking, and degradation behavior as a function of the *in vivo* regenerative outcome.

In engineering an osteochondral construct, it is essential to construct a mold that is specific to the joint. Computer-aided approaches have been developed to construct molds that will both accurately replicate the anatomy of the joint as well as preserve the intricate architectural integrity of the interior of the scaffold. These intricate details can range from pore size to channel orientation to surface texture and can effectively contribute to the synthesis, or lack thereof, of the tissue one is trying to engineer. Common methods for 3D mold fabrication are based on software programs that read and digitize computerized tomography or magnetic resonance imaging. Solid free-form fabrication (SFF) technology can be used to produce an actual 3D scaffold through combining the interior architecture image and the external scaffold image, which is done via a layering process from computer-aided design files. SFF shows excellent promise due to the

possibility of controlling the aforementioned necessary parameters needed in scaffold fabrication.

Growth Factors Are Necessary for Modulating Cell Behavior

Growth factors are proteins and polypeptides capable of modulating all aspects of cell behavior such as proliferation, differentiation, and apoptosis. Cells can be regulated by self-released growth factors (autocrine effect), or by growth factors released by other cells (paracrine effect). For chondrogenic differentiation, TGF- β superfamily is frequently used (e.g., 176,189). The de-differentiation and re-differentiation of chondrocytes are regulated by combinations of TGF- β 1, fibroblast growth factor-2, and sequential exposure to IGF-I (190). TGF- β s also stimulate GAG synthesis in isolated cultured meniscus cells (191). Platelet-derived growth factor (PDGF) promotes chondrogenesis in chick limbs both *in vitro* and *in vivo* (191). Resting zone chondrocytes treated with PDGF shows hypertrophic activity in forming new cartilage (192). Although many growth factors have provided positive results, the optimal scheme of their application is not yet fully understood. The reader is referred to several recent in-depth reviews of growth factor delivery in cartilage regeneration (154,183,193).

Functional Tissue Engineering of Articular Cartilage and Meniscus

The field of functional tissue engineering has been proposed in response to the need to engineer tissues that have not only the appropriate cellular and matrix structures, but also the necessary physical properties (194,196). The aforementioned mechanical properties of both articular cartilage and meniscus are quite complex and intricate to replicate. The rather severe loading environment of cartilage in a synovial joint attributes to poor repair capabilities as well as degeneration. It has been proposed that a potential solution to engineer tissues with the appropriate physical properties lies in the physical factors, among which mechanical stress is most well studied (194–196). Prior to the conception of functional tissue engineering, it is widely acknowledged that mechanical factors can effectively influence cell behavior such as proliferation, differentiation, and matrix synthesis. Significant evidence exists that physical stress can accelerate or improve tissue regeneration and repair *in vitro*. The preference of chondrocytes to synthesize proper ECM components at an accelerated pace can help engineer cartilage and meniscus in an efficient manner. This concept can be used to enhance engineered grafts to more accurately represent native tissue. In order to better provide these stresses, a movement has begun to construct mechanical bioreactors that increase matrix synthesis through different approaches. Examples in which mechanical stimulation has proven advantageous in synthesizing cartilage has been through fluid flow (197,198), simulated hypogravity (199), simulated microgravity (200), static and cyclic compression (201–203), and hydrostatic pressure (204). Recent studies have suggested that external mechanical loading of cells or cell-polymer constructs may enhance their mechanical strength (e.g., 186,205,206). Although practical in theory, the type, frequency, area, and amount of

loading still need to be determined to furnish the optimal results of engineering each individual tissue.

The mechanical properties of engineered articular cartilage and meniscus can be readily tested, in many ways similar to the mechanical testing of native articular cartilage and meniscus. The results of compressive moduli of native and engineered articular cartilage or meniscus tissue using excised tissue plants and *in vitro* testing can be directly compared. However, loading measurements of native or engineered articular cartilage and meniscus have not been accomplished *in vivo*. Therefore, the ideal mechanical properties of tissue engineered articular cartilage can only be estimated, not accurately determined. Various biomaterials have been investigated for articular cartilage repair and have various mechanical properties that must be considered when designing a suitable scaffold. Engineering a scaffold that is too stiff may detrimentally affect cell viability and matrix synthesis. Stress shielding may occur and surrounding tissue may degrade as physiological loads are transferred to the more mechanically stiff implant. In contrast, a scaffold too soft will not exhibit the needed mechanical stiffness for the applied loads, causing physical breakdown and degradation of the material, leaving a void in the host tissue. Various zones of articular and fibrocartilage have different mechanical properties (56,207). Whether regional differences in the mechanical properties of articular cartilage and meniscus need to be simulated in tissue engineering remains to be explored (79).

SUMMARY AND CONCLUSIONS

Articular cartilage and meniscus are load-bearing and hydrated tissues that are key structures of diarthrodial joints. The similarities between the two structures include their remarkable capacity for resistance to and transmission of mechanical stress and their ability to enable joint lubrication. However, articular cartilage and meniscus have many important differences. Articular cartilage, in the overwhelming majority of human synovial joints, consists of hyaline cartilage, whereas the meniscus is composed of fibrocartilage. The mechanical properties of native articular cartilage and meniscus have been studied extensively and shown to vary with species, location, and even the orientation of test specimens. Motivated by the concept of functional tissue engineering, the mechanical properties of engineered articular cartilage from cells and biomaterials have also been investigated in recent years. As a result of drastically different structural and mechanical properties between articular cartilage and meniscus, the engineering challenges of the two tissues are different. Mesenchymal stem cells, or other stem cells, need to be differentiated into chondrocytes for the engineering of articular cartilage, whereas these stem cells may need to be differentiated into fibroblasts and chondrocytes, or perhaps fibrochondrocytes, for the engineering of meniscus. The optimal biomaterials for the engineering of articular cartilage and meniscus remain to be identified or fabricated. At least, the engineered articular cartilage and meniscus must adapt to possess similar mechanical properties of their native target tissues. The existing knowledge

on the biological and mechanical properties of articular cartilage and meniscus provides the necessary foundation for the eventual goal to regenerate or replace diseased or lost articular cartilage and knee meniscus with engineered tissue analogs.

INTRODUCTION: NATURE OF BLOOD CELLS (1,2)

Cells compose ~ 50% of the volume of normal human blood, while plasma constitutes the remaining volume. Generally, cells in blood are divided into three categories: platelets, erythrocytes (or red blood cells, RBCs) and leukocytes (or white blood cells, WBCs) (Table 1) (3). Among these, the platelets or thrombocytes are small, irregular, disk-shaped cells that lack a nucleus. They are of size 2–3 μm in diameter. These cells primarily function to stop bleeding or hemorrhage, and they also participate in coronary artery disease. They do so by being part of the blood coagulation cascade and by aggregating with each other. Platelets are found in blood at a concentration of $0.15\text{--}0.5 \times 10^6$ cells- mm^{-3} . The second type of cells in blood, erythrocytes, contains a red respiratory protein called hemoglobin. These are disk-shaped, biconcave cells without nuclei. Their diameter ranges from 6 to 8 μm and their thickness is 1.5–2.5 μm . The primary function of erythrocytes is to transport oxygen and carbon dioxide between the lung and body tissues. Erythrocytes are the most numerous blood cells at concentrations of $4\text{--}6 \times 10^6$ cells- mm^{-3} . Mature erythrocytes emerge from precursors that are called reticulocytes. Erythrocyte counts are on average ~ 10% higher in the human adult male population than those in the female population. Lack of iron and hemoglobin in erythrocytes can lead to anemia, a pathological deficiency in the oxygen-carrying component of blood. The third type of blood cells is the leukocytes, whose primary function is to provide the body with immunity and to protect it from infection. Leukocytes are fewer in number than the erythrocytes with a concentration of ~ $5\text{--}10 \times 10^3$ cells- mm^{-3} . These cells are roughly spherical in shape and they contain nuclei, and considerable internal and cell-surface structures.

Leukocytes are categorized in various ways depending on their function and differentiation pathway. One com-

mon method subdivides these cells into myeloid and lymphoid cells. Myeloid cells differentiate into phagocytes, while lymphoid cells primarily produce lymphocytes. The phagocytes include polymorphonuclear granulocytes and monocytes–macrophages. Of these, the former have lobed, irregular shaped (polymorphic) nucleus. They are further subdivided into neutrophils (55–70% of all leukocytes), eosinophils (2–4%), and basophils (0.5–1%), on the basis of how the cellular cytoplasmic granules are stained with acidic and basic dyes. Leukocytes are also commonly characterized based on particular cell-surface receptors that are expressed by them, since these are specific to a particular subpopulation. Many of these receptors are recognized by monoclonal antibodies. A systematic nomenclature has now evolved in which the term CD (Cluster Designation) refers to a group of antibodies that recognize a particular cell-surface antigen. The CD classification is thus often used to classify and identify particular leukocyte subpopulations. A method of blood cell counting called flow cytometry (described below), often uses the fluorescence of labeled antibodies to distinguish between various cell types.

Among the granulocytes, neutrophils are the most abundant cell type. These represent the body's first line of defense during immune response. They are characterized by a number of segmented nucleus lobes connected by fine nuclear strands or filaments. Immature–young neutrophils have a band- or horseshoe-shaped nucleus. Thus, while the younger neutrophils are known as band neutrophils, the mature cells are the segmented neutrophils. Segmented neutrophils are the predominant species in human blood, while band neutrophil levels are elevated following bacterial infection or acute inflammation. The term left shift is used to indicate an increase in the number of circulating immature neutrophils. Condition under which the number of circulating neutrophils is increased is called neutrophilia, while a decrease in this cell type results in neutropenia. Another important morphological characteristic of neutrophils is the virtual lack of endoplasmic reticulum and mitochondria. Mature neutrophils have short lifetimes in circulation and they migrate into tissues to defend against invading microbes during inflammation. Eosinophils, like other granulocytes, possess a polymorphous nucleus, generally with two lobes. They can response to allergy and parasitic infection. They attack large parasites such as helminthes via their C3b receptors. Eosinophils release various substances from

Table 1. Characteristic of Normal Blood Cells^a

Cell Type	Concentration	Size, μm	Density, g/mL	Shape	Nucleus	Cytoplasm
Platelet(thrombocyte)	$0.15\text{--}0.5 \times 10^6 \cdot \mu\text{L}^{-1}$	2–3	1.03–1.06	Small disk shape	None	Granular
Erythrocyte (RBC)	$4\text{--}6 \times 10^6 \cdot \mu\text{L}^{-1}$	6–8	1.09–1.11	Biconcave disk	None	Hemoglobin
Leukocyte (WBC)	$5\text{--}10 \times 10^3 \cdot \mu\text{L}^{-1}$	8–20	1.05–1.10			
Neutrophil	55–70% of WBC	9–15	1.08–1.10	Various	Lobed	Granular
Eosinophil	2–4% of WBC	9–15	1.08–1.10	Various	Lobed	Granular
Basophil	0.5–1% of WBC	10–16	1.08–1.10	Various	Lobed	Granular
Monocyte	3–8% of WBC	14–20	1.05–1.08	Various	Round	Fine
Lymphocyte	20–40% of WBC	8–16	1.05–1.08	Round	Round	Clear

^a(Adapted from Ref. 3, pp 3–6.)

their eosinophilic granules. These include major basic proteins, plus cationic proteins, peroxidase, phospholipase D and histaminase. The number of eosinophils can augment in blood during allergy (eosinophilia), dermatological disorder and parasitic infection. Basophils have a two-lobe nucleus. They release inflammatory mediators, such as histamine and bradykinin, and prostaglandins and leukotrienes. Basophils play an important role in inflammatory and allergic response. Their number is increased in patients with hypoactive thyroid conditions and during certain malignancies like chronic myeloid leukemia.

Monocytes and macrophages (tissue monocytes) represent the second type of phagocytes and these are relatively large, long-lived cells compared to polymorphonuclear granulocytes. Their cytoplasm is transparent with typically a horseshoe-shape nucleus. Monocytes are involved in both acute and chronic inflammation. The transformation from monocytes to macrophages is controlled by different cytokines. When responding to chemical signals at the inflammation site, monocytes quickly migrate from the blood vessels and start to perform phagocytotic activity. These cells also have an intense secretory activity that results in the production and secretion of chemical mediators such as lysozymes and interferons. The number of monocytes in circulation is increased whenever there is increased amount of cell damage, such as during recovery from infection.

Lymphocytes are mononuclear cells that constitute ~20–40% of all leukocytes. These cells have a round or oval shaped nucleus that is typically large in comparison to the overall cell size. Besides circulating in blood vessels, lymphocytes also populate the lymphoid organs, as well as the lymphatic circulation. The specificity of immune response is due to lymphocytes, since these cells can distinguish between different antigenic determinants. Lymphocytes are subdivided into three main categories: (1) T-cells, (2) B-cells, and (3) natural killer (NK) cells. T-Cells are responsible for cellular immune response and are involved in the regulation of antibody reactions by either helping or suppressing the activation of B lymphocytes. B cells are the primary source of cells responsible for humoral-antibody responses. These are responsible for the production of immune antibodies. The NK cells destroy target cells via nonphagocytic reaction mechanisms that are termed cytotoxic reaction. Lymphocyte number may increase in blood in patients with skin rashes from certain viral diseases such as measles and mumps, in patients with thyrotoxicosis, and in patients recuperating from certain acute infections.

RATIONALE FOR CELL COUNT

Blood cell count is achieved by determining the concentrations and other parameters of different cell types in a unit volume of circulating blood. It can be a complete blood count (CBC, defined later in this article), which examines every blood component, or it may measure only one element. Table 1 demonstrates the characteristic of normal blood cells from a healthy adult. These values vary with age, sex, race, living habit, and health status. Further, under pathological conditions, the distribution of blood cells may be perturbed and

thus blood cell counting can aid diagnostics. For example, a typical symptom of common anemia is an inadequate amount of RBCs. The increase or decrease in the numbers of the different types of WBCs may indicate infection and inflammation as discussed above. In addition to the cell numbers, other information regarding blood cells, such as cell size, is also important. For example, in patients with anemia caused by vitamin B₁₂ deficiency, the average size of the RBCs is larger than normal and this disease state is called macrocytic anemia. On the contrary, if red blood cells are smaller than normal, as in the case of microcytic anemia, the condition may be indicative of iron deficiency. Therefore, a routine blood test, which includes not only blood cell count but also measurement of other parameters, can aid disease diagnosis and treatment by health professionals.

HISTORY AND BASIC PRINCIPLES FOR BLOOD CELL COUNTING (4–10)

Cell counting has evolved over the centuries from a manual method that heavily relied on microscopic examination, to one where electrical and optical measurement strategies, along with computer automation, are playing an increasingly important role. Indeed, manual methods are still important in research laboratories that study a wide variety of animal systems and cell types, in addition to human blood. On the other hand, automated systems are typically used in clinical studies. In this context, modern technology has automated the process of blood cell counting and the assessment of various blood cell parameters. A CBC, thus, not only provides a panel of tests to quantify the composition of whole blood, it may also include more detailed information regarding the cell profile. Based on technical feasibility and cost, either a simple manually operated cell counter or a more advanced automated blood count platform can be applied to serve the specific medical diagnose need. A brief history and rationale that has lead to current strategies for blood cell counting is outlined below.

Microscopy Coupled with Manual Visualization

Notable, among the early attempts to count blood cells, was the work by Anton van Leeuwenhoek in the seventeenth century who counted the number of chicken erythrocytes in a glass capillary of known dimensions using his microscope. Later, in the nineteenth and early twentieth century, Burker employed a shallow rectangular chamber with a thin coverglass as a counting chamber. Advances in this basic design have now resulted in the laboratory hemocytometer, which is commonly employed for manual cell counting. Ehrlich's classical work on the staining of white blood granules laid the foundations of hematology and differential cell counting. In these studies, he demonstrated that it is possible to distinguish between the various blood cell subgroups using acidic and basic dyes that differentially stained the cellular granules and nucleus.

Hemocytometer

One device that utilizes the light microscope for cell counting is the hemocytometer. This is a commercially

available counting chamber that is used for manual blood counting. It consists of two parts: a microscopic slide with improved Neubauer ruling, and a special thick flat cover slip (Fig. 1a). Both the hemocytometer slide and cover slip must meet specifications of the National Bureau of Standards. The slides have two raised surfaces for duplicate cell counting, each of them bearing square-shaped grids of dimensions 3×3 mm. The two raised surfaces are separated by an H-shaped moat. Each of the 3×3 mm squares has a central area of size 1×1 mm that is further subdivided by 25 groups of 16 smaller squares (Fig. 1b and c). During cell counting, the coverslip is placed on top of the counting surface such that the distance between the counting surface and the coverslip is 0.1 mm. Thus, the total volume in the space between the central 1×1 mm area and the coverslip is fixed at 0.1 mm^3 . Samples to be studied can be loaded into the chamber using a standard laboratory pipette placed at the point labeled V-slash.

A phase contrast microscope is used to view blood on a hemocytometer slide. In such runs, a sample of diluted blood mixture is placed in a hemocytometer. For a proper count, cells should be evenly distributed. In a white cell count, blood is typically diluted 1:20 in a solution that lyses red cells and stains white cells. Because red cells are so much more numerous than white cells, blood is normally diluted 1:200 for red cell counts. The total number of cells in the central area with fixed volume of 0.1 mm^3 is

counted and this measurement is used to estimate the concentration of cells per cubic millimeter (mm^3) according to, cell concentration = number of cells counted \times dilution factor / volume under central grid. For simplicity, instead of counting all the cells in the central 1×1 mm area, counting cells present in a sufficient number of representative squares is also reasonable as long as the acceptable level of accuracy can be ensured. A suitable convention should be applied to avoid counting cells twice, for example, by counting only those cells that touch the top and right-hand margins of a square and omitting cells that touch the bottom and left margins. The World Health Organization (WHO) has recommended methods for the visual determination of WBC count and platelet count using hemocytometer (Recommended methods for the visual determination of WBC count and platelet count. Geneva: World Health Organization, 2000. WHO/DIL/00.3). It describes the detailed sample preparation procedure and counting techniques, and this could be used as a basic protocol for cell counting using the hemocytometer.

Electrooptic Measurements

Advances in electronics and electrooptics in the twentieth century have dramatically simplified blood cell counting and made automation of these processes possible. Some examples of early advances are illustrated in Fig. 2. Panel a describes a method developed in the 1940s where cells

Figure 1. (a) Diagram of hemocytometer with cover slip. (b and c) Expanded view of ruled area as seen under a microscope.

Figure 2. (a) Schematic of an early instrument using the ensemble method to obtain a blood cell count. The intensity of light that is scattered onto a ring-shaped photodetector is measured. The intensity is proportional to cell concentration. (b) Schematic of a photoelectric device that optically counts cells under flow. Here, a fluid stream containing cells is passed through a microscope viewing station. The photomultiplier detects the passage of cells. (c) Schematic diagram of a device using a photoelectric spot scanning method. Mechanical motion is provided to scan cells contained in the counting chamber (3).

were electrooptically measured based on turbidimetry. Here, light lost per millimeter of path length based on scattering or absorbance by blood cells was related to cell concentration. Using cell reference or artificial standards, thus, RBC concentrations could be determined. In this approach, instead of detecting cells individually, the cell concentrations were measured using principles analogous to Beer's law. Panel b illustrates a photoelectric device from 1953, where a thin fluid stream was created such that single cells passed via a microscope viewing station. Images of these cells were magnified and detected using a photomultiplier tube. Panel c illustrates another early instrument where erythrocytes could be counted automatically by means of photoelectric spot-scanning of a thin

layer of diluted blood. Here the manual visual counting chamber technique discussed above was improved by introducing a photomultiplier and an electronic counting unit. A motor drives the counting chamber. An instrument based on this principle is the Casella Counter shown in Fig. 2c.

Electronic Cell Counter

In 1950s, Wallace Coulter (Founder of Coulter Company, now Beckman-Coulter Co.) developed a method for cell counting based on electric impedance. This method now forms the basis of most particle size analysis methods in the world. This method, also called low voltage direct

Figure 3. Schematic diagram of electronic cell counter using electric resistance method.

current (dc) method, is based on the measurement of changes in electrical resistance as cells pass through a small orifice that separates two electrodes. In this type of device (Fig. 3), cells are suspended in an electrically conductive diluent, such as saline. Low frequency electrical current is applied between two electrodes; one of them being placed in the cell medium and the second within the aperture tube. The aperture tube has a small orifice or sensing aperture that is typically of size 50–200 μm in diameter. During the measurement, cells are drawn through the aperture using a pressure gradient that is either generated by a mercury manometer or oil displacement pump. Cells are assumed to be non-conducting. Electrical resistance between the two electrodes or impedance in the current occurs as the cells pass through the sensing aperture, causing voltage pulses that are measurable. The number of pulses is proportional to the number of cells counted. The size of the voltage pulse is directly proportional to the size (volume) of the cell. This principle allows discrimination between cells of different sizes. Counting of specific-sized cells is also possible using threshold circuits that cut-off voltage pulses above and below predetermined values. The quantity of suspension drawn through the aperture is precisely controlled to allow the system to count and size particles precisely. Finally, several thousand particles are individually counted within seconds in this device. Measurements are independent of particle shape, color, and density.

Analogous to the above method is the radiofrequency (RF) resistance method where high voltage electromagnetic current is flown between the two electrodes instead of dc. This current circuits the cell membrane lipid layer and penetrates into the cell. While the dc method defines the volume of the cell, changes in conductivity measured using the RF method correlate with the cell's interior structure including the nucleus volume and density, and cytoplasm granule composition. Both dc and RF may be applied simultaneously and this can yield different information about cell size and cellular structure. Such a dual measurement strategy is employed by Sysmex cell counters to quantify the differential leukocyte counts (DLC) as discussed later.

Several factors affect the precision and accuracy of measurements made using the electric impedance meth-

ods. First, the aperture size is critical. The instrument is set to count only particles within the proper size range. The upper and lower levels of the size range are called size exclusion limits. Any cell or material larger or smaller than the size exclusion limits will not be counted. Sample must also not contain other material that might erroneously be counted as cells. In practice, erythrocyte and platelet aperture should be smaller than leukocyte aperture in order to increase platelet count sensitivity. Besides the size exclusion limits and aperture size, cell shape and physical properties are also important in determining the shape factor or the ratio of electrically measured volume to the geometric volume. Erythrocytes may result in different signals depending on their orientation with respect to the aperture in the sensing zone. Simultaneous passage of more than one cell at a time through aperture may also cause artificially large pulses, and thus circuits to correct for this coincidence error are required. The magnitude of the coincidence error increases with cell concentration. Correction should be completed by the countercomputer based on the relationship of cell count with cell concentration and aperture size. Finally, an internal cleaning system to prevent or slow down protein buildup in aperture is beneficial in minimizing aperture blockage.

Hydrodynamic focusing as discussed below helps to solve many of the problems above and it provides improved cell counting and characterization. This has been developed and assembled in many cell counters today and this feature dramatically improves the cell volume distribution resolution.

Laser Light Scattering and Fluorescence Detection

Optical scattering can be used alone or in combination with other electrical measurement strategies discussed above for cell counting and characterization. A key feature of such instruments is hydrodynamic focusing where an external sheath flow allows alignment of blood cells one-at-a-time in the path of a light beam, usually within a quartz flow cell (Fig. 4a). Incident light on cells within this flow stream are scattered or redirected in a manner that is dictated by the size of the cell and the intracellular distribution of refractive index. Lasers are generally preferred as the light source since it produces monochromatic light that has a small spot size. Photomultiplier tubes (PMTs) are used to collect the weak signal of scattered light. The light scattered at angles from 5–10° (forward scatter) in general correlates with cell size. Light scattered at 90° is called side-scatter and this is related to the cell shape, orientation, and cellular content. A cell with many complex intracellular organelles will also give a larger side-scatter signal than a cell with fewer intracellular organelles. The design of precise angles where scattered light signals are measured is specific to instrument manufacturers and the cell-enumeration strategy employed. In general, these scatter data together allow reliable identification of distinct populations, such as platelets, RBCs, monocytes, and neutrophils in a mixture. They can also allow enumeration of lymphocyte subsets and reticulocytes. While, optical scattering methods reveal information about cells that is

Figure 4. (a) Schematic of flow cytometry showing hydrodynamic focusing of cells by sheath fluid that brings the cells in the path of a laser beam. Light scattered by cell at various angles is collected. These are passed through an arrangement of optical filters to yield measures of forward scatter, side scatter and particle fluorescence. (b) Stokes shift is depicted for the fluorescent probe fluorescein where the wavelength of the absorbed and emitted quanta are shifted, with the emitted wavelength being longer than the absorbed light.

distinct from that obtained from the above electrical methods, their estimates of cell volume are not as accurate as the electrical methods.

A major advantage of optical methods using lasers is that such methods can be readily coupled with fluorescence detection (Fig. 4b). Fluorescent conjugated antibodies to specific cell-surface CD markers or specific ligands can be used not only to identify particular blood cells, but also to label cellular components that may be indicative of disease states. In such work, when the laser light reaches these cells, a fraction of the photons are absorbed by the fluorescent probe, which then reemit the photon at a longer wavelengths. The quantity of this emitted light (both scattered and fluorescent) is measured using photomultiplier tubes that are arranged in conjunction with a series of optical filters and dichroic mirrors as shown in Fig. 4a. The detection and conversion of scattered or fluorescent light into electrical signals is accomplished by photodetectors

that capture photons on a light sensitive surface that elicits an electron cascade. The signal output from such detectors is amplified (either linearly or logarithmically) and then converted from analog to digital form for computer analysis. Multidimensional plots of various scattering properties with fluorescent signals can thus be generated to individually characterize each cell in a complex mixture.

COMPLETE BLOOD CELL COUNT (5,10)

Computer Blood Cell Count is a series of tests that result in the quantitation of the number of erythrocytes, leukocytes, and platelets in a volume of blood. The measurements also estimate the hemoglobin content and packed cell volume (or hematocrit) of erythrocytes. This can be done manually using a microscope along with cytochemical dyes, such as Wright-Giemsa stain. The combination of acidic and basic

dyes here can differentially stain the granules, cytoplasm, and nuclei of various blood cell types. Alternatively, in clinical laboratories an automated cell counter can be used to count cells in a given volume. Low end instruments offer RBC and platelet analysis with three-part differential leukocyte count (DLC) while higher end instruments may include a five-part differential count along with reticulocyte analysis. The speed of the instrument and level of automation varies with the class of instrument. The analysis thus obtained is compared with the normal range and assessed for clinical or research purposes. A complete blood cell count mainly includes the following parameters:

Hemoglobin

Hemoglobin concentration (HGB) is reported in grams per deciliter ($\text{g}\cdot\text{dL}^{-1}$) of blood. This parameter typically varies in proportion to erythrocyte concentration in blood. The normal range for hemoglobin is age and sex dependent. Traditionally, hemoglobin is measured using the cyanmethemoglobin method, as recommended by the International Council for Standardization in Hematology (ICSH). Here, a lysing agent is added to disrupt RBCs and to release cellular hemoglobin. This hemoglobin is converted into a stable form called cyanmethemoglobin (see reaction below), the quantity of which can be measured using a spectrophotometer for absorbance measurement at ~ 540 nm.

Since cyanmethemoglobin measurements contain poisonous cyanide reagent, other more environmentally friendly methods for automated HGB measurement have been developed. Among them, sodium lauryl sulfate-hemoglobin (SLS-Hb) method is used by Sysmex automated cell counters. Here, the lauryl group of the ionic surfactant, which is hydrophobic, binds strongly with hemoglobin. This binding leads to rapid globin molecular conformation change and conversion of hemoglobin from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. The hydrophilic group of SLS now binds with Fe^{3+} to form a stable SLS-Hb. The absorption maximum of SLS-Hb occurs at 535 nm with a shoulder at 560 nm, and this feature is used to determine hemoglobin content. This reaction mechanism is useful since conversion to SLS-Hb occurs rapidly within 10 s.

Platelet Count

Platelet count (PLT) is normally expressed as thousands per microliter (μL) and can be measured manually using the hemocytometer. Care must be taken during such measurements to avoid platelet clumps that can occur in the absence of appropriate anticoagulant. Electronic counting of platelets can also be performed using electric impedance or light scattering methods. Such measurements are typically performed in channels that are designed to discriminate between erythrocytes and platelets. Size distributions resulting from platelet counts can be used to estimate the mean platelet volume (MPV), which is a measure of the platelet volume variation. In general, increased MPV

may be expected in regenerative thrombocytopenia, which is accompanied by an increased production of platelets by bone marrow.

Red Blood Cell Count

The RBC or erythrocyte count is expressed in millions per microliter of whole blood. Such counts can be measured manually using the hemocytometer. In hematology analyzers, RBC content is typically measured using either the dc impedance method, light scattering analysis, or a combination of the two. Attention is placed during these measurements to discriminate between small RBCs and platelets. Results of such analysis typically result in a RBC size distribution plot from which other indices can be estimated. These indices include: (1) Hematocrit (HCT), which is also called packed cell volume (PCV). This is a measure of the volume fraction of RBCs in whole blood expressed in %vol/vol. Normal adult hematocrit ranges from 35 to 50%, and this is both sex and age dependent. Traditionally, hematocrit is determined by monitoring the height of packed RBCs after centrifugation in a standard microhematocrit tube, relative to the column length. Electronic cell analyzers can also estimate hematocrit by measuring the individual volumes of RBCs (also called MCV as described below) and determining the product of RBC count and MCV. (2) Mean corpuscular volume (MCV) is the mean volume of RBCs expressed in femtoliters (fl). The normal range is ~ 80 – 100 fL. The MCV can be experimentally determined from the RBC size distribution height. Alternatively, if HCT value is known, MCV is calculated based on the ratio of hematocrit and RBC count. This parameter is analogous to MPV, which can be derived from platelet data. When the MCV is low with normal HCT, the blood is said to be microcytic. (3) Mean corpuscular hemoglobin concentration (MCHC) is the mean concentration of hemoglobin in the RBCs in grams per deciliter ($\text{g}\cdot\text{dL}^{-1}$). This is calculated based on the ratio of HGB by HCT. Red cell populations with normal, high, or low values of MCHC are referred to as normochromic, hyperchromic, or hypochromic, respectively. The last case can occur during strongly regenerative anemia, where an increased population of reticulocytes with low HGB content pulls the average value down (an increased MCV would be expected under this scenario). (4) Mean corpuscular hemoglobin (MCH) is a measure of the mean mass of hemoglobin (HGB) in RBC, and is expressed in picograms (pg). (5) Red cell distribution width (RDW) is an index of the variation in cell volume within the RBC population. It is mathematically determined by (Standard deviation of RBC volume/ MCV) $\times 100$. The normal range for RDW is 11–15%. While, red cell populations with normal RDW are called homogeneous, those with higher than normal are termed heterogenous. For example, increased number of reticulocytes, which is associated with erythropoiesis, will cause increased RDW values. The RDW index may be an early indicator of changes in red cell population sizes, for example, during anemia caused by iron deficiency. In this case, the presence of few microcytic RBCs may increase the standard deviation of the cell distribution even before marked changes in MCV are observed.

White Blood Cell Count

White blood cell or leukocyte count is measured in thousands per microliter. During manual WBC count, RBCs in blood are lysed and diluted sample is charged into the hemocytometer. Nucleated cells are counted and WBC concentration is determined. Alternatively, impedance-based electronic cell counters can be used to measure WBC count. Besides these basic methods, in automated cell counters, one of many technologies can be applied for WBC differential count. Beckman–Coulter instruments employ the VCS (volume, conductivity, and scattering) technology. In this method, the dc impedance principle is used to physically measure the volume of the cell that displaces the isotonic diluent. Alternating current in the RF range short circuits the bipolar lipid layer of the cell membrane allowing energy penetration into cell. This probe provides information on cell size and internal structure. This data is adjusted by the cell volume measurement to obtain an index called opacity. Finally, coherent light scattering from an incident laser beam is collected to obtain information on cellular granularity and cell surface structure. In Sysmex instruments both dc and RF methods are employed along with differential lysis of cells using lysis solution and temperature treatment. In CELL-DYN instruments from Abbott laboratories, the Multi-Angle Polarization Scattering Separation (M.A.P.S.S.) technology is used to obtain the differential count. Here light scattered by cells localized in a hydrodynamically focused flow stream is measured at three angles (0, 10, and 90°). Polarized light at 90° is also measured. Together these four parameters are used to perform the five-part differential count. Two methods are employed in the Bayer cell counters for differential leukocyte count. In the first method called the peroxidase method, RBCs are lysed and white cells are stained with peroxidase. These cells are counted based on size by forward scatter analysis, and absorbance using dark field optics. The second method, called the basophil method, involves stripping the cells using a non-ionic surfactant in acidic solution. Basophils are resis-

tant to lysis while RBCs and platelets are lysed and other leukocytes are stripped of their cytoplasm. Light scattering analysis distinguishes basophils from other polymorphonuclear and mononuclear cells. The above peroxidase and basophil methods thus provide automated differential cell count by separating the cells into clusters.

Reticulocyte Count (RTC, RET, or RETIC)

Reticulocytes are formed in the last stages of erythropoiesis. These cells spend ~ 2 days in the bone marrow and 1–2 days in peripheral blood prior to maturing into RBCs. These are nonnucleated RBC, which by definition upon staining with supravital dyes contain two or more particles of blue-stained material that correspond to ribosomal RNA (ribonucleic acid). With new methylene blue, reticulocytes stain bluish-purple. Reticulocyte count as a percentage of RBCs is a measure of the erythropoietic activity in the bone marrow. This is a useful marker of bone marrow suppression following chemotherapy, recovery from anemia, and so on. Reticulocyte counts may be high when the body is replenishing the RBCs in circulation. Reticulocyte counts can be performed using microscopy and supravital stains, such as new methylene blue or brilliant cresyl blue. Reticulocyte counts can also be done using automated instruments. Here light scattering is typically applied to detect cell size and cell fluorescence–absorbance measurements in conjunction with dyes like Auramine O and new methylene blue for quantitation of reticulocytes. Such methods provide good discrimination between reticulocytes and mature RBCs, with greater accuracy than microscopy examination.

AUTOMATED CELL COUNTERS (4,5)

Manufacturers of automated cell counters typically present a vast product line with varying levels of sophistication to meet the market needs. Although the analysis principles may differ, all cell counters have some common basic components, specifically hydraulics, pneumatics and electrical systems (Fig. 5). Among these, the hydraulic

Figure 5. Flow diagram of an automated multi-channel cell counter. (Adapted from Ref. 3).

system is designed to dispense, dilute and mix samples prior to analysis. The pneumatic system operates various valves and drives the sample through the hydraulic system. The electrical system controls the operation sequences including optical–electrical detection of signals and computer-assisted data analysis. Instrument electronic analyzers typically have at least two channels. In one channel a diluent is added and RBCs are counted and sized. In the second, lysing agent is added to remove red blood cells and leave WBC intact for counting. These also produce a solution in which hemoglobin can be measured. Platelet count may be performed in either of these two channels or in a different channel. Normally, a separate channel will be required for reticulocyte count measurement. Analysis of a single blood specimen can be performed rapidly within 1 min, and results are presented in the form of numerical tables, histograms, or cytograms. The degree of analysis is both software and user dependent. Upon comparison with standard values, the software may also place flags on the output data that indicate either potential problem with analysis or deviation from cell count characterization of normal controls.

Numerous companies manufacture automated cell counters. Table 2 presents the characteristics of four high end instruments manufactured by some of them.

The Beckman–Coulter LH750 (Beckman Coulter Inc., Fullerton, CA) is a new instrument that provides CBC and five-part DLC. Additionally, it provides automated detection of subpopulations of pathological cells, such as immature granulocytes and atypical lymphocytes. It uses the three-dimensional (3D) Volume, Conductivity, Scatter (VCS) technology to probe hydrodynamically focused cells. A helium–neon laser and multiangle light scattering analysis provide information about cellular internal structure, granularity and surface morphology.

Abbott Cell-DYN 4000 (Abbott Laboratories, Abbott Park, IL) is capable of providing 41 parameters, including fully automated reticulocyte and immature granulocyte count. It uses four-angle argon-laser light scattering (M.A.P.S.S. technology) and two-color fluorescence flow cytometry (two fluorescence emission laser optics) to perform automated leukocyte counts, reticulocyte count, and DLC analysis. Both hydrodynamically focused impedance

count and optical method are used for optimal erythrocyte and platelet size distribution analysis. Hemoglobin concentration is measured in a separate sample aliquot based on spectrophotometry. Immature granulocyte and variant lymphocytes are detected by a multiparameter, multi-weighted discriminant function: This function generates a flag and reports a confidence fraction (i.e., the probability that these cells are classified correctly).

Sysmex XE-2100 (Sysmex Corporation, Japan) provides analysis of 32 parameters including simultaneous WBC, five-part DLC, human progenitor cell and reticulocyte analysis. Using flow cytometry with a semiconductor laser, RF, and dc measurements, this instrument analyzes the size and the structural complexity of cells. Selective dyes and reagent assist in differentiating the WBC, nucleated RBCs and reticulocyte. The RBC and platelet counts are measured using sheath flow dc detection method. Hemoglobin concentration is measured using a non-cyanide hemoglobin method.

The Bayer ADVIA 120 hematology system (Bayer Diagnostics, Tarrytown, NY) is an automated analyzer with four independent measurement channels. The peroxidase [PEROX and basophil-lobularity (BASO)] channels determine WBC and DLC count. Hemoglobin channel is used to measure HGB. The last channel is the RBC/PLT channel that provides information on platelet activation in addition to measuring PLT and RBC indices. This instrument measures the intensity of light scattered by platelets at low angles ($2\text{--}3^\circ$) to obtain cell volume/size data and high angles ($5\text{--}15^\circ$) for information on internal complexity. From these paired intensities the instrument computes platelet volume (MPV) and platelet component concentration on a cell-by-cell basis. The mean platelet component concentration (MPC) is indicative of platelet activation state. Mean platelet mass can also be computed from the MPV and MPC.

CONCLUDING REMARKS

This article discussed the basic principles of hematology with emphasis on humans. Enumeration of cell population

distribution in peripheral blood is examined using optical, electrooptical and light scattering techniques. As seen, such experimental modalities can be automated and the resulting hematology analyzers can be used for clinical application. Even though the exact strategy of cell counting varies between various manufacturers of automated cell counters, performance standards for such instrumentation have been established by the National Committee for Clinical Laboratory Standard (NCCLS) and the International Council for Standardization in Hematology (ICSH). The parameters evaluated here include (1) accuracy in measurement within a single batch and between batches of blood samples; (2) carryover of parameters between consecutive samples; (3) linearity or the ability to get similar measurements when the sample is diluted to different levels before being read; and (4) clinical sensitivity or the specificity and efficiency with which flags are generated during analysis to detect abnormal readouts. In order to evaluate the above and to tune the instrument for higher accuracy and sensitivity, blood count calibrators are also available from instrument manufacturers. Suitable preparations of preserved blood can also be made by individual laboratories as described by WHO document LAB/97.2 (Calibration and control of basic blood cell counters. Geneva: World Health Organization, 1997. WHO/DIL/97.2). Besides automated counting, manual and semiautomated methods are also applied by research laboratories. Establishment of such methods requires optimization of blood anticoagulant [ethylenediaminetetraacetic acid (EDTA), heparin, or sodium citrate typically], definition of appropriate electrolyte for sample dilution and design and optimization of lysis reagents required for specific experimental systems.

While the last 50 years have seen the automation of blood counting using hematology analyzers, a plethora of cell-specific antibodies have also been developed more recently. While some of these reagents are already being applied in the modern blood analyzer, their application may increase in the future. Such development can not only increase the range of parameters measured by the analyzer, they can also improve the accuracy and sensitivity of today's instrumentation.

CELLULAR IMAGING

AMMASI PERIASAMY
University of Virginia
Charlottesville, Virginia

INTRODUCTION

For decades, autoradiography has been used widely to follow the synthesis of macromolecules by using radioactive isotopes (1). Interpretation of autoradiograms depends on knowledge of biochemical pathways and precursors and are carefully chosen so that they are used by the cell to build only one kind of molecule. On the other hand, light microscopy techniques have become a powerful tool for cell biologists to study cells live or fixed noninvasively (2–4). Fixed cells can also be studied using electron microscopy, which provides higher resolution than the light microscopy system (5,6). However, the light microscopy system allows studying live cells in physiological conditions.

The microscope has been an essential tool found in virtually every biological laboratory after the observation and description of protozoa, bacteria, spermatozoa, and red blood cells by Antoni van Leeuwenhoek, in the 1670s (7,8). The ability to study the development, organization, and function of unicellular and higher organisms and to investigate structures and mechanisms at the microscopic level has allowed scientists to better grasp the often misunderstood relationship between microscopic and macroscopic behavior. Further, the microscope preserves temporal and spatial relationships that are frequently lost in traditional biochemical techniques and gives two- (2D) or three-dimensional (3D) resolution that other laboratory methods cannot. The benefits of fluorescence microscopy techniques are also numerous (3,9). The inherent specificity and sensitivity of fluorescence, the high temporal, spatial, and 3D resolution that is possible, and the enhancement of contrast resulting from detection of an absolute rather than relative signal (i.e., unlabeled features do not emit) are

several advantages of fluorescence techniques. Additionally, the plethora of well-described spectroscopic techniques providing different types of information, and the commercial availability of fluorescent probes, many of which exhibit an environment- or analytic-sensitive response, broaden the range of possible applications. Recent advancements in light sources, detection systems, data acquisition methods, and image enhancement, analysis, and display methods have further broadened the applications in which fluorescence microscopy can successfully be applied (2,3). Particularly, the fluorescent probes can be used to target many cellular components to follow the cell signaling in space (nm to m) and time (ns to days).

There are a number of microscopic techniques that have been established for cellular imaging including transmitted light–differential interference contrast microscopy (DIC)–phase contrast, reflection contrast microscopy, polarization microscopy, luminescence microscopy, and fluorescence microscopy (2,3,10). Fluorescence microscopy has been categorized into wide-field fluorescence microscopy, laser scanning confocal microscopy, multiphoton excitation microscopy, Förster (or fluorescence) resonance energy-transfer (FRET) microscopy, fluorescence lifetime imaging (FLIM) microscopy, fluorescence correlation spectroscopy (FCS), total internal reflection fluorescence (TIRF) microscopy, and fluorescence recovery after photobleaching (FRAP) microscopy (2–4,10–15). Some of the other advanced microscopy techniques include near-field microscopy (16,17), atomic force microscopy (18), scanning force–probe microscopy (19), X-ray microscopy (20), and Raman microscopy (21,22). In this article, selected fluorescence microscopy techniques (see Fig. 1) used for cellular imaging such as wide-field, confocal, multiphoton, FRET, FLIM, and CARS microscopy with biological examples are described.

Figure 1. Illustration of various fluorescence microscopy techniques that could be coupled to any upright or inverted epifluorescent microscope. The respective instrumentations are described in the literature. Wide-field (23); confocal (2); multiphoton (3); wide-field FLIM (24); confocal FLIM (25); MP-FLIM (26); FCS and image correlation spectroscopy (27,28).

BASICS OF FLUORESCENCE

Fluorescence is one of the many different luminescence processes in which molecules emit light. Fluorescence is the emission of light from the excited singlet state. Since this type of transition is usually allowed within the molecular orbitals, the emission rates of fluorescence are in the order of 10^8 s^{-1} , and fluorescence lifetimes are in nanoseconds. In contrast, phosphorescence is the emission of light from the triplet excited state and this transition is typically forbidden. The emission rates are much in the order of 10^0 – 10^3 s^{-1} , and phosphorescence lifetimes are typically milliseconds to seconds.

The excitation of molecules by light occurs via the interaction of molecular dipole transition moments with the electric field of the light and, to a much lesser extent, interaction with the magnetic field. The fluorescence processes following light absorption and emission are usually illustrated by a Jablonski diagram shown in Fig. 2. Examination of the Jablonski diagram in Fig. 2 reveals that the energy of the emitted photon is typically less than that of the absorbed photon. Hence, the fluorescence occurs at lower energy (longer wavelength) and this process is called Stokes' shift. The reasons for the Stokes' shift are rapid transition to the lowest vibrational energy level of the excited state S_1 , and decay of the fluorophore to a higher vibrational level of S_0 . The excess of the excitation energy is typically converted to the thermal energy.

Very intense radiation fields, such as those produced by ultrafast femtosecond lasers, can cause simultaneous absorption of two or more photons (two-photon, three-photon absorption, etc.). This phenomenon was originally predicted by Maria Göppert-Mayer in 1931 (30). It is important to realize that fluorescence intensity resulting from one- and two-photon excitation has a different dependence on excitation light intensity (power). Consequently, the fluorescence intensity depends on the squared laser power for two-photon excitation, the cubed (3rd) power for three-photon excitation, and the fourth power for four-photon excitation. This very strong dependence of fluorescence signal on the excitation power is frequently used to control the mode of excitation.

FLUOROPHORES AND FLUORESCENCE MICROSCOPY

Fluorescence microscopy (FM) plays a vital role in the biological and biomedical sciences, where fluorescence

Figure 2. Jablonski energy level diagram. S_0 , S_1 , and S_2 are singlet ground, first, and second electronic states, respectively; T_1 = triplet state (4,29).

probe specificity and sensitivity can provide important information regarding the biochemical, biophysical, and structural status of cells. The continuing development of fluorescent probes, such as various mutant forms of green fluorescent proteins (GFPs) or fluorophores in conjunction with the strong emergence over the past two decades of confocal and multiphoton microscopy (and specialized applications, such as FRAP, FRET, and FLIM), has been a major contributor to our understanding of dynamic processes in cells and tissue (3,4,12,30–34).

Fluorescence microscopy can be applied noninvasively to the study of living cells in tissue down to detection levels corresponding to single molecules. Fluorescent probes bound to cellular components with monoclonal antibodies, specific ligand affinities, or covalent bonds allow us to measure chemical properties, such as ion concentrations, membrane potential, and enzymatic activity (35). They allow the experimenter to observe the distribution and function of macromolecules (proteins, lipids, nucleic acids) in living cells and tissues. Techniques have been developed that allow the investigator to place, in cells and tissues, chemically blocked (caged) molecules that can be released or activated (uncaged) by a pulse of light (photolysis) (36). Therefore, a variety of ions, metabolites, drugs, and peptides can be released at carefully controlled times and locations within the specimen. Fluorescent probes and reagents are available from Amersham Pharmacia Biotech, Calbiochem, Fluka, Jackson ImmunoResearch Laboratories, Molecular Probes, Polysciences, Serotec, Sigma-Aldrich, and others. Fluorescent proteins (GFP) and GFP vectors are available from Clontech Laboratories, Quantum Biotechnologies and Life Technologies. Details regarding the selection of fluorophores, labeling, and loading conditions for live cell imaging have been described in the literature (37).

Wide-Field Fluorescence Microscopy

Wide-field fluorescence microscopy is a conventional fluorescence microscope equipped with a movable *xyz*-axis stage that permits imaging of the specimen at different focus and lateral positions, a higher quantum efficiency CCD camera for quantification of the light emitted by the specimen at different spectra, excitation and emission filter wheels, and an appropriate software package that is capable of synchronizing hardware, acquiring images, and correcting them for distortions and information loss inherent in the imaging process (22). To allow simultaneous monitoring of spectral emissions at two or three wavelengths, a dichroic, double, or triple pass filter is used that reflects the respective excitation wavelength to excite the double- or triple-labeled cells and transmit the respective emission bands (www.chromatech.com; www.omegaoptical.com).

Wide-field microscopy is the simplest and most widely used technique. It is used for quantitative comparisons of cellular compartments and time-lapse studies for cell motility, intracellular mechanics, and molecular movement (www.api.com). For example, new fluorescent indicators have allowed the measurement of Ca^{2+} signals in the cytosol and organelles that are often localized (38,39) and nondestructive imaging of dynamic protein tyrosine kinase activities in

single living cells (40). This microscope has also been used for localizing protein molecules in living cells (22,41–43). Moreover, it is essential to implement digital deconvolution approaches to remove the out-of-focus information from the images collected in wide-field microscopy (22) (www.api.com).

Laser Scanning Confocal Microscopy (LSCM)

Wide-field microscopy, however, suffers from a major drawback due to the generation of out-of-focus fluorescent signals. Laser scanning confocal microscopy (LSCM) provides the advantage of rejecting out-of-focus information, and also allows associations occurring inside the cell to be localized in three dimensions. A confocal image with improved lateral resolution yields a wealth of spectral information with several advantages over a wide-field image including controllable depth of field and the ability to collect serial optical sections from thick specimens. Owing to its nanometer depth resolution and noninvasiveness, confocal provides a new approach to measure viscoelasticity and biochemical responses of living cells and real-time monitoring of cell membrane motion in natural environments (2). The LSCM has been widely used in many biological applications, such as calcium, pH, and membrane potential imaging (2,35).

Confocal microscopy was introduced in 1957. Since then, the technique has gained momentum, particularly after the invention of lasers in the 1960s. Commercially available LSCM generate a clear, thin image (512×512) within 1–3 s or less, free from out-of-focus information. A single diffraction-limited spot of laser or arc lamp light is projected on the specimen using a high numerical aperture objective lens. The light reflected or fluorescence emitted by the specimen is then collected by the objective and focused upon a pinhole aperture where the signal is detected by a photomultiplier tube (PMT). Light originating from above or below the image plane strikes the walls of the pinhole and is not transmitted to the detector (see Fig. 3). To generate a 2D image, the laser beam is scanned across the specimen pixel-by-pixel. To produce an image using LSCM, the laser beam must be moved in a regular 2D raster scan across the specimen. Also, the instantaneous response of the photomultiplier must be displayed with equivalent spatial resolution and relative brightness at all points on the synchronously scanned phosphor screen of a CRT monitor. For a 3D projection of a specimen, one needs to collect a series of images at different *z*-axis planes. The vertical spatial resolution is $\sim 0.5 \mu\text{m}$ for a 40×1.3 NA objective; for lenses with higher magnification, the vertical spatial resolution is even smaller. Three-dimensional image reconstruction can be accomplished with many commercially available software systems. Another alternative is a commercially available spinning disk based confocal microscope that can be used for cellular imaging (44) (www.perkinelmer.com).

The LSCM has been widely used in many biological applications and as an example here we describe protein localization using Förster resonance energy transfer (FRET) (4,43,45–48). FRET is a distance-dependent physical process by which energy is transferred nonradiatively from an excited molecular fluorophore (the donor) to

Figure 3. Illumination and detector configuration for wide-field, confocal, and multiphoton microscopy systems. DM = dichroic mirror, WF = wide-field, LSCM = laser scanning confocal microscope, MEFIM = multiphoton excitation fluorescence imaging microscopy, N = nucleus, C = Cytoplasm (22).

another fluorophore (the acceptor) by means of intermolecular long-range dipole–dipole coupling. It can be an accurate measurement of molecular proximity at nanometer distances (1–10 nm) and highly efficient if the donor and acceptor are positioned within the Förster radius (the distance at which half the excitation energy of the donor is transferred to the acceptor, typically 3–6 nm). The efficiency of FRET is dependent on the inverse sixth power of intermolecular separation (29,49,50) making it a sensitive technique for investigating a variety of biological phenomena that produce changes in molecular proximity (51). As an example Fig. 4 shows acquisition and data analysis for localization of CFP- and YFP-C/EBP α proteins expressed in live mouse pituitary GHFT1-5 cell nucleus.

Multiphoton Excitation Microscopy

The instrumentation configuration of multiphoton excitation microscopy (MEM) is generally the same as the LSCM with the exceptions of the excitation light source and the optics. In the LSCM, a visible or ultraviolet (UV) light source is used and an infrared (IR) light source is used for MEM system [see Fig. 3; (52)]. In one-photon (wide-field or confocal) fluorescence microscopy, the absorption of laser energy excites the fluorescent molecules to a higher energy level and results in the emission of one-photon fluorescence. The fluorescence intensity increases at a linear rate with the excitation intensity. Typically, some of the absorbed light energy is dissipated as heat, so the emission wavelength is longer than the absorption wavelength. For example, a fluorophore might

absorb one photon at 365 nm and fluoresce at a blue wavelength ~ 420 nm.

The fluorophores exhibit two-photon absorption at approximately twice (730 nm) their one-photon absorption wavelengths, while two-photon (2p) emission is the same as that of one photon (420 nm), allowing the specimen to be imaged in the visible spectrum. When an IR laser beam is focused on a specimen, it illuminates at a single point and the fluorescence emission is localized to the vicinity of the focal point. The fluorescence intensity then falls off rapidly in the lateral and axial direction. In one-photon (1p) microscopy, illumination occurs throughout the excitation beam path, in an hourglass-shaped path (22). This results in absorption along the excitation beam path, giving rise to substantial fluorescence emission both below and above the focal plane. Excitation from other focal planes contributes to photobleaching and photodamage in the specimen planes that are not involved in imaging. The IR illumination in 2p excitation also penetrates deeper into the specimen than visible light excitation due to its higher energy, making it ideal for cellular imaging involving depth penetration through thick sections of tissue.

Two-photon absorption was theoretically predicted by Göeppert-Mayer in 1931 and was experimentally observed for the first time in 1961 using a ruby laser as the light source (30,53). Denk and others have experimentally demonstrated 2p imaging in a laser scanning confocal microscope (54). Two-photon excitation occurs when two photons of $h\omega$ and $h'\omega'$ are absorbed simultaneously and a molecule is excited to the state of energy $E = h\omega + h'\omega'$ (h = Planck's constant, ω = frequency). The probability that

Figure 4. Localization of CFP- and YFP-C/EBP α proteins expressed in live mouse pituitary GHFT1-5 cells studied using confocal-FRET microscopy. Seven images (a–g) are required to remove the contamination in the FRET image (f). The PFRET (processed FRET) image was obtained after removing the donor (DSBT) and acceptor (ASBT) spectral bleedthrough using the PFRET software (shown on the left panel, www.circusoft.com). The spectral bleedthrough varies depending on the excitation power for the donor and acceptor molecules. The respective histogram for the processed (Hist_PFRET) and the contaminated FRET (Hist_f) demonstrates the importance of removing the spectral bleedthrough signals. The energy-transfer efficiency ($E = 20\%$) was estimated after implementing the detector spectral sensitivity correction for the donor and acceptor channel (43).

2p absorption will occur depends on the colocalization of two photons within the absorption cross-section of the fluorophore. The rate of excitation is proportional to the square of the instantaneous intensity. This extremely high local instantaneous intensity is produced by the combination of diffraction-limited focusing of a single laser beam in the specimen plane and the temporal concentration of a femtosecond (fs) mode-locked laser (typically of the order of 10^{-50} – 10^{-49} $\text{cm}^4 \cdot \text{s}^{-1}/\text{photon}^{-1}/\text{molecule}$) (55). Three- or four photon (or multiphoton) is the extension of two-photon excitation (56).

Two-photon excitation microscopy has been widely used in the area of biomedical sciences including tissue engineering, protein–protein interactions, cell, neuron, molecular, and developmental biology (3,13,22,57–60). Here, we demonstrate as an example the importance of MEM in drug molecule cellular uptake, where MEM is the ideal system for monitoring cellular drug uptake. The separation between excitation and emission wavelengths is considerably more than the 1p (wide-field and confocal) excitation and emission. For example, the excitation for the YK-II-140 drug molecule is 416 nm and emission is at 528 nm and a Stokes shift is ~ 112 nm. In the case of MEM, the excitation for the same drug molecule is 770 nm and the Stokes shift

separation is wider than 112 nm. Moreover, in MEM we were able to detect 100 μM drug cellular uptakes compared to 1.0 mM in the wide-field microscopy. The sensitivity of drug detection is improved largely due to the advantage of the MEM (see Fig. 5 for details).

Spectral Imaging Microscopy

Human color vision is a form of imaging spectroscopy, by which we determine the intensity and proportion of wavelengths present in our environment. Spectral imaging improves on the eye in that it can break up the light content of an image not just into red, green, and blue, but into an arbitrarily large number of wavelength classes. Furthermore, it can extend the range to include the invisible UV and IR regions of the spectrum denied to the unaided eye; this type of imaging is usually known as hyperspectral (61). The result of (hyper) spectral imaging is a data set, known as a data cube, in which spectral information is present at every picture-element (pixel) of a digitally acquired image. Integration of spectral and spatial data in scene analysis remains a challenge.

These multispectral imaging approaches have been used to analyze multiple dyes within a sample. Recently,

Figure 5. Comparison of one- and two-photon excitation of a living PC-3 cell loaded with YK-II-140 anticancer drug (1.0 mM concentration). Wide-field microscopy provides more autofluorescence from the cell and media (a) compared to the two-photon microscopy (b). The less autofluorescence improves the detection sensitivity of the drug cellular uptake. Wide-field (Ex 416 nm and Em 528 nm). MEFIM or two-photon (Ex 770 nm and Em 528 nm). Biorad Radiance 2100 confocal-multiphoton microscopy was used for the data acquisition.

Carl Zeiss (www.zeiss.de) introduced the Laser Scanning Microscope (LSM) 510 META system with the revolutionary emission fingerprinting technique permitting the clean separation of several even spectrally overlapping fluorescence signals of a specimen (62). The number of dyes that can be used and detected in the experiment is almost unlimited. The new system overcomes the limits of existing detection methods and permits both qualitative and quantitative analyses quickly and precisely *in vitro* and *in vivo*. Furthermore, it is beneficial in many cases for the elimination of unwanted signals, such as background noise or autofluorescence.

The Zeiss 510 Meta system scan head contains two conventional photomultiplier tube detectors (PMT), where the wavelength of the emission light is selected by means of either bandwidth or long passes filters. In the third detector, emission light is passed through a prism and the resulting spectrum is projected onto a detector consisting of a linear array of 32 PMTs, thus enabling the spectral detector to detect a full emission spectrum from a given fluorophore (www.zeiss.com). The advantage of detecting a broad spectrum of emissions is fully realized by the process of linear unmixing (63). This is an image analysis technique that is intrinsic to the LSCM controlling software that compares the experimentally derived emission data to a previously recorded reference spectrum for that fluorophore. In a situation involving samples with multiple overlapping spectra, linear unmixing allows the resolution of fluorophores with closely related emissions, the accurate distinction between GFP and FITC or GFP and YFP being the most often cited example of this feature.

There are other commercial spectral imaging units available including Leica AOBs (www.leicamicrosystems.com) and Olympus FV1000 (www.olympus.com). The main

differences between these three commercial systems are FV1000 based on Grating/slit/PMT two-channel bidirectional scanning mode; Leica system based on Prism/slit/PMT; and the Zeiss system based on Grating/multi-anode PMT.

Here, as an example we provided the data acquired using the Zeiss multiphoton Meta system to measure FRET signals resulting from protein-protein interactions involving C/EBP α . The GHFT1-5 mouse cells that expressed either the CFP- or YFP-C/EBP α fusion protein were used to collect the reference spectra. These reference spectra were used for the linear unmixing of spectra from cells expressing both proteins. Images were then acquired of cells expressing both the CFP- and YFP-C/EBP α bound as dimers to DNA elements in regions of heterochromatin that form clearly defined focal bodies in the nuclei of the mouse cells used here (Fig. 6). Images collected (ex 820 nm; em 545 nm) from cells expressing both the CFP- and YFP-C/EBP α lambda (λ) stacks were spectrally unmixed to reveal the donor bleed-through into the FRET channel (Fig. 6a), allowing the FRET signal to be corrected for the bleed-through signal (Fig. 6b). The emission spectrum for the signal in the FRET channel (Fig. 6c) was determined (b-FRET in panel d) and was then reacquired after selective photobleaching of YFP (a-FRET) using 514 nm, showing the unquenched donor signal. These results demonstrate the power of spectral FRET imaging using the Meta system to detect protein-protein interactions in a single living cell.

Fluorescence Lifetime Imaging Microscopy

Each of the fluorescence microscopy techniques described above uses intensity measurements to reveal fluorophore concentration and distribution in the cell. Recent advances in camera sensitivities and resolutions have improved the

Figure 6. Spectral FRET imaging microscopy. Reference spectra (CFP, YFP) were established using cells expressing either CFP- or YFP-C/EBP α ; alone, and the emission spectra are shown in panel D. Images were then collected from cells expression both the CFP- and YFP-C/EBP α , and the signals were spectrally unmixed to reveal the donor bleed-through (a) into the FRET channel (c), the corrected FRET signal is shown in b. The emission spectrum for the signal in the FRET channel (b-FRET) is shown in panel D, and was reacquired after selective photobleaching of YFP (a-FRET). CFPex 820 nm; YFPex 920 nm. Zeiss510 META system was used for the data acquisition.

capability of these techniques to detect dynamic cellular events (3). Unfortunately, even with the improvements in technology, these fluorescence microscopic techniques do not have high speed time resolution to fully characterize the organization and dynamics of complex cellular structures. In contrast, the time-resolved fluorescence (lifetime) microscopic technique allows the measurement of dynamic events at very high temporal resolution (nanoseconds). Fluorescence lifetime imaging microscopy (FLIM) merges the information of the spatial distribution of the probe with probe lifetime information to enhance the reliability of the concentration measurements. This technique monitors the localized changes in probe fluorescence lifetime (14,24,25,29,43,64–67) and provides an enormous advantage for imaging dynamic events within the living cells.

The fluorescence lifetime (τ) is defined as the average time that a molecule remains in an excited state prior to returning to the ground state. In practice, the fluorescence lifetime is defined as the time in which the fluorescence intensity decays to $1/e$ of the initial intensity (I_0) immediately following excitation (i.e., 37% of I_0). If a laser pulse excites a large number of similar molecules with a similar local environment and as long as no interaction with another protein or cell organelles occurs, the lifetime is the “natural fluorescence lifetime”, τ_0 . If energy is transferred, however, the actual fluorescence lifetime, τ , is less

than the natural lifetime, τ_0 , because an additional path for deexcitation is present (28).

Conventional fluorescence microscopy provides images that reveal primarily the distribution and amount of stain in the cell based on measurements of intensity. In contrast, the time-resolved fluorescence microscopic (or FLIM) technique allows the measurement of dynamic events at very high temporal resolution and can monitor interactions between cellular components with very high spatial resolution, as well. A fluorophore in a microscopic sample may exist, for example, in two environmentally distinct regions and have a similar fluorescence intensity distribution in both regions, but different fluorescence lifetimes. Measurements of fluorescence intensity alone would not reveal any difference between two or more regions, but imaging of the fluorescence lifetime would reveal such regional differences (52).

Instrumental methods for measuring fluorescence lifetimes are divided into two major categories: frequency-domain (29,65) and time-domain (52). With the time-domain method (or pulse method), the specimen is excited with a short pulse and the emitted fluorescence is integrated in two or more time windows (24). The relative intensity captured in the time windows is used to calculate the decay characteristics. The determination of prompt fluorescence with lifetime in the range of 0.1–100 ns requires elaborate fast excitation pulses and fast-gated

detection circuits. As an alternative to the time-domain method, the frequency-domain method uses a homodyne detection scheme and requires a modulated light source and a modulated detector. The excitation light is modulated in a sinusoidal fashion. The fluorescence intensity shows a delay or phase shift with respect to the excitation and a smaller modulation depth (29).
