IDDM	Insulin dependent diabetes mellitus	IT	Intrathecal
IDE	Investigational device exemption	ITEP	Institute of Theoretical and Experimental Physics
IDI	Index of inspired gas distribution	ITEPI	Instantaneous trailing edge pulse impedance
I:E	Inspiratory: expiratory	ITLC	Instant thin-layer chromatography
IEC	International Electrotechnical Commission; Ion-exchange chromatography	IUD	Intrauterine device
IEEE	Institute of Electrical and Electronics Engineers	IV	Intravenous
IEP	Individual educational program	IVC	Inferior vena cava
BETS	Inelastic electron tunneling spectroscopy	IVP	Intraventricular pressure
IF	Immunofluorescent	JCAH	Joint Commission on the Accreditation of Hospitals
IFIP	International Federation for Information Processing	JND	Just noticeable difference
IFMBE	International Federation for Medical and Biological Engineering	JRP	Joint replacement prosthesis
IGFET	Insulated-gate field-effect transistor	KB	Kent bundle
IgG	Immunoglobulin G	Kerma	Kinetic energy released in unit mass
IgM	Immunoglobulin M	KO	Knee orthosis
IHP	Inner Helmholtz plane	KPM	Kilopond meter
IHSS	Idiopathic hypertrophic subaortic stenosis	KRPB	Krebs-Ringer physiological buffer
II	Image intensifier	LA	Left arm; Left atrium
IIIES	Image intensifier input-exposure sensitivity	LAD	Left anterior descending; Left axis deviation
IM	Intramuscular	LAE	Left atrial enlargement
IMFET	Immunologically sensitive field-effect transistor	LAK	Lymphokine activated killer
		LAL	Limulus amoebocyte lysate
		LAN	Local area network
		LAP	Left atrial pressure
		LAT	Left anterior temporalis
		LBBB	Left bundle branch block
		LC	Left carotid; Liquid chromatography

LCC	Left coronary cusp	MDP	Mean diastolic aortic pressure
LCD	Liquid crystal display	MDR	Medical device reporting
LDA	Laser Doppler anemometry	MDS	Multidimensional scaling
LDF	Laser Doppler flowmetry	ME	Myoelectric
LDH	Lactate dehydrogenase	MED	Minimum erythema dose
LDPE	Low density polyethylene	MEDPAR	Medicare provider analysis and review
LEBS	Low-energy brief stimulus	MEFV	Maximal expiratory flow volume
LED	Light-emitting diode	MEG	Magnetoencephalography
LEED	Low energy electron diffraction	MeSH	Medline subject heading
LES	Lower esophageal sphincter	METS	Metabolic equivalents
LESP	Lower esophageal sphincter pressure	MF	Melamine-formaldehyde
LET	Linear energy transfer	MFP	Magnetic field potential
LF	Low frequency	MGH	Massachusetts General Hospital
LH	Luteinizing hormone	MHV	Magnetic heart vector
LHT	Local hyperthermia	MI	Myocardial infarction
LL	Left leg	MIC	Minimum inhibitory concentration
LLDPE	Linear low density polyethylene	MIFR	Maximum inspiratory flow rate
LLPC	Liquid-liquid partition chromatography	MINET	Medical Information Network
LLW	Low-level waste	MIR	Mercury-in-rubber
LM	Left masseter	MIS	Medical information system; Metal-insulator-semiconductor
LNNB	Luria-Nebraska Neuropsychological Battery	MIT	Massachusetts Institute of Technology
LOS	Length of stay	MIT/BIH	Massachusetts Institute of Technology/ Beth Israel Hospital
LP	Late potential; Lumboperitoneal	MMA	Manual metal arc welding
LPA	Left pulmonary artery	MMA	Methyl methacrylate
LPC	Linear predictive coding	MMECT	Multiple-monitored ECT
LPT	Left posterior temporalis	MMFR	Maximum midexpiratory flow rate
LPV	Left pulmonary veins	mm Hg	Millimeters of mercury
LRP	Late receptor potential	MMPI	Minnesota Multiphasic Personality Inventory
LS	Left subclavian	MMSE	Minimum mean square error
LSC	Liquid-solid adsorption chromatography	MO	Membrane oxygenation
LSI	Large scale integrated	MONO	Monocyte
LSV	Low-amplitude shear-wave viscoelastometry	MOSFET	Metal oxide silicon field-effect transistor
LTI	Low temperature isotropic	MP	Mercaptopurine; Metacarpal-phalangeal
LUC	Large unstained cells	MPD	Maximal permissible dose
LV	Left ventricle	MR	Magnetic resonance
LVAD	Left ventricular assist device	MRG	Magnetoretinogram
LVDT	Linear variable differential transformer	MRI	Magnetic resonance imaging
LVEP	Left ventricular ejection period	MRS	Magnetic resonance spectroscopy
LVET	Left ventricular ejection time	MRT	Mean residence time
LVH	Left ventricular hypertrophy	MS	Mild steel; Multiple sclerosis
LYMPH	Lymphocyte	MSR	Magnetically shielded room
MAA	Macroaggregated albumin	MTBF	Mean time between failure
MAC	Minimal auditory capabilities	MTF	Modulation transfer function
MAN	Manubrium	MTTR	Mean time to repair
MAP	Mean airway pressure; Mean arterial pressure	MTX	Methotroxate
MAST	Military assistance to safety and traffic	MUA	Motor unit activity
MBA	Monoclonal antibody	MUAP	Motor unit action potential
MBV	Maximum breathing ventilation	MUAPT	Motor unit action potential train
MBX	Monitoring branch exchange	MUMPI	Missouri University Multi-Plane Imager
MCA	Methyl cryanoacrylate	MUMPS	Massachusetts General Hospital utility multiuser programming system
MCG	Magnetocardiogram	MV	Mitral valve
MCI	Motion Control Incorporated	MVO ₂	Maximal oxygen uptake
MCM1	Millon Clinical Multiaxial Inventory	MVTR	Moisture vapor transmission rate
MCT	Microcatheter transducer	MVV	Maximum voluntary ventilation
MCV	Mean corpuscular volume	MW	Molecular weight
MDC	Medical diagnostic categories		
MDI	Diphenylmethane diisocyanate; Medical Database Informatics		

NAA	Neutron activation analysis	OPG	Ocular pneumoplethysmography
NAD	Nicotinamide adenine dinucleotide	OR	Operating room
NADH	Nicotinamide adenine dinucleotide, reduced form	OS	Object of known size; Operating system
NADP	Nicotinamide adenine dinucleotide phosphate	OTC	Over the counter
NAF	Neutrophil activating factor	OV	Offset voltage
NARM	Naturally occurring and accelerator- produced radioactive materials	PA	Posteroanterior; Pulmonary artery; Pulse amplitude
NBB	Normal buffer base	PACS	Picture archiving and communications systems
NBD	Neuromuscular blocking drugs	PAD	Primary afferent depolarization
N-BPC	Normal bonded phase chromatography	PAM	Pulse amplitude modulation
NBS	National Bureau of Standards	PAN	Polyacrylonitrile
NCC	Noncoronary cusp	PAP	Pulmonary artery pressure
NCCLS	National Committee for Clinical Laboratory Standards; National Committee on Clinical Laboratory Standards	PAR	Photoactivation ratio
NCRP	National Council on Radiation Protection	PARFR	Program for Applied Research on Fertility Regulation
NCT	Neutron capture theory	PARR	Poetanesesthesia recovery room
NEEP	Negative end-expiratory pressure	PAS	Photoacoustic spectroscopy
NEMA	National Electrical Manufacturers Association	PASG	Pneumatic antishock garment
NEMR	Nonionizing electromagnetic radiation	PBI	Penile brachial index
NEQ	Noise equivalent quanta	PBL	Positive beam limitation
NET	Norethisterone	PBT	Polybutylene terephthalate
NEUT	Neutrophil	PC	Paper chromatography; Personal computer; Polycarbonate
NFPA	National Fire Protection Association	PCA	Patient controlled analgesia; Principal components factor analysis
NH	Neonatal hepatitis	PCG	Phonocardiogram
NHE	Normal hydrogen electrode	PCI	Physiological cost index
NHLBI	National Heart, Lung, and Blood Institute	PCL	Polycaprolactone; Posterior chamber lens
NIR	Nonionizing radiation	PCR	Percent regurgitation
NIRS	National Institute for Radiologic Science	PCRC	Perinatal Clinical Research Center
NK	Natural killer	PCS	Patient care system
NMJ	Neuromuscular junction	PCT	Porphyria cutanea tarda
NMOS	N-type metal oxide silicon	PCWP	Pulmonary capillary wedge pressure
NMR	Nuclear magnetic resonance	PD	Peritoneal dialysis; Poly-p-dioxanone; Potential difference; Proportional and derivative
NMS	Neuromuscular stimulation	PDD	Percent depth dose; Perinatal Data Directory
NPH	Normal pressure hydrocephalus	PDE	Pregelged disposable electrodes
NPL	National Physical Laboratory	p.d.f.	Probability density function
NR	Natural rubber	PDL	Periodontal ligament
NRC	Nuclear Regulatory Commission	PDM	Pulse duration modulation
NRZ	Non-return-to-zero	PDMSX	Polydimethyl siloxane
NTC	Negative temperature coefficient	PDS	Polydioxanone
NTIS	National Technical Information Service	PE	Polyethylene
NVT	Neutrons versus time	PEEP	Positive end-expiratory pressure
NYHA	New York Heart Association	PEFR	Peak expiratory now rate
ob/gyn	Obstetrics and gynecology	PEN	Parenteral and enteral nutrition
OCR	Off-center ratio; Optical character recognition	PEP	Preejection period
OCV	Open circuit voltage	PEPPER	Programs examine phonetic find phonological evaluation records
OD	Optical density; Outside diameter	PET	Polyethylene terephthalate; Positron-emission tomography
ODC	Oxyhemoglobin dissociation curve	PEU	Polyetherurethane
ODT	Oxygen delivery truck	PF	Platelet factor
ODU	Optical density unit	PFA	Phosphonoformic add
OER	Oxygen enhancement ratio	PFC	Petrofluorochemical
OFD	Object to film distance; Occiputo-frontal diameter	PFT	Pulmonary function testing
OHL	Outer Helmholtz layer	PG	Polyglycolide; Propylene glycol
OHP	Outer Helmholtz plane		
OIH	Orthoiodohippurate		

PGA	Polyglycolic add	PURA	Prolonged ultraviolet-A radiation
PHA	Phytohemagglutinin; Pulse-height analyzer	PUVA	Psoralens and longwave ultraviolet light photochemotherapy
PHEMA	Poly-2-hydroxyethyl methacrylate	P/V	Pressure/volume
PI	Propidium iodide	PVC	Polyvinyl chloride; Premature ventricular contraction
PID	Pelvic inflammatory disease; Proportional/integral/derivative	PVI	Pressure-volume index
PIP	Peak inspiratory pressure	PW	Pulse wave; Pulse width
PL	Posterior leaflet	PWM	Pulse width modulation
PLA	Polylactic acid	PXE	Pseudo-xanthoma elasticum
PLATO	Program Logic for Automated Teaching Operations	QA	Quality assurance
PLD	Potentially lethal damage	QC	Quality control
PLED	Periodic lateralized epileptiform discharge	R-BPC	Reverse bonded phase chromatography
PLT	Platelet	R/S	Radiopaque-spherical
PM	Papillary muscles; Preventive maintenance	RA	Respiratory amplitude; Right arm
PMA	Polymethyl acrylate	RAD	Right axis deviation
p.m.f.	Probability mass function	RAE	Right atrial enlargement
PMMA	Polymethyl methacrylate	RAM	Random access memory
PMOS	P-type metal oxide silicon	RAP	Right atrial pressure
PMP	Patient management problem; Poly(4-methylpentane)	RAT	Right anterior temporalis
PMT	Photomultiplier tube	RB	Right bundle
PO	Per os	RBBB	Right bundle branch block
P_{O_2}	Partial pressure of oxygen	RBC	Red blood cell
POBT	Polyoxybutylene terephthalate	RBE	Relative biologic effectiveness
POM	Polyoxymethylene	RBF	Rose bengal fecal excretion
POMC	Patient order management and communication system	RBI	Resting baseline impedance
POPRAS	Problem Oriented Perinatal Risk Assessment System	RCBD	Randomized complete block diagram
PP	Perfusion pressure; Polypropylene; Postprandial (after meals)	rCBF	Regional cerebral blood flow
PPA	Phonemic process analysis	RCC	Right coronary cusp
PPF	Plasma protein fraction	RCE	Resistive contact electrode
PPM	Pulse position modulation	R&D	Research and development
PPSFH	Polymerized phyridoxalated stroma-free hemoglobin	r.e.	Random experiment
PR	Pattern recognition; Pulse rate	RE	Reference electrode
PRBS	Pseudo-random binary signals	REM	Rapid eye movement; Return electrode monitor
PRP	Pulse repetition frequency	REMATE	Remote access and telecommunication system
PRO	Professional review organization	RES	Reticuloendothelial system
PROM	Programmable read only memory	RESNA	Rehabilitation Engineering Society of North America
PS	Polystyrene	RF	Radio frequency; Radiographic-nuoroscopic
PSA	Pressure-sensitive adhesive	RFI	Radio-frequency interference
PSF	Point spread function	RFP	Request for proposal
PSI	Primary skin irritation	RFQ	Request for quotation
PSP	Postsynaptic potential	RH	Relative humidity
PSR	Proton spin resonance	RHE	Reversible hydrogen electrode
PSS	Progressive systemic sclerosis	RIA	Radioimmunoassay
PT	Plasma thromboplastin	RM	Repetition maximum; Right masseter
PTB	Patellar tendon bearing orthosis	RMR	Resting metabolic rate
PTC	Plasma thromboplastin component; Positive temperature coefficient; Pressurized personal transfer capsule	RMS	Root mean square
PTCA	Percutaneous transluminal coronary angioplasty	RN	Radionuclide
PTFE	Polytetrafluoroethylene	RNCA	Radionuclide cineangiogram
PTT	Partial thromboplastin time	ROI	Regions of interest
PUL	Percutaneous ultrasonic lithotripsy	ROM	Range of motion; Read only memory
		RP	Retinitis pigmentosa
		RPA	Right pulmonary artery
		RPP	Rate pressure product
		RPT	Rapid pull-through technique
		RPV	Right pulmonary veins
		RQ	Respiratory quotient

RR	Recovery room	SEBS	Surgical isolation barrier system
RRT	Recovery room time; Right posterior temporalis	SID	Source to image reception distance
RT	Reaction time	SIMFU	Scanned intensity modulated focused ultrasound
RTD	Resistance temperature device	SIMS	Secondary ion mass spectroscopy; System for isometric muscle strength
RTT	Revised token test	SISI	Short increment sensitivity index
r.v.	Random variable	SL	Surgical lithotomy
RV	Residual volume; Right ventricle	SLD	Sublethal damage
RVH	Right ventricular hypertrophy	SLE	Systemic lupus erythemotodes
RVOT	Right ventricular outflow tract	SMA	Sequential multiple analyzer
RZ	Return-to-zero	SMAC	Sequential multiple analyzer with computer
SA	Sinoatrial; Specific absorption	SMR	Sensorimotor
SACH	Solid-ankle-cushion-heel	S/N	Signal-to-noise
SAD	Source-axis distance; Statistical Analysis System	S:N/D	Signal-to-noise ratio per unit dose
SAINT	System analysis of integrated network of tasks	SNP	Sodium nitroprusside
SAL	Sterility assurance level; Surface averaged lead	SNR	Signal-to-noise ratio
SALT	Systematic analysis of language transcripts	SOA	Sources of artifact
SAMI	Socially acceptable monitoring instrument	SOAP	Subjective, objective, assessment, plan
SAP	Systemic arterial pressure	SOBP	Spread-out Bragg peak
SAR	Scatter-air ratio; Specific absorption rate	SP	Skin potential
SARA	System for anesthetic and respiratory gas analysis	SPECT	Single photon emission computed tomography
SBE	Subbacterial endocarditis	SPL	Sound pressure level
SBR	Styrene-butadiene rubbers	SPRINT	Single photon ring tomograph
SC	Stratum corneum; Subcommittees	SPRT	Standard platinum resistance thermometer
SCAP	Right scapula	SPSS	Statistical Package for the Social Sciences
SCE	Saturated calomel electrode; Sister chromatid exchange	SQUID	Superconducting quantum interference device
SCI	Spinal cord injury	SQV	Square wave voltammetry
SCRAD	Sub-Committee on Radiation Dosimetry	SR	Polysulfide rubbers
SCS	Spinal cord stimulation	SRT	Speech reception threshold
SCUBA	Self-contained underwater breathing apparatus	SS	Stainless steel
SD	Standard deviation	SSB	Single strand breaks
SDA	Stepwise discriminant analysis	SSD	Source-to-skin distance; Source-to-surface distance
SDS	Sodium dodecyl sulfate	SSE	Stainless steel electrode
S&E	Safety and effectiveness	SSEP	Somatosensory evoked potential
SE	Standard error	SSG	Solid state generator
SEC	Size exclusion chromatography	SSP	Skin stretch potential
SEM	Scanning electron microscope; Standard error of the mean	SSS	Sick sinus syndrome
SEP	Somatosensory evoked potential	STD	Source-tray distance
SEXAFS	Surface extended X-ray absorption fine structure	STI	Systolic time intervals
SF	Surviving fraction	STP	Standard temperature and pressure
SFD	Source-film distance	STPD	Standard temperature pressure dry
SFH	Stroma-free hemoglobin	SV	Stroke volume
SFTR	Sagittal frontal transverse rotational	SVC	Superior vena cava
SG	Silica gel	SW	Standing wave
SGF	Silica gel fraction	TAA	Tumor-associated antigens
SGG	Spark gap generator	TAC	Time-averaged concentration
SGOT	Serum glutamic oxaloacetic transaminase	TAD	Transverse abdominal diameter
SGP	Strain gage plethysmography; Stress-generated potential	TAG	Technical Advisory Group
SHE	Standard hydrogen electrode	TAH	Total artificial heart
SI	Le Système International d'Unités	TAR	Tissue-air ratio
		TC	Technical Committees
		TCA	Tricarboxylic acid cycle
		TCD	Thermal conductivity detector
		TCES	Transcutaneous cranial electrical stimulation

TCP	Tricalcium phosphate	UHMWPE	Ultra high molecular weight polyethylene
TDD	Telecommunication devices for the deaf	UL	Underwriters Laboratory
TDM	Therapeutic drug monitoring	ULF	Ultralow frequency
TE	Test electrode; Thermoplastic elastomers	ULTI	Ultralow temperature isotropic
TEAM	Technology evaluation and acquisition methods	UMN	Upper motor neuron
TEM	Transmission electron microscope; Transverse electric and magnetic mode; Transverse electromagnetic mode	UO	Urinary output
TENS	Transcutaneous electrical nerve stimulation	UPTD	Unit pulmonary oxygen toxicity doses
TEP	Tracheoesophageal puncture	UR	Unconditioned response
TEPA	Triethylenephosphoramidate	US	Ultrasound; Unconditioned stimulus
TF	Transmission factor	USNC	United States National Committee
TFE	Tetrafluorethylene	USP	United States Pharmacopeia
TI	Totally implantable	UTS	Ultimate tensile strength
TICCIT	Time-shared Interaction Computer-Controlled Information Television	UV	Ultraviolet; Umbilical vessel
TLC	Thin-layer chromatography; Total lung capacity	UVR	Ultraviolet radiation
TLD	Thermoluminescent dosimetry	V/F	Voltage-to-frequency
TMJ	Temporomandibular joint	VA	Veterans Administration
TMR	Tissue maximum ratio; Topical magnetic resonance	VAS	Visual analog scale
TNF	Tumor necrosis factor	VBA	Vaginal blood volume in arousal
TOF	Train-of-four	VC	Vital capacity
TP	Thermal performance	VCO	Voltage-controlled oscillator
TPC	Temperature pressure correction	VDT	Video display terminal
TPD	Triphasic dissociation	VECG	Vectorelectrocardiography
TPG	Transvalvular pressure gradient	VEP	Visually evoked potential
TPN	Total parenteral nutrition	VF	Ventricular fibrillation
TR	Temperature rise	VOP	Venous occlusion plethysmography
tRNA	Transfer RNA	VP	Ventriculoperitoneal
TSH	Thyroid stimulating hormone	VPA	Vaginal pressure pulse in arousal
TSS	Toxic shock syndrome	VPB	Ventricular premature beat
TTD	Telephone devices for the deaf	VPR	Volume pressure response
TTI	Tension time index	VSD	Ventricular septal defect
TTR	Transition temperature range	VSWR	Voltage standing wave ratio
TTV	Trimming tip version	VT	Ventricular tachycardia
TTY	Teletypewriter	VTG	Vacuum tube generator
TUR	Transurethral resection	VTS	Viewscan text system
TURP	Transurethral resections of the prostate	VV	Variable version
TV	Television; Tidal volume; Tricuspid valve	WAIS-R	Weschler Adult Intelligence Scale-Revised
TVER	Transscleral visual evoked response	WAK	Wearable artificial kidney
TW	Traveling wave	WAML	Wide-angle mobility light
TxB ₂	Thromboxane B ²	WBAR	Whole-body autoradiography
TZ	Transformation zone	WBC	White blood cell
UES	Upper esophageal sphincter	WG	Working Groups
UP	Urea-formaldehyde	WHO	World Health Organization; Wrist hand orthosis
UffIS	University Hospital Information System	WLF	Williams-Landel-Ferry
UHMW	Ultra high molecular weight	WMR	Work metabolic rate
		w/o	Weight percent
		WORM	Write once, read many
		WPW	Wolff-Parkinson-White
		XPS	X-ray photon spectroscopy
		XR	Xeroradiograph
		YAG	Yttrium aluminum garnet
		ZPL	Zero pressure level

CONVERSION FACTORS AND UNIT SYMBOLS

SI UNITS (ADOPTED 1960)

A new system of metric measurement, the International System of Units (abbreviated SI), is being implemented throughout the world. This system is a modernized version of the MKSA (meter, kilogram, second, ampere) system, and its details are published and controlled by an international treaty organization (The International Bureau of Weights and Measures).

SI units are divided into three classes:

Base Units	
length	meter [†] (m)
mass [‡]	kilogram (kg)
time	second (s)
electric current	ampere (A)
thermodynamic temperature§	kelvin (K)
amount of substance	mole (mol)
luminous intensity	candela (cd)
Supplementary Units	
plane angle	radian (rad)
solid angle	steradian (sr)

Derived Units and Other Acceptable Units

These units are formed by combining base units, supplementary units, and other derived units. Those derived units having special names and symbols are marked with an asterisk (*) in the list below:

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
*absorbed dose	gray	Gy	J/kg
acceleration	meter per second squared	m/s ²	
*activity (of ionizing radiation source)	becquerel	Bq	1/s
area	square kilometer	km ²	
	square hectometer	hm ²	ha (hectare)
	square meter	m ²	

[†]The spellings “metre” and “litre” are preferred by American Society for Testing and Materials (ASTM); however, “-er” will be used in the Encyclopedia.

[‡]“Weight” is the commonly used term for “mass.”

§Wide use is made of “Celsius temperature” (*t*) defined $t = T - T_0$ where *T* is the thermodynamic temperature, expressed in kelvins, and $T_0 = 273.15$ K by definition. A temperature interval may be expressed in degrees Celsius as well as in kelvins.

<i>Quantity equivalent</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable</i>
* capacitance	farad	F	C/V
concentration (of amount of substance)	mole per cubic meter	mol/m ³	
* conductance	siemens	S	A/V
current density	ampere per square meter	A/m ²	
density, mass density	kilogram per cubic meter	kg/m ³	g/L; mg/cm ³
dipole moment (quantity)	coulomb meter	C·m	
* electric charge, quantity of electricity	coulomb	C	A·s
electric charge density	coulomb per cubic meter	C/m ³	
electric field strength	volt per meter	V/m	
electric flux density	coulomb per square meter	C/m ²	
* electric potential, potential difference, electromotive force	volt	V	W/A
* electric resistance	ohm	Ω	V/A
* energy, work, quantity of heat	megajoule	MJ	
	kilojoule	kJ	
	joule	J	N·m
	electron volt [†]	eV [†]	
	kilowatt hour [†]	kW·h [†]	
energy density	joule per cubic meter	J/m ³	
* force	kilonewton	kN	
	newton	N	kg·m/s ²
* frequency	megahertz	MHz	
	hertz	Hz	1/s
heat capacity, entropy	joule per kelvin	J/K	
heat capacity (specific), specific entropy	joule per kilogram kelvin	J/(kg·K)	
heat transfer coefficient	watt per square meter kelvin	W/(m ² ·K)	
* illuminance	lux	lx	lm/m ²
* inductance	henry	H	Wb/A
linear density	kilogram per meter	kg/m	
luminance	candela per square meter	cd/m ²	
* luminous flux	lumen	lm	cd·sr
magnetic field strength	ampere per meter	A/m	
* magnetic flux	weber	Wb	V·s
* magnetic flux density	tesla	T	Wb/m ²
molar energy	joule per mole	J/mol	
molar entropy, molar heat capacity	joule per mole kelvin	J/(mol·K)	
moment of force, torque	newton meter	N·m	
momentum	kilogram meter per second	kg·m/s	
permeability	henry per meter	H/m	
permittivity	farad per meter	F/m	
* power, heat flow rate, radiant flux	kilowatt	kW	
	watt	W	J/s
power density, heat flux density, irradiance	watt per square meter	W/m ²	
* pressure, stress	megapascal	MPa	
	kilopascal	kPa	
	pascal	Pa	N/m ²
sound level	decibel	dB	
specific energy	joule per kilogram	J/kg	
specific volume	cubic meter per kilogram	m ³ /kg	
surface tension	newton per meter	N/m	
thermal conductivity	watt per meter kelvin	W/(m·K)	
velocity	meter per second	m/s	
	kilometer per hour	km/h	
viscosity, dynamic	pascal second	Pa·s	
	millipascal second	mPa·s	

[†]This non-SI unit is recognized as having to be retained because of practical importance or use in specialized fields.

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
viscosity, kinematic	square meter per second	m ² /s	
	square millimeter per second	mm ² /s	
	cubic meter	m ³	
	cubic decimeter	dm ³	L(liter)
	cubic centimeter	cm ³	mL
wave number	1 per meter	m ⁻¹	
	1 per centimeter	cm ⁻¹	

In addition, there are 16 prefixes used to indicate order of magnitude, as follows:

<i>Multiplication factor</i>	<i>Prefix</i>	<i>Symbol</i>	<i>Note</i>
10 ¹⁸	exa	E	
10 ¹⁵	peta	P	
10 ¹²	tera	T	
10 ⁹	giga	G	
10 ⁸	mega	M	
10 ³	kilo	k	
10 ²	hecto	h ^a	^a Although hecto, deka, deci, and centi are SI prefixes, their use should be avoided except for SI unit-multiples for area and volume and nontechnical use of centimeter, as for body and clothing measurement.
10	deka	da ^a	
10 ⁻¹	deci	d ^a	
10 ⁻²	centi	c ^a	
10 ⁻³	milli	m	
10 ⁻⁶	micro	μ	
10 ⁻⁹	nano	n	
10 ⁻¹²	pico	p	
10 ⁻¹⁵	femto	f	
10 ⁻¹⁸	atto	a	

For a complete description of SI and its use the reader is referred to ASTM E 380.

CONVERSION FACTORS TO SI UNITS

A representative list of conversion factors from non-SI to SI units is presented herewith. Factors are given to four significant figures. Exact relationships are followed by a dagger (†). A more complete list is given in ASTM E 380-76 and ANSI Z210.1-1976.

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
acre	square meter (m ²)	4.047 × 10 ³
angstrom	meter (m)	1.0 × 10 ^{-10†}
are	square meter (m ²)	1.0 × 10 ^{2†}
astronomical unit	meter (m)	1.496 × 10 ¹¹
atmosphere	pascal (Pa)	1.013 × 10 ⁵
bar	pascal (Pa)	1.0 × 10 ^{5†}
barrel (42 U.S. liquid gallons)	cubic meter (m ³)	0.1590
Btu (International Table)	joule (J)	1.055 × 10 ³
Btu (mean)	joule (J)	1.056 × 10 ³
Bt (thermochemical)	joule (J)	1.054 × 10 ³
bushel	cubic meter (m ³)	3.524 × 10 ⁻²
calorie (International Table)	joule (J)	4.187
calorie (mean)	joule (J)	4.190
calorie (thermochemical)	joule (J)	4.184 [†]
centimeters of water (39.2 °F)	pascal (Pa)	98.07
centipoise	pascal second (Pa·s)	1.0 × 10 ^{-3†}
centistokes	square millimeter per second (mm ² /s)	1.0 [†]

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
cfm (cubic foot per minute)	cubic meter per second (m ³ /s)	4.72 × 10 ⁻⁴
cubic inch	cubic meter (m ³)	1.639 × 10 ⁻⁴
cubic foot	cubic meter (m ³)	2.832 × 10 ⁻²
cubic yard	cubic meter (m ³)	0.7646
curie	becquerel (Bq)	3.70 × 10 ^{10†}
debye	coulomb-meter (C·m)	3.336 × 10 ⁻³⁰
degree (angle)	radian (rad)	1.745 × 10 ⁻²
denier (international)	kilogram per meter (kg/m)	1.111 × 10 ⁻⁷
	tex	0.1111
dram (apothecaries')	kilogram (kg)	3.888 × 10 ⁻³
dram (avoirdupois)	kilogram (kg)	1.772 × 10 ⁻³
dram (U.S. fluid)	cubic meter (m ³)	3.697 × 10 ⁻⁶
dyne	newton(N)	1.0 × 10 ^{-6†}
dyne/cm	newton per meter (N/m)	1.00 × 10 ^{-3†}
electron volt	joule (J)	1.602 × 10 ⁻¹⁹
erg	joule (J)	1.0 × 10 ^{-7†}
fathom	meter (m)	1.829
fluid ounce (U.S.)	cubic meter (m ³)	2.957 × 10 ⁻⁵
foot	meter (m)	0.3048†
foot-pound force	joule (J)	1.356
foot-pound force	newton meter (N·m)	1.356
foot-pound force per second	watt(W)	1.356
footcandle	lux (lx)	10.76
furlong	meter (m)	2.012 × 10 ²
gal	meter per second squared (m/s ²)	1.0 × 10 ^{-2†}
gallon (U.S. dry)	cubic meter (m ³)	4.405 × 10 ⁻³
gallon (U.S. liquid)	cubic meter (m ³)	3.785 × 10 ⁻³
gilbert	ampere (A)	0.7958
gill (U.S.)	cubic meter (m ³)	1.183 × 10 ⁻⁴
grad	radian	1.571 × 10 ⁻²
grain	kilogram (kg)	6.480 × 10 ⁻⁵
gram force per denier	newton per tex (N/tex)	8.826 × 10 ⁻²
hectare	square meter (m ²)	1.0 × 10 ^{4†}
horsepower (550 ft·lbf/s)	watt(W)	7.457 × 10 ²
horsepower (boiler)	watt(W)	9.810 × 10 ³
horsepower (electric)	watt(W)	7.46 × 10 ^{2†}
hundredweight (long)	kilogram (kg)	50.80
hundredweight (short)	kilogram (kg)	45.36
inch	meter (m)	2.54 × 10 ^{-2†}
inch of mercury (32 °F)	pascal (Pa)	3.386 × 10 ³
inch of water (39.2 °F)	pascal (Pa)	2.491 × 10 ²

INTRODUCTION

The use of subatomic particles to treat cancer and other medical conditions can be traced back (1) to the discovery of natural radioactivity by Bequerel in 1896. Marie Sklodowska Curie and her husband Pierre Curie quickly identified the primary radiation emitted by radioactive materials such as uranium and thorium as consisting of three principal types: α , β , and γ rays. Among these rays, only γ rays, being high energy photons, are a form of electromagnetic radiation. Therefore, they are similar to lower energy photons and, in particular, X rays with regard to their interaction in matter (2–4).

In contrast, the α and β rays were observed to be much more ionizing than γ rays, and unlike γ rays had a finite range in materials. The latter feature is characteristic of energetic subatomic particles and, indeed, the α ray was later identified as an energetic 4He ion. It is emitted via nuclear α decay from heavy radioactive elements. Likewise, β rays were identified as energetic electrons emitted via nuclear β decay from light and heavy radioactive elements. Subsequently, the Curies were able to identify one particular highly radioactive element, radium. With considerable time and effort, they were able to extract small but usable pure samples of this from large amounts of uranium ore. As is also the case with X rays, workers using strong radioactive sources, including the Curies, often developed skin rashes and other symptoms related to exposure to natural radiation from radioactive materials. Medical doctors quickly realized that this radiation also could be used in medical applications.

Thus, following closely on the work by Roentgen et al. on the application of manmade radiation (i.e., X rays) to treat cancer, the Curies and others used radium and other natural radioactive sources to treat cancer tumors (Fig. 1) (1). Although the α , β , and γ rays emitted from nuclear decay were emitted with a much higher energy (MeV vs keV for X rays), the α and β particles had very short ranges in tissue (e.g., a mm or less for α particles and a few cm for β particles). Therefore, these sources, particularly including the associated MeV gamma rays, primarily were used to treat surface tumors (Fig. 1). An early form of brachytherapy using radioactive needles also was developed to treat deeper tumors (1).

Figure 1. An early form of radiation treatment (ca. 1920) using radioactive sources (1).

It would await the development of high energy particle accelerators after WWII to provide α and β particles (helium ions and electrons) with sufficient energy and intensity to be effective in treating deep tumors (5). However, belatedly, in 1932, Chadwick discovered another basic subatomic particle, the neutron. Being uncharged, neutrons unlike α and β particles behave more like X rays and γ rays in tissue. The discovery of the neutron coincided with the invention of the cyclotron by E. Lawrence, and an early use of the cyclotron was to produce energetic neutrons (5–7). Stone et al. proposed to use neutrons for the treatment of cancer and many treatments were performed in the late 1930s.

The modern era of particle-beam radiotherapy begins after WWII with the development of linear accelerators (LINACs), betatrons, the synchro-cyclotron, and the synchrotron (5–8) to provide electron, proton, α and heavy-ion beams at energies sufficient to penetrate many centimeters of tissue. Much of this work was pioneered at the University of California-Berkeley by E. Lawrence, his brother

Adopted from PTOG 35 Newsletter (Jan. 2005) (12).

John, a medical doctor, and C. Tobias. Using the 184 inch synchro-cyclotron to accelerate high energy α particles, an active radiation therapy program, as an adjunct to the primary nuclear physics research program, was carried out from 1954 to 1986 (Table 1) (9–12).

The justification for using a heavy, charged subatomic particle such as a proton, α or heavier ion lies in the fact that the main kinetic energy loss per path length in tissue ($\Delta E/\Delta X$) occurs primarily via collisional losses i.e., via many collisions with atomic electrons (2). Each collision absorbs a small amount of energy with only minimal scattering of the incident particle, which produces a well-defined energy loss vs depth curve (linear-energy transfer or LET) and hence range of the particle in tissue or its near equivalent, water (Fig. 2) (13). In medical

physics, LET is usually specified in $\text{keV}/\mu\text{m}$ or, alternatively, $\text{keV}/\text{g}/\text{cm}^2$ for a specific medium. Specifically, in a given material, the LET for a charged, nonrelativistic heavy particle of mass m and atomic number z moving at a velocity v [hence, kinetic energy $E = (1/2)mv^2$] has the behavior (2–5)

$$\begin{aligned} \text{LET} &= k z^2/v^2 \\ &= K z^2/(E/m) \end{aligned} \quad (1)$$

where k and K are constants that depend on the atomic composition of the medium. Suitable integration of LET from $E =$ incident $E (= E_0)$ to $E = 0$ then gives the range, R of the particle in the medium. Based on the above, we would expect R to then be proportional to E_0^n with $n = 2$, which is approximately true but, because of various

Figure 2. Depth-dose curves in water (which is similar to soft tissue) for various types of photons and particles commonly used in radiation therapy (arbitrary normalization; adapted from Ref. 13).

atomic effects (2–5), one typically has $1.4 < n < 2$ depending on z and E_0 .

Owing to the $1/E$ dependence of LET (Eq. 1, above), protons, alphas, and heavier particles such as ^{12}C ions exhibit a very high LET at the end of their range, resulting in a sharp “Bragg peak” (Fig. 2). In cancer treatment, this sharp LET peak is often then spread out using energy-loss absorbers or other means to produce a spread-out Bragg peak (SOBP) suitable for treating an extended tumor (Fig. 3).

In the case of heavy particles, the biological dose will depend on the LET as well as the relative biological effectiveness (RBE) of the incident particle (2). The RBE may

Figure 3. Illustration showing modification of a particle depth-dose curve by means of a spread-out Bragg peak (SOBP; adapted from Ref. 5).

depend on m , z , E , and several other factors including the LET. Although electrons, X rays, and γ rays generally have an RBE near unity, heavy particles (including neutrons) can have much larger values *viz.* $\text{RBE} = 4$ or greater (5–11,14,15). In addition, energetic heavy particles can lose energy and even transmute into a different particle via nuclear reactions and fragmentation (9–11,14–16), which can extend the net LET beyond the range of the incident particle due to atomic collisional losses alone and also introduce scattering of the incident beam. These features can become significant for heavier particles such as α particles and ^{12}C ions.

In contrast, photons such as X rays and γ rays lose energy through several different mechanisms (2), which normally only involve a few collisions for a particular photon. Each collision usually produces a scattered, secondary electron that can carry away (and hence absorb) significant energy from the photon as well as scatter the photon. The energy loss of all the secondary electrons and their RBE (near unity) yields the biological radiation dose attributed to the photon. One can sum this dose over many incident photons to generate a dose-distance curve for a beam of photons (Fig. 2). However, no single X-ray or γ -ray photon has a well-defined energy-loss curve or range per se. Instead, like visible-light photons, a beam of such radiation primarily will be attenuated or scattered as it passes through tissue and thus yield the dose–distance curves shown in Fig. 2.

In contrast to charged particles, most of the dose for a single photon beam thus occurs near the surface and continues through the treatment area including the exit region (Fig. 2). Treating deep-seated tumors while sparing adjacent healthy tissue from a lethal dose requires multiaxis beam treatment planning together with fractionation of the dose (15–20), which can present a problem for tumors near critical organs, such as the spinal cord, and optical nerve, and, for such tumors, certain particle beams can be advantageous.

Energetic electron beams exhibit characteristics of both particle beams as well as X rays and γ rays. Although the primary energy loss is via collisions with atomic electrons, owing to the incident mass also being that of an electron, this energy loss is accompanied with significant scattering of the primary electrons (2), which results in a complicated dose-distance profile (Figs. 2 and 4) (21). In addition, the electrons used in radiation therapy are at relativistic energies (i.e., $E_0 > 1$ MeV) and their range, unlike that of heavier particles, increases more slowly (2) with incident energy ($n \approx 1$), but, due to scattering, the range along the incident beam axis is not well defined. Hence, the large penumbra exhibited (Fig. 4) can limit the usefulness of electron beams in treating deep tumors. The application of a magnetic field to reduce the penumbra has been proposed and is under active study by several research groups (see below).

Subatomic antimatter particles such as antiprotons and positrons (antielectrons) have also been proposed for cancer therapy, which is based on past work (14–22) done at the Los Alamos Meson Factory (LAMPF) using another form of antimatter, the negative pi meson (negative pion). Antimatter particles like the negative pion undergo a

Figure 4. A 2D profile of a ca. 20 MeV electron beam incident on a tissue-equivalent plastic phantom (21).

nuclear annihilation reaction when they stop near the end of their range, which converts the mass of the antiparticle and a related nuclear constituent into photon energy, which produces additional radiation to enhance the dose near the end of the range (and enhanced dose peak, Fig. 5). The LAMPF, TRIUMF, and SIN nuclear research laboratories had active negative pion radiation oncology treatment programs from the early 1970s to the early 1990s (Table 1). However, owing to practical considerations associated with the large accelerator needed, this type of treatment is no longer in active use.

A characterization of the dose and LET of various particle beams used in radiation oncology is displayed in Fig. 6 (23). The features noted can help determine the type of beam and treatment plan that may be optimal to treat a specific type of tumor. Table 2 lists the various types of particle-beam modalities, their characteristics, and the type of cancers generally treated with each modality (24).

Until recently, excluding electrons, most particle-beam cancer treatment facilities used accelerators primarily designed and operated for nuclear physics research. Such accelerators were generally not optimized for radiation

Figure 5. Dose-depth curve for negative pions (a form of antimatter) in water. Note the enhanced dose at the end of the range due to annihilation radiation (adopted from Ref. 5).

Figure 6. Characteristics of dose and LET for various forms of radiotherapy beams (23).

therapy and were costly to operate and maintain. As an example, nuclear research accelerators are often designed for much higher beam intensities and beam energy than needed for tumor treatment. Beam time also may be limited, which complicates treatment by requiring fractionated doses, and the patient-related aspects in a research laboratory are not ideal in most cases. Nonetheless, these facilities, many still in operation, demonstrated the effectiveness of particle-beam therapy for certain types of tumor treatment, which has led to the construction (or planning) of several dedicated particle-beam cancer treatment facilities throughout the world. A listing of these, together with some of the pioneering, older charged-particle facilities is given in Table 1.

In the following sections, we will describe in more detail specific types of particle-beam treatments and related apparatus. Additional information may be found in other sections of this volume as well as in several review articles (9–11,14).

In addition, several groups such as the Proton Therapy Co-operative Group (PTCOG) (25) and the TERA Foundation (26) issue newsletters and hold regular conferences with proceedings covering recent advances in particle-beam therapy.

Many of the techniques used in particle-beam radiation therapy are similar to those used in more conventional radiation therapy using photons, and extensive literature for the latter exists (17–20, 27–30). Likewise, several detailed references discuss the effect of radiation on cell survival and, hence, RBE for particular types of radiation including particle beams (2–5,7,15,31–35).

ELECTRON-BEAM RADIOTHERAPY

The most common type of particle-beam radiotherapy involves the use of energetic electrons, either directly from an electron accelerator (8,17,27,36) or as the ionizing radiation in radio-isotope brachytherapy. Most hospital-based radiation-oncology departments use an electron LINAC, typically with electron beam energies from 5 MeV to 25 MeV. This beam produces, via bremsstrahlung, on a tungsten or similar target, the megavolt X rays (i.e., high energy photons used for standard radiotherapy)

Table 2. Summary of Present External Beam Radiotherapy Options for Malignant Tumors^a

Particle	Tumor Characteristics	Energy deposition	Bragg peak	Radiation source	Accelerator cost ^b
Photons	Rapidly growing, oxygenated	Low LET	No	Cobalt 60; electron linac; microtron	1
Electrons	Superficial	Low LET	No	Electron Linac; microtron	1–2
Protons	Early stage, near-critical structures	Low LET	Yes	Synchrotron; cyclotron	10–15
Fast neutrons	Slow growing, hypoxic	High LET	No	Proton linac; cyclotron;	8–10
Heavy ions	Same as fast neutrons	High LET	Yes	Synchrotron	40
Pions	Same as fast neutrons	High LET	Yes	Proton linac; cyclotron	35–40
Slow neutrons	Glioblastoma; Some melanomas	Very high LET with BNCT	No	Low energy accelerator; nuclear reactor	1–2

^aAdopted from Table 3 of Ref. 5.

^bRelative cost not including building and clinical equipment costs. Assumes room-temperature magnets. Superconducting magnets can reduce accelerator cost in some cases (e.g., see Ref. 24).

(Fig. 7) (8). The electron LINAC usually is used in conjunction with an isocentric gantry (Fig. 8) (8) to permit stereotactic treatment with minimal movement of the patient.

In principle, with an electron beam of sufficient intensity and energy, the direct beam also can be used for radiotherapy. However, as noted, the large collisional scattering of the electrons in tissue results in a large angular spread (i.e., penumbra) (2) of the beam (Fig. 4), which limits the usefulness of the direct beam for therapy other than for treatment of skin cancer, other shallow tumors, or for noncancerous skin diseases (Table 2). However, owing to their compactness, a gantry-mounted electron-beam system (Fig. 8) can also be used in an operating room to directly irradiate an internal tumor (or surrounding area) made accessible via surgery. This technique, interoperative electron-beam radiation therapy (IOERT), may be particularly advantageous for treatment of certain types of cancers when combined with more conventional treatment (37).

It was once thought that higher energy electrons ($E > 25$ MeV) and the corresponding high energy X rays produced could have advantages in radiotherapy relative to the more typical energies used ($E < 25$ MeV). These higher energy electrons were typically produced using a special LINAC or a compact race-track microtron (36) accelerator (Fig. 9) with a separate gantry for the beam (Fig. 8). High energy electrons possibly suitable for radiation therapy also recently have been produced using high power compact pulsed lasers (38).

At the higher electron energies, nuclear reactions and significant bremsstrahlung can take place and contribute to the patient dose. Although the higher energy may have some benefit, it is generally offset by the larger dose imparted to surrounding healthy tissue because of the longer range of the secondary electrons involved. Likewise, improvements in radiotherapy techniques using lower energy photons, such as intensity-modulated radiotherapy (IMRT) and Monte-Carlo treatment planning (17,18), have offset most of the advantages of higher energies. Thus, few

Figure 7. Schematic diagram of an electron LINAC of the type used for radiation therapy (8).

Figure 8. Various isocentric gentry arrangements used with electron accelerators for radiation treatment using secondary X rays or the direct electron beam (8).

facilities use electron beams or X rays with energies greater than 25 MeV. However, it has been indicated by theoretical calculations and by recent experiments with phantoms (21,39–44) that high energy direct electron beams confined by a high magnetic field potentially could be useful for some cancer treatments (see below).

FAST AND SLOW NEUTRON RADIOOTHERAPY

Fast Neutrons

As noted previously, it was realized shortly after their discovery in 1932 by Chadwick that fast neutrons could have advantages over X rays and γ rays in cancer therapy (5–7,14). Unlike protons and α particles, neutrons being massive, yet uncharged, can penetrate more easily into tissue even at modest energies (e.g., 20–40 MeV in kinetic energy). Such neutron energies are readily available via nuclear reactions such as $^9\text{Be}(d, n)$ using conventional cyclotrons, including many of those available during the

1930s (6). Hence, fast neutrons were used in cancer treatment well before high energy protons, α , and other heavy particles became available.

As a neutron therapy beam is produced as a secondary beam from a nuclear reaction on a production target with a primary charged-particle beam, the associated accelerator generally must have a high primary beam current (e.g., a proton or deuteron beam at the μA level). The accelerator facility also must then have the necessary massive shielding for fast neutrons. In some cases, the primary accelerator also can then be used to produce radioisotopes (such as ^{18}F and ^{11}C) that can be used for positron emission tomography (PET). Like other early cancer-therapy accelerators, most of the first-generation fast-neutron treatment facilities were adjuncts to nuclear research facilities. Recently, several new dedicated fast-neutron treatment facilities have become available (6,23,45).

Neutrons in tissue (and other material) behave quite differently than protons, α particles, or other heavy charged particles. Specifically, being uncharged, the dose

Figure 9. Compact race-track electron microtron used to produce high energy electrons; $E > 25$ MeV (36).

deposited along the path is *not* due to a large number of low LET collisions with atomic electrons. Instead, large-LET nuclear collisions play a dominant role with neutron-proton and neutron-nucleus collisions important in tissue (2,6,7). The latter produce secondary ionization and biological dose due to the recoil protons and other recoiling tissue nuclei. In this sense, recoil protons (and other recoil nuclei) play the role that the secondary electrons play in X-ray and γ -ray therapy. It, then, is not surprising that the deposited dose curve due to fast neutrons looks similar to that from X rays and γ rays (Fig. 2). However, the RBE for neutrons is generally greater than that of the latter e.g., $\times 4$ or larger (2,5–7,23,45).

Like X rays and γ rays, and unlike charged particles, neutrons are attenuated and scattered in tissue and do not have a well-defined range. Treatment of a localized tumor requires either highly fractionated doses or stereotactic treatment to spare healthy tissue, which, together with uncertainties in the RBE for neutrons, was a major problem in early studies of fast-neutron cancer therapy. Many patients were found to suffer long-term complications from the treatment (7), and many of the early neutron treatment facilities ceased operation until the latent effects of the therapy were better understood.

Today, fast-neutron therapy is usually restricted to treatment of special types of tumors (Table 2) where this type of therapy has been shown to be advantageous, yet without a high probability of long-term complications, or where such complications may be justified (e.g., for older

patients), which includes cancers of the salivary glands, prostate cancer, and several types of soft-tissue and inoperable cancers. Neutrons have been shown to be especially advantageous (23,45) in treating radiation-resistant cancer cells.

A recent state-of-the-art dedicated fast-neutron treatment facility is the one located at the Harper-Grace Hospital in Detroit, Michigan (23,45), which uses an innovative gantry-mounted, compact super-conducting cyclotron (45) to produce a high intensity 48 MeV deuteron beam (Fig. 10) (23). This beam then impinges on a beryllium target to produce a range of MeV-energy neutrons for treatment. Having the cyclotron mounted on the treatment gantry minimizes the size of the facility. A special multipin collimator is used to collimate the 2D profile of the treatment beam. Treatments are generally fractionated and done in a special prescribed sequence with X-ray therapy to enhance destruction of radiation-resistant tumor cells that could later metastasize. This type of treatment appears to significantly enhance the long-term survival rate for certain stages of prostate cancer (23,45).

Slow Neutrons and BNCT

As suggested by G. Locher in 1936, one method to increase the localized dose from fast and slow neutrons is to tag tumors with certain elements such as boron, which preferentially capture neutrons (46). Boron, specifically the isotope ^{10}B , which is about 20% of natural boron, has a

Figure 10. Schematic of the Harper-Grace Hospital (Detroit) gantry-mounted compact super-conducting cyclotron and treatment area used for fast-neutron radiotherapy (23).

high cross section for the reaction $^{10}\text{B}(n, \alpha)$ and produces (Fig. 11) (23) highly localized, low energy α particles (1.47 MeV) and ^7Li recoil ions (0.8 MeV), which quickly stop, yielding a highly localized LET that greatly enhances the local dose to a tumor. The boron is preferentially attached to the tumor site using a tumor-specific boron-loaded pharmaceutical (46,47). As this technique works particularly well with slow neutrons (keV to MeV), it can be used with slow or low energy neutrons produced from small accelerators or from nuclear reactors, which is the basis for boron-neutron capture therapy (BNCT), and a number of clinical trials using BNCT are underway, primarily outside of the United States.

Related to BNCT, the manmade isotope ^{252}Cf , which produces both energetic α particles ($E_\alpha = 6.1$ MeV) together with fission fragments and associated fission neutrons ($E_n \approx 2-3$ MeV), has been proposed (46,47), together with boron-loaded tumor-specific compounds, as a special form of BNCT brachytherapy.

Figure 11. Illustration of the nuclear processes involved in BNCT (adopted from Ref. 23).

Proton-Beam Radiotherapy

Excluding electron beams, which, as noted, have limitations for treatment of deep tumors, protons are presently the primary beams used in particle-beam therapy. A number of cyclotrons, originally operated as nuclear research facilities, have since been converted for use as medical treatment facilities (Table 1). A conventional cyclotron i.e., one that uses a fixed radio frequency (RF) accelerating voltage and a single large conventional magnet (6) is typically limited in proton beam energy to less than 80 MeV, which limits the penetration depth to less than a few cm in tissue (Fig. 2). Hence, these facilities (about one-third of all proton-beam therapy facilities) are generally limited to treatment of shallow tumors, especially eye tumors, or for treatment of certain noncancerous conditions such as age-induced macular degeneration (AMD) (10,12,48,49). As many of these facilities are located in a nuclear research laboratory rather than in or near a hospital, certain treatments requiring fractionated doses or treatment done in combination with other modalities can be problematic.

Treatment of deep-seated tumors requires a proton beam energy of 200 MeV or more (Fig. 2). At this energy, the protons' relativistic increase of mass with increasing velocity requires the use of a large separated-sector cyclotron or high field cyclotron, such as those in use at Indiana University, Massachusetts General Hospital (Fig. 12) (49), and elsewhere, or a "race track" synchrotron adapted from high energy physics. An example of the latter is the synchrotron at the Loma Linda proton-beam treatment facility (49). Synchrotrons are also generally used to produce heavier particles [e.g., ^{12}C ions used for radiation treatment (see below)].

A cyclotron produces a beam with a 100% macroscopic duty cycle, although it still has a beam modulated by the accelerating voltage RF, typically tens of MHz (6). The synchrotron produces a beam modulated by the ramping time of the variable-field accelerator magnets. The latter can be on the order of seconds (6), which generally is not a problem in radiation therapy and can be used as an advantage in some treatments. A third type of accelerator, the synchro-cyclotron, developed after WWII at LBL and used at LBL for α -beam radiotherapy for many years, is presently only in limited use (Table 1).

As the direct proton beam in these accelerators is used for therapy, only a modest beam intensity is required relative to the beam intensities needed for a nuclear research accelerator or one used to produce neutrons or pions, *viz.* namps vs μ amps, which can simplify the accelerator design, the building, and shielding required. However, in some cases, a high intensity beam is desirable in order to produce radioisotopes used in PET and other imaging methods.

All types of proton facilities, owing to the high "magnetic-rigidity" of high energy protons, require a set of large (and costly) beam-switching magnets and patient-treatment gantries (Fig. 13) (49). Likewise, raster-scanning the beam and varying the dose-depth required to treat a particular tumor is not trivial, which can be done (Fig. 14) (49) with electronic elements (active scanning) or with shaped absorbers (passive modulation).

Figure 14. Schematics of typical passive and active ion-beam raster-scanning apparatus used to generate suitable dose profiles for treatment of specific tumors. (Reprinted with permission from Ref. 49, copyright 2002 American Physical Society.)

Although the primary energy loss mechanism and, hence, dose from high energy protons is still due to collisions with atomic electrons (2), a significant fraction of the incident beam can induce nuclear reactions in beam collimators and in the patient, which, in the patient, can lead to the production of neutrons or other reaction products complicating the calculation of the biological dose. Some of these reactions can be detected by observing the annihilation radiation (i.e., emission of back-to-back 511 keV γ rays) from proton-rich positron-emitting nuclear reaction products (9,10,50). This technique (based on PET) has been adapted to image the dose profile of heavy-ion beams used in radio therapy (see below) where the beam itself may fragment (10,11,15,16) into positron-emitting nuclei.

Related to this technique, collimating an energetic proton beam and stopping it (including in a patient) can produce copious amounts of fast neutrons. Although the direct internal dose to the patient due to the neutrons may be small, the facility itself may require extensive neutron shielding for protection of the workers and surrounding environment (Fig. 12), which results in a very large “foot-print” for such a facility and a building cost that often exceeds the cost of the accelerator and beam line themselves. As a result, only a few hospital-based proton-therapy facilities presently exist. These facilities are generally

dedicated to the treatment of certain tumors (Table 2) and for conditions that are otherwise inoperable or difficult to treat with conventional radiotherapy. However, it is estimated that, in the United States alone, over 10,000 patients/year could benefit from proton-beam radiotherapy treatment (12).

As the advantages of proton therapy becomes better documented for certain types of tumors, more medical insurance companies will likely approve treatment, which would justify the construction of more facilities. Nonetheless, the number of patients treated worldwide with protons has increased steadily, with over 40,000 treated through 2004 (Table 1).

Heavy-Ion Radiotherapy

Excluding antimatter particles, the particle beams with the highest LET and, hence, dose rate per unit path length (i.e., dose-depth profile) are heavy ions (HI) with $z \geq 2$. (Eq. 1), which leads to an extremely sharp Bragg peak and, hence, localization of the dose near the end of the HIs’ range (2,10,11,14). Also, the biological dose is enhanced over the HI LET alone owing to the large values of RBE determined for HIs. The latter can be on the order of 10 or more near the end of the HIs’ range (15).

As with proton therapy, in a typical treatment, the sharp Bragg peak in the dose curve is spread out using absorbers (or other means) to provide a suitable overlap with the tumor (SOBP) (9–11,14). Like protons, energetic HIs, like those needed for therapy (typically a few hundred MeV/nucleon), can also induce nuclear reactions. In the case of HI therapy beams, these reactions, which are primarily beam fragmentation, can transmute the incident beam into other nuclear species (9–11,14–16), which usually include lighter, lower z fragments, which can extend the radiation dose well beyond the range of the primary HI beam (16). Fortunately, many of the fragments and residual nuclei produced in HI (or, as noted, proton) beam-induced nuclear reactions are positron emitters and their intensity and location can be imaged via the back-to-back 511 keV γ rays emitted (PET) (9,10,50–52), which is now being actively exploited in treatment planning at GSI and elsewhere (see below).

It also has been suggested to specifically produce a short-lived positron-emitting secondary beam such as ^9C for radiation treatment and, thus, facilitate direct imaging of the treatment beam itself (51), however, while feasible, it is not yet a practical option. Among other problems, such beams are easily fragmented, and as a secondary beam, production requires a high intensity primary HI beam accelerator. Instead, like proton therapy, a direct, low intensity HI beam is more practical for therapy (53–55).

Excluding the use of natural α -emitting radioactive sources, the use of HIs in cancer therapy was pioneered at the University of California, Berkeley, laboratory now known as the Lawrence Berkeley Laboratory (LBL). The Bevatron at LBL, which originally was constructed to discover the antiproton, was converted to accelerate HIs such as ^{12}C , ^{16}O , and ^{20}Ne at energies up to several hundred MeV/nucleon (9–11,14). These energies are those required for cancer treatment of deep tumors. Over 400 patients were treated from 1975 to 1992 at LBL with HIs.

As part of this program, many techniques were developed for controlling and monitoring the HI dose-depth profiles, and providing a suitable SOBP when needed, which included imaging positron-emitting HI beam fragments (9–11,14) and reaction products, which, as noted, is a technique later adapted for proton and HI therapy at other facilities.

More recently, the HI nuclear research facility at Darmstadt, Germany (GSI) has run a HI prototype cancer therapy facility primarily using ^{12}C beams at energies of several hundred MeV/nucleon. They have implemented the online PET imaging technique to deduce dose-depth profiles (52) for clinical treatment planning and verification (Fig. 15) (52). They, likewise, have done extensive measurements and modeling to determine the RBE appropriate for HIs in tissue (15), which, as noted previously, can be relatively large ($\times 10$ or more) and thus must be included in treatment planning (51–56). (The latter also has implications for space travel and other activities involving radiation from heavy particles in cosmic rays, etc.).

Many of the tumors treated at the GSI facility cannot be optimally treated with conventional radiotherapy or surgery due to the close proximity of the tumor to a critical area (Fig. 15). As with other particle-beam therapies, most

Figure 15. Example of a tumor treatment plan used for HI radiotherapy at GSI (52).

HI treatments involve fractionated doses, and the HI therapy is often used in conjunction with other treatment modalities such as chemotherapy or photon therapy. Like other pioneering particle-beam facilities, GSI is a nuclear research facility and not *a priori* part of a hospital facility, which can often limit patient throughput. Nonetheless, several hundred patients have been treated since 1997 (Table 1). Based on the results demonstrated, the GSI nuclear and biomedical research group together with a hospital facility in Heidelberg, Germany is finishing the constructing of a dedicated HI accelerator and HI treatment facility. This facility is expected to become fully operational in mid-2005 and will serve as a German national treatment facility for the 3000 or more patients identified as optimal for HI therapy each year in Germany. A similar facility is under construction in Italy (12).

At present (2005), the primary facilities built and dedicated to HI cancer therapy are the HIBMC and HIMAC facilities (53) in Japan (Fig. 16) (54). As at GSI, these facilities primarily use ^{12}C ions at energies of several hundred MeV/nucleon. (HIBMC also has the capability to use protons in radiotherapy). Several thousand patients have been treated at HIBMC and HIMAC (Table 1). Like proton therapy facilities, the large footprint (Fig. 16) and costs associated with an HI accelerator and the associated treatment facilities will generally limit their availability. In countries with national health services, one, two, or at most three HI facilities may accommodate those patients who might benefit from HI therapy. The situation becomes complicated in countries like the United States where private insurers must approve treatment.

FUTURE DEVELOPMENTS

Magnetically-Confined Electron Beams

It has been suggested, and recently demonstrated with experiments, that one might use high energy electrons ($E \leq 100$ MeV) for radiotherapy with suitable magnetic fields applied to reduce (Fig. 17)(21) the penumbra from scattering (21, 31–44). Again, if the direct electron beam is used, relatively low intensity beams can be used, which simplifies the accelerator, beam handling, and shielding. Most hospitals operate and maintain electron accelerators ($E = 10$ –25 MeV), mostly LINACs, for radiation therapy

Figure 16. Layout of the HI-beam cancer treatment facility HIMAC in Chiba, Japan (adopted from Ref. 54).

and higher energy electrons (50–100 MeV) are readily produced using expanded versions of LINACS (6) or tabletop race-track microtrons (36). Both are quite feasible for operation at most hospital clinical oncology facilities.

Recent developments in super-conducting magnet technology including gantry-mounted systems and LHe-free systems make such magnets technically feasible. These magnets could be used in conjunction with a suitable electron accelerator for cancer therapy for certain types of tumors (soft tissue, etc.). A sample of a calculated multibeam dose profile in a skull-tissue phantom using

35 MeV electrons confined with an axial (solenoidal) $B = 6$ T magnetic field (44) is shown in Fig. 18.

Superconducting Accelerators and Beam Gantries

One method to possibly reduce the footprint (and cost) of proton and HI radiotherapy facilities is to use, more widely, superconducting magnet technology for both the accelerator and beam line components (24). However, extensive radiation shielding may still be required.

Figure 17. Measured and calculated 2D isodose profiles for a ca. 20 MeV electron beam incident on a tissue-equivalent phantom with an applied 2 T longitudinal magnetic field. Compare with Fig. 4 (adopted from Ref. 21).

Figure 18. A simulated stereotatic dose profile in a head phantom for a set of 35 MeV electron beams confined by a $B = 6$ T longitudinal magnetic field (44).

Pulsed-Laser Accelerators

It is now possible to produce very high electric fields in plasmas using compact ultra-fast pulsed lasers, which can be used to accelerate electrons, protons, and other ions to MeV energies (38). Although the particle-beam intensities and, in some cases, energies demonstrated so far are less than those needed for radiotherapy, such “table-top” accelerators may prove viable in the future.

INTRODUCTION

What Is Intraoperative Radiotherapy?

Intraoperative radiotherapy (IORT) is a technique that combines radiation therapy with surgery to irradiate tumors *in situ*, without delivering a significant dose to surrounding normal, critical structures and is usually performed using electron beams from linear accelerators. This contrasts with external beam therapy using X-ray beams where the dose that can safely be delivered to most tumors is limited by the dose that is given consequentially to normal, critical structures.

The practice of IORT began soon after X rays were used therapeutically, almost 100 years ago. However, although several investigators used this technique over the ensuing years with various X-ray modalities, it was not until the mid-1960s that intraoperative radiotherapy made a serious mark on the field of radiotherapy with the work of Abe (1–4) in Japan using electron beams from linear accelerators. This was rapidly followed in the mid-1970s by investigations in the United States, first at Howard University (5), then at the Massachusetts General Hospital (MGH) (6), followed by the National Cancer Institute (7), and then the Mayo Clinic (8). The reason for this dramatic change was due to the introduction of linear accelerators capable of generating high energy electron beams.

In 1992, Coia and Hanks (9) reported on patterns of care study, which indicated that of 1293 radiation oncology facilities in the United States, 108 reported doing IORT, of which 29 have two or more residents. Since there were ~88 training programs in existence at that time, roughly one-third of hospitals or medical centers with residency training programs were performing IORT. They did not

indicate whether or not this list included only electron beam IORT or other modalities.

Initially, IORT flourished in both the academic and community hospital setting, but it is clear from informal surveys and anecdotal evidence that fewer centers are now performing IORT compared with 1992. The reasons for this decline in interest are twofold. First, establishing the usefulness of IORT as a beneficial adjunctive therapy has been difficult. Second, IORT as practiced by the majority of centers, those that do not have the luxury of a dedicated or conventional mobile linear accelerator in the operating room (OR), is technically difficult and demands time on the part of a clinical staff that is under great time constraints, brought on by the present reimbursement climate. Thus, this method taxes the interests of all the parties after a number of years. The uphill battle faced by proponents of intraoperative radiation therapy is the high cost of a dedicated facility in the operating room. A dedicated linear accelerator in an operating room is no longer a cost-effective option for any hospital (10), due to the cost of the machine as well as the radiation shielding. The entry into the field of IORT of mobile linear accelerators that can be used in existing OR rooms without requiring additional shielding makes the cost and logistics of setting up an IORT program much easier and therefore provides a stimulus to the field. There are now three manufacturers of such equipment and >30 units have been installed in the United States and Europe.

In addition to using electron beams from linear accelerators, many other radiotherapy modalities can be classified as IORT. They all share the same principle that the dose is delivered only locally, so that dose to the skin uninvolved adjacent tissues and organs is minimized. These include high dose rate brachytherapy that is delivered in an operative setting and stereotactic radiosurgery using a 50 kV X-ray device. The Papillon technique (11) was a technique whereby 50 kVp X rays were used to irradiate lesions on the rectal wall by inserting the X-ray tube into the dilated rectum. Orthovoltage X rays are still used in one or two places (12), based on the issue of lower cost, but there is a clinical price to pay since the dose to any bone in the field is much greater than the prescribed dose to tissue, and this can result in osteoradionecrosis. However, this can be obviated to some extent by heavy filtration of the beam at the cost of a lower dose rate.

General Description of the Treatment Apparatus

Historically, adapters were made to fit existing linear accelerators so that the electron beam could be directed onto the tumor while at the same time protecting normal tissue. This was first achieved by having an applicator, ~30 cm long and generally circular in cross-section that mates with another cylinder attached to the head of the linear accelerator. This mating piece is centered with the radiation beam and only slightly larger than the treatment applicator. Thus, by adjusting couch movements very carefully, the treatment applicator can be slid into the mating piece, even when the gantry is angled far from the vertical. The greater the gap between the two pieces, the easier it is to achieve docking, but the greater the possible degree of

Figure 1. Diagram of optical system used for a hard dock system. Note that the unit slides in and out of the field and that the reflector is metallic.

misalignment, meaning the beam is not aligned with the applicator in the patient, so the beam, as delivered, will have different dose characteristics from a perfectly aligned system. Typically, the gap between the two cylindrical pieces is $\sim 0.2\text{--}0.3$ mm. This method is known as the hard dock technique (13). The advantage of this method is that the system is self-aligning, within limits defined by the gap between the two mating pieces, but the disadvantages are that (1) the docking process can be lengthy, depending on the gantry angle, (2) there is a potential safety issue if either the couch or the gantry moves during the procedure, and (3) the treatment field is no longer visible once the docking process is complete. Hence, the hard dock procedure requires a lock-out system for the drive motors during the treatment when there is no one in the treatment room and an optical system to view the field enclosed by the applicator after the applicator has been docked. A cut-away view of such an optical system is shown in Fig. 1. A photograph of a completed hard dock process is shown in Fig. 2. This photo shows that the docking or alignment process can be a complex and time-consuming task in some situations.

The alternative method that avoids the problem of the hard dock procedure is the soft dock procedure. In this method, the treatment applicator is separated from the head of the machine and thus the potential for patient injury is greatly lessened and the treatment field can be

Figure 2. Example of electron beam alignment using the hard docking process. The linear accelerator is a conventional machine in the therapy department and the applicator was fabricated in-house.

viewed even after the docking is complete. The disadvantage of this method is that an alternative to the simple mechanical alignment is needed. This need has been answered by a variety of optical systems as explained below. A description of two commercial alignment systems is given below. A description of several noncommercial soft-docking systems has been published by several authors (14–17).

The Clinical Rationale for IORT

To understand the rationale for intraoperative radiotherapy, it is necessary to understand some of the basic principles of radiotherapy. Patients are routinely treated for cancer using fractionated radiation. This means that the radiation is delivered in increments on a daily basis, 5 days week⁻¹ for up to 8 weeks, depending on the lesion under treatment. The reason for doing this is that if one were to deliver a tumoricidal amount of radiation to the tumor in one or a few fractions, serious long-term side effects to normal tissue and organs would result. By fractionating the radiation, an equivalent tumoricidal dose can be given to the tumor without serious long-term side effects. Fractionation schemes currently in use have developed empirically over the history of radiotherapy going back to the use of early X-ray tubes. The daily fraction dose is limited by acute radiation effects. These effects, such as reddening of the skin in the era of low energy X rays, bowel problems, and so on, appear during the course of treatment, but will generally resolve themselves without long-term consequences after the radiation treatment has been completed. This maximum radiation dose may produce acute effects in a few patients, due to biological variation between individuals and, hence, their response to radiation. The prescription dose or the maximum overall dose, which is the number of daily fractions times the daily dose, is also limited. This limit is due to normal tissue and organ tolerance. Thus, for example, abdominal radiation for rectal or colon cancer is limited to ~50 Gy because of small bowel complications (Gy is the unit of absorbed dose and is expressed in J·kg⁻¹). The kidneys can tolerate a dose of no more than ~15 Gy and treatment for lung cancer requires keeping the dose to the spinal cord below ~45 Gy to avoid transverse myelitis. Some organs, such as the liver, can tolerate varying amounts of radiation, depending on the fraction of liver that is irradiated. The smaller the fraction of organ treated, the larger the dose that can be tolerated. Excess dose to the whole lung can produce fibrosis, resulting in a nonfunctional lung. However, even with these dose limits, local control rates, or control of the primary tumor that is being irradiated is not 100%, so it would be highly desirable to have a method for increasing the dose to the tumor without increasing the dose to the surrounding normal tissue. This is known as improving the therapeutic ratio, which, for a given dose fractionation, is defined as

$$\text{Therapeutic ratio} = \frac{\text{tumor control probability/normal tissue complication probability}}{\text{normal tissue complication probability}}$$

Ideally, this ratio should be as high as possible. One method to improve this ratio is through the use of intraoperative irradiation. In this technique, the area to be

treated, whether a tumor or tumor bed, is exposed during surgery and normal tissue (e.g., small bowel) is moved out of the way by using an applicator through which the radiation is delivered. By irradiating with electrons rather than photons (see section below for comparison between therapeutic photon and electron beams), the radiation can be safely and effectively limited to the area of the tumor. It has been firmly established using experiments on dogs (18,19) that a safe upper limit for single fraction doses is ~20 Gy. Doses delivered through IORT generally range between 7.5 and 20 Gy.

While IORT can increase the therapeutic ratio by excluding normal tissue and organs from the radiation field, it suffers from the fact that it is a single fraction procedure, which, as noted above is limited and therefore, by itself may not provide a curative dose of radiation for all tumors. The reason for this is that such processes as repair of sublethal damage, repopulation, redistribution, and reoxygenation (20), which contribute to enhancing the therapeutic ratio for fractionated radiation, are limited in single-dose therapy. While the initial Japanese study used IORT as the only source of treatment radiation, it has been customary in the United States to use IORT as a boost therapy. This means that the patient is treated using the standard fractionation scheme using external radiation and is given the IORT as an additional boost dose. Thus the tumor dose has been increased with only a small increase in dose to a fraction of the surrounding tissue. Table 1 (21) shows the radiobiological equivalent fractionated dose of single doses of radiation between 10 and 25 Gy. Assuming a conventional fractionation scheme for external therapy of 2 Gy per fraction, a single dose of 10 Gy is equivalent to 17 Gy for tumors. For late effects in normal tissue, this figure is much higher at 26 Gy, but is considerably lower if the dose per fraction is only 50%. Thus normal tissue toxicity determines the maximum dose that can be delivered intraoperatively.

Historical Review of IORT

The first cases of IORT were reported by Beck as far back as 1907 (22) and again in 1909 (23). He used X rays (probably 50 kVp, see below) to treat several cases of stomach and colon cancer. Several years later, Finsterer, in 1915 (24), reported on the treatment of stomach and colon cancer. He used doses between 2500 and 4500 R using X rays with filtration that varied between none, variable thicknesses of

Table 1. Equivalent Dose of a Single Dose of Radiation in Terms of the Fractionated Dose for Both Acute and Late Normal Tissue Reactions

IORT Single Dose, Gy	Equivalent Dose for Tumor and Acute Normal Tissue Reactions ^a	Equivalent Dose for Late Normal Tissue Reactions ^a

25	73	140

^a2 Gy fractions.

aluminum, or 0.25–0.45 mm Cu. The “R” stands for the roentgen, which is a unit of radiation exposure; 1 Gy is roughly equivalent to 87R in air. Note that no external radiation was given to these patients. The choice of filtration was dictated by the thickness of the lesion. It was noted by Abe (25), in his historical review of the topic, that the practice of IORT then was different from that of today; however, it is different only in the sense that kilovoltage radiation is exponentially attenuated and delivers its maximum dose at the surface, whereas electron beams have a maximum dose below the surface and the dose falls sharply beyond a given depth, depending on energy. Thus, the intent then was the same as it is now, namely, to give additional dose to the tumor and spare normal tissues, even though there were more practical problems in dose delivery and differences in beam quality. However, there are photon beam modalities used in IORT that get around the problems mentioned above with X rays. High dose rate brachytherapy using radioactive ¹⁹²Ir sources, for example, is able to deliver a high tumor dose with a low dose to nearby critical structures.

Barth (26) gives a long account of the technique he used for many anatomical sites where he opened the skin and treated the underlying tumor with 50 kVp X rays at 2 cm SSD for very small field (~2.5 cm diameter) sizes. Many of these sites were in the head and neck region, just below the skin; more deep-seated tumors would have been hard to treat with this technique. Interestingly, Goin and Hoffman (27) describe instances, where IORT was delivered on more than one occasion. He reports on 13 patients, all but 1 of whom received IORT from 2 to 12 times, with overall doses ranging from 500 to 30,672 R. Thus surprisingly, fractionated IORT was practiced then, something that would not be countenanced today.

Current Status of IORT Application (User Surveys)

A survey of current institutions practicing IORT in the United States (28), whether using electron beams, orthovoltage X rays, the Photon RadioSurgery System (PRS) device or by High Dose Rate (HDR) was conducted in 2003. It was found that the number of institutions practicing IORT by each technique is shown in Table 2.

It can be seen that ~55% of the institutions perform IORT in the OR and 75% perform IORT with a dedicated unit. One of the centers using orthovoltage X rays and another using a dedicated linac in a shielded OR are converting to mobile linear accelerators. Approximately

Table 2. Number of Institutions in the United States Practicing the Various IORT Modalities (2003)

Type of IORT Practiced	Number of Institutions
Mobile linear accelerator	6 (15.8%)
Dedicated linac in shielded OR	4 (10.5%)
OR in radiotherapy department	8 (21.1%)
IORT by patient transport	9 (23.7%)
Orthovoltage X-rays	2 (5.3%)
Intrabeam (50 kV X ray)	5 (13.2)
HDR	4 (10.5)

72% of the institutions above responded to the survey, including all six with mobile units and all four dedicated units in the OR. The remaining eight responders consisted of six sites with an OR in the therapy department and two that used patient transport. By comparison with the 1992 survey, it was found that the greatest decline in the number of centers involved with IORT was the group performing IORT by patient transport, and these were primarily community centers. Thus a higher proportion of those sites still practicing IORT are academic centers. Of the institutions using nonmobile units, the average date inception of the program was 1986 (±4 years), whereas all the mobile units were installed after 1998. The most commonly used energy was 9 MeV, followed by 12 MeV. This certainly justifies the choice of maximum energy of the mobile units. Slightly more institutions use the soft-docking (61%) rather than the hard-docking technique. The most commonly used field size is a 7 cm diameter applicator, followed by a 6 cm diameter applicator. Finally, the average number of IORT treatments performed by the reporting centers (72% of institutions responded) is 500, whereas the number of treatments performed in the last 12 months is 428. The respective numbers per institution are 31.2 ± 23.5 (range, 10–90) and 26.8 ± 22.7 (range, 0–70).

A similar survey was recently carried (29) out for European institutions and there are some similarities and differences. Table 3 shows the number in institutions performing each type of IORT.

The chief difference is that there are 40% more sites in Europe than in the United States and that more than one-half the European sites have mobile linear accelerators compared with 16% in the United States. Moreover, >60% of the treatments carried out are for breast cancer compared with almost no cases in the United States. Also, the average number of patients treated is in excess of 1000, compared with 500 in the United States, noted above. Of great importance is the fact that there are a number of clinical trials underway in IORT in Europe, whereas there are no trials in progress in the United States.

What the two continents have in common is the typical applicator sizes and energies. This result is what one would expect if each were treating the same distribution of disease sites. However, since those distributions are not the same, this commonality is quite remarkable. Finally, one other similarity is that a large percentage of institutions are performing a few cases and a few institutions

Table 3. Number of Institutions in Europe Practicing the Various IORT Modalities (2005)

Type of IORT Practiced	Number of Institutions
Linear accelerator in radiotherapy department	11 (31.6%)
Dedicated linac in shielded OR	5 (13.2%)
Mobile linear accelerator	21 (55.3)
Intraoperative interstitial brachytherapy	6 (15.8%)
Intraoperative HDR flaps	7 (18.4%)
Intrabeam (50 kV X ray)	2 ^a (5.3%)

^aThis figure may be substantially higher.

(primarily academic centers in the case of the United States) are performing a large number of cases.

IORT TECHNOLOGY

Early Technology

Radiotherapy prior to the 1960s used primarily X-ray machines for the treatment of cancer patients, although in the years just before that Cobalt-60 teletherapy units were coming into widespread use. Schultz (30) describes in great detail the history of the development of X-ray machines of increasing energy. Thus, in the early days, X-ray machines were the only modality to carry out IORT. In the earliest applications of IORT, Practitioners used 50 kV X rays with a focus-to-skin (FSD) distance of ~ 2 cm with a field size (diameter) of about the same dimension, varying the filtration to achieve sufficient penetration. Henschke and Henschke (31) provide considerable detail on the practical application of this technique to the treatment of large fields. They show that this can be accomplished either by increasing the FSD, primarily to increase the percent depth dose, or by use of multiple, overlapping fields at short FSD. Thus, until X-ray machines operating at higher energies with adequate dose rates at larger distances and covering larger fields became available, the role of IORT was relatively limited. Beginning in the late 1930s through the 1940s, such high energy units became available. Eloesser (32) described the use of an X-ray machine with filtrations between 0.25 and 0.5 mm Cu. He notes that the filtration depends on the thickness of the tumor being treated; the FSD was 30 cm. In 1947, Fairchild and Shorter (33) describe a technique using 250 kV X rays with a half value layer (HVL) of 1.7 mm Cu. At a FSD of 21.7 cm, a dose rate of $100 \text{ R} \cdot \text{min}^{-1}$ could be delivered over a 13 cm field diameter. Note that since these high energy X-ray beams were not collimated, lead sheets had to be placed around the surgical opening and internal viscera to provide adequate radiation protection.

Whereas the difficulty of using low energy X-ray beams is one of insufficient penetration, the problem with high energy X-ray beams is that, although their intensity is exponentially attenuated, tissues or organs beneath the tumor to be treated can receive a considerable dose of radiation. For this reason and many technical reasons associated with using an X-ray machine in an OR, it is clear that IORT could not have been anything other than an experimental technique pursued by a few investigators.

Recent IORT Technology: Photons versus Electrons

In the 1960s, the first linear accelerators appeared in clinical use for the treatment of cancer. One of the first units in the United States was a 6 MV machine (Varian Medical Associates, Palo Alto, CA), which produced a bremsstrahlung X-ray beam from a beam of 6 MeV electrons. However, it was not until the 1970s that linear accelerators were capable of producing clinical electron beams. Omitted from this historical review is a discussion of the betatron. Designed and built in the early 1940s by Donald Kerst, the first patient was treated with X rays in

Figure 3. Comparison between electron (6, 9, 12, 15, and 18 MeV) and X ray (1.5 mm Cu X rays) percent depth dose curves.

1948; electron beams were a natural by product of this machine, although the dose rates were quite low. However, the betatron played no role in the field of IORT, and there are no betatrons currently in clinical use in the United States. Clinical electron beams are produced by passing the electron beam exiting the linear accelerator's waveguide through high atomic number scatterers (34). The great advantage of electron over X-ray beams is in the depth dose curve. Figure 3 shows a comparison of the percent depth dose curves, normalized to 100%, between electron beams of various energies and a 1.5 mm Cu X-ray beam. What is immediately apparent is that while the curve for the X-ray beams fall off more or less exponentially with distance beyond the depth of maximum dose, the curves for electron beams show a very sharply falling dose and have a finite range. This range is a function of the electron beam energy, so the higher the energy the greater the range. A rule of thumb is that for every 3 MeV of electron energy, the depth of the 80% dose changes by 1 cm. There are currently only one or two active IORT programs in the United States using orthovoltage X rays.

Dedicated IORT Units

The IORT programs can use one of two approaches. In the first approach, patients are transported from the OR to the radiation therapy department and the IORT treatment is delivered on one of the department's linear accelerators that normally treats outpatients with external beam therapy. Thus IORT is blended in with the other treatments. In the second approach, IORT treatments are delivered on a dedicated machine. Dedicated linear accelerators are those accelerators that are used exclusively for the treatment of patients through the intraoperative technique. The word dedicated is used here to mean that the linear accelerator, conventional (X rays plus electrons or electron-only) or mobile, is used exclusively for IORT. It is recognized here that no more electron-only linear accelerators of the conventional, non-mobile type, will be built in the future. Dedicated linear accelerators may be located in the OR itself or in a room in the radiotherapy department. If the former, the room is basically an OR that also contains a linear accelerator. If the latter, it is a radiotherapy room that is equipped as an operating room. The former is preferred since it is part of the total OR complex and the patient does not have to be moved outside the room. In the

Figure 4. Mevatron ME by Siemens Medical Systems located in an OR. Note that the machine is a conventional accelerator whose gantry (C-arm) support system is mounted in the end wall. Since the room is slightly oversized for an OR room at this hospital, this still leaves adequate room for surgery.

latter case, the patient undergoes surgery far from the hospital's main OR and issues of maintaining sterility of the operating area have to be addressed as well as the problem of what to do if a surgical emergency arises for which the satellite OR is not equipped to cope. There are currently very few dedicated units in the OR in the United States; there are slightly more located in the therapy department. For the non-dedicated linear accelerator, the need to transport the patient for each case from the OR to the radiotherapy area is a disincentive to the IORT program. For this reason, programs using nondedicated linear accelerators have seen a decline in numbers (see Fig. 4). It is highly unlikely that any more dedicated units of the conventional or electron-only type will be installed in the United States in the future for the reasons outlined above. An example of a dedicated electron-only linear accelerator located in the OR is shown in Fig. 4. The room measures $\sim 6.1 \times 8.0$ m and the unit is mounted into the wall at one end, ensuring an adequate space for surgery.

Experience has shown that centers with dedicated OR suites or mobile systems perform more IORT procedures than centers that use the patient transport technique. Details of the shielding aspects of an OR-based IORT machine have been published (13,35).

Mobile IORT Units

The cost of installing a dedicated linear accelerator in an operating room along with the required shielding is very high. A linear accelerator, even though it is run only in the electron mode, has a price tag of $\sim \$1.5$ – 2 M and the shielding costs for a room that is not located in a basement, which is often the case, can be a substantial fraction of the linear accelerator cost. Given that the number of patients to be treated with an intraoperative machine is unlikely to be >5 per week, it is clear that the economics for such a unit are not altogether favorable (10). Since 1996, several mobile linear accelerators have become commercially

available. These are the Mobetron, produced by IntraOp Medical (Santa Clara, CA), the Novac7 produced by Hitesys (Aprilia, Italy) and the Liac produced by Info&Tech (Udine, Italy). These are linear accelerators that have special features, in addition to being mobile, that reduce the need for extensive shielding in the adjacent walls, ceiling, and floor. This means that they can be used for treating patients in any OR room with little more than a portable lead shield to protect personnel in the surrounding areas, as well as above and below. (However, note that for commissioning and annual quality assurance purposes, a well-shielded room is required because of the high beam-on time needed for these tests.) This reduction in radiation leakage has been achieved in several ways. The first is to limit the maximum energy of the electrons that can be accelerated so that photoneutrons are not generated; the Mobetron has a maximum energy of 12 MeV, the Novac7 has a maximum energy of 9 MeV and the Liac has a maximum energy of 10 MeV (Note that according to European law, energies >10 MeV cannot be used in an OR without special protective shielding in the walls and floor). The second is to use an in-line beam, that is, the direction of the electron beam in the waveguide is the same as the direction of the beam that treats the patient. This avoids the use of a heavy magnet. Thus avoids the use of a heavy magnet. Conventional medium-to-high energy linear accelerators generally use a 270° bending magnet to bend the electron beam from the horizontal direction in the waveguide toward the patient at isocenter (34). The reason is that with the need to have a fully isocentric C-arm machine with an acceptable isocenter height, (Fig. 4), typically ~ 125 cm above the floor, the waveguide cannot be pointing toward the isocenter, given the length of the guide. This reduction of leakage also means that the shielding around the waveguide (usually lead or a tungsten alloy) is lower than for a conventional therapy linear accelerator, so the weight of the unit is reduced—essential for good mobility. Thus the major advantage of a mobile electron linear

accelerator is that minimal, in-room shielding is required for the unit so that it can be moved to any OR room, provided mechanical access is possible. A comparison of some of the other properties of these three mobile linear accelerators is in order since their method of beam generation and delivery are different. Major differences are that the Mobetron is a gantry-mounted unit that uses soft docking for alignments, whereas the two Italian models have the waveguide mounted on a robotic arm. Furthermore, the Mobetron waveguide operates in the X-band mode (8–12 GHz) whereas the Italian models operate in the conventional S-band mode (3 GHz). Note that the length of the accelerator's waveguide depends inversely on the frequency, so, for the same final electron energy, the X-band waveguide will be shorter.

Mobetron. The first Mobetron was installed and treated its first patient in 1997. There are currently 12 Mobetron units installed worldwide, 7 operating in the United States, 1 in Japan, and 4 in Europe. This unit operates with electron energies of 4, 6, 9, and 12 MeV. A view of this unit is shown in Fig. 5. The unit is mounted on a gantry, cantilevered with a beam stopper to intercept the X-ray component of the primary beam after it has passed through the patient. This ensures that the radiation exposure in the room below is sufficiently low as to be within the limits set for the general public and is the principal feature that allows this unit to be used in any OR without additional shielding. Although the unit is gantry mounted, the beam direction is not limited to the plane of gantry rotation, as

Figure 5. Mobetron mobile linear accelerator by IntraOp Medical Inc. Note that this unit has a gantry that also allows the linac head to pivot in a direction orthogonal to the gantry rotation plane.

with external beam linear accelerators, since the head can tilt in and out of this plane. This increases its versatility in setting up patients for treatment and reduces the amount of time needed to align the radiation field with the applicator. The beam stopper also moves in synchrony with this gantry motion to ensure that the primary beam is always intercepted.

A review of the salient mechanical properties and operating parameters of the machine is in order. The weights of the treatment module and modulator are 1250 and 432 kg, respectively. The Mobetron is moved around through the use of a modified pallet jack. Thus the two units can be moved with reasonable ease between different ORs. The gantry can rotate off vertical by 45° in each direction, while the head tilt has a range of $\pm 30^\circ$. Since the distance between the machine target and the patient's skin is 50 cm, half that of a conventional linear accelerator, the maximum dose rate is $10 \text{ Gy}\cdot\text{min}^{-1}$. Thus the maximum treatment time is ~ 2 min. For setting up the machine to treat the patient, the unit has five degrees of freedom. There are two orthogonal translational motions whereby the stand can be moved relative to the base by up to ± 5 cm. There is also a translation motion of the head along the axis of the waveguide and, finally, there are 2 rotational degrees of freedom of the head, one the gantry rotation and the other tilt in and out of the gantry plane.

Meurk et al. (36) reviewed the physical properties of this device and Mills et al. (37) and Daves and Mills (38) provide a comprehensive review of the commissioning and shielding requirements of a Mobetron accelerator.

Novac7. The first Novac7 unit was installed in Rome in 1997. To date, there are 20 Novac7 systems operating in Italy, Germany, and Greece. The Novac7 operates with electron energies of 3, 5, 7, and 9 MeV. Unlike most conventional linear accelerators and the Mobetron, the Novac7 is mounted on the end of a cantilevered robotic arm, not a C-arm, has a total weight of 500 kg. Figure 6 shows the Novac7 unit as well as the beamstopper to attenuate the forward directed X rays. The beamstopper operates independently of the machine and must be put in place by the medical physicist responsible for the IORT procedure. In many situations, however, movable wall barriers must also be used. The applicators have diameters of 4, 5, 6, 7, 8, and 10 cm with available bevel angles of 0, 15, 22.5, 30, and 45° . Note, however, that while the unit can be adjusted mm by mm, the cylinder attached to the linac cannot be moved coaxially with the applicator; instead, movements are made through a combination of rotational movements. By using a robotic arm, the unit has more degrees of freedom available for aligning the electron beam with the cone set up in the patient than a conventional accelerator or the Mobetron. In addition to its movement across the floor, it possesses four rotational degrees of freedom, which provides flexibility in setting up the device for treatment. Interestingly, the machine does not use scattering foils to produce a broad, uniform beam, but, instead, relies on electrons scattering in the air within the tubes and from the walls of the tubes to produce the desired, flattened fields. As a result, the length of the applicator used depends on the applicator size selected.

(a)

(b)

Figure 6. (a) Novac7 mobile linear accelerator by Hitesys; (b) beam stopper for Novac7. Note that this unit is a robotic arm with several degrees of freedom. It also uses the hard dock procedure.

Partly because of this, the dose rate varies between 6 and 26 $\text{Gy}\cdot\text{min}^{-1}$, significantly higher than most linear accelerators. At these dose rates, treatments typically last <1 min. The lower dose rate corresponds to the largest applicator and lowest energy while the higher dose rate corresponds to the smallest applicator and highest energy.

Figure 7. Liac mobile linear accelerator by Info&Tech. This unit looks similar to the Novac7 in terms of its movements and clinical set up, but there are differences in the design (see text for details).

These high dose rates result in substantial dosimetric problems, which have been studied and quantified by Piermattei et al. (39). A full technical description of the Novac7 has been given (40) and a review of the physical and dosimetric properties of the machine has been described by Tosi and Ciocca (41).

Liac. The first Liac unit (prototype) was installed in Milan in 2003. In its mechanical operation it is very similar to the Novac7 unit (see Fig. 7), with the accelerator guide mounted on a robotic arm. However, there are several major differences between the two units. First of all, the highest electron energy is now either 10 MeV (four energies of 4, 6, 8, and 10 MeV) or, potentially, 12 MeV (four energies of 6, 8, 10, and 12 MeV). This allows a greater penetration of tissue by the radiation, so that more deeply seated tumors can be treated. Second, the weight and dimensions of the machine are both lower, so the unit can be moved between rooms in the OR more readily, pass through doors more easily and fit into an elevator. The applicator system is the same as that of the Novac7, namely, it uses a hard docking procedure with no scattering foils. However, the applicator that defines the extent of the radiation field in the patient is now 30 cm in length. This length is standard for most commercial and noncommercial systems and allows the radiation oncologist and surgeon to view the radiation field directly, just before docking the applicator with the machine.

The Liac has the same high instantaneous dose rates as the Novac7, in this case 1.5–13 $\text{Gy}\cdot\text{min}^{-1}$ for the 10 MeV version and 3–22 $\text{Gy}\cdot\text{min}^{-1}$ for the 12 MeV version.

Table 4. Variation in the Depth of the 90% Dose with Electron Beam Energy

Electron Beam Energy, MeV	Depth of 90% Dose, cm ^a
6	1.7
9	2.6
12	3.7
15	4.5
18	5.1

^aFor a 7 cm diameter circular applicator that is commonly used in IORT; note that in IORT, the dose is normally prescribed to 90% level, taking into account that the surface dose is at or about that level.

Comparison between Conventional and Mobile Units

It is worthwhile comparing the pro’s and con’s of conventional linear accelerators in the OR versus mobile linear accelerators. The conventional machine has the advantage that since it is fully shielded for the highest energy available, ~18 MeV or higher, tumors with a greater depth can be treated. As a general rule, the depth of treatment increases by ~1 cm for every 3 MeV increase in energy at the 80% dose. Table 4 shows the depth of the 90% dose for one conventional unit.

However, the question arises as to how many treatments are delivered at high energy versus low energy. Figure 8 shows data from the MGH on the use of the various electron energies. It can be seen that all but 15% of the treatments were at 12 MeV or less, indicating that high energies are infrequently used. In contrast, the disadvantages are the cost of the machine, generally greater than for a mobile unit, and the shielding for neutrons as well as photons. At MGH, this shielding amounts to ~50 metric tons, which makes retrofitting existing ORs all but impossible. Moreover, should the machine malfunction, the OR becomes unavailable for the duration of the repair. Another fundamental difference is that conventional machines use a 270° bending magnet with momentum slits to focus the electrons onto the scattering foil, whereas the mobile units have no energy or momentum selection. While both units change energy by adjusting radio frequency (rf) power, the conventional units have the advantage of better energy selection. This leads to a higher surface dose and slower fall-off in the depth dose curves for mobile units (48).

Mobile linear accelerators, on the other hand, have distinct advantages over the conventional unit. First of all, the units are mobile so that they can be moved to any OR that has sufficient space. This is possible because the units require almost no additional shielding to operate

Figure 8. Fraction of treatments delivered at a given energy as a function of the energies available. From this graph, one can see that the majority of treatments are at 9 MeV or less and that <15% or patients are treated with an energy >12 MeV.

safely. However, a beam stopper is required for the primary beam in all mobile units. Whereas a dedicated unit is limited to isocentric movement, all mobile units have more degrees of freedom, allowing for greater flexibility in setting up the patient.

A summary of the chief differences between the three different modes of IORT is given in Table 5.

Treatment Applicators

There have been two types of applicators used in electron beam IORT, those made from poly methyl methacrylate (PMMA) and those made of metal, usually chrome-plated brass. The supposed advantage of the PMMA applicators was that one could see the tissues to be irradiated through the walls, although this turned out to be largely not the case. The disadvantage of using PMMA applicators is that they have to be sufficiently thick so as to prevent radiation penetrating through the walls and damaging normal tissue; this minimum thickness is ~6 mm. Metal applicators, on the other hand, do not have to be so thick because of their greater density. Since the pelvis is a tight area, anatomically, having a thick-walled applicator can restrict the treatment area for a pelvic side wall lesion. Thus, metal applicators are preferred, also because they can be flash (steam) sterilized at the time of the procedure, whereas applicators made from PMMA must be gas sterilized to avoid heat-related deformities and this requires ~12 h. Figure 9 shows examples of plastic applicators. Examples of metal cones are shown in Fig. 10.

Table 5. Comparison among the Three Methods of IORT Using Linear Accelerators

Mode of IORT	Advantages	Disadvantages
Linac in oncology department (patient transport)	Inexpensive; needs minimal additional equipment	For a busy outpatient machine, can do only 1–2 cases per week. Enthusiasm wanes due to effort required
Dedicated conventional linac in OR	Available on full-time basis. Maximizes convenience for surgical staff	Requires expensive shielded suite with low use factor
Mobile accelerator	Can be used in almost any OR; minimal additional shielding required	Limit on the maximum energy due to leakage X rays and neutrons

Figure 9. Examples of plastic applicators used in electron IORT. From left to right are shown an elliptical, a circular with beveled end, a circular, and a rectangular applicator.

Most manufacturers of dedicated linear accelerators provide applicators with a range of dimensions, usually circular in cross-section. A description of the design of treatment applicators for an OR-based IORT unit has been given by Hogstrom et al. (42)

Beam Alignment Devices

For nondocking machines, a system is required to align the electron beam from the waveguide with the axis of the treatment applicator in the patient (this is unnecessary for hard-docking systems since alignment is guaranteed with the tolerance between the two mating pieces). This is usually achieved optically. In the case of one dedicated, conventional linac (Siemens Mevatron ME, Concord, CA; this unit is no longer manufactured), beams from two lasers are split into four point sources and four line sources. When the points converge with the lines on a particular radius, then the distance is correct and the beam axis is correctly angled with respect to the treatment applicator. A metal disk with this radius drawn on it is placed on top of the treatment applicator for this purpose. A view of how

Figure 10. Examples of metal cones used in electron IORT. From left to right are shown a circular with bevel, a circular, an elliptical, and a rectangular applicator.

Figure 11. Example of the optical alignment used on the Mevatron ME linear accelerator. This test jig is used before each procedure to check the alignment of the lasers. Alignment is correct when the dots and lines (not easily seen here, but overlapping the radial lines) cross on the circle.

the correct alignment should look is shown in Fig. 11 for the test jig. Clearly shown is the circle with four laser dots at 90° intervals; the laser lines are in alignment with the radial lines shown, but on a black/white image, they are not visible. This system requires training to fully understand what movements should be made with the couch and gantry to align the treatment applicator with the beam when the dots and lines are not aligned. A more sophisticated system, that is simpler to use, is adopted with one of the mobile linear accelerators (Mobetron by IntraOp Medical, Inc.). This system also uses optical alignment, but provides visual indicators as to how to adjust the gantry to complete the alignment. As with the other system, laser light is reflected off a mirror on top of the applicator and is sensed by detectors in the head. This display is shown in Fig. 12, which shows the status of the alignment that is complete

Figure 12. Display of the alignment system used with the Mobetron mobile unit. (Photo courtesy of G. Ezzel, Mayo Clinic.)

when each of four parameters is indicated by a single yellow bar either side of a green bar (colors not indicated). Parameters on the display are the gantry rotation, the docking or distance between the head and the applicator, the tilt of the head and the position of the stand (in-out and left-right). The display shown indicates that the stand has to be moved from in to out and from right to left to complete the docking. When the alignment is complete, the alignment is accurate to 2 mm along any one axis and 0.1° in angle.

IORT Treatment Logistics

Since the radiation is delivered through linear accelerators, there are several options for performing this technique. The first is that the patient is transported from the operating room (OR) to the radiation therapy department and set up and treated on one of the linear accelerators usually used for treating cancer patients with external beams. The second is to have a dedicated treatment room in the OR. In this case, the patient has to be moved only from one side of the room to the other where the linear accelerator is located. The third option is a mobile linear accelerator. A mobile linear accelerator is one that can be moved from one OR to another. A fourth option is a hybrid of the first and second methods in that a linac in the radiation therapy suite serves also as an operating room so that both the surgery and IORT are carried out in the same room. The problem with this option is that if this room is far from the other operating rooms and if difficulties are encountered during the surgery, assistance might be problematic, particularly if specialized equipment is required.

There is a significant difference between the first option and the other three options since the patient has to be transported from the OR to the radiation therapy area. Once there, the machine used for these treatments is sequestered for the duration of the set-up and treatment. Additional time is required before and after the IORT procedure to prepare and clean up the room. Thus there are two negative effects, one, the surgical procedure is lengthened because of the transport and reset-up of the patient, and two, the therapy department loses significant time on one of its linear accelerators. Clearly, a department having only one or two machines with a busy outpatient workload could not readily perform these procedures, or, at least, not more than once a week. Finally, while the patient is being transported or in the therapy area, the OR has to be held open for surgical closure or additional surgery and this has an impact on a busy surgical department and its resources.

IORT Dosimetry, Calibration, QA, and Radiation Safety Electron Beam Calibration, Dosimetry, and Quality Assurance. Important components of IORT dose delivery are the calibration of the of the electron beam, dosimetry and routine quality assurance. These three important areas of IORT will be addressed separately. Electron beams are calibrated using a recommended methodology (43) and according to national protocols. In the United States and Canada, the appropriate protocol has been established by the American Association of Physicists in Medicine (AAPM) (44). This protocol dictates that measurements be made using an

ionization chamber in a water phantom under specific conditions. The ionization chamber is typically a cylindrical chamber having an air volume of 0.6 cm^3 , although the protocol also recommends the use of plane parallel chambers for low energies. The specific conditions relate to the depth of measurement as a function of electron beam quality and chamber dimensions. The protocol provides factors to calculate the absolute dose from the measured chamber exposure. The chamber is calibrated at an AAPM certified laboratory whose calibration standards are, in turn, referenced to the National Institute for Standards and Technology (NIST). Thus users' chambers around the country have calibration factors that are traceable to NIST so that 1 cGy in one institute is equal to 1 cGy in any other institute. The 2σ uncertainty in the users' calibration is stated to be 1%.

Having calibrated the IORT electron beam under standard conditions, it is necessary to determine the dose delivered to the patient under the most general conditions. For this purpose, medical physicists perform a series of measurements on the machine, including the variation of dose with depth and applicator size. Using these measurements, medical physicists can recommend the optimal energy for treating a specific lesion given the depth of the lesion and will then set the parameters on the accelerator to deliver the dose prescribed by the radiation oncologist.

Quality assurance is a very important aspect of radiation therapy, both external and IORT. In general, quality assurance is mandated by state and federal agencies and recommendations are made by the AAPM (45). These laws and recommendations specify the types and frequency of tests that must be carried out on linear accelerators used in radiation therapy. For IORT, quality assurance is of particular importance since, unlike external radiation therapy where up to 42 fractional doses may be given over an 8 week period, the dose is given in a single fraction. Therefore, quality assurance tests must be particularly probing to ensure that the probability of any error is as low as possible (46). The AAPM has made specific recommendations for IORT (47,48) at the daily, monthly and annual level. Table 6 shows the data taken from the latest AAPM report (48).

In addition, additional, independent quality assurance on electron beam output and percent depth dose is provided by the Radiological Physics Center in Houston, using mailable TLDs (49).

Radiation Safety Issues

All radiation-producing equipment is subject to state and federal regulations. These regulations restrict the dose that a member of the general public can receive to 1 mSv year^{-1} or $0.02 \text{ mSv-week}^{-1}$. There is also a further restriction that such a person may receive no more than 0.02 mSv in any 1 h. For controlled areas (not accessible to the general public), the allowed limits are higher. Since many of the linear accelerators are located/used in the operating room environment, regulations for the general public apply.

As noted above, radiation safety requirements for electron beam IORT depend on the approach taken. For treatment

with a linac in a radiotherapy department, the room is already well shielded for any number of IORT treatments. For a dedicated, conventional linear accelerator in the OR, the shielding is usually designed for a specific number of cases per week. A maximum number would be 10 cases per week, based on the length of an average surgical procedure. However, patient demographics and past IORT experience indicate that this limit is never reached on a continuing basis. However, the machine has to undergo acceptance testing and commissioning when first installed and extensive checks every year by the medical physicists that require extensive beam-on time (there are also daily and monthly checks, but these require much less beam-on time). Therefore, this work has to be carried out at night and over the weekend when personnel are generally not present. For corridors in the OR that are still in use, this may require installing temporary barriers with appropriate radiation warning signs; rooms above and below have to be checked to ensure that they are not occupied. For mobile linear accelerators, it was noted above that, due to their low leakage, considerably less shielding is required for their use in the OR, apart from a primary beam stopper. Lead shields placed strategically around the patient provide secondary shielding. However, before any OR can be used for treatment with a mobile linear accelerator, extensive surveys have to be carried out to determine radiation levels in the immediate vicinity with and without the secondary shielding. Based on these readings, the number of cases that can safely be performed on a weekly basis without exceeding the maximum permissible dose can readily be calculated. Clearly, this exercise has to be performed for every OR in which IORT cases may be performed. As noted above for the dedicated, conventional linear accelerator, there are occasions when the medical physicist has to perform extensive testing of the equipment. This can also only be done at night or on weekends, provided the occupancy of nearby areas can be controlled. If this cannot be done, the unit

has to be taken to a shielded area for testing, such as the radiotherapy department. Issues relating to the radiation safety aspects of mobile linear accelerators are fully covered in the AAPM's report on mobile linear accelerators (48). In all cases, consultation with the hospital's radiation safety officer is highly recommended.

OTHER IORT TECHNIQUES

INTRABEAM System for Intracranial Lesions

Another device that has come into use for the intraoperative treatment of intracranial and other lesions is the INTRABEAM System. This device was originally manufactured by Photoelectron Corporation, but is now marketed by Care Zeiss Surgical GmbH, Germany. This system is a 50 kV device that fits into a standard neurosurgical stereotactic frame. Figure 13 shows the INTRABEAM device; electrons are accelerated down a 10 cm long 3.2 mm diameter evacuated tube, striking a gold target at the tip. The thicker section between this tube and the body of the device contains coils to steer the electron beam. Built into the body of the device is a scintillation detector that detects backward emitted photons in a fixed geometry. This

Figure 13. INTRABEAM X-ray tube. The body of the device contains the high voltage electronics, power for the steering coils and the electron gun. It also contains the internal radiation monitor for integrating the radiation output of the device, similar to the internal ionization chambers in a linear accelerator. Electrons are accelerated to the tip of the probe where they strike a gold target and produce the X rays. The large diameter section contains the steering coils.

Figure 14. The INTRABEAM device inserted into a stereotactic head frame demonstrating how the device is used for the treatment of intracranial lesions.

is known as the internal radiation monitor. Figure 14 shows the X-ray device inserted into a CRW neurosurgical frame so that the probe tip can be placed at the location of the stereotactic site to within an accuracy of better than 1 mm. Thus an intracranial lesion is first imaged using Computerized tomography (CT) and the coordinates of the center of the lesion determined so that, in addition to the neurosurgeon performing a stereotactic biopsy, the tip of the X-ray source, where the X rays are generated, can be accurately located at this point and a tumoricidal dose of radiation delivered. Figure 15 shows a series of isodose curves generated using radiochromic film (Gafchromic film, type MD-55, ISP Technologies Inc., Wayne NY). The outline of the probe tip in the north-south direction

Figure 15. Isodose curves for the INTRABEAM X-ray device. It can be seen that the tip of the probe is the center of the X-ray source and that the source is nearly isotropic in intensity except in the backward direction close to the tube.

can easily be identified as the source of the radiation. The horizontal line and the line extending from the probe tip represent cuts in the film. The dose depth curve for 50 kV X rays in water is shown in Fig. 16. The dose rate from this device is about $2 \text{ Gy}\cdot\text{min}^{-1}$ at 1 cm from the probe tip in water. The dose falls off as the inverse third power of the distance and, hence, the dose delivered outside the tumor drops very rapidly. At this dose rate and for this dose fall-off, typical treatment times last from 15 to 30 min, depending on the treatment radius. A fuller description of the apparatus and the clinical testing of the device has been given by Beatty et al. (50). A Monte Carlo has been performed (51) to predict both the spectrum and output of the X-ray beam with good accuracy.

Although initially developed for intracranial lesions, the INTRABEAM system is approved by the U.S. Food and

Figure 16. Distance-dose curve for the INTRABEAM device for 50 kVp X rays. The output falls off as the inverse of the third power of the distance from the probe tip. In addition to inverse square, there is an additional factor due to the attenuation of the X-ray beam, which is significant at these energies.

Drug Administration (FDA) for application to any location in the body. To that end, a set of spherical applicators was developed that could be used to treat meningiomas or breast cancer, after surgical resection. For breast and other extracranial treatments, the stereotactic frame is not used. Instead, a stand developed by Zeiss is used to support the INTRABEAM device. It can be set and locked into any position so that it remains stationary during the procedure. In Europe, the treatment of breast cancer is one of the principle uses of this device. There are currently ~30 units operating in the United States and Europe. Of note is the fact that since this device delivers X rays at very low energies, the shielding requirements are minimal. All personnel, except for the operator and perhaps the anesthesiologist, leave the room. A portable diagnostic X-ray shield is used to protect the operator and anesthesiologist. All entry doors except one, beyond which all the other OR personnel wait during the treatment, are locked.

High Dose Rate (HDR) Brachytherapy

Brachytherapy is a technique whereby sealed radioactive sources are placed inside the body or in body cavities, usually for a short duration of time or, in some cases, permanently. Most of the sources for temporary implants have activities such that the dose rate to an isodose line surrounding the tumor is $\sim 50 \text{ cGy}\cdot\text{h}^{-1}$. With the typical doses given in conventional, low dose brachytherapy, this means that the treatment time is often several days and the patient has to be hospitalized. However, by using a HDR source (typically 10 Ci of ^{192}Ir), the treatment time can be shortened to minutes. Figure 17 shows an HDR (Nucletron Microselectron HDR) with one catheter inserted. The other end of the catheter is placed in a well counter, a chamber used by medical physicists to measure the strength of the radioactive source. A total of 18 catheters can be attached to the unit and a computer control system (not shown) guides the single source down each catheter to a given position for a predetermined dwell time. By varying the dwell time of the source at each location, the dose distribution can be optimized for each treatment. In

Figure 17. View of the HDR system with one catheter hooked up to a well chamber for calibration of the source by a medical physicist.

Figure 18. Sample H.A.M. applicator. The catheters are embedded in a 1 cm thick silicone rubber mat. Note the clear identification numbers on each catheter. The manufacturer supplies applicators with varying numbers of catheters. (Photo courtesy of Felix Mick.)

this procedure, as many catheters as are required to cover the tumor or tumor bed are inserted into the patient or placed on the outside for skin treatments; a single source is used and this is mechanically driven along each catheter, programmed to dwell at preselected positions for lengths of time determined by the treatment planning program. The HDR treatments took some time to be accepted by the medical community because it was initially thought that dose rate effects in brachytherapy were crucial and that HDR treatments would be less effective than those using conventional, low dose rate techniques. Because of this shortened treatment time, it became possible to perform exploratory surgery in the OR, lay out the catheters in the area of residual disease, treat the patient while still on the operating room table and then close up the patient. Figure 18 shows a Harrison-Anderson-Mick (H.A.M.) applicator for HDR-IORT. This applicator consists of a number of catheters embedded in a 1 cm thick silicone rubber mat. The catheters are located mid-plane and therefore 0.5 cm from each surface. Applicators are available with the edges curved in a half circle (not shown here) to help maintain a more uniform dose at the surface. Applicators are available in sizes from 3–24 channels in groups of 3, namely, 3, 6, 9, and so on. Because this is a planar application of ^{192}Ir sources, the depth of treatment is almost always taken to be 1 cm, that is, 0.5 cm from the surface of the applicator, to avoid an excessively high dose at the skin-applicator interface. This restricts the number of applications for which this approach can be used, typically lesions that have been resected with positive margins, compared with electron beams, which, as shown above, can penetrate much greater depths. Care must be exercised in the planning dosimetry for these applications since the dose depends on the curvature of the applicator (52) and the lack of backscatter material (53). Figure 19 shows an applicator in place in a patient prior to treatment. Note the curvature of the applicator.

Shielding, in the form of concrete or lead is required in the walls and floor if a significant number of patients are

Figure 19. View of a H.A.M. applicator inserted in a patient and ready for treatment. (Photo courtesy of Dr. C. Willett.)

treated. The exact thicknesses will depend on the number of cases treated per week.

At present, there are four institutions in the United States performing HDR in the OR. Excellent technical descriptions of the HDR technique applied in the operative setting have been given by Harrison et al. (54) and Nag et al. (21).

CLINICAL RESULTS

Disease sites that have been treated with IORT include pelvic lesions such as pancreas, rectum, colon, retroperitoneal sarcoma, bladder, kidney, sacrum, liver, endometrium, cervix, and ovary. Extra-pelvic sites include head and neck, breast, and distal limbs. At the MGH, the most commonly treated disease sites include the pancreas, rectum, colon, and retroperitoneal sarcoma. UCSF reported in 2003 that a majority of treatments had been in the area of head and neck and thorax. A considerable number of pediatric patients had also been treated in a few centers. Thus the type of sites treated in different institutions reflects the interests of the surgical and oncology departments of those institutions.

One of the problems encountered when comparing the efficacy of IORT combined with external beam radiotherapy (EBRT) with EBRT alone in terms of overall survival is that distant metastases play a major role in many disease sites. While it is true that IORT combined with EBRT provides a result as good as any EBRT alone series, the difference in survival is often not significant. Moreover, due to the rapid progression of distant metastases, it is often not possible to know the exact pathologic stage of each patient under treatment, and so comparisons among different series is difficult. Data from MGH (unpublished) shows that overall survival for patients with pancreatic cancer depends on the field size of the treated field, the smaller the field, the greater the survival. What this says is that patients with bulkier disease will experience more rapid development of distant metastases.

One of the success stories of IORT, however, is colorectal cancer since the effect is statistically significant. Table 7 shows the results from MGH for primary and recurrent

Table 7. Clinical Results for IORT Treatment of Primary and Recurrent Rectal Cancer Using Electrons

Primary Colorectal Cancer					
	No. Pts	Median (month)	Survival, years		
			2	3	5
EBRT	17	18	35%	24%	24%
EBRT+IORT	56	40	70%	55%	46%
Recurrent Colorectal Cancer					
	No. Pts	Median (month)	Survival, years		
			2	3	5
No IOERT	64	17	26%	18%	7%
IORT+/-EBRT	42	30	62%	43%	19%

colorectal cancer. This was not a randomized trial, but a comparison between EBRT with electron beam IORT and historical controls, EBRT alone. In each case, the survival is greater when IORT is used, even up to 5 years. While this does not have the power of a randomized trial, the difference in the results in each case is both statistically significant and impressive. Moreover, similar results have been observed at other institutions, for example, the Mayo Clinic (55). Similar results have been obtained with HDR-IORT.

Current results in the treatment of gastric cancer indicate that while some benefits may accrue from IORT, further studies are needed to demonstrate a significant benefit. Interestingly, gastric cancer was one of the sites first chosen by the Japanese for IORT, which is quite understandable, given the high rate of incidence of that disease in Japan. For locally advanced primary and recurrent gynecological malignancies IORT has shown that results are comparable to historical results with standard salvage therapy. In one of the rare randomized trials involving IORT, a study of retroperitoneal sarcoma accumulated 35 patients between two arms, EBRT and EBRT+IORT. With a minimum follow-up of 5 years and a median follow-up of 8 years, a significant difference in local control was found between the two groups (56). However, as with studies for other diseases, there was no difference in median survival between the two groups. Two major centers, the Mayo Clinic and the Denver Children's Hospital, have been involved with pediatric malignancies. They have shown that IORT is effective in local control for locally advanced pediatric malignancies. Interestingly, the Denver Children's Hospital used only IORT whereas the Mayo Clinic used combined IORT and EBRT. In bladder cancer, IORT has been shown to be effective in bladder preservation. Investigators found few complications related to these treatments.

Perhaps the greatest thrust at the moment in the field of IORT is the treatment of breast cancer. This is actively being pursued in Europe, particularly Italy, followed by Germany and the United Kingdom (UK), and, to a lesser extent, in the United States. The drive for this is related to the need to shorten the overall duration of the conventional

external therapy treatment time. In this area, IORT is competing with several other techniques, including partial breast irradiation and temporary implants using ^{192}Ir brachytherapy seeds and the INTRABEAM system. The IORT and the INTRABEAM systems would, of course, require only a single fraction treatment. Although a large number of breast cancer patients have been treated intraoperatively to date, the follow-up time is too short to draw any conclusions.

At MGH, interstitial radiosurgery with the INTRABEAM has been performed for intracerebral metastases, primary malignant gliomas and as adjunct to resective surgery in meningiomas. Local control of metastases was possible in 80–85% of cases ($n = 73$), which is consistent with other forms of external radiosurgery. In a handful of cases with malignant gliomas, tumor recurred as expected beyond the areas of high dose irradiation. In 12 parasagittal meningiomas where residual tumor was left along the sagittal sinus, there has been no evidence of local recurrence with mean follow-up of 3 years, which is too early to determine efficacy.

FUTURE DIRECTIONS

If one looks at the history of IORT, one sees that the procedure has been practiced almost as long as there have been X rays. One of the driving forces for IORT in the early days was undoubtedly the need to overcome the limitation in dose delivery due to skin desquamation, a breakdown of the skin, resulting from the highest dose being at the surface. Certainly, the conditions of using X-ray equipment available at that time could not have been conducive to ease of use in an OR setting. It is clear, however, that the history of its practice has been punctuated by the introduction of new technology, first the change from low kilovoltage X rays (50 kV) through orthovoltage X rays to electrons. However, it was clearly the introduction of linear accelerators with electron beams that provided the greatest impetus over the last century, although the technique was not universally adopted because of cost, time, and many other factors. Indeed, there was a decline after the 1990s associated with these factors. It was not until the introduction of mobile linear accelerators that the field regained its strength. Part of the reason for this is the desire, for logistical reasons, particularly in Europe, to speed up the radiation therapy treatment process. Granted that this is also possible using external beam techniques, such as partial breast irradiation, but IORT certainly has a role to play in this change in therapeutic practice. The increase in the number of units attests to this: In 1997, the first unit was installed and at the time of this writing, 33 have been installed worldwide with units available from three manufacturers. This technology has enabled more centers to participate in IORT procedures, allowing both surgeons and radiation oncologists more convenient ways to treat patients. Moreover, several photon modalities have come into increasing use in IORT, including HDR-IORT and the Zeiss INTRABEAM device. These are playing a greater role in IORT, in part because the capital investment in these technologies is considerably less than a dedicated mobile linear accelerator.

However, before the widespread acceptance of IORT is possible, proponents need to demonstrate clearly that IORT provides a therapeutic advantage for their patients. While this has been shown for a subset of patients with rectal cancer, based on retrospective studies, it is clear that randomized trials are needed for other disease sites to provide unequivocal evidence for IORT's benefit. This is currently being done for breast cancer in Europe.

Thus, while the field is still small, it continues to grow, thanks to better technology. More widespread use of IORT will determine whether the procedure confers a benefit to patients across a broad class of diseases.

RADIO THERAPY, THREE-DIMENSIONAL CONFORMAL

GEORGE STARKSCHALL
The University of Texas
Austin, Texas

INTRODUCTION

The goal of radiation therapy is to deliver a sufficient dose of radiation to a tumor site to control the disease while keeping doses to uninvolved tissue within tolerable limits. In order to achieve this goal, radiation beams are typically directed to the tumor target from several directions. Consequently, multiple beams irradiate the target, but only a few beams irradiate the uninvolved tissue surrounding the target, thus reducing the dose to the uninvolved tissue. The portals used to define the radiation fields are carefully shaped to fit the target in order to further reduce the amount of radiation reaching the tissue surrounding the target. In three-dimensional conformal radiotherapy (3DCRT), the radiation dose distribution is designed to conform to the contours of a target volume. The method by which the beam geometries and treatment portals of 3DCRT are designed differentiates 3DCRT from earlier methods of radiation treatment planning and delivery.

Prior to the 3DCRT era (mid-1990s), radiation treatment planning was based on a small number of computed tomography (CT) images of the patient and radiographic images from a simulator, a diagnostic X-ray machine whose geometries simulated the geometries of the radiation treatment machine. Beam configurations were determined based on a CT image of the patient in a single transverse plane, typically the plane containing the central axes of the radiation beams. Treatment portals were determined from the simulation radiographs; the design of these portals was based primarily on bony landmarks that were visible on the radiographs. Radiation doses were computed in the plane containing the beam central axes, and plans were evaluated on the basis of information displayed in that plane (1).

With the development of fast CT scanners and fast treatment planning computers with inexpensive memory, radiation therapy moved into the 3DCRT era. Whereas in the past, radiation treatments were planned and evaluated on the basis of information in a single or limited number of planes, radiation treatment planning is now based on patient volume. Patient information is acquired over a volume of the patient, treatment portals are designed to irradiate a target volume, doses are calculated in volumes of tissue, and treatment plans are evaluated based on dose-volume considerations. The 3DCRT process currently used in contemporary radiation therapy consists of the following steps: (1) accurately imaging the tumor and normal tissue in three dimensions, (2) precisely defining the target volumes, (3) optimizing beam geometries and beam weights, (4) translating the treatment plan to produce accurate delivery of radiation according to the treatment plan, and (5) verifying the accuracy of the delivery of radiation.

IMAGING FOR RADIATION ONCOLOGY

In the current state of practice in 3DCRT, treatment planning is based on virtual (CT) simulation. A 3D CT

image data set of the patient is acquired with the patient in the treatment position. Patients are typically positioned in an immobilization device, and marks are placed on the patient's surface to assist in maintaining setup reproducibility. The desired setup accuracy may vary from submillimeter accuracy for treatments in the head, where the tumor may lie very close to highly critical, radiosensitive, normal anatomic structures, to accuracies of 0.5–1 cm in areas of the thorax or abdomen.

Various types of CT scanners are used to acquire patient information. The third generation CT scanner consists of a single radiation source emitting X rays in a fan-shaped radiation pattern, which is detected by a single array of detectors. The gantry containing the radiation source makes a single (whole or partial) rotation around the patient with the detectors on the opposite side of the patient. Following acquisition of projection data from a single transverse slice, the table is indexed and another slice is acquired. This procedure continues until the entire region of interest is scanned.

Technologic developments in CT image acquisition include helical, or spiral, CT. This technology combines gantry rotation with table translation so that the path of the radiation source with respect to the patient forms a spiral trajectory. Image acquisition times using helical CT are significantly faster than times using third generation CT. Even faster is a new technology in which a multislice X-ray detector is used. Typically, such detectors can acquire from 4 to 16 image slices simultaneously. Multislice helical CT has the potential for increased axial resolution as well as scan times that can be as short as 3–5 s (2).

The ability to increase the axial resolution of CT image data sets brings up the issue as to the desired axial resolution for planning 3DCRT. Prior to the 3DCRT era, CT scans were typically acquired at planar separations of ~10 mm. This axial resolution should be compared with the typical picture element (pixel) dimensions in each plane of $<1 \text{ mm}^2$. The ideal axial resolution would be comparable with the planar resolution; however, a submillimeter axial resolution would result in a very large number of CT images. Because the contours of tumors as well as those of some normal anatomic structures have to be manually delineated on the CT images for treatment-planning purposes, requiring such delineation on so many CT images would result in an extraordinarily time-consuming, labor-intensive task. Consequently, axial resolutions presently used in 3DCRT represent a compromise and are typically in the vicinity of 3 mm.

A key component in CT simulation is the production and display of digitally reconstructed radiographs (DRR). A DRR is a radiographic image that models the transmission of an X-ray beam through the patient (3). A DRR is obtained by tracing the path of X rays from the location of the radiation source through the 3D CT patient image data set to a plane beyond the data set and calculating the X-ray transmission through the CT data set. Generating a DRR offers several advantages over obtaining radiographic images from a conventional simulator. Whereas tumors are sometime difficult to visualize on a conventional radiograph, they can often be visualized more easily on a CT image. The contours delineating the tumor can be drawn on

Figure 1. A digitally reconstructed radiograph illustrating a tumor in a patient's right lung.

the CT image data set and projected onto the DRR. Treatment portals are then designed based on the projected contours. The design of a treatment portal based on the volumetric extent of the tumor is a key component of the 3DCRT process. In addition, many soft-tissue anatomic structures may also be difficult to visualize on a conven-

tional radiograph. Contours delineating these structures can be drawn on the CT image data set and projected onto the DRR as well. Display of these projected contours can assist the treatment planner in selecting radiation-beam geometries that will irradiate the tumor while avoiding critical anatomic structures. Finally, the DRR can be compared with a radiographic image of the treatment field acquired on the treatment machine to verify that the patient is correctly set up on the treatment machine. Figure 1 illustrates a DRR with a target volume drawn on it.

Computed tomography image data sets are not the only images used in planning the 3DCRT. They are the images of choice for performing actual radiation-dose calculations because the values of the CT volume elements (voxels) can best be correlated to the extent of interactions of the X-ray beam with the patient. However, other imaging modalities may be more effective than CT in imaging the tumor. For example, magnetic resonance (MR) imaging is often more reliable for imaging soft tissue, especially for planning radiation treatment of brain tumors. Positron emission tomography (PET) is a very useful modality for imaging tumor metabolism and often provides additional information about the presence and extent of lung tumors. Figure 2 illustrates a CT image and a PET image illustrating the differences in the information provided by the two imaging modalities.

A major issue encountered in the use of multimodality imaging for 3DCRT planning is that of image registration, that is, the geometric correlation of information from the various imaging modalities with that of the CT image data set. The coordinate systems used in the acquisition of images from various modalities are typically different, requiring some sort of registration so that information delineated on one image data set is correctly displayed on the treatment-planning CT data set. Moreover, MR images are sometimes subject to geometric distortion,

Figure 2. Coronal CT and PET images of a patient with lung cancer.

Figure 3. A combination PET/CT scanner.

especially near the periphery of such images, making the registration problem more complex. The PET and CT images are very difficult to register manually, as the two modalities image very different properties of the patient. Registration of PET and CT image data sets is sometimes accomplished by registering the CT image data set with a transmission scan taken on the PET scanner and used to make corrections in the PET scan for patient attenuation. A new device, in which a PET and a CT scanner are mounted together, has recently been introduced. An example of such a device is shown in Fig. 3. Using this device, the patient first undergoes a CT scan. With the patient immobilized, the support table is translated into the PET scanner, and a PET scan is obtained. In this manner, the geometries of the PET scan and CT scan differ only by a known table translation, making image registration a simple process.

DEFINITION OF TARGET VOLUMES

Because dose prescriptions used in 3DCRT are based on irradiating volumes of tissue, more uniformity in terminology has been required in the specification of dose prescriptions. The International Commission on Radiation Units (ICRU) has developed a series of documents that describe a methodology for specification of target volumes (4,5). The ICRU definitions constitute a methodology for reporting radiation treatments in an unambiguous manner.

The ICRU defines the gross tumor volume (GTV) to be the “gross demonstrable extent and location of the malignant growth” (4). The GTV consists of the primary tumor, involved lymph nodes, and metastatic disease that can be visualized. The specific method of visualization is not specified; the GTV might be identified and delineated on clinical examination, radiographs, CT images, MR images, or any other visualization method. Moreover, the extent of the GTV may be different for different examinations, depending on the method of visualization. One of the aims of the radiation therapy is to deliver a tumoricidal dose to the entire GTV. The patient may have several GTVs depending on the nature of the malignant disease, and each GTV may have a different therapeutic aim. In some

cases, in particular after surgical intervention, the GTV may not exist.

In addition to clinically demonstrable disease, the patient is likely to have subclinical disease that can only be visualized under pathologic examination. This subclinical disease must also be eliminated for the tumor to be controlled. The combination of GTV and subclinical disease constitutes the clinical target volume (CTV). The radiation oncologist establishes the margin that defines the CTV on the basis of clinical experience. In a few cases, such as nonsmall cell lung tumors, pathology studies have helped the radiation oncologist define the CTV margin. In the case of surgical intervention, a CTV might exist without a GTV. The existence of GTVs and CTVs are based on general oncologic principles and are independent of any therapeutic approach. The GTVs and CTVs can be identified and delineated prior to the selection of the treatment modality and the treatment-planning procedures.

Treatment planning for 3DCRT is typically based on information obtained from a CT image data set acquired a few days before treatment is scheduled to begin. An inherent assumption in basing the treatment plan on the CT data set is that the data set accurately models the patient during the entire course of radiation therapy. In reality, the patient moves, exhibiting intrafractional motion such as respiratory and cardiac motion, as well as interfractional motion such as bladder and rectum filling and tumor regression. In order to account for motion, an internal target volume (ITV) is defined. The ITV is the CTV with an internal margin (IM). In many cases, the ITV is assumed to be the CTV with a uniform, isotropic IM, established from clinical experience; but in some cases, the ITV is explicitly defined from multiple CT image acquisition.

A final margin needs to be added to the ITV to account for the fact that there is some degree of nonreproducibility in the day-to-day setup of the patient for radiation treatment. Consequently, a planning target volume (PTV) is defined to include the ITV along with a setup margin (SM) to account for these setup uncertainties. The PTV is thus defined to be a region that, if irradiated to the prescription dose, makes sure that the entire CTV will be irradiated to the prescription dose, regardless of internal motion or setup uncertainty. The extent of the SM is based on the device used to immobilize the patient. When invasive devices are used, the SM may be reduced to <1 mm; typically, however, the SM is in the range 0.5–1.0 cm. Figure 4 illustrates an axial CT image of a patient's lung with the GTV, CTV, and PTV identified.

In 3DCRT, a DRR with the delineated PTV is normally displayed to the treatment planner. A radiation-treatment portal is established to include the entire PTV along with an additional 5–7 mm margin that accounts for the fact that the edge of the radiation beam is fuzzy due to the finite size of the radiation source as well as effects of scattered radiation. Thus, a GTV is expanded by a margin to account for microscopic disease to generate a CTV, which is expanded by a margin to account for motion to generate an ITV, which, in turn, is expanded by a margin for setup uncertainty to generate a PTV.

In addition to identifying and delineating target volumes, the 3DCRT planning process must also identify

Figure 4. An axial CT image of a patient's thorax, illustrating a GTV, CTV, and PTV. The CTV is obtained by expanding the GTV by a uniform 0.8 cm margin, and the PTV is obtained by expanding the CTV by a uniform 1.5 cm margin.

and delineate organs at risk (OAR), which are defined to be “Normal tissues whose radiation sensitivity may significantly influence treatment planning and/or prescribed dose” (5). For example, in planning the radiation treatment of lung tumors, the OARs typically include the right and left lung, heart, esophagus, and spinal cord, whereas in planning the radiation treatment of prostate tumors, the OARs typically include the bladder, rectum, and femoral heads. Setup uncertainty and OAR motion are accounted for in defining the planning organ at risk volume (PRV), which contains the OAR along with an internal margin and a setup margin (5). Thus, in the planning of 3DCRT, the planner must determine one or more beam geometries and treatment portals that will adequately irradiate the PTV, while keeping doses to the various PRVs within tolerable limits.

DOSE PRESCRIPTION

Prior to the development of 3DCRT, radiation-dose prescriptions were generally based on point-dose methodology. A dose prescription might have read, “66 Gy to the isocenter”, where the isocenter was the point around which the gantry of the radiation machine rotated. Another prescription might have read, “72 Gy to the 95% isodose”, where the 95% isodose represented the locus of those points receiving 95% of the dose to isocenter. In both cases, the dose prescriptions described doses to a single point, typically the point at isocenter.

In 3DCRT, one is concerned with doses delivered to volumes, in particular, the target volumes. The goal of a 3DCRT treatment plan is to irradiate the entire CTV to the prescription dose. Because the CTV may move anywhere within the PTV, it would also be desirable for the entire PTV to be irradiated to the prescription dose as well. However, because the CTV does not lie in the entire PTV for the entire treatment, one may allow a small

amount of the PTV (typically 5%) to receive a dose less than the prescription dose without adversely compromising the goals of the radiation treatment, especially if doing so would significantly improve organ sparing. If <100% of the CTV receives the prescription dose, the radiation oncologist may have to address the potential consequences that could occur if tumor cells do not receive a tumoricidal dose. However, compromises in CTV dose may be necessary to avoid excessive morbidity. In many cases, the 3DCRT planning process represents a compromise between the dose needed for adequate tumor control and the dose that would cause unacceptable side effects of the radiation.

BEAM DETERMINATION

Determination of radiation beam geometries for 3DCRT is, to an initial approximation, a trial-and-error process based on class solutions. For example, a pair of parallel-opposed beams delivers approximately a uniform dose to the entire volume irradiated by the beams. Tumors, however, rarely extend completely through the patient; so in 3DCRT, more than two beams are likely to be used. Placing two more beams at right angles to a parallel-opposed pair of beams generates what traditionally has been called a “four-field box”. This configuration delivers ~50% of the target dose to regions that are irradiated by only two of the four beams. More complicated beam geometries are sometimes used based on the need to avoid irradiation of critical structures. Figure 5 illustrates a multiple-field beam configuration used to treat prostate cancer. Incorporating couch rotations resulting in beams whose axes are noncoplanar can sometimes be used to improve avoidance of critical structures. Wedge-shaped metallic filters placed in the beam to generate dose gradients can be used to compensate for dose nonuniformities generated from certain beam configurations.

Figure 5. A multiple field beam configuration used to treat prostate cancer.

Treatment portals are determined for each beam geometry and designed to encompass the PTV along with a margin to allow for the fact that the beam does not end abruptly at the geometric edge but rather the dose distribution has a finite slope at the beam edge. Caused both by the fact that the radiation source is not a point source and that radiation can scatter from the irradiated region to the blocked region, this penumbra requires that the treatment portal surround the PTV with a margin of from 0.5 to 1 cm in order to deliver a high dose to the PTV. The treatment planning typically designs the treatment portal based on viewing the BEV projection of the PTV on a DRR.

In addition to optimizing the beam geometries, the planning often must also optimize the beam weights. Typically, this optimization consists of manual fine tuning of the beam weights to deliver a more uniform dose across the target volume, decrease the dose to specific critical structures, or both of these outcomes. However, if specific prescription goals are established, such as desired doses to target volumes and maximum allowed doses to critical structures, various computer algorithms can be used to optimize the beam weights. If additional conformality of the dose distribution to the target volume is desired, techniques exist for the planning and delivery of intensity-modulated radiation therapy (IMRT). This technique is particularly useful if the target volume is concave.

DOSE CALCULATION

In most current radiation treatment planning systems, X-ray dose distributions are calculated using a convolution algorithm (6,7). In this algorithm, the radiation dose is obtained by convolving an incident fluence distribution with a dose-spread array. The dose-spread array represents the distribution of radiation dose around a point in

which a unit amount of X-ray fluence is seen. Because the dose-spread array is dependent solely on the X-ray energy and distance from the point of fluence deposition, dose-spread arrays, one for each energy, need only be computed once, and then stored in the treatment-planning computer. The in-air fluence exiting the linear accelerator is determined once for each linear accelerator and is modeled by a set of parameters. The X-ray fluence is calculated by propagating the in-air fluence through the CT model of the patient, attenuating the fluence based on exponential attenuation, characteristic of X-ray propagation through matter.

More accurate calculations of X-ray dose distributions in the patient can be achieved by more accurate modeling of the interactions that X rays undergo with the patient using Monte Carlo techniques (8). Originally limited in applicability by limitations in computing power, newer high speed processors are making such calculations clinically feasible.

CONFORMAL PARTICLE THERAPY

The 3DCRT can also be achieved using beams of charged-particle radiation, such as electrons or protons. In some respect, achieving 3DCRT is easier with charged-particle beams than it is with X-ray beams. One feature that differentiates the dose distribution from charged-particle beams from that of X-ray beams is that the dose distribution from charged-particle beams, at least to a first approximation, is constant from the patient surface to a depth equal to the range of the charged particle, and then goes rapidly to zero. This distribution results from the charged particle's property of depositing a fixed amount of energy per interaction until the particle energy is exhausted; beyond that depth, no energy is deposited. Consequently, the lateral extent of a charged-particle beam can be shaped based on the BEV projection of the PTV, just as are X-ray beams, but the depth of penetration of a charged-particle beam can be made to track the distal surface of the PTV by spatially modulating the energy of the beam, which shifts the range of the charged particles. A simple method for range-shifting involves placing a sufficient amount of attenuating material in the path of the beam to reduce the local energy of the beam so that its range is slightly greater than the depth of the distal surface of the PTV. Alternatively, one could modify the spatial distribution of the energy of the beam by modifications in the beam transport in the head of the particle accelerator.

Particle therapy, on the other hand, has some limitations. The margins of electron beam dose distributions are not as sharp as those for X-ray beams because of multiple scattering. In addition, heterogeneities and surface irregularities cause significant perturbations in the electron beam dose distributions. Widespread use of proton beams may be limited because of the significantly higher cost of production of therapeutically useful beams.

RADIATION DELIVERY

Once a 3DCRT treatment plan has been developed, it is necessary to translate the treatment plan accurately to the

radiation-delivery system. Although this can be done manually, the complexity of modern treatment plans demands that plan information be transferred automatically from the treatment-planning computer to a linear accelerator. Because of the variety of treatment-planning systems and linear accelerators, significant effort has been expended to standardize the exchange of information among the imaging systems, treatment planning computers, and treatment delivery systems.

VERIFICATION OF DELIVERY

The final step in 3DCRT is that of quality assurance, verification that the radiation beams delivered to the patient are consistent with those planned for delivery. All components of the planning and delivery process need to be reviewed as part of a quality assurance process, including the validity of the treatment plan, the accuracy of the machine settings, the validity of the transfer of data from the planning system to the radiation machine, the accuracy of the portal for delivery of the radiation beam, the accuracy of the patient setup, and the accuracy of the radiation delivery.

The first step in verification is that of verifying that the treatment plan accurately reflects the radiation dose that is actually designed to be delivered to the patient. This is achieved by implementation of a quality assurance program for the treatment planning system. In such a program, one verifies that the treatment-planning system accurately depicts the patient images, contours, and beams that are provided as input into the dose calculations, and that the beam models are accurate, so that the doses calculated by the treatment planning system are accurate (9).

The next component of verification is that the machine setting determined by the treatment-planning system will deliver the correct dose to the target. Accuracy of machine setting is verified initially when the beam model is first commissioned and introduced into the treatment-planning system and is verified for each dose calculation by and independent calculation of radiation doses to individual points within the patient.

Next, it is necessary to verify that the machine settings, such as beam geometries, and monitor units are accurately transferred from the treatment-planning system to the machine. In many radiation oncology clinics, a record and verify (R&V) system is used to record the machine settings used to deliver the radiation beams to the patient, ensuring that machine settings lie within clinically accepted tolerances of the values established on the treatment plan. A component of a comprehensive quality assurance program verifies that the machine settings determined by the treatment-planning system are accurately transferred into the R&V system.

Another key step is to verify that the treatment field actually delivered to the patient is identical to the treatment portal as determined on the treatment plan. In order to accomplish this task, a radiographic image of the delivered treatment portal is acquired. The portal image is then compared to a DRR of the treatment field extracted from

the treatment-planning system. Ideally, the geometric relationship between the tumor target and the treatment portal would be compared, but tumors are rarely visible on portal images. Consequently, bony landmarks in the vicinity of the tumors are typically used as surrogates for the tumors. Originally, the portal image was recorded on radiographic film, but many radiation oncology clinics are acquiring this information using an electronic portal imaging device (EPID). The use of digital images produced by EPIDs allows for rapid display of the portal images as well as off-site review of the portal images. Figure 6 illustrates a DRR and a portal image used to verify the accuracy of the treatment portal.

One important issue regarding the use of portal images for treatment portal verification is the substantial difference in image quality between simulation and portal images. Simulation images are typically acquired in the energy range of 50–100 keV. In this energy range, the primary interaction between the incident X rays and the patient results in absorption of the incident X rays. Consequently, the only X rays that reach the detector are those that are not absorbed in the patient. Moreover, in this energy range, bone absorbs significantly more radiation than soft tissue; hence, the contrast between bony anatomy and the surrounding soft tissue anatomy results in clear, sharp radiographic images. Portal images are acquired at much higher X-ray energies, typically several megaelectronvolts, the energies that are used in radiation therapy. In this energy range, the difference in absorption of radiation between bone and soft tissue is significantly less, resulting in lower contrast. Moreover, the presence of scattered radiation resulting from X-ray interactions with the patient at these energies results in a significant amount of radiation reaching the detector that gives no indication of the point of origin, resulting in a noisy image.

In addition to verifying the geometry of the treatment portal, acquisition of a portal image is one of several techniques used to verify that the patient has been set up in a reproducible manner for each treatment. Because the treatment field is often positioned adjacent to critical uninvolved anatomic structures, accurate and reproducible patient positioning is essential so that these uninvolved anatomic structures do not get unnecessarily irradiated. Perhaps the simplest method of position verification is through the use of external markings. Lasers in the walls and ceilings are all directed to a particular point in space, the machine isocenter, where the axis of gantry rotation coincides with the axis of collimator rotation. In 3DCRT, the patient is often positioned so that the isocenter lies in the approximate center of the tumor volume. The points at which the lasers intersect the patient surface are marked and used on a daily basis to assist in ensuring that the patient is set up reproducibly.

In conjunction with external markings, patients are often placed in immobilization devices to assist in reproducible positioning. Immobilization devices have many forms. For example, invasive devices, such as stereotactic head frames, which are screwed into the patient's skull, can achieve submillimeter reproducibility and are necessary when the geometric tolerances are very small. When

Figure 6. A DRR of an anterior pelvic treatment field compared with a portal image of the same field used to verify that the patient is set up accurately and that the location and extent of the irradiated region is as per plan.

submillimeter tolerance is not as crucial, less invasive devices can be used, including thermoplastic masks, molds, and vacuum bags.

Portal-imaging studies have demonstrated differences between true setup errors and random uncertainties in patient setup, which are a consequence of the degree of patient immobilization, and have indicated guidelines as to when and how to correct for setup inaccuracies. In the treatment of some cancer sites, for example, the prostate, daily variations in patient anatomy have led to the development of more sophisticated methods of setup verification. Differences in bladder and rectal filling on a daily basis combined with the tight treatment margins typical of 3DCRT may cause one or more radiation beams to miss part of the target volume. One technique that enables correction for daily anatomic variations is to scan the patient just prior to treatment using an ultrasound technique. Figure 7 illustrates an example of the unit used in such an ultrasound process. The outlines of the target volumes and anatomic structures, which are extracted from the radiation treatment plan, are superimposed on the ultrasound scan, and the patient is moved so that the image of the target volume on the scan is superimposed on the outline of the target volume on the treatment plan, thus ensuring accurate delivery of radiation to the target volume. Figure 8 illustrates the use of the ultrasound images in realigning a patient.

Another promising technique involves placing a CT scanner in the treatment room in a configuration that

allows both imaging and treatment on the same patient couch. The patient is set up in the treatment position and then scanned. It is then possible to compare the CT image data set thus acquired with the data set from which the treatment plan is based, allowing for the patient to be repositioned or even replanned. Rather than allowing the patient table to move through the CT scanner, as is conventionally done, this device moves the CT scanner while the patient remains stationary, hence the device is referred to as “CT-on-rails”.

In addition to verifying that the radiation beams accurately irradiate the target volume and spare surrounding normal-tissue anatomy, it is essential to verify that the radiation dose actually delivered to the target is identical to the radiation dose prescribed on the treatment plan. This is achieved by means of a thorough quality assurance system, including a regular schedule of well-defined daily, monthly, and annual evaluations of the output of the radiation machine, including accurate measurements of the magnitude of the radiation emitted from the linear accelerator as well as the energy of the radiation (10). In addition, techniques exist for measurement of doses to accessible parts of the patient during treatment, using small radiation detectors such as thermoluminescent dosimeters (TLD) or diode detectors, which can be placed either on external surfaces of the patient or in accessible cavities within the patient. Current studies are underway to assess the safety and accuracy of radiation detectors that can be implanted into the tumor inside the patient.

CLINICAL CONSEQUENCES OF 3DCRT

Finally, it is necessary to determine whether 3DCRT represents an improvement in the treatment of cancer.

Treatment-planning studies can readily demonstrate that 3DCRT allows higher doses to be delivered to target volumes than was possible with conventional radiation therapy. Higher radiation doses have been shown to lead to increased rates of tumor control. An early study comparing 3DCRT to conventional radiation therapy in the treatment of prostate cancer was conducted by Pollack (11) in the mid-1990s. In this study, patients were randomly selected to receive radiation therapy based on conventional treatment planning or a dose ~10% higher based on 3DCRT. Pollack demonstrated a significant increase in freedom from failure for intermediate-to-high risk patients, but with some increase in rectal toxicity.

CONCLUSIONS

Three-dimensional conformal radiotherapy is a radiation treatment planning and delivery technique in which the design of the radiation-treatment portals is based on images of the tumor target. Planning is based on high resolution CT images that explicitly display the tumor as well as provide a mathematical model for the patient. Additional imaging modalities are often used to define the extent of tumor involvement more clearly. Sophisticated algorithms are used to calculate the magnitude of radiation dose deposited in the patient, allowing the assessment of the potential for tumor control as well as toxicity of the treatment plan. In order to make certain that the radiation is delivered to the tumor and not the surrounding uninvolved tissue, as indicated in the treatment plan, extensive quality assurance procedures are required that verify the accuracy of the geometry as well as the radiation dosimetry.

INTRODUCTION

Treatment of solid tumors typically involves some combination of surgery, chemotherapy, and radiation therapy. With any of these approaches—indeed, as with so much of

medicine—the objective is to eradicate or control the disease without producing unacceptable side effects. Radiation therapy, in particular, is used for one-half of all cancer patients in the United States, and can frequently contribute to the cure of a malignant tumor, or at least to a significant improvement in quality of life.

Intense localized irradiation of the region of a solid tumor can both incapacitate or kill cancer cells directly, and strangle them through damage to tumor-bed microvasculature. High doses of ionizing radiation will kill not only the cells of tumors, however, but also those of healthy tissues. So a successful treatment must target the tumor accurately, with little radiation ending up elsewhere; it would be of questionable benefit to eradicate a tumor of the esophagus if this also led to severe functional complications in the spinal cord.

Radiation therapy is therefore preceded by a careful, and sometimes extensive, planning process, and a search for a best treatment plan.

This article is based on material found in Ref. 1.

ASSESSING BENEFITS AND RISKS

Deciding upon a medical strategy, like most other activities in life, involves an optimization process. In some situations, the proper approach is so obvious (Take two aspirin and call me in the morning!) that one hardly gives thought to the matter. In the treatment of cancer with radiation, however, the decisions are usually much more difficult. It may not even be clear, in fact, how the various possible criteria should be balanced in choosing the best treatment.

Ultimately, the desired result of radiotherapy is the complete disappearance of the disease, or at least long-term palliation, without the onset of unacceptable side effects. For some types of cancer, such as carcinomas of the skin, the malignant cells can be exposed directly to radiation, with limited risk to any critical organs. Also, they may be inherently more susceptible to radiation damage than are the adjacent healthy tissues. The reasons for this, while not completely understood, involve the tendency of tumor cells to divide faster than healthy ones—if both kinds are irradiated, a greater fraction of the cancer cells will be undergoing division, during which time they are more vulnerable to radiation damage, and a greater fraction of them will die. They may also have a diminished ability to repair radiation damage. In any case, complete cure without complication is frequently achievable.

For diseases in which the neoplastic (cancerous) cells are relatively radioresistant or less accessible to irradiation, however, the odds are greater that a curative dose of radiation would cause extensive damage to surrounding healthy tissues. The amount of radiation to be delivered to the tumor region and the means of physically delivering it must then be determined by assessing the likelihood of effecting a cure or prolonged survival against that of inducing unacceptable complications.

Thus any new patient presents the radiation oncologist, in theory, with a fundamental, three-part problem. For

every reasonable treatment strategy (including the various reasonable dose distributions and their timing), the physician has to

1. Estimate the probabilities of eradicating the disease, on the one hand, and of inducing complications of a range of severities, including death, on the other; such numbers are, in general, not well known.
2. Assuming that they have somehow arrived at plausible values for these probabilities, the physician and staff must then assign a weight, or measure of the seriousness or undesirableness, perhaps relative to death by the disease, to all the possible complications; such an assignation cannot help but be highly subjective.
3. Finally, they must combine the probability and undesirability information for every strategy in such a way as to arrive at a medically significant overall figure of its merit; the treatment plan with the best such score would then indicate the regimen of choice. Unfortunately, there is no obvious or simple way of doing this.

Thus the physician and patient must together decide how much they would be willing to compromise the quality of life in an attempt to preserve it. Unfortunately, the currently available data on the probable outcomes of the different therapeutic approaches are both sparse and crude. The response of liver to non-uniform irradiation has been studied, for example, but this kind of work is still in an early stage (2,3). And even if the essential statistical information were available, there is no unequivocal way of weighting it with the necessary value judgments on harm in a systematic treatment-selection process. In other words, there is considerable art in treatment planning, in addition to the science.

A PRELIMINARY EXAMPLE

Let us begin by considering some of the difficulties to be found in even the simplest of idealized cases.

A hypothetical patient presents with pockets of lethal disease within a single vital organ, and will die if either the disease spreads or the organ fails. Suppose that it is possible to irradiate this tumor-bearing organ uniformly and without risk to other tissues. And finally, assume that the dose-response characteristics both of the tumor and of the organ itself have separately been determined, Fig. 1.

The probability that the patient will survive the ravages of the disease, and that the tumor will be controlled, $S_{\text{tumor}}(D)$, will improve with increasing dose, D , until every viable tumor stem cell has been eliminated. On the other hand, the odds that the patient will escape unacceptable (e.g., life-threatening) complications to the organ, $S_{\text{organ}}(D)$, will be a decreasing sigmoidal function of D . (Either way, S is used to denote the probability of patient survival, or well being.) The parameters $S_{\text{tumor}}(D)$ and $S_{\text{organ}}(D)$ are also known as the tumor control probability (TCP) and normal tissue complication probability (NTCP), respectively, and by other names as well.

Figure 1. For this idealized, hypothetical example, the tumor is spread throughout a single critical organ, and only that organ is irradiated. The probability of the patient surviving the ravages of the disease, $S_{\text{tumor}}(D)$, increases with dose, D , to the tumor volume. Unfortunately, the likelihood of escaping an unacceptable complication that might arise from the treatment, $S_{\text{organ}}(D)$, decreases with D . The compound odds of both eradicating or controlling the disease and avoiding the complications is then $S_{\text{tumor}}(D) \times S_{\text{organ}}(D)$. This overall survival probability, $S_{\text{patient}}(D)$, reaches its maximum for some optimal value of the dose, D_{opt} .

At any level of uniform dose, D , the overall likelihood of uncomplicated survival, $S_{\text{patient}}(D)$, is then given by the law of multiplication of probabilities for independent events,

$$S_{\text{patient}}(D) = S_{\text{tumor}}(D) \times S_{\text{organ}}(D) \quad (1)$$

shown as the dashed line. At low doses, failure of the treatment through continuing tumor growth is likely. At high doses, an unacceptable complication in the organ is liable to occur. But between these two extremes, the patient may well survive both the disease and the effects of the treatment. At some particular optimal value of the dose, D_{opt} , the probability of that happening is greatest, and $S_{\text{patient}}(D)$ passes through a maximum.

Figure 1 illustrates a case in which there is a fairly broad range of dose over which the probability of uncomplicated cure is high, a situation said to be of good therapeutic ratio. When this is not the case, radiation treatment is a less promising option.

If the sole consideration in selecting D were the maximization of the probability of complication-free survival, then the appropriate value would be D_{opt} . This theoretical criterion, however, is often difficult to apply in practice, since it is generally accepted that the incidence of severe complications must be kept to a "tolerable" level. Hence, the dose actually chosen for treatment would normally be somewhat $< D_{\text{opt}}$, and the odds of its failure would likely be correspondingly greater.

This example is highly idealized, of course, but it can serve as a backdrop against which to contrast some of the issues that arise in real cases:

1. It is frequently difficult to determine in 3D, even with computerized tomography (CT), positron emission tomography (PET), or magnetic resonance imaging (MRI), the location and extent of a tumor; and it is virtually impossible to track down nearby microscopic clusters of neoplastic cells which, if untreated,

might themselves grow into tumors. The temptation is therefore to treat the region thought to harbor disease with generous spatial margins of healthy tissue; the risk of inducing complications, on the other hand, will increase with the volume of healthy tissue taken to high dose.

2. Commonly in clinical practice, one standard (but not necessarily optimal) treatment objective is to irradiate the tumor as uniformly as possible (4–10). But it would be better to sculpt a unique, patient-specific distribution of dose, non-uniform within the region of suspected disease, that takes into account the spatial variations in the density and responsiveness of tumor cells, the uncertainty in the physician's estimate of their whereabouts, and the sensitivity and criticality of the infiltrated and surrounding healthy tissues (4,5,9). The kinds of information necessary are not readily obtainable.
3. Equation 1 is meaningful only when any possible complication is of a seriousness comparable to that of death. The various complications that can arise in practice, however, differ greatly in severity. (And who is best able to assess the severity? The patient? The doctor? The insurance companies?) In any case, the gravity of any one acute or chronic complication (not only its probability of occurrence) is likely to vary with dose.
4. Equation 1 is valid only so long as $S_{\text{tumor}}(D)$ and $S_{\text{organ}}(D)$ are completely independent of one another; if the tumor reacted to intense irradiation by emitting a toxin or other biochemical that compromises the resistance of healthy organ tissue (or of the entire person) to radiation damage, for example, then equation 1 would begin to break down. Likewise, a number of organs doubtless will be at least partially irradiated in any real treatment, and some of these might behave as coupled systems, affecting one another's radiation responses; here, too, the generalization of equation 1 becomes nontrivial.
5. Even if one could apply equation 1 directly in some situations, information on $S_{\text{organ}}(D)$ is difficult to obtain from patient or radiobiological data, and little of it is yet available (11,12). Most healthy organs in a patient undergoing treatment will be irradiated non-uniformly, moreover, making the prediction of their responses considerably more complex.
6. The above points have concerned the spatial distribution of dose. The timing of treatments is equally important, adding yet another facet to the problem. It has been found that healthy tissues fare better than do tumor cells if the dose is fractionated, or spread out over an extended period; they seem to retain more ability to repair damage to DNA over time. Since the normal tissue is irradiated heterogeneously, there may be, in addition to the cellular repair between the irradiations, organ repair on a macrolevel; that is, tissue rescuing units (cells migrating from the healthier parts of the organ, which received much lower doses) may help the organ to reestablish some of its damaged functionality.

Treatment is therefore delivered typically in 20–30 smaller fractions, rather with a single shot.

These and other issues, together with patient-specific factors, leave the radiation oncologist with a formidable, multidimensional treatment-planning optimization problem. The usual solution in real clinical situations is to sublimate most aspects of the probabilistic issues described above, and employ empirically established, time-tested protocols. It is in modifying these procedures, as warranted by the condition and response of the individual patient, that the acquired skills and informed judgment of a radiation oncologist are essential.

THE TREATMENT PLANNING PROCESS

The objective of curative radiotherapy is to deliver a tumoricidal dose to a clinically determined target volume (i.e., the volume of suspected gross disease plus a suitable margin), while depositing safe doses in the neighboring healthy tissues. The optimal strategy depends on the sensitivity of the tumor to radiation and its accessibility to treatment, and on the sensitivity and criticality of adjacent tissues that will be unavoidably dosed in the treatment.

For a superficial, radiosensitive lesion, it is often appropriate to employ an electron beam from a linear accelerator, which deposits most of the dose near the surface and leaves the underlying tissues unaffected.

The most common means of treatment of a deep-seated tumor in a modern medical setting is by means of highly penetrating, high-energy photons from a linac. (This article will use external photon-beam examples, but exactly the same issues are of concern for any form of radiotherapy.) Typically two to five X-ray beams cover a wide enough area (tumor region plus a *margin*) in their cross-fire region to eliminate any small clusters of cancer cells that may have extended into tissues adjacent to the primary target. The beams are arranged so as to deposit an adequate and uniform dose to the lesion, but without exceeding the tolerance levels in healthy tissues elsewhere. (It may often be helpful later to add a local *boost*, with a smaller-field photon or electron beam, or with brachytherapy, to increase the dose locally in the immediate vicinity of the primary tumor.) The resulting Compton (which predominate at high energies in soft tissue) and photoelectric interactions ionize the tissues they traverse. The production of free radicals and other molecular instabilities leads to damage to DNA and to the tissue microenvironment. That, in turn, is intended to kill the tumor cells.

In the first step in the treatment planning process itself, the radiation oncologist and treatment planning staff identify the tumor, through some combination of CT, MRI, PET, or by other means, and also the healthy critical structures to be avoided; multimodality imaging, in particular CT–PET fusion, is playing an increasingly important role in this. The oncologist then determines, based on experience and generally accepted treatment protocols, the dose that should be delivered to the tumor, and limits (to the known tolerance levels) the doses to be allowed at the normal tissues and critical organs. The radiation oncologist also

decides upon the *fractionation* schedule (the timing of the treatments.)

After the position, size, and shape of the lesion are determined, an *isocenter* (the single point at which the central axes of all treatment fields intersect) is chosen within it. Information on the patient's external shape, variations in tissue density, tumor geometry, and so on, is entered into the treatment planning computer, and one or more transverse planes are selected for the future display of the organs and superimposed topographical *isodose map*, with its contour lines of constant dose deposition.

The radiotherapy physicist and/or dosimetrist (a professional especially trained in treatment planning) then make an educated guess as to the energy, number, orientations, sizes, and weightings (the relative strengths, or relative contributions to the total dose at isocenter) of the beams, which can either be stationary or rotate through an arc, taking into account ways to block or otherwise modify parts of each one.

The computer then draws upon previously stored data to generate a representation of the spatial distribution of dose imparted by each of these beams, correcting for the patient's body shape, the lower density of lung tissue, and so on. Finally it sums, at each point of interest, the doses delivered by all the beams together, thereby producing a 3D isodose map. Although some work remains to be done for tissue inhomogeneities (especially lung and bone) for both photon and electron beams, most of the necessary dose calculation software has been developed. With our current abilities to model the interaction of high energy photon and charged particle beams with matter, and to localize healthy and pathological body structures, the computer can generate such maps with uncertainties in dose of less than a few percent.

In all likelihood, the plan can be improved by changing some of the beam parameters, so the process is repeated iteratively several times with different treatment configurations until a good (or at least clinically acceptable) dose distribution is obtained, as determined visually. (Numerical information, such as that from dose-volume histograms and the other approaches discussed below, is also being used increasingly as a guide.) This may involve the manipulation of a fair number of variables, and the plan ultimately selected may be only locally, rather than globally, optimal. Indeed, the limiting factors in the selection process may be the experience, creative skills, patience, and available time of the staff. This process is usually referred to as *forward treatment planning*.

The radiotherapy community has established a few empirical ground rules for judging treatment plans:

1. The entire tumor and a small margin should all receive at least the prescribed dose, and irradiation of the target volume should be reasonably uniform, to ensure the absence of any cold spots.
2. The highest dose isodose lines or surfaces should, when superimposed upon a set of CT or MRI scans, conform closely to the target volume.
3. The dose should decrease rapidly away from the target. Although a fair amount of healthy tissue

may have to be irradiated (and may thereafter become nonfunctional), the volume of it taken to high dose should be as small as possible, and dose falloff within it should be as fast as possible.

4. Dose to most of the lung, to all of the spinal cord, and so on, must be kept below their presumed tolerance levels; the tolerance dose of a healthy organ, however, may depend on the fraction of it that is being irradiated—although for some organs, such as the spinal cord or some of the brain, the dose limit applies to any small volume of tissue—which clearly complicates matters.

In summary, dose throughout the target should achieve the prescribed level, the volume of healthy tissues should be minimized, and doses to critical structures should be below their tolerance levels.

EXAMPLE OF PLAN OPTIMIZATION

A unique treatment plan of beam configurations must be designed for each patient, based upon the specific clinical situation and requirements. Figure 2, for example, presents three possible plans and dose distributions for treating an oblong tumor of the pancreas, following surgery. The primary objectives are to take the entire tumor to a curative dose, typically 50–68 Gy, while making certain that the normal tissues of concern, the kidneys, spinal cord, and small bowel, remain functional. We shall examine a single-field plan first, then a pair of parallel-opposed fields, and finally a four-field plan.

For the single anterior field configuration, the dose across the target region ranges from 125% to 80% of the value at isocenter, taken to be at the center of the tumor, Fig. 2a. The spinal cord is at ~ 65% of the treatment value, which it can tolerate, and the maximum dose of 160% is situated in the anterior subcutaneous tissue layer. The lateral aspects of the kidneys are clear of any substantial dose. But this plan is not satisfactory because of both the cold area within the tumor and the anterior hot region, even though it has good cord- and kidney-sparing characteristics.

When a posterior beam is added to the anterior beam, the dose uniformity improves greatly, Fig. 2b. The dose gradient across the target region for this parallel-opposed plan is of the order of 5%, and the kidneys are still okay. The spinal cord now receives 105% of the target dose, however, which is too high.

Figure 2c is a four-field "box" plan that shows dose uniformity across the target and a high dose encompassing it. The spinal cord gets 60% of the tumor dose, and the kidneys and anterior bowel are spared reasonably well.

After going through such an analysis for a number of potential plans, it is usually apparent which ones work best for the patient. In the case of Fig. 2, an experienced physicist or dosimetrist would know immediately to begin with the box, but still would have to play with it to find the best weightings, or relative contributions, of the four fields. For some more difficult cases, it takes considerable effort to find a set of fields, and their settings, for which the ratio of

(a)

(b)

(c)

Figure 2. As possible plans for treatment of the pancreas with 10 MV X-ray beams, the physicist and/or dosimetrist consider the isodose maps for (a) a single AP field; (b) a pair of parallel-opposed fields; (c) a standard four-field box plan that covers the tumor relatively uniformly, spares most healthy tissue, and does not exceed the tolerance levels of either the kidney or the spinal cord.

dose in tumor to dose in the surrounding tissues is high; tumor dose is reasonably uniform; relatively little normal tissue is taken to high dose; and critical organs are not in serious jeopardy.

THE NEED FOR QUANTITATIVE OPTIMIZATION TOOLS

At present, visual inspection is still the standard process for optimizing isodose plans, as is done in this example, but this can be highly time and energy consuming. Meanwhile, the patient population is growing rapidly as the baby boomers reach older ages. Also, treatment strategies are becoming significantly more complex and demanding, especially so with the advent of intensity-modulated radiation therapy (IMRT), in which the beam direction, shape, intensity, and so on, may vary continuously over time during irradiation. So efficiencies in treatment planning that once were desirable are now becoming essential.

A means of assigning reliable numerical scores to competing plans would be of great value, not only in speeding up the through-put of routine cases, but also in facilitating decisions on the more complicated ones. Such scoring capability, moreover, forms the backbone of any computer-based expert system developed for automated treatment plan decision making. Much of the heavy mathematical machinery to find a maximum in an *objective function*, or *Figure of Merit*, is already available; the major problem, rather, is to find clinically meaningful criteria by which plans may be judged, and quantitative forms in which these criteria can be expressed.

Two fundamentally different approaches have arisen to the use of computers in judging treatment plans.

The first draws upon some of the physical and geometrical rules of thumb that are commonly adopted in visual plan assessment. How constant is the dose throughout the target volume, and does the prescribed-dose isodose surface conform closely to its surface? How much dose is being deposited in healthy tissues, and is the tolerance level of any critical organ exceeded? Such criteria have the benefits of being easily understood and clinically widely accepted, and of being easy to implement in an automated optimization system. On the downside, it is not clear that the plan with the most uniform tumor dose is necessarily most likely to effect a cure, or that the one with the lowest average dose to healthy tissue will most probably avoid complications. The obvious physically-based criteria, either individually or in combination, do not necessarily reveal the strategy most likely to work.

The second is somewhat more abstract, and more removed from traditional clinical practice. It attempts to draw upon various kinds of available dose-response information on normal tissues to estimate the probabilities that any particular dose distribution in an organ will lead to complications (13–15). This biologically and probabilistically based mathematical modeling work is still in early stages of development, and obtaining and interpreting the necessary data on radiation damage is difficult. Nonetheless, some researchers feel that the approach has perhaps greater potential for eventual success.

Either way, three aspects to the optimization process must be addressed:

1. First, it is necessary to decide what would constitute an ideal treatment. A plan judged to be nearly perfect according to one criterion might well be far from it according to another; the best overall optimization criterion to be found might, indeed, be some balanced amalgam of several others.
2. One must then find a quantitative measure of the deviation of any computer-generated plan from the ideal.
3. Finally, an algorithm is needed to search out quickly the plan that deviates least from the ideal, as beam weights, field sizes, and other parameters are varied.

OPTIMIZATION USING PHYSICAL/GEOMETRICAL CRITERIA

Several traditional criteria for the visual optimization of plans are in common use. One would like the prescription-dose isodose surface to wrap as closely as possible around the target volume. Also, some have argued, the dose throughout the tumor should be uniform. It is desirable to keep the amount of dose to healthy tissues to a minimum, and doses to all critical structures must be maintained below their tolerance levels. All of these ideas, it turns out, have been easy to incorporate into computer-based optimization programs.

For all of what follows, we shall partition the region of interest into J small voxels, all of volume Δv , and assume that a particular configuration of beams delivers the dose D_j to the j th such voxel. For simplicity, we shall also consider situations in which all beam parameters have already been chosen by the treatment planner, with the exception of the best values of the relative weightings, w_k , of the K beams (w_k refers to the relative dose at isocenter produced by the k th field).

For any possible treatment plan, the dose in the j th voxel is now fixed completely by

$$D_j = \sum_k^K d_{jk} w_k \quad (2)$$

where $w_k \geq 0$. For each particular configuration of beams, the matrix of elements d_{jk} determines the dose deposited at the j th voxel by the k th field. A standard treatment planning program is designed to calculate such matrices. Changing the energy, orientation, blocking, and so on, of the beams, however, will result in a revised matrix of d_{jk} values.

Healthy Tissue Integral Dose

The simplest single measure of the irradiation of a block of healthy tissue is the *integral dose* (ID). Integral dose is defined through the function

$$f_{ID} = \sum_j^J D_j \Delta v \quad (\text{healthy tissue}) \quad (3a)$$

where the sum is confined to healthy tissues outside the target volume. Equation 3a serves as the objective function that is to be minimized, by manipulating various beam parameters, when integral dose is selected as the optimization criterion. Note that apart from a factor of $J\Delta v$, the integral dose is just the average voxel dose. By equation 2, the integral dose may be expressed as

$$f_{ID} = \sum_j^J \sum_k^K d_{jk} w_k \Delta v \quad (\text{healthy tissue}) \quad (3b)$$

It is intended, moreover, that the distribution deliver at least a tumoricidal dose, $D_{\text{prescribed}}$,

$$D_l \geq D_{\text{prescribed}} \quad (\text{tumor}) \quad (4a)$$

at previously selected points within the target volume. Similar constraints,

$$D_{l'} \leq D_{\text{tolerance}} \quad (\text{point } l' \text{ in critical organ}) \quad (4b)$$

protect any critical structure, such as the spinal cord.

The task now is to find those weights that deliver the prescribed dose to the target volume, but minimize the integral dose objective function, while keeping irradiation of certain voxels below specified limits. The objective function is linear in the weights w_k , the variables of interest, and equations 3 and 4 define a routine linear programming problem whose solution can be obtained in seconds with the Simplex method.

Despite the mathematical attractiveness of the integral dose objective function, its application does not necessarily lead to results in accord with clinical experience. Taking an entire organ to 30 Gy, for example, yields the same f_{ID} as does taking half of it to 60 Gy; but the two irradiation schemes could lead to vastly different results if the organ's tissues exhibit a response threshold at 45 Gy. This may serve as a reminder of a fundamental, but sometimes overlooked truth: The availability of powerful mathematical optimization algorithms does not ensure the clinical value of an objective function upon which they can be employed.

Optimal Point Doses

In perhaps the most widely explored and successful of the physical-geometric approaches, the physician prescribes the doses to be delivered at a designated set of points within the patient; some of these, in the tumor and in critical organs, act as rigid constraints. The treatment planning system then uses available mathematical techniques to find that plan (i.e., set of beam sizes, angles, relative weightings, etc.) for which the calculated doses at these points come closest, on the whole, to the prescribed values. Points might be selected, for example, on the tumor border, to force the prescribed-dose isodose surface to envelope it closely, while also satisfying the constraint requirements. Alternatively, they might be placed throughout the target volume, to maximize tumor dose uniformity.

Again, let the variable parameters be the relative beam weightings, and now suppose that the objective is to maximize tumor dose uniformity (TDU). The M prescription

points will be scattered throughout the tumor, and, by our criterion, doses there should all be nearly the same. The deviation of any plan from the ideal may be expressed as

$$f_{TDU} = \sum_m^M (D_m - D_{av})^2 \quad (5)$$

where the D_m provided by equation 2 are functions of the w_i values, and D_{av} is the average dose for the selected points.

Similar objective functions can be devised to force the prescribed isodose line to lie as near as possible to the target volume boundary, or to cause certain discrete anatomic regions to receive prescribed doses. Methods such as quadratic programming and constrained least-squares algorithms are available for rapidly finding extrema in functions of the form of equation 5, subject to constraints like equations 4. While optimization with such objective functions may not alone yield clinically appropriate plans, they can often provide starting points for further manual searching.

Developments in computer-controlled radiation treatment have stimulated renewed interest in such approaches. Computers have long been employed to monitor a linear accelerator's treatment parameters, verifying and recording every field's gantry angle, jaw setting, dose delivered, and so on. More recently, with the growing adoption of IMRT systems, dedicated computers are controlling variables such as collimator configuration, dose rate, gantry angle, table movements in real time. While such flexibility allows the implementation of highly refined treatment plans, the associated planning process can be very cumbersome and time consuming. The problem would be totally unmanageable were it not for the availability of various objective functions and search programs (known as inverse planning algorithms) to help in finding suitable time-dependent linac output parameters (16,17).

References that describe optimization by way of physical-geometric criteria may be found in Ref. 18.

BIOLOGICAL-PROBABILISTIC APPROACHES TO TREATMENT PLAN OPTIMIZATION

The physical-geometric approaches just discussed could perhaps best be called pragmatic. They reflect mathematically some of the conventional clinical criteria for plan optimization; as such, they can discriminate among plans only as effectively as do the standard clinical guidelines that they mimic. They cannot choose, for example, between a treatment that irradiates a sizable portion of lung to a dose near its tolerance level and another treatment that takes even more lung to a somewhat lower dose, other aspects of the case being equal.

The biological-probabilistic methods, admittedly in their infancy, attempt to address directly the fundamental question: How probable is it that some given spatial and temporal distribution of dose will eradicate or control a tumor, and do so without resulting in severe complications? Asking this returns us to the thinking illustrated in Fig. 1.

Limited theoretical progress has been made on several fronts. Among them, we can derive some dose-response curves of the general form of S_{tumor} and S_{organ} from more

basic radiobiological principles. We have elementary ideas on how to use such information to estimate the probability of complications arising in a healthy organ irradiated non-uniformly, and we can crudely model the radiation response of a tumor.

Shape of a Tumor Dose-Response Curve, S_{tumor}

Of an initial cluster of $n(0)$ of any kind of cells, only $n(D)$ of them will remain viable after receiving an initial dose of D Gy; the rest will die before or while attempting to divide. If an incremental dose, ΔD , soon follows (before repair or repopulation occurs), the number of surviving cells diminishes by an additional

$$\Delta n = -c(D)n(D)\Delta D \quad (6a)$$

equivalently,

$$c(D) = -\Delta n/n(D)\Delta D \quad (6b)$$

is the probability per unit dose of inactivating a cell that has already been given D . There is no physics or real biology in the picture yet—everything so far is just bookkeeping.

For the purposes of this article, the discussion will be greatly simplified by restricting the biophysics being considered. Although low Linear Energy Transfer (LET) radiations, namely high-energy photons and electrons, are almost always employed in practice, here the treatment is by way of a beam of energetic, heavy charged particles, such as cyclotron-produced protons. Every proton leaves a dense trail of ionization in a cell it traverses, and damage to any DNA molecule it passes sufficiently close to is likely to involve irreparable breaks in both sugar-phosphate strands (19). Cells in which this occurs will probably be completely inactivated by a single hit of an incident particle; most cells more distant from its track, on the other hand, will be oblivious to its passage. Cell killing in this situation is thus an all-or-nothing affair. Surviving cells retain no memory of earlier irradiations, and $c(D)$ becomes a constant, commonly called $1/D_0$, independent of dose.

In addition, it is assumed that the tumor cells of concern do not communicate with one another in any significant way; that is, radiation damage in one voxel does not notably affect (by releasing toxins, cutting off the influx of nutrients, etc., as in "bystander" phenomena) the dose-response characteristics of an adjacent voxel.

After replacing $c(D)$ in equation 6 with $1/D_0$, the associated differential equation

$$dn/dD = -(1/D_0)n(D) \quad (7a)$$

can be integrated to yield

$$n(D)/n(0) = e^{-D/D_0} \quad (7b)$$

This is the fraction of cells, either in the tumor or in any small part of it, that survives irradiation to dose D . It may be viewed equally well as the survival probability for an individual tumor cell. Expressing $n(0)$ as the product (ρV) , where ρ is the tumor cell density and V is the tumor volume, this becomes

$$n(D) = n(0)e^{-D/D_0} = (\rho V)e^{-D/D_0} \quad (7c)$$

This is the number of cells statistically expected to survive when the entire tumor receives a dose of D . All the relevant radiobiology and radiation physics reside within D_0 , which can be a complex function of any number of interesting parameters that may, or may not, be understood. (With X rays or electrons, single-strand DNA breaks occur; some degree of repair can take place, and $c(D)$ is not independent of D . Integration of equation 7a then leads to a cell survival curve with a shoulder, rather than equation 7c.)

It is believed that a tumor can repopulate from a single clonogenic cell. The desired outcome of a curative treatment must therefore be the total eradication of all tumor cells. That is, the probability that *no* cells survive must be high. Poisson (or binomial) statistics provides a way of assessing that probability: if the average number of times some event takes place in a situation of interest is μ , then the probability of exactly zero such events occurring, $P_\mu(0)$, is $e^{-\mu}$,

$$P_\mu(0) = e^{-\mu} \quad (\mu = \text{average number of events}) \quad (8a)$$

In the present case, the average number of cells expected still to be clonogenic after an irradiation of D is given by equation 7c. From equation 8a, then, the probability, $P_D(0)$, that there will be *no* tumor cells left viable is

$$S_{\text{tumor}}(D) = P_D(0) = e^{-(\rho V)e^{-D/D_0}} \quad (8b)$$

This can be rewritten in terms of the geometrical characteristics of the curve, namely D_{50} the dose resulting in 50% probability of complication, $S_{\text{organ}} 0.5$ (see also Ref. 20), and slope, γ_{50} :

$$S_{\text{tumor}}(D) = (1/2)^{e^{2\gamma_{50}(1-D/D_{50})/\ln 2}} \quad (8c)$$

This fits clinical data sufficiently well (21,22); indeed, a number of tumor cell populations characterized by different parameter values result in almost indistinguishable sets of dose response curves, in part because of strong correlations between the parameters. The D_{50} and γ_{50} values for a number of sites have been published (21).

Equations 8b and 8c provide, and Fig. 1 displays, one particular form for the probability, $S_{\text{tumor}}(D)$ of equation 1, that the patient will survive the disease. It increases sigmoidally with dose, as certainly expected. It also decreases exponentially with tumor size; equation 8b indicates that the doses required to eradicate (with equal probabilities of success) two otherwise identical tumors that differ only in pre-irradiation volume are related as

$$D_2 = D_1 + D_0 \ln (V_2/V_1) \quad (8d)$$

This model is simple but, not too surprisingly, it agrees with the clinical finding that larger tumors require more dose to achieve a cure than do smaller tumors of the same histological type.

Equation 8 describe the irradiation characteristics of a tumor exposed uniformly. The result is of legitimate clinical interest since it is common practice to attempt to impart a fairly flat dose across the target volume. In the case of non-uniform irradiation, the tumor can be viewed as

consisting of J voxels that receive doses D_j , with control probabilities of $s(D_j)$, again assuming their statistical independence. The parameter S_{tumor} is then given by

$$S_{\text{tumor}} = \prod_j^J s(D_j) \quad (8e)$$

One of the main characteristics of a tumor is its comparatively fast repopulation rate. To account for this in conjunction with the Poisson (or binomial) distribution, several authors in the 1980s proposed setting the initial number of clonogens to $n(0)$, after which $n(t) = n(0)e^{-\lambda t}$, where λ and t are the rate constant and repopulation time, respectively (23–26). This approach predicts a $S_{\text{tumor}}(t)$ that always tends to zero for large post-treatment times, which is incorrect. Later, taking clonogen repopulation between fractions (27–30) into account lead to the Zaider–Minerbo model (31) of $S_{\text{tumor}}(t)$, which is applicable for any temporal treatment protocol. An expression for $S_{\text{tumor}}(t)$ with different time intervals between consecutive irradiation fractions and with varying cell survival probability per fraction was obtained by Stavreva et al. (32) based on the Zaider–Minerbo approach. Animal experiments support the validity of the Zaider–Minerbo approach (32).

Other approaches to the determination of S_{tumor} are discussed in the literature (33–36).

Integral Response for a Healthy Organ

Several ways have been devised to address the non-uniform irradiation of healthy tissues. One of these is an extension of the integral dose idea, introduced in equations 3 and 4. It does not focus on the spatially varying dose distribution within a tissue *per se*, as do the physical–geometric approaches, but rather on the local biological response that the dose elicits. Variation on the approach, of a range of levels of complexity, have been discussed by a number of researchers (18,37–41).

Imagine an organ or biological compartment that produces some physiologically important substance (such as a critical enzyme or hormone) or that performs an important task (like phagocytosis or gas exchange). If too many of its cells are inactivated by irradiation, then the organ cannot do its job adequately, and the organism runs into trouble. As before, mathematically partition the organ into J small volume elements of size Δv , and assume that the radiation response of any such voxel (or of the cells within it) is nearly independent of its neighbor's response. If, moreover, high LET radiation is again involved, the dose–response relationship is of the form of equation 7b, where D_0 contains all the important biophysics.

Of the entire organ, only the fraction

$$v = (1/J \Delta v) \sum_j^J e^{-D_j/D_0} \Delta v \quad (9a)$$

of its tissue will remain functional, where $(J \Delta v)$ is its volume. (The parameter $(1 - v)$ thus provides a direct measure of the amount of radiation damage to the organ.) For the case of nearly uniform irradiation to the level D ,

v reduces to the

$$n(D)/n(0) = e^{-D/D_0} \quad (9b)$$

of equation 7b. This observation, along with the form of equation 9a, suggests that v be viewed as a generalized, or spatially averaged, dose-response parameter, prompting adoption of the name “integral response” (18,34).

The probability that the patient will escape serious complications, S_{organ} , is a nondecreasing function of the relative amount of organ that remains intact,

$$S_{\text{organ}} = S_{\text{organ}}(v) \quad (9c)$$

the shape of which must be obtained experimentally or by other means (39,40). The parameter $S_{\text{organ}}(v)$ and equations 2 and 9a together define the integral response (IR) objective function, f_{IR} , and the optimization problem is bound by the constraints of equations 3 and 4.

If Q radiobiologically independent organs are irradiated, and if the possible complications are all of comparable severity, then the overall survival probability may be given by the product

$$S_{Q \text{ organs}} = \prod_q^Q S_{\text{organ } q} \quad (9d)$$

Automated treatment plan optimization may then be carried out, in principle, with a combination of equations 2, 4, and 9.

Another possible method of handling non-uniform irradiation of such an organ is based on its N -step dose-volume histogram. The idea is to reduce it in such a fashion as to yield a revised histogram that corresponds to the same complication probability, but that contains only an $(N - 1)$ steps; this calculation is repeated $(N - 1)$ times, until there is left a single-step histogram, the S_{organ} of which can be obtained from experiment or clinical observation.

Several algorithms have been proposed for carrying out the histogram-reduction process (42–47).

Healthy Organ Composed of Separately Critical Voxels

The integral response objective function is based on the effectiveness of operation of a healthy organ taken as a unit (48). A radically different approach is needed for an organ, such as the spinal cord or certain regions of the brain, that behaves like a chain or computer program, in which serious complications in any single small part can spell disaster for the whole.

Once again, consider an organ made up of J radiobiologically independent voxels. Let $s(D_j)$ refer to the probability that the organ will suffer no serious complications when the j th voxel is taken to dose level D_j and the rest is left unirradiated. If the entire organ is to escape damage, each of its J parts must do so separately, and

$$S_{\text{organ}} = \prod_j^J s(D_j) \quad (10a)$$

If the small-volume tolerance dose is exceeded in even a single voxel, then the objective function S_{organ} can become perilously low. If the organ is irradiated uniformly,

incidentally, equation 10a reduces to

$$S_{\text{organ}} = [s(D)]^J \quad (10b)$$

The methods just described for dealing with nonuniform irradiation make use of the assumption of the radiobiological independence of adjacent voxels. While this assumption clearly is not valid for most organs, nor perhaps for tumors, it may apply to some (e.g., the blood pool). More importantly, models built upon it may serve as jumping-off points for the development of more realistic pictures.

Other approaches to the determination of S_{organ} are discussed in the literature (49–52).

CONCLUSION

The radiation response of a tissue depends in an extremely complex way on a number of parameters, some of which the radiation oncologist can control directly, some indirectly, and some not at all. One can choose the modality (X rays, electrons, gamma-rays, protons, neutrons); the volume to be irradiated; the dose per fraction and number of fractions; the administration of response-modifying drugs; and the spatial dose distribution in healthy tissues. Some of the generally uncontrollable (or weakly controllable) parameters are radiosensitivity differences of different constituent parts of a tissue; tissue concentrations of oxygen, drugs, toxins, and other compounds; numbers of cells in each portion of the mitotic cycle; differential cell population kinetics; and repair of radiation-induced cellular injury. Manipulation of directly controllable variables may lead to changes in others: reoxygenation; differential cell cycle phase redistribution; differential recruitment of proliferative cells; and differential repair.

In view of this complexity, it is not clear how effective empirical or *ab initio* mathematical modeling can be in providing clinically useful descriptions of processes as intricate as the kinetics of irradiated tissues. At the present time, the subject is largely of academic interest. But it is to be expected that over the next several decades, computer-based expert systems will continue to spread throughout all of medicine. This development, together with the increasing automation of radiation delivery systems, will doubtless cause the search for quantitative methods of treatment plan optimization to expand.

RECORDERS, GRAPHIC

HERMAN VERMARIEN
Vrije Universiteit Brussel
Brussels, Belgium

INTRODUCTION

Graphic recorders, as considered here, are essentially measuring instruments that produce in real-time graphic representations of biomedical signals, in the form of a permanent document intended for visual inspection. Recorded data are thus fixed on a two-dimensional (2D) medium which can simply be called “paper” (although the material applied may differ from ordinary writing paper); A so-called hard copy of the information is generated. Equivalent names are paper recorder, direct writing recorder, plotter, chart recorder, and strip chart recorder (if long strips of paper are used); In some cases, the more general term hard-copy unit is also applied. The nomenclature oscillograph is sometimes used (in correspondence with the other display instrument, the oscilloscope). By the aspect of visual inspection the graphic recorder is distinguished from other data storage devices (e.g., magnetic or optical disk, solid-state memory), whereas in the property of permanence graphic recording differs from visual monitoring as realized by the oscilloscope or the computer screen. Real-time paper recordings have the benefit of direct visual access to signal information, allow immediate examination (and re-examination) of trends (as long strips of paper can be used), present better graphic quality than

most screens and can be used as a document for scientific evidence.

The graphic records are inspected through the human visual waveform recognition abilities; Moreover, discrete parameter values can be derived that are further evaluated. For the latter purpose, the measuring ruler still continues to be an intensively used instrument. Values for the physical variables presented, including time, can be derived, usually by comparing different related biomedical signals that were simultaneously recorded. For this purpose most biomedical recorders are multichannel recorders, which are able to process a set of signals. As the information has to be stored, the content of the records cannot be limited to the naked signal tracings; It is obviously essential that additional information concerning the recorded signals (identification, calibration, etc.) and the experimental circumstances (date, subject, experiment description, stimulus type, etc.) be kept in file, by preference directly on the recorded charts.

Two primary aspects describing the performance of the graphic recorder are (1) the properties of the instrument as a recorder of information, that is, measuring accuracy and the ability to display additional information, and (2) the quality of graphics, implying the clearness of the tracings and the overall graphic layout (e.g., including identification of the curves by color difference) in relation to ergonomics in visual examination. Also, the stability in time (permanence) of these graphic qualities can be catalogued under item 2. Secondary aspects (but not necessarily less important to the user) are ease of control of the apparatus (adjustments, calibration, adding alphanumeric information, remote control, computer connection and communication possibilities, paper loading), input amplification and signal conditioning facilities, unavoidable maintenance (ink, pens, mechanical parts), costs (the cost not only of the apparatus, but also of maintenance and, not negligibly, paper), and service life.

In early physiological experiments on mechanical functioning, such as muscle contraction, recording was performed with the aid of a directly coupled writing stylus; Suspended with minimal weight and friction, the stylus arm was applied as a cantilever, one end connected to the contracting muscle, the other end provided with a tip writing on a rotating drum. A directly coupled method is found in the spirometer: The low weight air cavity of the spirometer, which moves up and down as the subject expires and inspires, is mechanically linked to a pen writing on calibrated paper that moves at constant velocity, thus generating a trace of the course of lung volume versus time. Nevertheless, most recorders use a transducer that converts electrical information (signal voltage or current) into mechanical data, more specifically, position on the paper. This can be achieved by moving the writing element to the specific position (analog transducers) or by activating the correct point in a large array of stationary, equally spaced writing elements (digital transducers).

At present, sophisticated graphic recorders that offer a broad variety of possibilities to the operator are available. The measuring quality of transducers has continuously been improved and, as digital techniques have been applied, the possibilities of automatic control and addition

of alphanumeric information have been largely extended. A typical example is automatic recording of standard ECG derivations (frontal bipolar and unipolar, and precordial derivations) with calibration, identification of the curves, and determination of typical parameters (such as the duration of specific electrocardiographic intervals) and generation of diagnostics. Nowadays, the borderline between graphic recorders, digital oscilloscopes, data-acquisition systems, and PC-based virtual measuring instruments become less clear. There is a decreasing interest in analog recorders except for the multipen recorders having the benefit of simplicity, low price, and excellent identifiability of curves by the use of different colors. They are used in laboratory applications (and process monitoring) and handle slow varying signals. Digital recorders are generally provided with an LCD screen allowing monitoring with different colored tracings. Moreover, signal processing and data extraction, storage of data (and replay of original or processed signals), computer connection for handling data and control of recording settings are possible. Measurements where immediate visualization of the tracings on a long strip of paper is not required and data are to be digitally analyzed and stored, can be performed by PC with virtual instrument software and printer; Nowadays the majority of data collection is accomplished using digital PC approaches.

In giving an overview of graphic recorder function, one inevitably refers to technology of transducers. Especially in analog recorders the capacities and the limitations of the transducer is of major importance to the quality of the complete recorder. A number of mechanisms were applied in commercially available devices, but in many applications the analog types have been replaced by the digital type or by the PC system. Recorders can be called special purpose when built within a complete measuring system [e.g., an electrocardiograph (ECG), an electroencephalograph (EEG)], or they can be general purpose. The latter may be provided with specific signal conditioning modules to be connected to biophysical sensors (e.g., manometers for blood pressure measurements, Doppler probes for blood velocity assessment, thermal sensors for temperature recording) or, even more generally, to standard amplifiers allowing amplification levels, direct current (dc) adjustment, filtering, and so on. In most applications the graphic transducer, not the electronic signal conditioning hardware, is the crucial stage in the measuring chain. This article is intended to cover primarily the essentials of graphic recording, focusing on the principal aspects mentioned before: recording of information and graphic quality. For extensive practical details on recorders and signal conditioning modules, waveform monitoring, digital storage, processing and communication facilities, the manufacturers' data sheets should be consulted.

FUNDAMENTAL ASPECTS OF GRAPHIC RECORDING

Graphics: Images or Tracings

As the paper used for graphic recording is a 2D medium, two coordinates, x and y , can be defined: y represents the ordinate corresponding to paper width; x is the abscissa,

corresponds to paper length. If an exception is made for the strip chart recorder, the distinction between x and y is merely a matter of definition. In the most general case an image can be presented on the paper: At each point (x, y) a gray scale or color scale value is displayed. For example, in speech analysis, the so-called spectrograph displays amplitude in the form of a gray scale value versus frequency (y) and time (x). Such types are image recorders. Nevertheless, in most biomedical recordings the content of z is limited to some discrete values, sometimes two (black and white or, more generally, marked and not marked), or more, in case different colors or marking intensities are applied. As such, the image is reduced to a set of tracings. This implies that for each value of x a set of y values is marked. Marking intensity (gray or color scale) and line thickness are insignificant with respect to signal representation and can be beneficially used for trace distinction and identification in relation to the quality of graphic layout.

In most applications, x corresponds to time and y to the physical magnitudes recorded (a t - y recorder or y - t recorder). Most attention will be paid to these types. The number of y magnitudes then stands for the number of channels (signal inputs) of the recorder. If the recorder is designed for an arbitrary abscissa input, the indication x - y recorder is used. The ideal multichannel t - y recorder produces a graphic representation of a set of time signals (Fig. 1). The effect of time is generally originated by pulling a strip of paper at constant velocity; A site has to be marked to indicate the time reference. Sensitivities and reference (e.g., zero) levels have to be known for each channel. Paper velocity, time reference, sensitivities, and reference levels are important scale factors that, apart from a few exceptions, are absolutely necessary when tracings are examined. Indeed, in specific applications some of these parameters are not required as they carry no information. A typical example is the zero level in electrophysiological measurements using skin electrodes, such as ECG and EEG. In these signals, the dc level is not significant as it is not generated by the physiological source (the heart in ECG, the brain in EEG); Moreover, they are usually high pass filtered to eliminate baseline disturbance from electrode-tissue interface potentials. Evidently, the same does not apply for such information as blood pressure and blood velocity, where the zero level is indispensable for evaluation. An accurate time reference is required only if the recorded signal is of the evoked type, that is, a response to a specific stimulus. For the ideal apparatus the recording parameters are constants; Obviously, this is but an approximation for the real recorder and its quality as a measuring instrument is determined by the constraints imposed on the deviations of the parameters with respect to their nominal values.

Analog and Digital Recorders

Depending on the transducing device applied, two categories of recorders can be considered: analog and digital. In analog recorders, a physical displacement occurs: Positioning (y) of the pen (or ink jet, light beam or other), toward the site on the paper to be marked. In digital recorders, as

Figure 1. Time signals and graphic representation. On the left, two time signal examples are given: ECG (bipolar lead II) and aortic blood pressure. On the right, the t - y recording is sketched as executed by galvanometric rectilinear pen-writing devices on calibrated paper. For ECG and blood pressure the recording sensitivities have to be known. This is accomplished by recording a calibration pulse: 1 mV for ECG, 100 mmHg (0.133 kPa) for pressure. For pressure the zero level is obviously necessary. The time effect is generated by pulling a paper supplied from a paper roll over the writing table. Remark: Nowadays these types of signals are mostly recorded with a digital recorder (thermal array) or a PC application.

considered here, no moving parts are present. The writing device consists of a linear array of stationary writing styli, positioned at equal distances. The array is directed according to the y -axis and covers the complete width of the paper. The location y to be marked is identified by giving the address of the point in the array situated at the corresponding location.

Three elementary functions can be considered: x positioning, y positioning, and intensity control of the writing process. The most striking difference between analog and digital recorders is that in digital transducers the y positioning does not exist, as the function of indicating the y value to be marked is carried out by the intensity control on the stationary styli in the writing array. Analog recorders are capable of drawing continuous lines; digital recorders essentially put separate dots on the paper at discrete y levels corresponding to the positions of styli in the array and at discrete x values according to the incremental steps at the x input. Besides the continuous mode, analog transducers can be used in a discontinuous mode (scanning mode). In this case, the x drive is essentially similar to the one used for digital systems (a progression with equal steps) and at each step the transducer scans the paper width at high speed, putting dots (or dashes) at locations corresponding to the different signal values. As such, the digital transducers construct tracings by setting dots, the analog transducers used in the scanning mode generate tracings by setting dots or dashes directed according to the y axis. Only the analog transducer in continuous mode behaves as a real curve tracer, implying that the device is unable to generate images.

Digital transducers as well as analog transducers in the scanning mode can produce images that are composed as indicated (dots or lines). Applied as waveform recorders, both instruments have the special advantage that a single

transducer can handle a set of signals, the number being limited only by properties of resolution (dependent on the number of writing points of the digital transducer and on the recording width) and of identifiability of possibly overlapping curves. In the continuous mode a separate analog transducer is required for each channel to be recorded. To complete the discussion of analog and digital transducers, note that analog types can be used in a digital way, when positioning is bound to equal incremental steps, as applied in printers and plotters for computer graphic output. Moreover, analog recorders may be used in connection with digital systems, provided the necessary digital-to-analog conversion facilities are present. In such cases, simple digital transducers may be added to the apparatus design. A typical example is the analog apparatus equipped with printing heads for adding alphanumeric information to each tracing.

With these technological possibilities in mind, the problem of reporting the recording parameters (sensitivities, reference levels, paper velocity, timing reference) can be further discussed. Transducers capable of handling more than one signal (analog transducers in scanning mode and digital transducers) may draw calibration lines as well (ordinate and abscissa). The same is not possible for analog transducers in continuous mode. For example, for drawing a zero-level line an additional transducer would be necessary. It is obvious that this solution would be expensive. Moreover, it does not feature the benefits of accuracy as in the method where signals and calibration lines are generated by the same transducer. The problem is solved by using calibrated paper. Nevertheless, in some apparatus a separate timing marker is provided, writing small dashes that indicate time divisions (e.g., each second), or an event marker can be used to identify the start of an experiment (e.g., the stimulus if applied). Such timing devices are

evidently low cost, low performance elements and cannot be used as measuring instruments.

In the case of analog transducers and calibrated paper a zero line and a level corresponding to a standard value of the physical magnitude can be drawn before recording signal information (Fig. 1). For example, in the ECG the 1 mV pulse is commonly used. Ideally, this kind of calibration should cover the complete measuring chain: The zero line and standard level are to be applied at the biophysical sensor input. This can easily be performed in electrophysiological measurements, but for other physical magnitudes it is quite problematic, as it requires the continuous availability of a calibration setup (e.g., blood pressure measurements). In these cases one uses previously calibrated transducers and electrical calibrations corresponding to zero and standard levels of the physical magnitude are then simply provided at the recorder input (Fig. 1). Alternatively, one can draw a piece of zero line and keep the sensitivity values (physical unit/paper division) in file (written on the record). Evidently, both methods, with and without self-generation of coordinate lines, will feature different recording accuracy properties.

In the technique of analog transducing there are essentially two methods. In the direct method, the transducer generates a positioning directly determined by the electrical input. In the second method, the actual position of the writing device is measured by a sensor system and the result is compared with the recorder input value. The difference between both values is (following amplification and signal conditioning) fed to the transducer, which originates a movement tending to zero the position deviation. This second type is called the feedback, compensation, or servo method and corresponds to the well-known null detection technique in general measurement theory. Both methods, direct and feedback, are applied in analog recorders.

Chart Abscissa Generation

An essential feature of the graphic recorder is the ability of making recordings in real time. The time effect is generated by pulling a strip of paper at constant velocity and the name t - y recorder is applicable (Fig. 1). In digital recorders chart abscissa generation is performed essentially in small identical increments with the aid of a stepping motor that is controlled by a stable stepping frequency. In analog recorders, a continuous movement is envisaged and different types of motors are applied in the apparatus design (synchronous, direct current and also stepping motors). The motor can be combined with a tachometer: In this case, the actual velocity is measured through the tachometer, and with the result the motor velocity is corrected to the desired reference velocity value via a feedback circuit (null detection technique).

Paper can be fed in Z-fold or on a roll. The pulling of the paper can be achieved by sprocket wheels operating within equally spaced perforations at both sides of the paper. This method is seen mostly in low paper speed applications. At higher speeds, the paper is pressed between two rollers driven by the motor system (Fig. 1). In most cases as a result of the pulling force, the paper is pulled to the writing

table (e.g., pen writing) or to the writing head (e.g., digital systems), which is essential for thorough graphic recording. If necessary, additional pressing facilities are provided to ensure optimal contact with the writing device. Evidently the use of graphic recorders is not limited to real-time applications of the time signals. Delayed and time-expanded or compressed recordings can be realized if computing and memory facilities are provided (for digital as well as for analog recorders). For example, signals with a higher frequency spectrum in comparison with the bandwidth of the transducer, which thus fail to be plotted in real time without considerable distortion, can be recorded in this way: Data are stored at high speed in memory and are released afterward (off-line) at low speed to the recorder input.

Recorders equipped with identical input hardware for both x and y coordinates are called x - y recorders. In this case, the chart is stationary during recording. It can be supplied as separate sheets or from a roll. Different methods are used to stabilize the paper during recording (e.g., mechanical clamps, magnetic parts on an iron plate writing table), but electrostatic attraction to the writing table seems to be the most elegant method of fixation. An x - y recorder can also be used in the t - y mode by applying a linearly increasing voltage to the x input.

Recording Accuracy

Recording accuracy is the first principal quality of the graphic recorder to be discussed. This quality comprises the recorder's performance as a measuring instrument and its ability to display additional information concerning the measured tracings or images. With respect to measuring performance, the larger part of the discussion can be formulated as for other measuring instruments (1-3). Such aspects as accuracy, precision, resolution, static linearity, noise content (including drift), dead zone and hysteresis, dynamic behavior comprising frequency domain and time domain responses, and sampling and digitization effects are typical performance indicators. Parameters for both x and y axes have to be considered. It is known that energy transducing devices usually represent the most delicate functions in the chain. This is valid for biophysical sensors and it applies equally to electromechanical recording transducers. Moreover, the power amplifier driving the transducer may be critical (e.g., with respect to saturation effects). Signal amplification and conditioning modules generally play no limiting role in the overall performance. Properties of the biophysical sensors are not discussed, as this subject falls outside the scope of this article. Analog recording transducers suffer from the limitations and errors typical of analog systems, which are excluded from digital systems. In the latter case, limitations are determined by sampling (sampling frequency) and digitization (number of bits).

Accuracy is an overall parameter defined as the difference between the recorded and the true value, divided by the true value, regardless of the sources of error involved. In digital systems a number of error sources are excluded. Moreover, accuracy is largely dependent on how calibration is performed and how the recording parameters are

reported. It is evident that the recording method in which the transducer itself generates the coordinate lines (x and y) as well as the signal tracings is less subject to error effects than the method using precalibrated paper. In the first type, accuracy is simply related to the correctness of the coordinate values generated; In the second type, there are found a number of additional error sources caused by the mechanical positioning of the writing device (inherent to the analog electrical-to-mechanical conversion) and also the paper positioning. Two methods of analog transducing have been mentioned: It is known that higher accuracy can be achieved with the feedback type (null detection) than with the direct type. The same applies for the accuracy of paper velocity.

Precision of the graphic recording is related to the preciseness with which a value can be read on a tracing. It is thus dependent on the line thickness (a sharp line implies a high precision) and the paper width covered by the tracing (maximal deflection in the y direction) and, additionally, paper velocity (with respect to time readings, in the x direction).

Resolution, being the smallest incremental quantity that can be measured, is determined by the digitizing step in digital systems and the dead zone in analog systems. The dead zone usually originates as a consequence of static friction (e.g., in the case of moving, paper-contacting devices, such as pens, the friction between the paper and the writing element) or backlash in mechanical moving parts. The phenomenon also gives rise to hysteresis: A curve recorded in continuously increasing coordinates will not exactly fit the same curve recorded in continuously decreasing coordinates.

Error sources can be found in the instability of the recording parameters (sensitivity and reference level). There can be small alterations comparable to electronic noise. If the alterations occur very slowly they are called "drift". Drift can result from temperature variations. Digital transducers are not subject to drift. Nevertheless, a mechanical source of drift on the reference levels can be the shifting of the paper along the y axis. Also, the paper velocity might not be stable as a consequence of motor speed variations or paper jitter from the mechanical pulling system. It is obvious that such errors have minimal effect if the transducer itself generates the coordinate lines. This applies for drifts of the sensitivities as well as the reference levels. Noise due to electric mains interference can occur with poor channel isolation and/or poor grounding techniques. Gain and phase distortion due to impedance loading can occur if transducers are driving multiple data collection systems (i.e., chart recorder, medical monitor, VHS tape recorder, computer). As for any instrumentation system the use of appropriate preamplification may help to avoid these inconveniences.

Furthermore, the recording sensitivities may be slightly dependent on the values of the signals processed, implying that there is a deviation from strict static linearity. A specific nonlinearity problem arises in the case of galvanometric transducers where rotation has to be converted into translation. In digital transducers, linearity is determined by the accuracy of the construction of the array of stationary writing styli. Moreover, nonlinear effects are less

inconvenient if the transducer generates its coordinate lines, as these are consequently subject to the same non-linearity as the signals. Note that in transducers with moving parts a specific nonlinearity is introduced for safety purposes. By electrical means (saturation levels) or by mechanical stops the deflection of the moving part is limited (e.g., in multichannel galvanometric pen recorders).

The dynamic behavior of the recorder refers to its response to sine waves or to transients (pulses or step functions). For analog transducers, one describes the frequency dependence of the sensitivities; A general discussion can be found in linear system theory (1–3). Some typical properties of linear systems can be mentioned. For example, a sine wave finds itself, in any case, reproduced as a sine wave at the output of the system, possibly with altered amplitude and phase. Another typical feature is that the spectral bandwidth of the system is independent of the signal amplitude; likewise the sensitivity in the bandwidth. Most linear analog recording transducers act as low pass systems: Frequencies from 0 Hz (dc) up to a certain cutoff frequency (the bandwidth) are about equally recorded. Beyond the cutoff frequency, amplitudes are progressively attenuated as frequency increases. When a step input is applied, the recorder will not exactly follow: There will be some delay, a limited rise time, and possibly an overshoot with respect to the steady-state level. These parameters (cutoff frequency, delay, rise time, overshoot) are significant in characterizing the dynamic behavior of the analog recorder. Real analog transducers behave as a linear system only within restricted limits (of deflection, slew rate, and also acceleration). Nevertheless, their performance is characterized by the same parameters. Limitations and errors are due mostly to the electromechanical transducer itself and possibly to the driving power amplifier. As for any measurement system, insufficient bandwidth will give rise to gain and phase distortion, delay and decreased slew rate. In digital transducers, where no moving parts are present, there are no errors connected to electromechanical positioning, moreover, coordinate lines are easily reproduced. In this case, limitations are determined primarily by the act of sampling and digitization. The phenomenon of overshoot is nonexistent. Delay and rise time correspond to the interval between two writing (printing) actions (the writing (printing) period). The bandwidth in analog systems determined by the -3 dB frequency (the frequency at which the sensitivity is reduced to 70% of the static sensitivity), is seen in another way: It depends on the number of samples one finds necessary to represent a complete sine wave period. If 10 is the approved number of samples for a complete period, the bandwidth is restricted to one-tenth of the writing frequency (in real-time applications). With respect to bandwidth considerations one must keep in mind that the result, the graphic record, is intended for visual inspection and that paper velocity is limited. For example, with a 100 Hz sine wave to be recorded, at high paper velocity, such as 100 mm s^{-1} , a full sine wave period covers only 1 mm, implying a poor recognizability. If the latter is essential, memory recording has to be used.

The ability to display additional information is complementary to the measuring performance. Recording

parameters (sensitivities, reference levels, time references, paper velocity) are, as already indicated in relation to accuracy, best reported in the form of calibration lines. Alphanumeric information for identification of signals and calibration lines, on the one hand, and data concerning the circumstances of the experiment (patient or subject name, date, experiment identification, stimulus type, etc.), on the other hand, are indispensable for off-line examination. They either must be manually added to the record or, preferably, must be added through the recorder itself. Digitally controlled recorders (using digital as well as analog transducers) may allow the operator to introduce the alphanumeric data together with tracings, provided the device is able to do it. In the case of digital transducers this is only a matter of appropriate hardware and software (to be supplied in the recorder) and/or interfacing with a computer. Whereas in digital transducers recording is essentially based on intensity control, in analog transducers this aspect is not necessarily provided.

Reading stored paper tracings by using waveform tracing techniques in order to be able to process data in digital format may be interesting for a number of studies. Nevertheless, attention has to be paid to the recording accuracy of older tracings and the experimental procedures used.

Graphic Quality

As mentioned in the introduction, the second of the two principal recording properties is the quality of graphics. The correctness of locating the point to be marked is part of the performance of a measuring instrument. In this section, the quality of the apparatus in producing a graphic hard copy is discussed. The clearness of the individual tracings is the first quality. Sharp and clean tracings on a bright background give the best impression. Vague or blurred lines and dirty background are not wanted. Furthermore, curves should be easily identified: Ease and speed in examination are thus improved and the risk of misinterpretation is considerably decreased. Although the use of different colors seems most appropriate, other techniques may be applied if color differences are technologically excluded, for example, writing intensity (gray scale) or even line thickness. Also, the impression of continuous lines can assist in curve examination; Adequate interpolation between sample points is thus a specific problem to be handled in the case of digital and discontinuous analog recorders (Fig. 2).

In the graphic process, two steps are involved. First, the act of writing (putting a visual mark on the paper at the located point). Second, the act of fixation (to maintain the mark for a long time). This evidently has to do with the aspects of visual inspection and permanence in the definition of graphic recorders. Graphic quality also relates to the aspect of permanence. For example, depending on the fixation process, photographic records may be affected by environmental light in the form of a darkened background.

Attention should be paid to the fact that the flow of marking matter (ink, heat, light, etc.) is to be adapted to the writing velocity in order to have optimal line thickness and grayness. In analog transducers the writing velocity is determined by the paper velocity (in the x direction) and

Figure 2. Graphic quality. (a) Artificial signal to be recorded. (b) Record from a pen-writing system, showing the effect of deflection velocity on line thickness. (c) Record from an analog scanning system. Interpolation is performed by vertical dashes drawn between previous and present signal values at each writing act. The effect of the writing frequency is visible in comparing (c1) and (c2) (doubled writing frequency). (d) Record from a digital system with similar interpolation. The effect of resolution is visible in comparing (d1) and (d2) (halved distance between writing points, i.e., one added to the number of bits, and doubled writing frequency).

the deflection velocity of the writing device (in the y direction). In digital recorders, only the paper velocity is involved. Adapting the marking flow is evidently a matter of intensity control (ink pressure, heating power, light intensity, etc.). In low cost apparatus, manual intervention is necessary. Adaptation might not even be possible. In more sophisticated apparatus, writing matter flow is automatically adjusted in relation to paper velocity. In the steady state, then only alterations in intensity and line thickness are discernible in the case of variations of deflection velocity (Fig. 2). This explains why, in typical ECG pen recordings, the baseline appears much heavier compared with the slopes in the QRS complex. One could say that this side phenomenon has a beneficial effect on waveform recognizability since information on the signal

time derivative is also included in the graph. Evidently, this statement may be subjective. Some apparatus are even equipped with an intensity control that continuously adapts the writing flow to the total writing velocity. The latter is possible only if the response of the writing system is fast enough. A good example is the thermal system with a pen-tip writing device. Because of the small size of the heating resistance in the tip of the pen, the thermal time constant can be reduced to a few milliseconds and fast heating flow adaptation is possible. In the thermal edge writing device, the resistance producing the heat is much larger. The thermal time constant is then ~ 1 s so that the latter may even result in a nonnegligible waste of paper when the instrument is started at high speed paper velocity.

When ink is used, the paper can be marked by a contacting device, a pen, or by a noncontacting device, an ink jet. Pens can be designed as capillary tubes connected to a pressurized ink reservoir. They can be fiber-tip pens or ballpoint pens (disposable pens) and ink can be supplied from a common container or from (disposable) cartridges connected to each pen. In the case of ink jets, there is no contact with the paper. Ink is squirted as a very thin jet from a fine nozzle directed toward the paper. Fixation occurs as the ink is absorbed and dries. Ordinary paper can be used, satisfying the needs of absorbency quality and surface smoothness (in the case of contacting pens). A disadvantage with ink systems is the possibility of ink stains and smears, as fixation (absorbency and drying) does not occur instantaneously. A practical problem is that pens may clog or "bleed."

The following methods require special paper types. These can be composed of an appropriate paper base coated with a special layer functional with respect to the writing process (e.g., thermochemical). In the case of the burning method, an electric current from a stylus tip in contact with the paper is passed through the electrically conductive paper to the metal support on which the paper is mounted. The current gives rise to paper burn and thus blackening. The density of the burned mark depends on the current magnitude. Thus, a gray scale effect can be obtained. As burning is irreversible, the graphics remain fixed. This method finds application in the previously mentioned sound spectrograph. Furthermore, marking can be executed by heat on thermosensitive paper. The writing effect can be originated by thermally melting off a white coating from the chart paper and thus exposing the black underlayer. In another process, the base paper layer is covered with a thermochemical layer that irreversibly changes color after exposure to heat. In thermal writing, the color is usually black, but other colors can be generated. The shelf life of thermal chart recordings can vary on paper, transducer, and user storage techniques; Thermal recordings may be degraded by exposure to heat, light, friction, solvents, and so on.

In both electrostatic and photographic methods, the writing act comprises two phases. First, a latent invisible image is transferred to the paper. Second, the image is developed and thus made visible. In the electrostatic method, paper coated with a special dielectric layer is locally charged (the latent image) with electrical charges.

These charges attract, in a second step, ink particles from a toner supply (fluid or dry) after the excess toner is removed only ink is left at the electrically charged sites. Fixation is then achieved by drying (in the case of toner fluid with ink particles in suspension) or heating. In the photographic method, which uses photosensitive paper (the most expensive type), a light beam (generally ultraviolet, UV) activates the photolayer, leaving a latent image. Graphics are then visualized and fixed according to the photographic process used by exposure to visible light (environmental light or an additional light source specially provided) or by heating. Dependent on the process used, long exposure to environmental light may degrade the quality of the record after the examination by darkening the background. A darkened background may also appear in the electrostatic writing process if the apparatus is not optimally adjusted (e.g., if not all of the excess toner is removed). The photographic method is best fit for the production of images, but it has also been used for tracings.

Some commonly used writing techniques have thus been described. Acts of marking and fixing are typical technological problems and this area continues to evolve. The method used in a specific apparatus depends on different factors. With respect to the application envisaged and the type of transducer used, specific writing techniques may appear advantageous, but the manufacturers' patents also play an important role in apparatus design. The paper cost is certainly not to be neglected (e.g., in long-term recordings). Electrostatic and photographic writing have lost interest in modern chart recorder design.

A remark has to be added with respect to graphic quality as well as precision. As already mentioned, recorded tracings should be optimally identifiable, especially when they cross each other on the record. The use of different colors is obviously beneficial. In this respect, the paper width and the usable range for one channel are important. Traces can be limited within separate ranges or can cover the complete paper width. Precision is maximal in the latter case, but there are problems involved. Some transducers, more specifically galvanometric devices, produce only limited deflections. Furthermore, there is a problem with contacting devices (pens). Since it is physically impossible that they cross each other, they are spatially shifted with respect to the abscissa of the paper, which corresponds to a desynchronization on the records. If the complete paper width is covered, precision is maximal, but identifiability is decreased, especially when the use of different colors is excluded as in those devices where the color is not determined by the writing element, but by the paper properties. The latter applies to all devices other than ink-writing devices.

Another remark concerns immediate visibility of real-time recorded tracings. Although the recording may be preferably in real time, the visibility may not have the same benefit: More specifically, tracings can be seen after a small time delay. This is the case if the writing device is positioned within the recorders housing; The time delay is then dependent on the distance to the visual part of the paper and, evidently, of the paper velocity. Digital transducers have this shortcoming: pen recorders do not, except in the multipen recorder with dislocated pens (allowing

overlapping graphs). In this case, a pen offset compensation may be used to synchronize recorded tracings, also causing a time delay.

In this Paragraph a number of technological aspects were just mentioned. Some of these concepts have lost interest with respect to new design, but may still be found in older apparatus.

ANALOG RECORDERS

An analog recorder has been defined as a recorder that applies an analog electromechanical transducing principle. The electrical magnitude is transduced into a translational value, that is, positioning of a movable part, such as a pen, toward the site to be marked. Although analog recorders are used mostly for signals in analog form, they may also be applied to digital signals and consequently to computer output, provided digital-to-analog conversion facilities and appropriate control access (paper velocity, intensity control) are available.

For the description of the transducer, analog system theory is applicable (1–3). Two typical measurement principles are commonly used in transducer design. In the direct method, the electrical magnitude is directly transduced into a displacement magnitude. In the feedback method, corresponding to the null detection technique, the actual position of the marking device is measured with an accurate sensor. The difference (the error) between the measured and the input value is, after appropriate conditioning, fed back to the transducer, which generates a movement tending to zero the position error. In the latter case, the accuracy of the transducing system depends on the quality of the position sensor. It is known that with this method higher accuracies and more stable transducing properties can be achieved. Furthermore, an analog transducer can be applied in the continuous mode or the discontinuous mode. In the first case, a single continuous tracing is generated by each transducer; The number of channels is equal to the number of transducers provided in the multichannel recorder. Production of an image is excluded. In the second case, the writing device is repeatedly swept over the complete paper width, setting dots or dashes at sites corresponding to the signal values (the scanning mode). A single transducer can thus handle a set of signals. It is obvious that what is gained by the ability to process different signals is lost with respect to the writing speed of the system.

Positioning of the writing device can be caused by a transducer that causes a rotation (the galvanometric transducer) or a translation (the translational servosystem). The translational servotransducer evidently makes use of a feedback mechanism. The galvanometric transducer, originally strictly built as a direct device, has also been designed according to the feedback principle.

Whereas two decades ago a number of analog transducer techniques were applied in apparatus design for biomedical signal recording, mostly for obtaining different bandwidths and image recordings (as for echocardiography), only a few of them are still used. The galvanometric recorder and, more importantly, the translational servorecorder.

Galvanometric Recorders

Galvanometric recorders make use of transducers that are essentially rotational transducers, making use of the d'Arsonval movement as applied in ordinary galvanometers (4). A positioning, more specifically a rotation over a certain angle, is obtained as a result of an equilibrium between two torques, the first an electromagnetic torque, proportional to current, the second a mechanical torque, proportional to positioning (a rotation angle). A coil wound in a rectangular form is suspended within the air gap between the two poles of a permanent magnet and a stationary iron core. A current flowing through the coil gives rise to an electromagnetic torque that tends to rotate the coil. To position at a specific angle θ , there must be a restoring torque, essentially proportional to the angle, for example, a torsional spring characterized by its rotational stiffness. The signal to be recorded is fed to a current amplifier that drives the coil. As such, there is direct proportionality between the angle and the signal. This principle corresponds to the direct transducing method.

In a discussion of dynamic behavior, not only stiffness, but also damping (viscous friction) and inertial moment (of the coil and the attached mechanical parts, e.g., the pen) must be taken into account. As a first approximation the device acts as a second-order linear system, characterized by a resonant frequency and a damping factor. The resonant frequency depends on the ratio of stiffness divided by inertia. The resonant frequency and the damping factor determine the bandwidth of the system (with respect to sine wave response) and the time delay, rise time, and overshoot (with respect to step input transient response). For frequencies sufficiently above the resonant frequency, the corresponding amplitudes are attenuated proportional to the square of the frequency. A second-order system can show resonant phenomena, depending on the value of the damping factor. If this factor is <1 , the response of the transducer to a step input shows a ringing effect, implying that an overshoot exceeding the steady-state value has occurred. The smaller the damping, the smaller the rise time, but the higher the overshoot. At critical damping (damping factor = 1) no overshoot is present. Such an overshoot is considered inconvenient as it gives an erroneous impression of the waveform (especially if sudden alterations in the signal occur). With the damping factor in the proximity of 0.7 a good compromise is obtained between the overshoot (4%) and the rise time (3) (Fig. 3). The useful bandwidth of the recorder is thus determined by the resonant frequency and thus by the ratio of stiffness to inertia. To obtain a sufficient damping factor, extra damping must be applied within the galvanometer (mechanical or electromagnetic). In the case of paper-contacting devices, the damping should exceed the effect of the static friction of the writing element (e.g., the pen) on the paper (as this effect is unreliable and consequently is not allowed to affect the measuring performance).

The feedback technique has also been used. According to the general idea, the actual angle is measured by a position-sensing device, delivering an output proportional to the angle, which, after amplification and waveform conditioning, is negatively fed back to the input of the

Figure 3. Characteristics describing dynamic galvanometric transducer responses. (a–c) Linear system behavior; Damping factor 0.7. (d) Nonlinear behavior. Coordinates are given in generalized form (time = $f_r t$; frequency = f/f_r) (f_r = the transducer resonant frequency). (a) Time response to a unit step input. Delay, rise time, and overshoot are visible. (b) Amplitude frequency response (sine waves) in linear coordinates. (c) Amplitude frequency response in logarithmic coordinates. (d) Typical amplitude frequency responses (50 and 5 mm deflection) for a nonlinearly behaving system. The bandwidth appears to depend on the tracing amplitude (displayed: inversely proportional to the square root of the amplitude).

current amplifier driving the galvanometer. In case the position signal simply undergoes amplification, the effect of the negative feedback is a restoring torque proportional to the angle, thus resembling the effect of a rotational spring in an apparent stiffness. An equilibrium is reached when the coil angle (as measured) corresponds to the value at the input of the system. At equilibrium, the current through the coil equals zero (provided one does not take into account the effect of an additional mechanical spring). This is advantageous with respect to the current amplifier.

A real galvanometer usually does not feature constant linear system properties, such as stiffness (mechanical or apparent, as generated by feedback) and damping, independent on deflection, deflection velocity, and acceleration. Particularly with the feedback system, nonlinear effects can appear as a result of current saturation. In a linear system, the bandwidth is independent of the signal amplitude; In a real galvanometer, the same usually does not apply. For larger sine wave amplitudes, the useful bandwidth appears decreased and sine wave distortion occurs at frequencies in the vicinity of the apparent resonant frequency. A bandwidth inversely proportional to the sine wave amplitude to the power of m , with the exponent m approximately between 0.5 and 1, is obtained (Fig. 3).

Apart from nonlinearity in dynamic behavior, a problem with respect to static linearity arises. The galvanometric recorder essentially generates a rotation, not a translation, as one would expect for a graphic recorder. If a pen is connected to the coil of the galvanometer, the tip of the pen rotates with a radius equal to the pen arm length. Such a recording is curvilinear. It has been used on paper with curvilinear coordinate lines. Rectilinear recording is obtained with special techniques. Whereas in curvilinear recording mostly ink pens are used (a low cost solution), there are different methods for obtaining rectilinear records: pen methods (long-arm pens, knife edge recording, mechanical rectilinearization), ink jet method and light beam method) (Fig. 4). Curvilinear errors can be kept small if the radius is large, which is the case with long-arm pens. Knife edge recording is the simplest real rectilinear recording. The chart paper is pulled over a sharp edge, accurately directed according to the y -axis, and the writing stylus moves over and presses on it. The impression is thus made at the site of the edge and thus rectilinear. In this case, the marking method applied is thermal. It should be remarked that in this method a large part of the stylus has to be heated (as compared to the thermal point writing), giving rise to large thermal time constants (order of magnitude 1 s). This is inconvenient for high paper speeds as, when

Figure 4. Galvanometric pen-recording assemblies. An artificial recording is shown corresponding to a zero level, abrupt transition to maximal positive, holding, and finally abrupt transition to maximal negative deflection. Errors resulting from dynamic behavior are not considered in this figure. (a) Curvilinear recording. (b) The long-arm pen recording is curvilinear but, as a consequence of restricted angle deflection, approximates rectilinear recording. (c) Knife edge recording. Rectilinear recording as the writing essentially occurs at the site of the knife edge, where the pen presses on the paper. For thermal writing, the black end of the pen represents the part to be heated (minimal length indicated by the dashed lines). (d) Mechanical linkage for rectilinearization. The pen arm (length R_2) is connected to a pulley (diameter d_2), which is allowed to rotate at an axis at the end of the galvanometer arm (length R_1). A metallic belt attached at a point of the pulley is also fixed at a stationary circular part (diameter d_1) at the galvanometer frame. As the galvanometer arm rotates, the pen arm is subjected to a corresponding rotation dependent on the diameter ratio: $\beta = (d_1/d_2)\alpha$. When $\beta = \alpha$, the pen arm is moved parallel to the zero position and the pen point moves in the same curvilinear direction as the end of the galvanometer arm. Thus β must be larger than α , and more specifically so that the rotation through the angle $(\beta - \alpha)$ the curvilinear abscissa error of the galvanometer arm end is corrected for. A power series expansion shows that this is obtained when $R_1/R_2 = [(d_1 - d_2)/d_2]^2$.

the instrument is started, a significant amount of thermo-sensitive paper may be wasted. Instead of a hot stylus, a carbon ribbon with an ordinary stylus pressing on it has been used. In this case, ordinary paper can be used, but an additional mechanical device linked with the paper velocity equipment for driving the carbon ribbon is necessary. Rectilinear recordings can also be generated via mechanical linkages that compensate for the normal curvilinear movement of the pen and convert the rotary motion of the coil into an (approximately) straight-line motion of the pen tip. In the case of ink jet recorders, the writing device does not make physical contact with the paper. In this case, a fine ink jet is produced by pumping ink through a nozzle connected to and thus rotated by the galvanometer toward

the paper. The recording is rectilinear at the intersecting line of the paper plane and the plane of the rotating ink jet. The same holds for the optical method, where a sharp light beam is reflected by a small mirror connected to the rotating coil of the galvanometer. In this case (expensive), photosensitive paper has to be used.

The principal difference in the abilities of these types of galvanometers is in the achievable bandwidth. Galvanometric pen-writing systems have to produce a considerable torque, as the pen, being pressed to the paper for graph production, must be moved easily without interference from the static friction in the recorder performance. This implies a large driving current and, for a defined angle, a large stiffness. This stiffness, together with the amount of

inertia, determines the resonant frequency and thus the bandwidth. A typical bandwidth value for a galvanometric pen system is 100 Hz. Theoretically, a higher bandwidth could be obtained for the same inertia, but this would imply a larger stiffness and thus a larger current, the latter being limited by its heating effect on the coil. As this paper-contacting problem is nonexistent in ink jet and light beam galvanometric recorders, current and stiffness can be lower. Moreover, the coil assembly can be made with such low inertia that, notwithstanding the lower stiffness, a much higher resonant frequency can be obtained. An order of magnitude for ink jets is 1000 Hz. For optical systems, 10 kHz has been reached.

The static friction in the case of paper-contacting writers give rise to a dead zone: A zone in which input voltage can be altered without causing any pen movement. It thus determines the resolution of the pen recorder. Hysteresis phenomena can consequently be observed. A curve recorded in continuously increasing coordinates will not exactly fit the same curve recorded in continuously decreasing coordinates.

The paper width covered by galvanometric pen writers is usually small (40–80 mm) as a result of the angle limitation (with respect to linearity) and pen arm length restriction (with respect to inertia and consequently bandwidth). Moreover, as overlap of tracings is physically impossible (the pens might strike each other) in multichannel recorders, a limited part of the paper is assigned to each channel.

As already mentioned, galvanometric recorders have lost interest. Pen recorders (e.g., edge recorders) can still be found on the market, but the types with higher bandwidth (ink jet and light beam) have been replaced by digital (memory) recorders.

Translational Servorecorders

In the translational servorecorder, the writing device (usually an ink pen) undergoes a real translation as it finds itself bound to mechanical straight-line guidance. The translation is generated by a motor and an appropriate mechanical linkage composed of a wheel and closed-loop wire system (Fig. 5). It is essentially a feedback method. A position sensor supplies a voltage directly proportional to the position of the pen, that is, the distance with respect to its zero position. In most apparatus, this sensor is a rectilinear potentiometer; This explains the use of the alternative nomenclature (potentiometric recorder) for this type. A further description of its function agrees with the general feedback principle. The input signal is compared with the pen position value and the amplified and conditioned difference voltage drives the servomotor, causing the pen to move (rectilinear) until the position value equilibrates with the input signal. The ink pens used are capillaries, fiber tips, or ballpoint types, generally supplied with ink cartridges. Evidently different colors can be used for optimal signal discrimination. In modern designs, digital servodevices are being used, with position reading by optical or ultrasonic means.

The static linearity of the recording is determined by the linearity of the position sensor. Noise can result from problems with the sliding contact on the potentiometer

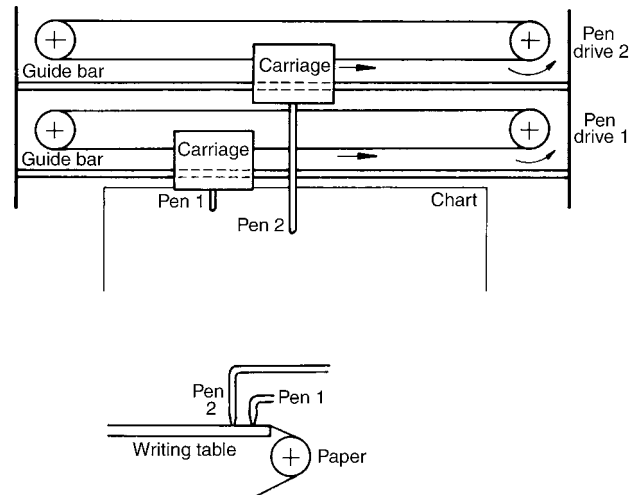

Figure 5. Translational servo t - y recorder. Two channels are shown. Pens (1 and 2) undergo real translations as they are connected to carriages that slide along guide bars. To be able to cover the complete paper width the pens are mechanically staggered with respect to the paper abscissa.

resistance. Hysteresis can be caused by the properties of the servosystem (e.g., static friction) and the mechanical backlash between the pen tip (the real location) and the wiper on the potentiometer (the location processed in the feedback loop). As for dynamic behavior, one can state that the servorecorder generally does not behave as a linear system (except for small amplitudes). It is characterized by a limited slewing velocity (order of magnitude: 0.5 – $2 \text{ m} \cdot \text{s}^{-1}$) dependent on the type of motor and mechanical linkage. Also, the acceleration of the moving parts is subject to limitations (order of magnitude: $50 \text{ m} \cdot \text{s}^{-2}$). If one of these limits is reached, the device ceases to act as a linear system and, as described for galvanometric recorders in the feedback mode, the bandwidth depends on the tracing amplitude (order of magnitude of the cutoff frequency: 1 – 5 Hz). As such, these recorders are fit for slowly varying parameters (temperature, heart rate, mean blood pressure, respiration, etc.). They are generally applied for higher precision: The common paper width is 200 or 250 mm. A writing control is normally provided in the form of a pen lift (on-off functioning) by electromagnetic and/or by manual means.

Servorecorders are used as strip chart recorders (t - y recorders) and also as x - y recorders. In the latter case, two servosystems are assembled. The x system drives a long carriage, directed parallel to the y axis and covering the complete width of the paper in the y direction. Hereon, the second servosystem y , which eventually positions the pen, is mounted. Paper is fixed on the writing table (preferably by electrostatic means). Driven by computer output these x - y recorders can plot arbitrary graphs (plotters). When addition, alphanumeric information and coordinate lines can be added if the pen lift control is used. Some x - y recorders also have the built-in facility of t - y recording (with a ramp signal at the x input).

In the case of the t - y recorder, several channels (1, 2, 4, 8, 12 channels) can be assembled, all of them covering the

complete paper width, provided the pens are mechanically shifted with respect to their abscissa position (Fig. 5). This mechanical offset, evidently corresponding to a shift in time on the graph, may be inconvenient if values of different signals at a specific time instant have to be compared. To overcome this disadvantage, most servorecorders can be supplied with a pen position compensation unit. All channels, except one corresponding to the first positioned pen along the time axis, are digitized and stored in memory. Data are released, converted to analog, and supplied to their corresponding channels with a time delay equal to the distance from the pen to the first pen divided by the paper velocity. This compensation is evidently beneficial for examination afterward, but can be inconvenient at the time the experiment is executed as the information is plotted only after a time lag dependent on the paper velocity (except for the first pen).

Some modern recorders have data-acquisition facilities. Data (signals and instrument settings) are digitally processed and can be stored, for example, on floppy disk or on a memory card. Communication with computers can be done via standard interfacing (GP-IB, RS-232C, IEEE-488). In some apparatus, a display is provided allowing visualization of recorder settings. As slowly varying signals are envisaged, sampling frequencies used range from 100 to 400 Hz.

DIGITAL RECORDERS

A digital recorder has been defined as a recorder that uses a digital transducer. In this case, no moving parts are present and the transducer consists of a stationary straight-line array of equally spaced writing styli covering the complete chart width (Fig. 6). As such, the nomenclature array recorders can also be used. Progression along the x axis is essentially discontinuous. The paper is held stationary during the writing act. At a given x position, a set of writing points is activated. The paper is marked with dots at the sites in intimate contact with these points. The resolution with respect to the y axis depends on the density of writing points. The resolution in time (x axis) depends on the writing (printing) frequency (the inverse of the writing

Figure 6. Thermal array recorder. The thermosensitive paper is pressed to and pulled over the thermal array by the paper driving roll.

interval) and on the paper speed. Signals are thus reproduced as discrete values at discrete times. Analog as well as digital signals can be processed. In the analog case, sampling and digitization are part of the recording process.

At present, the borderline between digital graphic recorders, digital oscilloscopes, and data-acquisition systems becomes unclear as a number of the latter instruments are also provided with graphic recording facilities with strip charts. Some digital recorder designs primarily focus on fast acquisition of data and storage in memory for reproduction afterward. These are indicated as memory recorders and generally their real-time properties do not match the fast graphical recording types. Digital graphic recorders have a number of properties regarding data-acquisition, monitoring, storage, and communication with computers.

The act of writing of the digital recorder is generally thermal on thermosensitive paper. Also, an electrostatic method has been used. The writing transducer is essentially a rectilinear array of equidistal writing points covering the total width of the paper. These writing styli consist of miniature electrical resistances that are activated, that is heated, by a current pulse of short duration. Typical resolutions are 8 or 12 dots·mm⁻¹ according to the y direction. Static linearity of the recorder thus depends on the quality of the construction of the array. Inconveniences resulting from mechanical moving parts are not present. There is no overshoot. Delay and rise time are equal to one writing interval. All processing occurs in digital form and recording is a matter of generating the correct addresses of writing points to be activated.

Evidently, the dynamic thermal properties of the resistances in close contact with the chart paper and the shape of the electric current pulse set a limit to the writing frequency. A typical value for the writing frequency is 1.6 kHz. In a memory recorder, it may be lower. Local heating of the thermosensitive paper results in a black dot with a good long-term stability, dependent on the paper quality. Evidently, thermal paper is sensitive to heat, but also care has to be taken with pressure, light, solvents, glue, and so on, in order to prevent deterioration of the graph. Generally, the heating pulse is controlled with respect to chart velocity in order to obtain an appropriate blackness and line thickness at different velocities. Nevertheless, at the highest velocities the print may become less black and sharp. Although possible within a limited range, blackness and thickness of tracings are seldom used for the purpose of trace identification.

Whereas the resolution according to the y axis is determined by the thermal dot array, the x -resolution is limited by the dynamic properties of the array, and thus by the paper velocity. At low velocities, generally 32 dots·mm⁻¹ (exceptionally 64 dots·mm⁻¹) are applied. At the highest velocities used (100 mm·s⁻¹, in some apparatus 200 and 500 mm·s⁻¹), the number of dots printed is determined by the writing frequency (e.g., 1600 Hz results in 8 dots·mm⁻¹ at 200 mm·s⁻¹).

Data acquisition is determined by the sampling frequency, expressed per channel recorded. According to the sampling theorem this should be at least twice the highest signal frequency in order to prevent aliasing

effects, but for obtaining a graph with minimal graphic quality at least 10 points are needed for a sine wave period. On the other hand, sampling frequency should be limited in order to prevent an excess of data stored in memory (if applicable). Sampling frequencies used are typical 100 or 200 kHz (exceptionally 500 kHz and 1 MHz). A basic component of the digital recorder is RAM memory in order to create high quality graphs. The sampling frequency is generally higher than the writing frequency. If the sample frequency equals the writing frequency, the recorder prints all dots between the former and the present value. In fact, curves composed only of points are difficult to examine and interpolation improves the impression of smoothness of the sampled curves. If the sample frequency is higher than the writing frequency, the recorder prints all the dots between the smallest and the largest values (including the former value within the writing interval). As such at each writing act vertical lines are drawn. In this way, fast transients, disregarded by the ordinary interpolation between former and present value, are also captured in the graph. Although the form of the transient cannot be interpreted, the graph provides evidence of its presence. A signal having a frequency larger than the writing frequency is consequently displayed as a continuous black band.

Typical digitization levels are 8 or 12 bits, exceptionally 16 bits. Widths of thermal arrays range from 100 to 400 mm. With a resolution of $12 \text{ dots} \cdot \text{mm}^{-1}$, the largest number of dots full scale is then 4800. In case 16 bits are used, a signal with a large dc offset can be reproduced with excellent graphic quality as the offset can digitally be removed and the scale adapted.

Coordinate lines (with identification) can be generated and precalibrated paper is unnecessary. Errors resulting from paper shifting are thus eliminated. Tracings can cover the full width of the paper. Tracing identification in alphanumeric form and comment on experiments performed can be easily added through an internal or external keyboard. Signals can be calibrated and real physical values and units can be printed at the calibration lines. Simple mathematical calculations can be performed on signals in real time and results recorded in virtual channels. In most performant recorders a screen, mostly color LCD, is provided, allowing display of tracings in different colors and settings of recording parameters. Monitoring signals certainly has advantages. In real-time recording signals are not directly visible as a result of a delay corresponding to the distance between the internal thermal array and the visible part of the paper, but can be observed without delay on the monitor. Recording parameters (gain, offset, ...) can be set using the monitor and thus avoiding paper spoiling. Signals stored in memory can be viewed before recording on paper. Cursors on the display can be used for reproduction of selected parts of signals. Some recorders have a built-in display (up to 18 in., 45.72 cm). Others can be connected with an external display.

Digital recorders, especially memory recorders, are able to store recorded data and apparatus setting. Besides RAM for fast storage, recorders may have a built-in hard disk, floppy, magneto-optical or ZIP disk drive and a slot for a memory card. Connections may be provided for external

memory media. Signals can thus be reproduced from memory, processed and recorded on chart. Time compression or expansion is obviously possible. As data can be sampled at a high rate, stored in memory, and then recorded as they are released at a reduced rate, a bandwidth higher than that determined by the writing frequency can be achieved. In this way, fast transients that cannot be handled on-line can be accurately reproduced. Data capture and/or graphic recording (with an appropriate speed) can be controlled by trigger functions (external or derived from recorded signals); Pre- and posttrigger may be chosen. Via memory x - y plots can be obtained. When appropriate software is available, FFT plots can be made.

Digital recorders can have analog and logic channels. Typical numbers of analog channels are 4, 8, 16 (and exceptionally 32 and 64). General monopolar or differential amplifiers or signal conditioners with analog antialiasing filters can be plugged-in, as well as special purpose amplifiers for biomedical purposes. Furthermore interfaces can be provided for computer connection (RS-232C, IEEE-488, GPIB, Ethernet, USB, SCSI) or external hardware. Software can be provided for control, data transfer and conversion of data to formats for popular data analysis software programs.

EVALUATION

Table 1 shows a list of manufacturers of recorders, website addresses and typical products. Analogue recorders with a rotating pen arm, analog recorders with a translating pen and digital thermal array recorders. Evidently, the list is incomplete and continuously changing. For extensive practical details on recorders, signal conditioning modules, displays, data storage and processing, computer interfacing, and so on, the manufacturers' data sheets should be consulted.

Analog recorders are characterized by their specific technological limitations: the bandwidth, restricted mostly by the inertia of the moving parts, imposing constraints on the frequency content of the signal; the paper width covered by a trace, the number of channels, and the trace overlap (including pen dislocation); the stability of the recording parameters (including shifting of calibrated paper) and the difficulties of adding coordinate lines and alphanumeric identification to the records. The use of auxiliary devices (timing marker, printing head, pen position compensation, etc.) has been shown to overcome some of the limitations. The bandwidth is considered one of the most important limitations and thus the signal's spectral content determines the choice of the recorder type. Galvanometric pen recorder types (100 Hz bandwidth) have lost interest but some types can still be purchased. A number of mechanisms have been applied in commercially available devices, but in many applications analog types have been replaced by digital types or PC set-ups. Translational servorecorders have kept their position in their specific domain; They can be used for slowly varying signals with a signal spectrum up to 5 Hz (body temperature, heart rate, mean blood pressure, laboratory applications, etc.).

Digital recorders are characterized by the typical features of sampling and digitization in waveform reproduction. Although the writing frequency is limited by the thermal time constant of the thermal dots, with respect to bandwidth, it does not impose a constraint on the signal frequency spectrum, because, by the use of facilities inherent to digital apparatus (including a high sampling frequency), the problem can be solved by off-line recording. Signals that vary too fast for on-line recording can be stored in memory and reproduced at a speed the recorder is able to handle. Moreover by the specific writing method where vertical dotted lines are printed varying from the minimal to the maximal value sampled within the writing interval, fast transients, disregarded by ordinary interpolation, are also captured in the graph. Although the form of the transient cannot be interpreted, the graph provides evidence of its presence. In digital recording, the addition of coordinate lines and alphanumeric information to the record presents no difficulty for the transducer, as there is no essential difference compared to recording signal tracings. As connections to computing devices are possible, processed data can also be recorded, reducing the work of visual inspection of the record. Also, in some translational servorecorders signals are processed completely digitally, but in this equipment typical transducer limitations still exist and the domain of applications (i.e., the slow varying signals) remains the same.

As digital recorders are generally sophisticated, one has to pay the price for the flexibility provided. In addition to low price, analog recording has the advantage that different-colored inks can be used, which is important in multi-channel recorders with overlapping (full range) curves. Available digital recorders allow only one color, thereby reducing identifiability. As the digital writing array is inside the apparatus there is a small latency between writing and appearing of the tracings. In overlapping multipen devices pens are physically dislocated and application of the pen offset compensation also creates a time delay. In digital recorders, displays are added to provide immediate visibility and easy setting of the recorder parameters. Control of the analog recorder is generally limited and accordingly simple to perform. Digital recorders provide more facilities, implying the need of training and experience to install instrument settings for the application envisaged.

Analog and digital systems thus have their specific limitations and benefits. The choice of the equipment for a specific application is a matter of performance, operating flexibility, and price. Measurements where immediate visualization of the tracings on a long strip of paper is not required and data are to be digitally analyzed and stored, can be performed by PC with virtual instrument software and printer. Nowadays the majority of data collection is accomplished using digital PC approaches. As previously stated, besides the measuring properties, the graphic quality is extremely important, as it assists visual examination of the records. In this case the general rule is applicable. Before one chooses an apparatus, one should see it in operation, that is, making graphic representations of the data.

REHABILITATION AND MUSCLE TESTING

W.K. DURFEE

INTRODUCTION

There is a growing need in clinical medicine to validate the quantitative outcomes of an applied therapy. In addition, the measurement of muscle function is an essential component of many neurological and physical exams. Muscle strength is correlated to function, work productivity, and general quality of life. Muscle function becomes compromised: (1) as we age, (2) when associated with a skeletal impairment, and/or (3) as a secondary consequence of many disease processes. Therefore, assessing muscle function is an important clinical skill that is routinely used by neurologists, orthopedists, general practitioners, anesthesiologists, and occupational and physical therapists. Evaluation of muscle strength is used for differential diagnosis, to determine if an impairment or disability is present, to decide if a patient qualifies for treatment, and or to track the effectiveness of a treatment.

In a research setting, the measurement of muscle function is used to further our understanding of the normal and potentially impaired neuromuscular system in human and/or animal experiments. In such research, muscle function can be assessed at the intact individual level (*in vivo*), in chronic and acute animal models (*in situ*), within isolated

muscle strips or even within single myofibrils (*in vitro*), and/or at the molecular–biochemical level. In this article, only whole muscle testing (*in vivo* and *in situ*) is discussed.

There are several components of muscle performance. The American Physical Therapy Association uses various definitions to explain the characteristics of muscle function (1). Muscle performance is the capacity of a muscle to do work. Muscle strength is the force exerted by a muscle or group of muscles to overcome a resistance in one maximal effort. Instantaneous muscle power is the mechanical power produced by the muscle (muscle force times muscle velocity). Muscle endurance is the ability to contract a muscle repeatedly over time. Of these performance indicators, muscle strength is the one most commonly measured when assessing the muscle function of intact humans.

In assessing muscle strength, the conditions under which the muscle contracts must be specified so that the muscle test data can be interpreted properly. The following conditions are relevant: “Isometric contraction”: the muscle contracts while at a fixed length; “Isotonic contraction”: the muscle contracts while working against a fixed load, for example, a hanging weight; “Isokinetic contraction”: the muscle contracts while moving at a constant velocity; (generally, isokinetic contractions are only possible with the limb strapped into a special machine that imposes the constant velocity condition); “Eccentric contraction”: the muscle contracts against a load that is greater than the force produced by the muscle so that the muscle lengthens while contracting; and “Concentric contraction”: the muscle contracts against a load that is less than the force produced by the muscle so that the muscle shortens while contracting.

Isometric muscle tests are the most common as they are the simplest to perform and reproduce and, because the test conditions are well defined, they are the most appropriate for comparing results within a population. Two considerations are important when testing muscle under isometric conditions. First, because muscle force varies with muscle length, the length of the muscle must be specified when planning and reporting a muscle test. For example the manual muscle test has strict and well-defined rules for the subject’s posture and joint positions that must be followed if one is to make clinical decisions based on the test (2).

Second, all isometric muscle tests of intact human muscle are conducted with the limb either held in a fixed position by the examiner, or with the limb fixed to a brace or jig (see the Stimulated Muscle Force Assessment section). While these methods hold the limb in a fixed position, the muscle will not be strictly isometric because of tendon stretch. The mismatch between limb condition and muscle condition only causes problems when trying to infer details about muscle dynamics, such as rise time or contraction speed from externally measured forces. Even if the whole muscle could be fixed at proximal and distal ends, during a twitch, the distance between z lines in the myofibril will shorten, which means the sarcomeres are shortening due to internal muscle elasticity. This is why the length tension and dynamic properties of whole muscle deviate somewhat from those of the isolated sarcomere. Nevertheless, length

Figure 1. Muscles wrap around joints. Muscle force is related to external force produced by a limb through skeletal geometry of joints and attachment points.

tension or ankle–angle/isometric–torque analyses can be done *in vivo* (3,4).

Testing of intact human muscle requires that muscle output be measured external to the body and, as a result, muscle force is never measured directly. As shown in Fig. 1, muscles wrap around joints and attach to limbs at the proximal and distal ends. There is a kinematic relationship between the measured force and the actual muscle force that depends on the details of muscle attachment and varies with joint angle. Therefore, to ultimately solve the kinematic relationship, one will require information about muscle attachment location, the geometry of the joint, and the joint angle. Such geometric information can be readily obtained from a magnetic resonance imaging (MRI) scan or a more generic geometry can be assumed, for example, obtained dimensions gathered from cadaver studies (5,6).

While often reported as a force, external testing of muscles more correctly should be reported as a torque. Figure 2 illustrates how force varies with location of the resistive load along the limb, while torque does not. Reporting muscle strength as torque about a joint eliminates this difficulty. If force is reported, the distance between the

Figure 2. A torque of 4 is produced about a joint. It takes an opposing force of 2 to balance the torque if the opposing force is applied at arrow 1. If the opposing force is applied at arrow 2 it only takes a force of 1 to balance the torque. Thus, the perceived torque, and therefore the scoring of muscle strength, depends on where along the limb the examiner places his/her hand.

joint and the resistive load point should be measured to permit conversion to torque.

External measurement of torque about a limb joint means that all of the forces acting on that joint are measured, and that the contribution of the muscle or muscle group under study cannot be easily separated out. In other words, there are confounding forces generated by synergistic muscles. For example, when testing foot plantar flexion to determine gastrocnemius strength, the soleus may also be contributing to the measured torque about the ankle. Yet, another complicating factor may be undesired activations of antagonist muscles. One example is when you “flex your arm muscles”. In general, the resulting torque from the biceps and triceps are in balance, the arm does not move, and no external torque will be measured even though the muscles are contracting actively.

MANUAL MUSCLE TEST

The simplest and most common method of assessing muscle strength is the manual muscle test (MMT). Manual muscle testing is a procedure for evaluating strength and function of an individual muscle or a muscle group in which the patient voluntarily contracts the muscle against gravity load or manual resistance (2,7). It is quick, efficient, and easy to learn, however, it requires total cooperation from the patient and learned response levels by the assessor.

The procedures for conducting the MMT have been standardized to assure, as much as possible, that results from the test will be reliable (2,7,8). The specific muscle or muscle group must be determined and the examiner must be aware of, and control for, common substitution patterns where the patient voluntarily or involuntarily uses a different muscle to compensate for a weak muscle being tested.

To conduct a MMT, the patient is positioned in a posture appropriate for the muscle being tested, which generally entails isolating the muscle and positioning so that the muscle works against gravity (Fig. 3). The body part proximal to the joint acted on by the muscle is stabilized. A screening test is performed by asking the patient to move the body part through the full available range of motion

Figure 3. Manual muscle test of the iliopsoas.

Table 1. Manual Muscle Test Scores^a

Score	Description
0	No palpable or observable muscle contraction
1	Palpable or observable contraction, but no motion
1+	Moves limb without gravity loading less than one-half available ROM ^b
2–	Moves without gravity loading more than one-half ROM ^b
2	Moves without gravity loading over the full ROM ^b
2+	Moves against gravity less than one-half ROM ^b
3–	Moves against gravity greater than one-half ROM ^b
3	Moves against gravity less over the full ROM ^b
3+	Moves against gravity and moderate resistance less than one-half ROM ^b
4–	Moves against gravity and moderate resistance more than one-half ROM ^b
4	Moves against gravity and moderate resistance over the full ROM ^b
5	Moves against gravity and maximal resistance over the full ROM ^b

^aAdapted from Ref. 2

^bROM = range of motion.

(ROM). The main test is then performed either unloaded, against a gravity load, or against manual resistance, and a grade is assigned to indicate the relative muscle strength.

Manual grading of muscle strength is based on palpation or observation of muscle contraction, ability to move the limb through its available ROM against or without gravity, and ability to move the limb through its ROM against manual resistance by the examiner. Manual resistance is applied by the examiner using one hand with the other hand stabilizing the joint. Exact locations for applying resistive force are specified and must be followed exactly to obtain accurate MMT results (2). A slow, repeatable velocity is used to take the limb through its ROM, applying a resistive force just under the force that stops motion. The instructions to the patient are, use all of your strength to move the limb as far as possible against the resistance. For weaker muscles that can move the limb, but not against gravity, the patient is repositioned so that the motion is done in the horizontal plane with no gravity.

Grades are assigned on a 0–5 scale with ± modifiers (1 = trace score, 2 = poor, 3 = fair, 4 = good, 5 = normal) (Table 1). Grades > 1 demonstrate motion, and grades >3 are against manual resistance. Other comparable scoring scales exist (7).

As noted above, importantly, the assignment of scores is based on clinical judgment and the experience of the examiner. The amount of resistance (moderate, maximal) applied by the examiner is also based on clinical experience and is adjusted to match the muscle being tested as well as the patient’s age, gender and/or body type.

A common alternative to motion-based MMT is the isometric MMT in which the limb is held in a fixed position while the examiner gradually applies an increasing resistance force. The instructions to the patient are, Don’t let me move you. The amount of force it takes to “break” the patient is used to assign a score. Scoring norms for isometric MMT are provided in Table 2. While the MMT is the most widely used method to assess muscle function, its reliability and accuracy can be questionable (9,10). The MMT

Table 2. Grading of Isometric Manual Muscle Test^a

Score	Description
3	Maintains position against gravity
3+	Maintains position against gravity and minimal resistance
4-	Maintains position against gravity and less than moderate resistance
4	Maintains position against gravity and moderate resistance
5	Maintains position against gravity and maximal resistance

^aAdapted from Ref. 2.

scores are least accurate for higher force levels (9,11,12). Interrater reliability for MMT is not high, suggesting that the same examiner should perform multiple tests on one subject or across subjects (2). While not entirely accurate, MMT scores do correlate well with results from handheld dynamometers (13), implying that both are valid measures of muscle strength. However, as explained in a later section, all tests based on voluntary activation of a muscle are prone to artifact because of patient motivation and examiner encouragement.

APPARATUS

The appeal of the MMT is that it can be performed simply with the patient, an examiner, and a bench or table. This makes it ideal for the routine clinical environment where specialized equipment is unavailable and time is short. It is also suited for situations in which testing must be

performed away from the clinic, for example, in nursing homes, rural areas, or remote emergency settings.

When greater accuracy of results is needed, instruments are available that provide precise readouts of the resistive force the muscle works against (14). One example is a handheld dynamometer, such as the one shown in Fig. 4. This instrument can be sandwiched between the examiner’s hand and the patient’s limb, and provides a “readout” of force. The interrater reliability for handheld dynamometers is good when used with a standard procedure (15–17), as is the test-retest reliability (13).

Other products have been developed for specific tests of muscle strength, for example, the hand dynamometer and pinch grip devices shown in Fig. 5. These are easy to use and common for diagnostic tests of the hand. Despite their quantitative nature, readings between different types and brands of dynamometers can vary (18,19).

Computer-controlled dynamometers offer a variety of loading conditions for muscle testing and for strengthening treatments (20,21) (Fig. 6). Along with isometric and isotonic loading, dynamometer machines provide isokinetic conditions in which the muscle group acts against a computer-controlled resistance that moves the limb at a constant angular velocity.

ADVANCED MUSCLE ASSESSMENT METHODS

Measuring Muscle Dynamics

Muscle is a complex actuator whose external properties of force and motion result from the action of thousands of muscle fibers which, in turn, result from the action of

Figure 4. Handheld dynamometer. Pictured is the Lafayette manual muscle test system from Lafayette instrument company (Lafayette, IN).

Figure 5. The Jamar hand dynamometer is pictured on the left (NexGen Ergonomics, Quebec, Canada), and the B & L Pinch Gauge is shown on the right (B & L Engineering, Tustin, CA).

Figure 6. Biodesx dynamometer for computer-controlled muscle testing (Biodesx Medical Systems, Shirley, NY).

millions of structural and active proteins whose interaction is triggered by biochemical events. While most muscle testing focuses on the overall strength of a muscle or muscle group, more sophisticated assessment can be useful for in-depth examination of muscle function, including its dynamic, kinematic and fatigue properties.

The approach used to measure muscle function in more detail involves developing a mathematical model of muscle activity and then using experiments to identify the parameters of the model. Overviews of these methods are provided in Zajac and Winters (22), Durfee (23), Zahalak (24), Crago (25), and Kearney and Kirsch (26). The modeler must first choose the appropriate complexity of the mathematical model. The optimum choice is a model that is sufficiently complex to reveal the behavior of interest, but not so complex that parameters cannot be identified. Generally, Hill-type input-output models (27,28) are a good balance, as they capture key force-velocity, force-length, and activation dynamics at a whole muscle level (Fig. 7).

Model parameters can be identified one at a time, using the approach followed by Hill (27), or all at once using modern system identification techniques (23,26). Electrical activation of the muscle is a particularly convenient means for excitation because, unlike voluntary activation, there is control over the input, an essential component for an effective system identification method. Testing can be done

Figure 7. Hill muscle model. The contractile element (CE) contains the active element with dynamics, force-velocity and force-length properties. The series element (SE) is the inherent internal elastic elements, and the parallel element (PE) represents passive connective tissue.

under isometric conditions for determining recruitment and twitch dynamic characteristics, or under arbitrary loading to find active and passive force-length and force-velocity properties.

Identification of muscle properties is most easily accomplished using isolated muscle in acute animal model studies. Here the muscle is unencumbered by joint attachments and extraneous passive tissue. Muscle tendon can be directly attached to a force sensor and placed in a computer-controlled servo mechanism to apply known length and velocity trajectories, all while being stimulated. For example, the isometric recruitment curve, the relationship between muscle force and stimulus strength, can be identified using either point-at-a-time or swept amplitude methods, the latter being efficient in implementation (29). Using the model shown in Fig. 8, active and passive force-length and force-velocity properties can be estimated using brief bouts of controlled, random length perturbations, and then verified through additional trials where both stimulation and length are varied randomly (23,30) (Fig. 9). Simultaneous identification of active and passive muscle properties for intact human muscles is more challenging and represents an ongoing area of research (26).

Electromyogram

Contracting skeletal muscle emits an electrical signal, the electromyogram (EMG). Electrical recording of the EMG using needle or surface electrodes is an important diagnostic indicator used in clinical neurology to diagnose neuromuscular disorders including peripheral neuropathies, neuromuscular junction diseases, and muscular dystrophies. The EMG is also used in research as an estimator of muscle activity for biomechanics and motor control experiments. The reader is referred to Merletti and Parker (31) and Basmajian and DeLuca (32) for a comprehensive discussion of surface and needle EMG used in research applications, and to Preston and Shapiro (33), Kimura (34), and Gnatz (35) for an introduction to clinical EMG. Nevertheless, these assessment approaches require volitional activation of the patient’s musculature under investigation.

STIMULATED MUSCLE FORCE ASSESSMENT

As described above, most devices used clinically to quantify force and increase objectivity still rely on voluntary effort, which can be problematic. Pain, corticospinal tract lesions, systemic illness, and inconsistent motivation can significantly affect voluntarily activated muscle force. In addition, some neurologically impaired patients have difficulty maintaining a constant velocity of limb movement, and some very weak patients are unable to complete a full range of motion in voluntary force assessment tasks (36,37). As a specific example, monitoring muscle function in patients confined to the intensive care unit is a difficult challenge. Often such patients are on potent pain medications (e.g., morphine) and/or are sedated, or may have significant alterations in levels of consciousness due to critical illness (38,39). Thus, it can be extremely difficult to ask such patients to provide reproducible voluntary

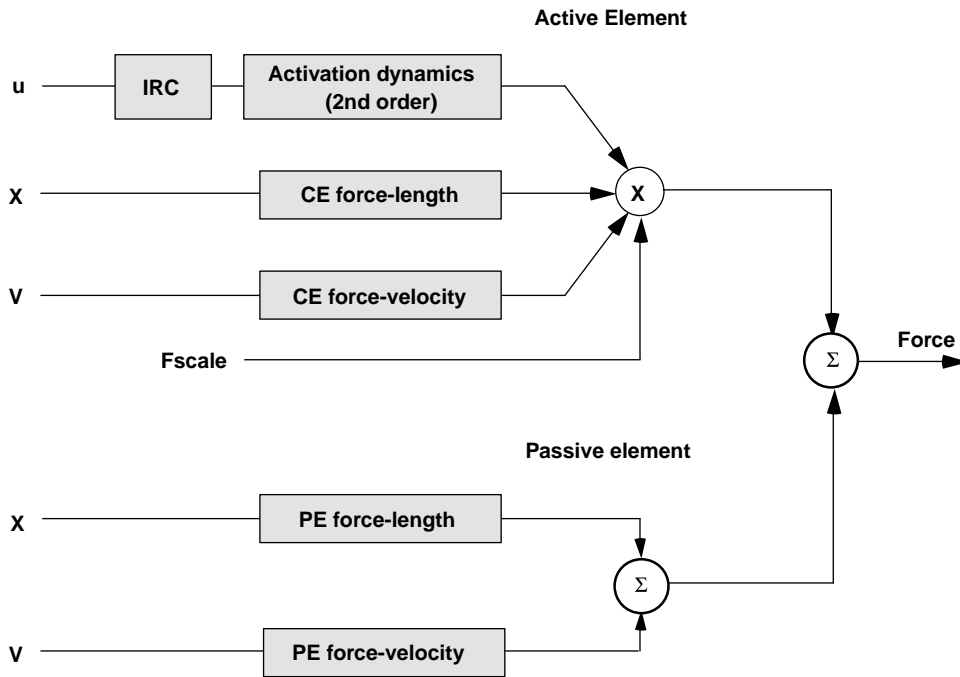

Figure 8. A model that can be used for muscle property identification. The active element has recruitment and twitch dynamics that multiplicatively combine with active force-length and force-velocity properties and sum with passive force-length and force-velocity properties to produce overall muscle force. (For details, see Refs. 23 and 30). IRC = isometric recruitment curve; CE = contractile element; PE = parallel element.

efforts. Even when cooperation is good, most measures of force assessment are qualitative, similar to using a hand-held unit for testing neuromuscular blockade.

Stimulated muscle force assessment is a versatile approach for quantitative involuntary muscle torque in humans. A muscle is activated by noninvasive nerve or motor point stimulation. A rigid apparatus is used to secure the appropriate portion of the subject's body in a predetermined position that confines movement to a specific direction, for example, ankle dorsiflexion, thumb adduction, arm flexion, or neck flexion (3,4,40,41) (Figs. 10 and 11). The innervating nerves or the motor points of the muscle are stimulated using surface electrodes, with either a single

stimulus to generate a twitch contraction or with short trains of stimuli to produce tetanic contractions (e.g., 5 ms interpulse intervals) (3,4). Incorporated strain gauges are used to measure isometric torque and, via acquisition software, all data are immediately displayed and on-line analyses are performed. Various parameters of the obtained isometric contractions are measured, for example, time between stimulus and torque onset, peak rate of torque development, time to peak torque, half-relaxation time, and other observed changes (Fig. 12; Table 3).

Such information is predicted to correlate with underlying physiological conditions and/or the presence of a myopathic or neuropathic disorder. To date, the average torque generated by healthy control subjects varies by <5% with repeated testing for contractions elicited from the various muscle groups studied (4,40,41). Thus, this assessment approach has potential utility in a number of research arenas, both clinical and nonclinical. Specifically, it has added clinical value in diagnosing a neuromuscular disorder, tracking weakness due to disease progression, and/or quantitatively evaluating the efficacy of a therapy (37,42–45). Compared to current assessment methods, we consider that monitoring isometric muscle torque generated by stimulation improves objectivity, reliability, and quantitative capabilities, and increases the type of patients that can be studied, including those under sedation (39) (Fig. 10). Stimulated muscle force assessment may be of particular utility in studying patients with a known underlying genetic disorder, for it could then provide important information as to genotype-phenotype associations (37).

The general configuration of the measurement system consists of the following main components: a stabilizing device that holds either the subject's arm or leg in a defined position; a force transducer that detects the evoked torque produced by a specific muscle group; hardware devices for nerve stimulation, signal amplification,

Figure 9. Results from an isolated muscle experiment where muscle active and passive properties were identified, then the resulting model was verified against experiment data. Data were generated while the muscle underwent simultaneous, random, computercontrolled stimulation and length perturbations (30).

Figure 10. Muscle force assessment system to determine involuntary isometric torque of the human dorsiflexor muscles. It is comprised of the following main components: (1) a stabilizing frame with knee supports; (2) the torque plate with mounted boot to fix the foot which can be rotated between -40° and 40° ; (3) a strain gauge system (Wheatstone bridge circuit) that detects the evoked torque; (4) a stimulator–amplifier unit that can supply variable stimulus pulse amplitudes and pulse durations and can amplify the voltage changes from the Wheatstone bridge circuit; and (5) a computer with data acquisition hardware and software for recording, analyzing and displaying all signals. (Modified from Ref. 39.)

and signal conditioning; a computer for stimulus delivery; and data acquisition software for recording, analyzing, and displaying all signals simultaneously (torque, EMG, applied stimulus) (Figs. 10–12).

The stabilizing device system currently used to study the dorsiflexors is a modification of a previously described apparatus (3). This device can be configured to maintain the subject's leg in a stable position while allowing access

Figure 11. Various applications of stimulated muscle force assessment: (a) dorsiflexor muscles in a seated individual with stimulation of the common peroneal nerve lateral to the fibular head; (b) adductor pollicis muscle following ulnar nerve stimulation; (c) activated biceps force with motor point stimulation; and (d) head stabilizing/force system to study sternocleidomastoid muscle function following motor point stimulation. (See also Refs. 4, 40, and 41.)

Figure 12. An example of a typical data display available to the investigator during subsequent off-line analyses. Graphically displayed are the muscle torque waveform and the stimulus administered (a double pulse with a 5 ms interpulse interval). Numerically displayed are various contractile parameters. Time 0 is the time of stimulation. The horizontal line indicates the time when half of the peak torque has been generated. The display shown is the torque generated by the dorsiflexor muscles of a normal, healthy subject.

for stimulation of the common peroneal nerve lateral to the fibular head (Fig. 11a). The torque about the ankle joint, produced by the dorsiflexor muscles (i.e., primarily generated by the tibialis anterior with contributions from the peroneus tertius and extensor digitorum muscles), is then quantified. One or two padded adjustable clamps can be used to maintain stability of the leg (knee slightly flexed in a supine position or flexed at 90° while seated). Modified in-line skate boots of varying sizes are affixed to the torque plate and adapted for either the right or left foot. The foot and ankle can be rotated within a 40° range while secured in the skate boot. This device can also be used for subjects in a supine position, in which case the support frame is secured to the upper leg proximal to the knee (Fig. 10) (39,45). To emphasize the extreme versatility of this methodology, note that a specialized version of this device was constructed and used to study dorsiflexor torques in hibernating black bears, *Ursus Americanus*, in the Rocky Mountains (46).

Briefly, the arm and hand stabilizing apparatus, used to measure muscle torque of the adductor pollicis, is easily attached to the main stabilizing frame (Fig. 11b). Using

straps, the forearm can be secured to the arm stabilizing unit, which can be adjusted for varying arm lengths. The digits (2–5) are placed in the hand well, and the thumb is secured to the constructed thumb bar attached to the torque plate. Shown in Fig. 11c is the configuration that is used to record force generated by the biceps muscle. As for the aforementioned muscles, force can be produced by peripheral nerve stimulation or by voluntary effort. In addition, we have successfully employed motor point stimulation of the muscle itself with large surface electrodes (40). The forces of the isometric muscle contractions are obtained as changes in torque applied to the instrument torque plate. Finally, we recently reported the optimization of an approach to study forces in the sternocleidomastoid muscle in the anterior neck (Fig. 11d), and plan to use these methodologies to study the effect of therapy in patients with cervical dystonia.

To date, this assessment approach has been used to study patients with a wide variety of disorders including: amyotrophic lateral sclerosis, Brody's disease, chronic inflammatory demyelinating polyneuropathy, malignant hyperthermia, muscular dystrophy, myotonia, periodic

Table 3. Contractile Parameters that Can Easily be Quantified

Parameter	Units ^a	Definition
Peak torque	N·m	Maximum amount of torque developed
Contraction time	s	Time from onset of torque to time of peak torque (e.g., calculated at 90% of peak)
Half-relaxation time	s	Time from peak torque to time when torque decays to half of peak torque
Peak rate of development	N·m/s	Maximum rate of torque development
Peak rate of decay	N·m/s	Maximum rate of torque decay
Time to peak development	s	Time from onset of torque to the peak rate of development
Time to peak decay	s	Time from peak rate of development to peak rate of decay
Half-maximal duration	s	Time when the generated torque is maintained at a level of half of the peak torque
Latency to onset	s	Time from the stimulus to the onset of torque development

^aN·m = newton meters.

paralysis, and nerve conduction blocks. The new insights to be gained by employing this approach in a variety of healthcare situations will further our clinical understanding of the underlying pathophysiologies, and provide us an accurate means to determine clinical outcomes. Recently, we employed this approach to evaluate athletes with potential overtraining syndrome (47), thus the applications for these methodologies could be considered quite limitless.

SUMMARY

The assessment of a patient's muscle strength is one of the most important vital functions that is typically monitored. Specifically, strength assessment is necessary for determining distribution of weakness, disease progression, and/or treatment efficacy. The particular assessment approach will be, in part, dictated by the clinical circumstance or severity of illness. Several assessment techniques and tools are currently available to the healthcare provider and/or researcher, yet each has its unique attributes. Nevertheless, as outcomes-based medical practice becomes the norm, the need for quantitative outcomes assessment of muscle strength will become even more important.

INTRODUCTION

The aim of this chapter is to provide an overview of current issues involving the use of computers in cognitive rehabilitation. The chapter begins with a brief historical review of computer use with a variety of disabilities including brain injury, learning disability, psychiatric disorders, and dementias. It continues to address selected research findings on the use of virtual reality for rehabilitation of impairments in attention, memory, and functional daily living activities. Finally, the chapter ends with conclusions and ethical reflections on using computers in research and direct care practice.

Impairments in cognitive function frequently occur as a result of acquired brain injury (i.e., trauma, cerebrovascular

accidents, anoxic encephalopathy, meningitis), specific learning disabilities, mental illness, Alzheimer's disease and other causes of dementia, and as a result of the natural aging process. These cognitive impairments can include, but are not necessarily limited to, decreased attention/concentration, memory, problem-solving and decision-making, planning, and sequencing. These impairments can negatively impact learning and skill acquisition, interfere with the ability to engage in everyday activities, preclude participation in social engagements, and hinder quality of life.

Cicerone et al. (1) and Giaquinto and Fiore (2) have defined cognitive rehabilitation as the systematic application of interventions to remediate or compensate for cognitive deficits and improve abilities in daily living skills and problem-solving. Cognitive rehabilitation interventions teach an individual to appropriately attend to, select, understand, remember relevant information, and apply the information appropriately in order to engage in meaningful daily activities and solve problems that occur in our complex society. Successfully completing daily activities and solving novel problems supports participation in meaningful societal roles such as breadwinner, husband, wife, and parent. Cognitive rehabilitation is generally carried out as part of a service delivery system that is interdisciplinary in nature (3). Services delivered are tailored to individual needs, are relevant to the person receiving the services, and bring about change that impacts daily functioning (1,2).

Over the past three decades, the personal computer has been employed as a tool to deliver interventions to remediate or compensate for cognitive deficits. Computers offer a number of advantages over traditional methods of cognitive remediation (i.e., flexibility, data collection, accessibility, portability, and cost), and, while not a treatment approach in and of themselves, computers can be a powerful tool to enhance the efforts of educators and clinicians.

COGNITIVE TRAINING FOR PERSONS WITH BRAIN INJURY

Computer-assisted cognitive retraining (CACR) for persons with acquired brain injury (ABI) began with the use of standard video games as an adjunct to traditional approaches to address deficits in attention/concentration, visual scanning, information processing speed, and divided attention (4). Lynch (4) reported that the initial use of video games for cognitive retraining was appealing to both clinicians and ABI survivors, as the games were inexpensive and widely available, and were interesting and motivating to the user. However, despite improvements on neuropsychological measures of basic cognitive skills reported in early single subject and small group pre-post design experiments using CACR (4,5), little carry over into everyday activities occurred. Other limitations existed as well, such as the inability to modify computer games for individual use and score user performance in a consistent and meaningful way (6). For these reasons, computer games gave way to educational programs that were developed for drills and practice of basic academic skills (i.e., vocabulary, math skills, and simple problem-solving/decision-making). However, the commercially produced educational software was

not without limitations, primarily the inability to easily modify the program to meet specific needs of an individual user or clinician. By the mid-to-late 1980s, specific computer software was developed for CACR with the ABI population. Some software programs addressed a number of cognitive skills (such as attention, memory, and sequencing) in a "package" (2,7). These programs allowed the clinician to vary levels of task complexity and individualize treatment by adjusting the speed of stimulus presentation, the delivery of cues/prompts, establishing reinforcement schedules, and so on. Results of studies using CACR to address specific deficits in attention/concentration (8,9), memory (10), visual processing (11), and visual scanning (12) also appeared in the literature.

Today, computers are used as assistive devices to help persons with cognitive deficits complete essential daily activities such as remembering appointments and items on a to-do list, and to overcome specific limitations such as difficulty speaking (voice synthesizer). Virtual environments also allow persons to practice skills in a safe, simulated environment (13,14). Weiss et al. (13) used a PC-based VR system to train stroke patients with unilateral spatial neglect to practice crossing a typical city street safely. Zhang et al. (14) developed a PC-based virtual kitchen allowing persons with acquired brain injury to practice cooking a meal. The computer program provided prompts as needed to assist the user to sequence and complete the task correctly. The use of virtual reality in cognitive rehabilitation is discussed in greater depth later on in the chapter.

COGNITIVE TRAINING FOR STUDENTS WITH LEARNING DISABILITIES

Personal computers appeared in the classroom in the late 1970s and early 1980s (15). Computer-assisted instruction (CAI) presented information in the three primary modalities: drill and practice, simulation, and tutorials. Drill and practice programs provided a single question or problem and elicited a response from the student. The student's answers were met with feedback from the computer program, followed by another question or problem. Simulation programs were more complex, requiring the student to process information on more than one level simultaneously and engage in a decision-making process. The computer program provided cues and feedback to assist the student in reaching the correct answer. Tutorial programs simulated the traditional style of classroom education delivered by most teachers. The information or content material was presented to the student. The computer program asked questions of the student, provided cues, prompts, and feedback as needed until the material was mastered. For some teachers and administrators, computers were thought to be the answer to problems associated with traditional approaches to instruction, particularly for educating challenging students. Teachers struggled with providing appropriate levels of instruction for students with a variety of learning styles, aptitudes, and in some cases, disabilities. With PCs in the classroom, gifted and talented students would be able to receive additional or more

challenging assignments, while ensuring additional drill and practice and self-paced learning for students who required more individualized assistance. Those who embraced early computer technology in the classroom experienced the PC as inexpensive, portable, and a way to provide challenging but nonthreatening instruction. Some viewed the computer as a "fashion statement," whereas others were afraid of the technology and resisted its use in the classroom. The greatest limitation of early computer technology for the classroom was memory capacity. Also, with pressure from parents and the booming PC industry, CAI programs for the classroom were introduced before being adequately assessed. Finally, it was difficult to measure the effectiveness of CAI as compared with traditional methods of instruction due to the number of variables that must be controlled in the classroom setting.

Over the past two decades, computer usage has increased, primarily due to the increased memory capacity available in today's computers. Special applications have been developed for the special education populations and for students with specific learning disabilities. Multimedia and hypermedia (i.e., presentation of information in text, graphics, sound, animation, and video) are now used with special populations to enhance writing skills (16) and mathematics and problem-solving skills (17). PCs are now used to overcome physical disabilities and language difficulties (i.e., problems understanding or using spoken or written language) of students participating in special education curriculums and continue to be used for drill and practice of basic academic skills. Research is mixed with regard to the impact of computer-assisted instruction on student's academic performance, primarily due to research design flaws in two critical areas: (1) inclusion of adequate controls and (2) holding instructional variables constant. However, a common theme emerging from most published studies is that technology cannot take the place of good teacher instruction. Use of computers in educational settings must include effective instruction from teachers, proper social organization of the classroom, and meaningful assignments.

COGNITIVE TRAINING FOR PERSONS WITH PSYCHIATRIC DISORDERS

Early use of computers in psychiatry and psychotherapy borrowed successes of the technology in educational settings and rehabilitation of persons with acquired brain injury (18,19). Mentally ill patients often demonstrate cognitive deficits similar to individuals with learning disabilities and traumatic brain injury, including decreased attention/concentration, memory, planning and problem-solving, and judgment/decision-making (18,19).

In the area of psychiatry, reports of computer-assisted interventions began to appear in the literature in the late 1980s. Computers were used as interviewing and assessment devices (e.g., diagnostic interviews) and for self-administered rating scales for depression and other mental illnesses (20–22). Computers were thought to have some advantage over a professional conducting a clinical interview, as some psychiatric patients were more willing to

disclose sensitive information to a computer rather than to a person (22).

Later, studies appeared in the psychiatric literature using computers to treat specific cognitive deficits, such as decreased attention and psychomotor speed in persons with schizophrenia (23,24).

Greater memory capacity and improved graphics allowed the development of multimedia presentations for patient education and specific data collection. In one study, Morss et al. (25) used a multimedia computer program to assess and evaluate the side effects of antipsychotic medication in persons with schizophrenia.

Finally, computers have been used in long-term psychiatric settings to teach high level vocational skills and to remediate educational disabilities. Brief (26) reported use of computers to teach advanced computer applications (such as database development for accounting and inventory, desktop printing and publishing, installing and upgrading software, and teaching staff word processing and spreadsheet skills), and to remediate deficits in mathematical abilities, reading comprehension, and vocabulary in persons with chronic mental illness. Brief (26) and Perr et al. (19) have cited numerous advantages of computer use with this population. Persons with chronic mental illness can learn to use computers and appear motivated to use the technology. Computers can be more engaging and provide for self-paced learning, making computer use more attractive than traditional classroom settings. Computer programs can be easily modified or individualized. Many patients demonstrate enhanced self-esteem as they master specific skills or become productive. Some other benefits of computer use with this population included increased attention/concentration and decreased frustration.

Computer technology has also been applied to the use of psychotherapy. Like psychiatry, computers have been used to aid in diagnostics, patient education and computer-assisted instruction, and cognitive rehabilitation (27). Computers have also been used in some forms of psychotherapy. With the advent of the PC, reports of the application of computer technology immediately began to appear in the literature in the late 1970s and early 1980s. Computers were used to desensitize anxious test-takers (28), in the treatment of agoraphobia (29), in the treatment of obesity (30), and in the treatment of sexual dysfunction in individuals and couples (31). Later, applications appeared in the field of behavioral health using computers for promoting smoking cessation and substance use/abuse (32).

In addition to numerous self-help applications, computers have been used in brief psychotherapy for presenting straightforward information or feedback (33).

Studies using computers in psychotherapy have shown that the technology is widely accepted and most people find computers to be a reliable source of information (databases, Internet, etc.). Similar to reports in the psychiatric literature, some persons find it easier to share sensitive information with a computer as opposed to a person. Rialle et al. (27) cite a number of advantages of computer-mediated psychotherapy services. First, regarding ethical considerations, it is highly unlikely that exploitation, abuse, or boundary issues will occur in a relationship between

a computer and persons receiving computer-assisted psychotherapy services. With continued increases in health-care costs, computers can be cost-effective and provide greater access to growing demands for mental health services. It is unlikely that computers, at least in the near future, will replace human psychotherapists given the complexity of the interaction that takes place in the course of intensive and long-term psychotherapy. The relationship between the person and the therapist is where the work of psychotherapy occurs, and computers cannot replace the warmth, empathy, and genuineness responsible for change in the therapeutic relationship.

COGNITIVE TRAINING FOR PERSONS WITH DEMENTIA

Reports of computer-assisted instruction and cognitive rehabilitation with the elderly have appeared in the nursing (34), geriatric (35), and psychology (36) literature over the past 15 years. PCs have been used in the treatment of age-related cognitive decline (37), Alzheimer's disease (AD), and other dementias (38). Computers have also been used for instruction, entertainment, and socialization of otherwise healthy elderly people without self-reported cognitive decline (39).

In the treatment of age-related cognitive decline, Gunther et al. (37) demonstrated that a 14 week computer-assisted cognitive rehabilitation program resulted in improved memory, information processing speed, learning, and interference tendency for 19 elderly participants who showed age-related cognitive decline without dementia. Follow-up five months after the completion of the cognitive rehabilitation program showed that information processing speed, learning, and interference tendency were maintained. The study also listed a number of advantages of computer use with this population, including the computer's value to motivate the elderly to learn, the computer's ability to directly measure success, its flexibility, and the ability to provide immediate and totally value-free feedback.

Computer-based interactive programs have been used to treat mild to moderate AD. Hoffman et al. (38) reported results from a pilot study of 10 AD patients. Although no evidence of general cognitive improvement or transfer of skills to real-life settings was noted, most participants in the study showed increased speed of computer use, required less assistance to use the computer program, and 8 of 10 made fewer mistakes. Mahendra (40) pointed out that many of the principles that facilitate learning in patients with AD or vascular dementia are easily incorporated into computer programs. For instance, repetition, active involvement in learning (i.e., interactive programs), cueing, feedback, and reinforcement of correct responses can easily be built into computer-assisted cognitive rehabilitation programs.

In a review article, Hendrix (39) reported on a number of studies that revealed computer usage by otherwise healthy elderly individuals resulted in improved self-esteem (i.e., from a sense of accomplishment or productivity), increased attention to task, and greater social interaction. Computer usage also provided entertainment and mental stimulation

in the form of games, puzzles, and the like. Many of the sensory (i.e., visual and hearing) and motor deficits associated with aging were overcome by the use of a PC. For example, increasing font size to at least 18 made text more readable. External speakers (for amplification) or visual indicators on the screen compensated for poor hearing. Touch screens, voice-activated typing programs, and keyboard guards were among other modifications that allowed the elderly to use computers for entertainment, research, and contact with friends and family.

Finally, computers and computer programs have recently been developed as a screening tool to identify mild cognitive impairment in early dementia patients (41). Future trends in the use of computers with the elderly will be aimed at preventing cognitive loss. "Geroprophylaxis" (37) or preventive therapies for the elderly may incorporate the use of computers in everyday activities, and probably at a younger age (for example, just after retirement) in an effort to prevent cognitive decline.

Although all these implementations present the conventional use of computers in cognitive rehabilitation, which have followed ever since the advent of computers in rehabilitation, VR technology, a more recent computer-based intervention in cognitive training, is increasing gaining attention. The technology offers a safe appendage to clinical interventions and is therefore just beginning to gain a therapeutic appeal in the area of rehabilitation. The following section discusses a few studies that have implemented the VR technology in cognitive rehabilitation.

VIRTUAL REALITY AS A COMPUTER-GENERATED TECHNOLOGY FOR REHABILITATION

VR provides a natural and intuitive interaction with a simulated environment because of the enhanced kinesthetic feedback gained by using various haptic devices. It provides the capability to display a 3D computer-generated environment, which allow individuals to interact and become immersed in the simulation as if they were in a naturalistic setting (42,43). Immersion or presence is achieved by a variety of projection systems ranging from basic flat-screen systems to projection walls and rooms known as CAVES (www.evl.uic.edu/pape/CAVE/). These projection systems produce virtual or mixed environments where real and simulated representations of objects and people can be used for evaluation and training of individual skills (44).

Specialized devices such as head-mounted displays (HMDs) combined with tracking systems, earphones, gesture-sensing gloves, and haptic feedback also facilitate the sense of immersion in the virtual environment (45). However, the VR headsets may produce deficits of binocular function after a period as short as 10 min (46,47). HMDs contribute to ocular discomfort, headaches, and motion sickness (48). Many factors may contribute to the symptoms when using HMDs, including the weight and fitting of the HMDs, the postural demands of the equipment, low illumination and spatial resolution, as well as the sensory conflict between the visual, vestibular, and nonvestibular proprioceptive system (48). Although some studies report

minimal risk or rapid dissipation of side effects when using VR technology, additional research is needed to determine the duration and severity of the symptoms (45,48).

Computer graphics techniques are used to create a virtual setting, complete with images and sound, that corresponds to what the user would experience in a real environment. The VR headset and a tracking system sense the position of the user's head and communicate the information to the computer that uses this spatial information to immerse and orient the user in the virtual setting.

Therefore, the user can navigate and interact with objects in the virtual environment using other VR devices such as data gloves, joy sticks, or even the natural hand (45,49). In other words, these collections of 3D computer-generated images can generate a continuum of high fidelity virtual environments. The VR devices and displays range from "virtual world objects" to "mixed reality" in which the real world and the virtual world objects are presented together within a single display (49,50).

The VR technology seems to offer many opportunities for evaluation and training of healthy and disabled populations. Successful reports include the U.S. National Aeronautics and Space Administration's use of VR training for astronauts to repair the Hubble telescope in space (51) and use of VR in the rehabilitation of people with intellectual disabilities (52).

VR FOR COGNITIVE TRAINING

This section will focus on the potential of VR for cognitive training. Persons who suffer from central nervous system damage may experience profound and pervasive difficulties with cognition. The beneficial aspects and limitations of VR for cognitive impairments will be discussed from the impairment and functional disability perspective. This model represents the continuum of the health-care services at the body and functional levels. VR training in cognitive rehabilitation has been divided into attention training and memory training.

VR FOR ATTENTION ASSESSMENT AND TRAINING

The brain allows individuals to constantly scan the environment for stimuli. Arousal, orientation, and focus are regulated in the brain. The reticular activating systems, the superior colliculus and the parietal cortex, and the lateral pulvinar nucleus in the thalamus are active processors of attention. All these brain structures in connection with the frontal lobes allow the individual to establish and maintain stimulus control and observe features in the environment. Attention is a multicomponent behavior and can be impaired in many neurological conditions. VR has been used for attention training. Some of the theories about the perception of reality in the virtual experience are, in fact, attributed to the three dimensions of attention (53). The three attention dimensions are (1) the focus of attention between presence and absence of reality; (2) the locus of attention between the virtual and physical world; and (3) the "sensus" of attention between arousal and the users internal physiological responses (53).

In general, attention is the ability to focus on critical aspects of the stimulus in the environment. VR technology can provide a controlled stimulus environment in which cognitive distractions can be presented, monitored, manipulated, and recorded using various levels of attention, including (1) **focused attention** (to perceive and respond to specific information/stimuli), (2) **sustained attention** (to maintain consistent concentration or vigilance on performing a task), (3) **selective attention** (to avoid distractions or competing stimuli), (4) **alternating attention** (to shift or alternate the focus of attention between tasks), and (5) **divided attention** (to respond to multiple stimuli or to give two or more responses simultaneously) (45,54). Several studies have supported the potential use of VR for the assessment and training of attention skills. In 2001, Rizzo et al. (55) reported on a virtual classroom environment, and in 2002, Lengenfelder et al. (42) reported on a driving course.

Divided attention specifically requires the ability to respond to multiple tasks at the same time or give two responses simultaneously. Lengenfelder et al. (42) used a VR driving course environment displayed on a computer screen to study divided attention of VR drivers with and without traumatic brain injury (TBI). The task required driving while identifying a four-digit number appearing in the same or random locations on the vehicle's windshield. The preliminary results showed no differences in relative speed between VR drivers with and without TBI on any of the four attention conditions used but rather the rate of the stimulus presentation seemed to influence the driving performance. In addition, the VR drivers with TBI showed a greater number of errors on the secondary task (number recall) performed while driving. Spearman's correlations between the VR performance of divided attention and neuropsychological measures of divided attention indicated that the more errors that were made during the VR divided attention task, the lower the number of correct responses on neuropsychological measures of divided attention. The findings suggest that VR may provide a way to measure divided attention and its impact on driving.

Other researchers have designed VR classrooms to examine children with attention deficit hyperactivity disorder (ADHD) during the control and manipulation of visual and auditory distracters (41,56). The preliminary results showed that children with ADHD had significantly more omission errors in the distracting conditions than the children without ADHD (56). Cho et al. (41) developed and studied two virtual cognitive training courses, VR classroom environment and a comparison computer cognitive training. The VR head-mounted display was used to validate the possibility of attention enhancement on 30 teenagers who had been isolated in a reformatory facility. The participants were assigned into three groups: VR group, nonVR (cognitive training) group, and control group (no special treatment). The interventions took eight sessions over two weeks. The results showed that the VR group was the most improved in attention training. These studies support the use of VR for attention impairment training. VR also has potential for memory impairment training.

VR FOR MEMORY ASSESSMENT AND TRAINING

An important feature of cognitive rehabilitation is neuropsychological assessment in order to determine the areas of impairment and function to use for training and compensation (45). Conventional standardized memory assessments have been criticized for lacking in ecological validity (57). VR may be able to increase the ecological validity that many conventional standardized memory assessments are lacking (57). VR can be designed for assessment and training of memory impairments after disability. Memory is a multifaceted process of brain function. Although many types of memory exist that activate a complex network of structures in the nervous system, memory requires attention to the information, encoding and maintaining information in short-term memory, followed by storing information in long-term memory, and finally, consolidating the information for retrieval as needed (54). At the cellular level, memory can be conceived as a specific neuronal association pattern that remains as a permanent pattern in the brain after the original information stimulus has ceased to exist (58).

Many brain structures are involved in memory function. Many areas are located anatomically beneath the cingulate cortex, and include the thalamus, fornix, mammillary bodies, hippocampus, amygdala, basal forebrain, and prefrontal cortex (59).

Some exploratory studies indicate that VR has potential for memory remediation in people with memory impairments. It has been found that VR can promote procedural learning and transfer to improved real-world performance (57). Burgess et al. (60) investigated four types of recognition memory in a VR town environment. Thirteen healthy young male volunteers explored the VR town until they felt confident they could find their way around. They were then asked four types of forced choice recognition memory questions about person, place, object, and the width of the object. Event-related functional magnetic resonance imaging (efMRI) was performed while participants answered the questions. The results revealed that no significant difference in performance existed between the memory for person and the memory for place. The performance on the memory for object was significantly better. By combining fMRI with VR technology, the investigators were able to investigate spatial memory in simulated life-like events. The results suggested that the retrieval of VR spatial events (place, location) activated medial temporal, parietal, and prefrontal systems in the brain.

In another study, Hoffman et al. (61) explored remembering real, virtual, and false memories using a Virtual-Real Memory Characteristic Questionnaire (VRMCQ). As people can differentiate between memories of real and imagined events, VR environments offer a new source of memories for events. The authors explored how accurately people can distinguish reality from VR in memory via a source identification test. Participants were exposed to real and virtual objects and, one week later, took an identification test in which they determined whether the object had been real, virtual, or new. They then rated the qualities and associated with each memory using the (VRMCQ). Clear differences in the qualities associated with real

and VR objects were found. The real objects were more likely than VR objects to be associated with perceptual cues (61,62).

A wide variety of exploratory studies have been reviewed by Brooks and Rose (57) indicating that VR can enable a more comprehensive and controlled assessment of prospective memory than is possible with paper-pencil standardized tests. Brooks and colleagues further investigated the differences between active and passive participation in the nonimpaired participants.

Phobias have been treated using VR to desensitize patients to heights (acrophobias) (63), public speaking (agoraphobia) (64), small spaces (claustrophobia) (65), and flying (66).

VR FOR ACTIVITIES OF DAILY LIVING ASSESSMENT AND TRAINING

VR Kitchen Environments

Effective VR assessment and training of activities of daily living have been reported in a variety of areas including a virtual kitchen (14,67–70). Our research team developed an HMD virtual kitchen environment designed to assess persons with brain injury on their ability to perform a 30 step meal preparation task (68). The prototype was tested using a sample of 30 persons with traumatic brain injury. The pilot results showed the stability of performance estimated using intraclass correlation coefficient (ICCs) of 0.73. When three items with low variance were removed, the ICC improved to 0.81. Little evidence of vestibular optical side effects was noted in the subjects tested. In 2001, our research team used the same virtual kitchen environment to assess selected cognitive functions of 30 patients with brain injury and 30 volunteers without brain injury to process and sequence information (70). The results showed that persons with brain injuries consistently demonstrated a significant decrease in the ability to process information identify logical sequencing and complete the overall assessment compared with volunteers without brain injury. The response speed was also significantly different. Our team's VR third pilot was designed to test the stability and validity of the information collected in the VR environment from 54 consecutive patients with TBI (14). The subjects completed meal preparation both in a virtual kitchen and in an actual kitchen twice over a three week period. The results showed an ICC value of 0.76. Construct validity of the VR environment was demonstrated. Multiple regression analysis revealed that the VR kitchen test was a good predictor for the actual kitchen assessment. Our investigations demonstrated adequate reliability and validity of the VR system as a method of assessment in persons with brain injury.

Exercising in VR environments offers the potential for gains in cognitive and motor functions (71–73). Refer to Fig. 1 for examples of a VR software program that has been used for cognition and motor skills training. Grealy et al. (71) supported the impact of exercise and VR on the cognitive rehabilitation of persons with traumatic brain injury in a study that provided a four week VR intervention and

compared it with control patients of similar age, severity, and time post injury. They found the patients performed significantly better than controls on the tests of psychomotor speed, and on verbal and visual learning. Significant improvements were observed following a single session of VR exercise.

VR Mobility Environments

VR environments have been developed to train aspects of mobility including street crossing, wheelchair mobility, and use of public transportation and driving. Strickland et al. (74) found that children with autism were able to accept and wear VR helmets. McComas et al. (75) also investigated the effectiveness of VR for pedestrian safety in healthy children. Their results showed that significant change in performance occurred after three trials with VR intervention. Children learned safe street crossing in a desktop VR program. Their crossing skills were transferred to real behaviors in the suburban school group but not in the urban school group. The investigators provided no explanation for the difference noted.

VR environments have been developed for detection of driving impairment in persons with cognitive disability in persons with TBI and persons with driving and flying phobias (76,77). As stated before, impairments in divided attention has an impact on driving skills; therefore, attention training is promoted for driving skills training.

CONCLUSION

The fast data recording and processing capabilities have stimulated the application of computers in cognitive rehabilitation since the mid-1970s. It was first used in the treatment of persons with traumatic brain injury and learning disability. The technology was later applied to persons with mental illness and, most recently, in the treatment of adults with Alzheimer's and other dementias. In all applications, computers have been found to be interesting and motivating to the users, an efficient stimulus presentation, and an excellent data collection system. Today's computers are portable, fast, and software can be customized to meet specific needs of an individual user, teacher, or therapist.

A growing body of research continues to accumulate investigating the potential of computer technology to improve impairments, functional performance, and societal participation in persons with disabilities. It is clear that some evidence exists to support computer-based interventions as an adjunct to clinician-guided treatment (78). However, sole reliance on repeated exposure and practice on computer-based tasks without some involvement and intervention by the therapists is not recommended for cognitive rehabilitation (78).

Computer technology can provide valuable opportunities to health-care providers, educators, and researchers. Computer technology training is not a simple or single solution, and although it can promote knowledge and solutions, we also need to address other implications for cognitive rehabilitation. For example, access to computer technology is needed for personal assistance and to provide

Figure 1. Examples of virtual reality environments. Image of the IREX™ system used with permission of GestureTek Inc™ - World Leaders in Gesture Recognition Technology www.gesturetek.com.

access to education, employment, and social opportunities. However, because of the expense that limits technology access because of constraints in institutions budgets, personal income limits, and funding inadequacies and constraints, only a limited number of persons with disabilities can access computer technology (79).

Finally, ethical considerations of computer technology, including VR, require mentioning. Several areas need to be considered, including (1) the patient or user must share the control and responsibility of the computer technology experience with the therapist, educator, or researcher; (2) careful care and monitoring is required for patients with certain psychopathology for potential user difficulties that may be encountered through the computer technology

experience; (3) research participants must not be deceived into believing that they are experiencing real-life events; and (4) the patient or user must not be deprived of real-life experiences.

The application of computer technology is promising. However, substantial work needs to be conducted to identify and improve best practices through this medium. An important question is whether the improvement in the individual who used computer technology training is transient or sustained. Cognitive rehabilitation needs to promote generalization to everyday functioning and everyday activities. We need more rigorous research activities geared toward establishing a body of evidence that supports the effectiveness of computer-based technology.

INTRODUCTION

Paralysis

Muscle weakness resulting from various forms of paralysis is the major type of disability treated with orthotic devices. Paralysis may be acute or chronic to varying degrees depending on the state of the disease causing paralysis. The degree of paralysis or paresis can change with time as recovery is accomplished through therapy or healing of the physiological cause. Thus, the orthotic need for support, control of joint motion, and so forth, may change with time for many of these patients. Orthotic devices in general are designed for long-term use because many of the designs were developed for chronic applications to polio patients in the late 1940s and 1950s. With many new applications and new materials, a variety of devices have been developed that are ideal for short-term applications to more acute conditions, for example, stroke, head injury, spinal cord injury, and fractures.

Neuromuscular Control

Patients who suffer loss of neuromuscular control in the form of spasticity, paralysis of isolated muscle groups, and/or recovery of neuromuscular function resulting from regeneration of neural tissue, which requires relearning of coordination, are often helped with orthotic devices. Although most of these applications are short term, a few are chronic, such as in cerebral palsy, established spinal cord injury, and head injury.

Deformity

Another common use of orthotics in a growing number of cases is for musculoskeletal deformity. The first type of deformity is related to mechanical instability of the limbs or spine. Mechanical instability can result from soft tissue or skeletal injury or from degenerative joint diseases that cause chronic and progressive instability of the musculoskeletal system. One form of soft-tissue injury relating to the instability of the skeleton is caused by surgical reconstruction of the joints. Therefore, many orthotic devices are used for stabilization postoperatively when the spine or upper or lower limb joints have been reconstructed. The surgery often causes necessary damage to the stabilizing soft-tissue structures that often adds to instability of prosthetic components that require bone healing for final stabilization. The second type of deformity is due to the growth or remodeling disturbances in the skeleton. Orthotic applications are both acute and chronic in problems relating to musculoskeletal deformity. Most chronic applications or orthotics are in progressive deformities resulting from degenerative joint diseases such as rheumatoid arthritis, osteoarthritis, hemophilia, and diabetes. Orthoses generally are applied in these instances to prevent progressive deformity and any resultant mechanical instability in the

skeleton that it may cause. In realigning limb mechanics, orthoses may also prevent some of the disabling pain of degenerative joint diseases. Acute applications of orthoses for deformities include the treatment of fractures and soft-tissue injuries about the joints and postoperative protection for fracture stabilization or joint reconstructive or arthrodesis procedures.

DEVICES

Orthoses have an almost infinite variety of materials, designs, and constructions. Many factors contribute to this variety: (1) performance criteria, (2) available materials, (3) skills of the orthotist, and (4) desires of the patient, surgeon, and therapist.

Performance Criteria

As mentioned, many devices are used in chronic applications with significant loading and require great

Figure 1. (a) This KAFO is designed for chronic use. It has metal uprights connected to metal bands covered with leather and padding and a "caliper" type of stirrup that attaches to the shank of an orthopedic shoe. All parts are custom fit from mostly prefabricated components. (b) The other KAFO is designed for short-term use and has a thermoplastic thigh and leg interface with the soft tissue, connected to a plastic knee hinge suspended with a plastic posterior shoe insert. All parts are prefabricated in standard sizes. Reprinted with permission from Mamed Orthopaedic Systems.

Figure 2. Splints that are used for short-term or long-term immobilization of joints are typically of a simple design and can be prefabricated as in (a) WHO (reprinted with permission from Maramed Orthopaedic Systems) or custom fabricated as in (c) KAFO or (e) TLSO. Orthoses for similar parts of the anatomy with much more complex control criteria have typically more complex designs as in the WHO in (b), which provides a tenodesis action to close the fingers with wrist extension, and the complex reciprocator, bilateral HKAFO in (d), which provides stability for the knee and ankle while providing assistance to hip flexion.

fatigue resistance. In other instances, the loading conditions are slight, but the application is long term; thus, the primary requirement is good compatibility with the skin. Applications for very short-term use under either heavy or light loading conditions are much

less demanding on the materials and design of the device (Figs. 1–3).

Many devices simply act as a splint to immobilize musculoskeletal structures for a short time (Figs. 2 and 7); the design for such a device is thus relatively simple. Other

Figure 3. Many material options can accomplish the same performance criteria for a particular orthotic prescription. In this example, a tibial fracture orthosis (AFO) is constructed by three different techniques to accomplish the same end result. Plaster can be molded directly to the patient's limb and attached to a prefabricated ankle joint (a), an isoprene thermoplastic material can be molded directly to the patient's limb attached to a metal ankle joint incorporated into a stirrup permanently attached to the shoe (b), or prefabricated components can be applied with hand trimming and assembly (c). Reprinted with permission from Maramed Orthopaedic Systems.

Figure 4. Typical fabrication techniques for orthoses include the use of metal uprights connected by metal bands with leather and padding for covering and skin interface (a), or custom laminated thermosetting plastic with fiber-glass or fabric reinforcement incorporating prefabricated joints (b), or custom molded thermoplastic sleeves incorporating prefabricated joints (c).

Figure 5. Various combinations of prefabricated and custom-fabricated components can be used to accomplish a particular prescription criterion as in this series of examples of AFOs. Prefabricated components are used for the stirrup connection to the shoe and the modular dorsiflexion assist ankle joint that are attached to custom-formed metal bands, and custom-fabricated leather cuffs and medial T-strap (a). These thermoplastic, posterior leaf AFOs (b) demonstrate totally prefabricated design (left, reprinted with permission from Maramed Orthopaedic Systems) for dorsiflexion assist, custom fabrication with complete limitation, or ankle motion (right). The patellar tendon bearing orthosis (PTB) is designed to transmit axial loads as well as to control ankle and subtalar motion. This example uses a custom-molded thermoplastic soft-tissue interface with the calf, incorporating metal uprights into modular, prefabricated limited motion-ankle joints connected to a stirrup custom formed from prefabricated components incorporated into a “UCB”-type shoe insert custom molded from a thermoplastic (c). A similar type of PTB orthosis uses totally custom-fabricated thermoplastic sleeves with a posterior leaf-limited-motion ankle control attached to a shoe insert (d). The CAM walker, which is totally prefabricated, provides a “roll over” sole to accommodate ambulation with an immobilized ankle, (e, reprinted with permission from Aircast, Inc.). This plantar fasciitis AFO is also completely prefabricated (f, reprinted with permission from Sky Medical, Inc.).

devices have complex prescription criteria if used for assisting, resisting, or holding motion of joints under a variety of temporal and spatial conditions; such designs might be complex (Fig. 2d).

Materials

The choice of material varies according to durability, strength, stiffness, skin compatibility, and fabrication requirements. For short-term applications, prefabricated devices that can be produced by sophisticated manufacturing techniques are often used. Thus, most any commonly available material may be used for short-term custom applications; materials that can be applied directly to the patient will often be used (Figs. 3 and 9–11). Four basic forms of such material exist: plaster, fabric reinforced, fiberglass reinforced, and solid sheets. Some are thermosetting materials activated by promoters or moisture; some are thermoplastics. Devices for long-term use tend to be custom fabricated from materials that are formed to measurements or molds of the patient. The materials are typically thermoplastic, laminated thermosetting materials with carbon fiber, fiberglass or fabric reinforcement, leather, fabric, aluminum, stainless steel, steel, and foam plastics and elastomers (Figs. 1–13).

Description of Conventional Devices

Tables 1–3 describe in a general nature the types of components that make up conventional orthoses and the functional controls and typical materials used. In general, the soft-tissue interfacing components tend to be custom fabricated, the structural members tend to be prefabricated, and the joint mechanisms tend to be prefabricated and modular. It is possible, however, to find prefabricated components and preassembled prefabricated devices in each of these areas. It is also common to find orthotic devices constructed completely from custom-fabricated components integrated together in a totally custom device for a given patient (Figs. 1–3, 5, 7, and 10).

Under functional controls, the word “feedback” is used to indicate that certain proprioceptive feedback signals may be incorporated into these components to give information to the patient regarding the load on the device and/or the position of the device in space. This is sometimes helpful to supplement loss of normal proprioception in the limb. It is possible for feedback mechanisms; EMG-, load-, OR microprocessor-activated locks; and/or resistive or assistive mechanisms at all of these joints to be applied; however, the tables simply reflect those applications that are used in relatively common practice in the field of orthotics. Applications not listed here, to the knowledge of the authors, are simply research

Figure 6. Many types of devices use components that are similar to classic orthoses, but at this time are considered by the authors not to be “classic” orthoses because they are not fabricated or applied by orthotists. An example is this acutely applied air splint for first aid or emergency, designed to control edema and limit motion at the ankle joint for short-term use (a). Orthotic-like devices are used to supplement various therapeutic regimens in the rehabilitation of patients post-injury and post-surgery. This example provides continuous passive motion to the joints through powered systems attached to orthotic-like components (b, reprinted with permission from Orthomed Medizintechnik, GmbH), and the other one provides a corrective force to gradually regain motion in joints with contractures, (c, reprinted with permission from Joint Active Systems, Inc.).

Figure 7. Most KOs are designed for the prevention or protection of knee injuries. Simple soft devices to limit knee motion (a), splints to immobilize the knee temporarily (b), custom orthoses with knee mechanisms to control motion and provide support to the knee (c), and orthoses that provide adjustable corrective forces or moments to the knee to alter knee mechanics (d), reprinted with permission from Generation II USA, Inc.), and even powered knee mechanisms with microprocessor controls, (e), reprinted with permission from Becker Orthopedic, Inc.).

applications not in common use. The description of typical design types and materials also reflects the opinion of the authors on the systems commonly used in orthotics today. Many sophisticated designs and materials are being used in research and may be commonly applied in the future.

Some conventional devices do not strictly meet the nomenclature system because they do not cross a joint or control a joint. They simply are a sleeve that compresses soft tissue to stabilize a fracture or protect a limb with soft-tissue injuries. These devices are only for short-time use until an injury can heal. Examples are shown in Fig. 14.

FUNCTIONAL EVALUATION

Evaluation of musculoskeletal function is the key to adequate prescription criteria or performance criteria, for conventional orthoses. Communication of this evaluation by the orthopedic surgeon to the orthotist is an important step in obtaining agreement on, and optimum use of, orthoses in the rehabilitation of the patient. To this end, the Committee on Prosthetics and Orthotics of the American Academy of Orthopedic Surgeons has devised the technical analysis form that is used for recording the functional evaluation of the patient, documenting the abilities and disabilities of the patient, and forming a

Figure 8. HKAFOs are generally used for the control of deformities. Axial rotation alignment of the lower limbs can be controlled with an HKAFO commonly called a twister brace (a), which uses a flexible cable to provide free motion at the knee and ankle in all degrees of freedom while applying a constant axial torque for rotation correction. An HKAFO for control of valgus at the knee provides three-point support through the soft-tissue interfacing sleeves with as little restriction to ankle and hip flexion and extension as possible (b). An HO is often used after total hip replacement to provide an abduction resistance to the hip during flexion to help prevent hip dislocation until the soft-tissue healing is completed (c, reprinted with permission from Sky Medical, Inc.).

Figure 9. WHOs can be of static (a) or dynamic (b) variety to control, support, resist, or assist motion of the fingers, hand, and/or wrist. These examples are made of low-temperature thermoplastics that can be applied directly to the patient.

Figure 10. EWHOs are most typically of the custom-fabricated type (a), but they are also available in prefabricated forms (b, reprinted with permission from Maramed Orthopaedic Systems), as shown in these examples of devices for the treatment of Colles' fractures.

recommendation for the orthosis. In a uniform, simplified system, these details can be communicated to the orthotist for construction and fitting of the device and rehabilitation of the patient. Evaluation of each segment of the musculoskeletal system is divided into parts as described in Fig. 14, which shows a typical evaluation form. Note that the range of motion of each joint is indicated on the background of the normal range of motion for that joint and there are places for recording the static position of each joint and part of the skeleton and the deformities that exist in the skeletal structures. The first page of the technical analysis form contains didactic information on the impairments and

Figure 12. TLSOs are used in a wide variety of forms, most typically a custom-fabricated thermoplastic design for control of spinal deformities, such as this low-profile scoliosis TLSO for control of spinal curvature (a). This anterior closing TLSO is used for instability of the low back or low back pain (b).

Figure 11. EOs typically are of the custom-fabricated type with prefabricated components for the control of elbow flexion and extension during rehabilitation post-injury (a) or elbow reconstruction, but many are totally prefabricated designs (b, reprinted with permission from Aircast, Inc.).

Figure 13. This CTLSO is designed to provide corrective forces for spinal curvature with thermoplastic skin interfacing components for the pelvis and chin and prefabricated, metal uprights (a) This halo orthosis is designed to protect the cervical spine after acute injury and after spinal fusion (b). The skull pins in the proximal portion of the orthosis are percutaneous components that anchor into the skull through the skin for positive control of head position.

a nomenclature system for their description on the physical evaluation form. A legend for description of fixed deformities, alterations of range of motion, and description of skeletal as well as muscular abnormalities is provided in Fig. 16 for use in the boxes in Fig. 15 for description of the physical examination. On the reverse side of this form, the treatment objectives are outlined and the orthotic recommendation includes a description of the controls for each part of the musculoskeletal system that are recommended as performance criteria for the orthosis. The orthotist is then given the choice of how to accomplish these recommendations in orthotic design and materials. The recommendation form is completed with standard nomenclature describing the control of the joints and musculoskeletal structures: F designates free motion, A assistance, R resistance, S stop, H hold, and L lock controls on motion. A “v” accompanying any of these designations will recommend a variable control of the type described for that degree of freedom (Fig. 17). The degrees of freedom are described across the top of the table for flexion, extension, abduction, adduction, internal and external rotation, and axial loading on the skeletal parts. Also note that a standard nomenclature system is developed to describe the joints that are encompassed by the orthosis. Thus, FO designates an orthosis that controls the foot; AFO describes an orthosis that controls the ankle and the foot, and so forth. In addition to the designations shown on the orthotic recommendation table, it is possible to have a device that simply

Table 1. Lower Limb Orthotic Devices

Component	Functional control		Typical Design Types	Typical Materials
	Passive	Active		
Soft-tissue interface	Alignment to structural members and joints	Feedback load/position	Wraparound or interlocking shells; adjustable pads and straps	Fabric, leather, hand laminates, thermoplastics, foam or elastomer polymers
Structural members	Alignment to joints and soft tissue interfaces, extension blocks	Feedback load/position	Modular uprights; reinforced shell; extension of joints and bands; single axis; 1 or 2 DOF, cam or drop lock	Metals, hand laminates, prepregs, thermoplastics
Hip joint	Lock, stop, free, assistive, resistive motions	Manual-activated lock	Single axis; 1 or 2 DOF; cam or drop lock	Metals, reinforced polymers, thermoplastics
Knee joint	Lock, stop, free, assistive, resistive motions, adjustable varus/valgus corrective force	Feedback position, load-, manual-, or EMG-activated lock or resistance	Single- or multiaxis; 1 DOF; variable stop; cam, link, or drop lock; friction resistance; elastic assistance; single lateral or posterior upright; medial-lateral upright	Metals, reinforced polymers, thermoplastics
Ankle joint	Lock, stop, free, assistive, resistive motions	Feedback position, load-, manual-, or EMG-activated lock or resistance	Single- or multiaxis; 1 DOF variable stop; cam; friction resistance; elastic assistance; single lateral or posterior upright; medial-lateral upright	Metals, reinforced polymers, thermoplastics
Foot	Alignment		Shoe insert: caliper or stirrup attached to shoe with shank	Metals, reinforced polymers, thermoplastics
FES or stimulation	Electrode placement	Microprocessor, load- or EMG-activated stimulus	Implantable: electrodes, self-contained power and control module, stimulator module RF to external power External: electrodes, stimulator, and controls	Silicone-coated silver-braided steel, silver-impregnated silicone, SS electrodes, epoxy- or silicone-encapsulated electronic components

controls one joint and does not include all joints distal to it. For example, an orthosis that encompasses and controls only the knee joint is termed a “KO”. A similar nomenclature system is shown for the upper limb and for the spine in Figs. 18 and 19, which show the orthotic recommendation

and treatment objective portions of the technical analysis form for each of those applications. For examples of orthoses fitting each nomenclature descriptor, see the figures associated with each table. Many orthotic facilities and surgeons have created their own forms for orthotic

prescription, but they include similar features to those in the accepted standards shown here.

OUTCOME

Orthotic devices are designed to improve the function of persons with musculoskeletal disabilities. The goals of treatment are outlined on the technical analysis form for each application. The optimal outcome is obviously achievement of these goals. In many instances, achievement of these goals is related to the provision of functional independence for many persons who would otherwise be partially or totally dependent. Where total or partial functional independence is not feasible, the goal is to provide a better quality of life. When orthoses are applied acutely for temporary stabilization or temporary protection until healing or recovery from a disabling injury can occur, the goal is often an uneventful recovery. In many instances, the patient returns to employment or functional independence, or function is completely restored before the injury heals. After sufficient healing, the orthosis is usually discontinued. In some cases, orthotic care allows the patient to be discharged from the hospital or transferred to a less expensive support system earlier, reducing the cost of medical care. In most short-term applications of orthotic devices, patients are relatively compliant and cooperative and use the orthoses well. Most long-term applications of orthoses are well accepted by patients, but in a higher percentage of chronic (compared with acute) applications, patients use orthoses for limited activities or periods of time and choose to alter the original treatment goals. Such behavior is also not unusual for the users of many external prosthetic devices. Such patients often develop compensatory means of function (i.e., retraining of the contralateral limb) or use other assistive devices (like wheelchairs) to accomplish their personal goals.

For acute applications of orthoses, there is a strong trend toward the greater use of totally prefabricated systems. For chronic applications, very few prefabricated systems have proved to be adequate; the trend here is to use more thermoplastic materials. Patients find these materials more lightweight, cosmetic, and comfortable.

Another trend helping to facilitate these changes is the increased use of central fabrication facilities. Traditionally, orthotists have measured the patient, designed the orthosis, and completely fabricated the orthosis before fitting and training the patient in its use. Today, orthotists are being trained to devote more attention to the measurement, fitting, and training of patients and less attention to the fabrication of devices. This is because most types of devices can be fabricated in a factory with highly skilled technicians using the prescription criteria and the measurements of the orthotist. This trend helps to reduce costs; if the orthotist spends most of his or her time evaluating, fitting, and training the patients, and the technicians fabricate the devices, the orthotist can care for a much greater number of patients and the consistency of fabrication of the devices is improved considerably. Fabrication of a replacement device for a patient already under the care of an orthotist is often

simplified with the availability of a central fabrication facility.

FUTURE

Historically, developments in orthotics have followed developments in the field of external prosthetics. If this continues to hold true, one can anticipate that in the immediate future, orthotics will make increased use of proprioceptive feedback systems, composite materials, microprocessor controls for the dynamics of the orthosis, automation of production facilities and improvements in the design of skin interfacing components, and temporary use of standardized devices for patient training before fabrication and fitting. Also, because orthotic devices are increasingly used for many new applications and means for increasing the number of skilled orthotists needed to meet the demands are not available, there will probably be major increases in the use of prefabricated systems, central fabrication facilities, and/or simplified systems for specific applications that can be handled by other paramedical personnel. There is a growing trend toward greater use of functional electrical stimulation for even the most complex neuromuscular disabilities using microprocessor-controlled multichannel systems to control coordinated muscular activity in limbs with paralysis or severe paresis. Recent advances in electrode design, miniaturized microprocessor systems, and knowledge of musculoskeletal functions are continually producing breakthroughs in research. CAD/CAM methods for automated measurement, modification, and fabrication of custom devices are developing also. The orthotist will find continuing advances in orthotic systems for preventive medicine in sports and the work environment. The rehabilitation team, of which the orthotist is an important member, will include new specialists for biofeedback, rehabilitation engineering, and new branches of therapy and physicians and surgeons from specialties that previously were not involved in rehabilitation.

DEFINITIONS

1. *Ortho.* From the Greek *orthos*, meaning straight or to correct.
2. *Orthosis.* Orthopedic appliance used to straighten, correct, protect, support, or prevent musculoskeletal deformities.
3. *Orthotics (orthetics).* Field of knowledge relating to the use of orthoses to protect, restore, or improve musculoskeletal function. (Note: This field overlaps the field of mobility devices, including wheelchairs, crutches, and special vehicles, for transportation of persons with musculoskeletal disabilities. Mobility aids will not be discussed in this article.)
4. *Orthotist (Orthetist).* A person practicing or applying orthotics to individual patients.

5. *Custom versus prefabricated orthoses.* Custom-fabricated orthoses are devices that have components that are molded specifically to the contours of the musculoskeletal structures of a patient. This fabrication can be accomplished by making molds, tracings, or careful measurements of the patient's anatomy for custom shaping in the fabrication of the device. Prefabricated orthoses are made completely from prefabricated components that are fit to the patient in standard sizes. Some systems are preassembled, and some are not. Prefabricated components may be used in custom-fabricated devices along with custom-fabricated components to provide a custom orthosis.
6. *Modular component.* A component that can be assembled from prefabricated parts and can be disassembled and reassembled in different combinations.
7. *Nomenclature.* A standard set of abbreviations for an orthosis related to the anatomic parts that are to be controlled by the orthosis (see Figs. 14–18); for example, AFO is ankle-foot orthosis.
8. *Free motion.* No alteration or obstruction to normal range of motion of an anatomic joint.
9. *Assistance.* Application of an external force for the purpose of increasing the range, velocity, or force of motion of an anatomic joint.
10. *Resistance.* Application of an external force for the purpose of decreasing the velocity or force of motion of an anatomic joint.
11. *Stop.* Inclusion of a static unit to deter an undesired motion in a particular degree of freedom of an anatomic joint. Variable control parameter that can have multiple adjustments without making a structural change.
12. *Hold.* Elimination of all motion in a prescribed degree of freedom of an anatomic joint or anatomic structure.
13. *Lock.* A device that has an optional mode of holding a particular anatomic joint from motion and that can be released to allow motion when desired.
14. *Paralysis.* Loss or impairment of motor function (paresis, incomplete paralysis).
15. *Volitional force.* Voluntarily controlled muscle activity.
16. *Hypertonicity.* High resistance for muscle to passive stretching.
17. *EMG.* Electromyography is a measure of electrical potential changes caused by muscle contraction/relaxation.

RESIN-BASED COMPOSITES

MARK CANNON
Northwestern University
Chicago, Illinois

INTRODUCTION

Composite dental restorative filling materials are synthetic resins that have had a revolutionary impact on dental practice. No other dental materials have stimulated such rapid change in an inarguably short period of time. The advent of resin-based composite occurred during the "Golden Age of Dentistry" and mirrored the overall effect that high technology had on society. Virtually everyone has been made aware of "bonding" or "cosmetic dentistry" by the mass media. The success of "bonding" or "cosmetic dentistry" depended on the development of esthetic dental restorative (filling) materials such as resin-based composites and to the advent of dental adhesives, which allowed for the successful placement of the new esthetic materials.

Composite resins have replaced the previous dental restorative materials for anterior teeth, silicate cements, and unfilled acrylic resins, because of superior physical properties. The overall improvement in physical properties has encouraged a great increase in the clinical use of composite resins. Composite resins are now used in virtually all aspects of dentistry. Their application was first limited to simple cavities in anterior teeth (incisors) or the repair of a broken tooth. However, composite resins are now used to cement orthodontic brackets onto teeth, seal pits and fissures in molars and premolars, splint periodontally or traumatically loosened teeth together for stability, repair not just broken teeth, but also porcelain restorations, revitalize and enhance the esthetic quality of discolored or misshapen teeth. Certainly, no other dental material systems offers such a broad range of applications or greater opportunities for the improvement of dental care. Researchers are working diligently to develop newer resins that possess all the necessary qualities required of an ideal dental restorative material, esthetic by nature and resistant to all the deleterious effects of the oral environment.

FABRICATION

Unfilled Acrylic Resins

The autopolymerizable, unfilled acrylic resin was one of the precursors to the development of composite resin materials. The composite resins were introduced to overcome the problems associated with the clinical use of the unfilled resins. The unfilled acrylic resins were supplied as powder and liquid preparations. The powder consisted of the polymer, polymethylmethacrylate and an initiator, benzoylperoxide (1). The monomer consisted mostly of methyl methacrylate, a cross-linking agent (ethylene dimethacrylate), a tertiary amine, and an inhibitor (methylhydroquinone). Although the unfilled resins were considered to be

Acronym	Organic compounds
Bis-GMA	Bisphenol- α -glycidyl methacrylate

Figure 1. Bis-GMA.

polishable and esthetically acceptable, numerous problems were reported clinically. Pulpal irritation and sensitivity were noted and probably related to microleakage. The microleakage was undoubtedly due to the high degree of polymerization shrinkage and the higher coefficient of thermal expansion of unfilled resins to tooth structure. The expansion and contraction of the unfilled resin restoration would “percolate” deleterious salivary contents leading to pulpal sensitivity, marginal discoloration and secondary caries.

Resin Based Composite

Dentistry has long recognized the need for an esthetic anterior restorative material. The unfilled acrylic resins and the silicate cements were generally considered to be clinical failures and inadequate for many situations commonly seen in dental patients (veneering of discolored teeth, repair of badly fractured teeth, etc.) The composite principle, using filler particles with a proper index of refraction, thermal expansion coefficient similar to enamel and a resin adhesion capability was advocated in 1953 by Paffenbarger et al. (2) The term composite may be defined as a three-dimensional (3D) combination of at least two different materials with a distinct interface (3). A composite resin restorative material consists of three phases: the organic phase (matrix), the interfacial phase (coupling agents), and the dispersed phase (filler particles).

Matrix Phase

One of the main components of all composites is the addition reaction product of bis(4-hydroxyphenol), dimethylmethane, and glycidylmethacrylate known as “Bis-GMA” (4). Bis(4-hydroxyphenol) is an oligimer with a fairly high molecular weight. Figure 1 shows its generalized structural formula.

Other aromatic dimethacrylates are also used in composite resin materials (5). These oligimers include Bis-MA (2,2-bis[4-(2-methacryloyloxyphenol)] propane), Bis-EMA (2,2-bis [4-(3-methacryloyloxyphenol)] propane) and Bis-PMA (2,2-bis[4-(3-methacryloyloxypropoxy)] phenol] propane. To decrease the high viscosity of the Bis-GMA resin systems, low viscosity liquids, such as TEGDMA (triethyleneglycol dimethacrylate) and EGDMA (ethyleneglycol dimethacrylate) are used. Figure 2 shows the structural formula for TEGDMA.

Inhibitors are necessary to prevent the premature polymerization of the dimethacrylate oligimers and viscosity controllers. An example of an inhibitor would be BHT (2,4,6- tritertiarybutylphenol). Autopolymerizable compo-

site resins (paste mixed with paste or powder mixed with liquid two component systems) utilized a thermochemical initiator, most commonly, benzoylperoxide. The decomposition of benzoyl peroxide results in free radicals that initiate polymerization. The initiator would be present in only one portion of the two-component system. The other portion would contain the accelerator, such as, a tertiary aromatic amine. When the two components of an autopolymerizable composite resin are mixed, the tertiary aromatic amine (e.g., *N,N*-dimethyl *p*-toluidine) interacts with benzoyl peroxide to produce free radicals necessary to initiate the matrix polymerization (6). The main disadvantage of auto-cure resin-based composites was the inability of the clinician to control the setting time. Once mixed, the material would irreversibly begin to polymerize whether the clinician was totally prepared or not.

The ability to initiate the polymerization reaction when most desired has been achieved by the introduction of photochemically initiated composites. The first photochemically initiated composite resins used in dentistry required ultraviolet (UV) radiation (7). The UV radiation source employed a high pressure mercury arc and provided a simple mechanical shutter to mask off the radiation when not in use. The UV radiation was emitted through a light guide to expose the composite resin. The effective wavelength was between 364 and to 367 nm. An organic compound that generates free radicals when exposed to 365-nm wavelength electromagnetic radiation, such as, benzoin alkyl ether, was added to composite resins in place of the thermochemical initiator (benzoyl peroxide). Visible light initiated composite resins depend on a diketone (e.g., camphoroquinone) and an organic amine (e.g., *N,N*-dimethylaminoethylmethacrylate) to produce free radicals that result with polymerization initiation. The diketone absorbs electromagnetic radiation in the 420–450 nm wavelength range. The unit that provides the electromagnetic radiation (dental curing light unit) usually consists of a light source, a filter that selects the range of transmitted wavelength and a light tube that directs the light beam to the composite. The units generally emit wavelength in the 400–550 nm range. There is some concern over the potential of damage to the eyes of dental operators (8). Indeed, health concerns

TEGDMA Triethyleneglycol dimethacrylate

Figure 2. TEGDMA.

over the use of UV radiation for polymerization initiation initially encouraged the investigation into using “visible” light instead.

Dispersed Phase

Inorganic filler particles were added to dental resins as early as 1951. It was a number of years, however, before composite materials were generally utilized by dentists. The research of Bowen (4) improved the mechanical properties of filled resins. Bowen treated silica powder with 1.0% aqueous solution of tris(2-methoxyethoxy) vinyl silane to which sodium hydroxide was added and the resultant slurry dried at 125°C. Peroxide was added in an acetone solution and the solvent evaporated. This treatment resulted with an organophilic silica powder. The first dental composites utilized fillers, such as E-glass fibers, synthetic calcium phosphate, fused silica, soda-lime glass beads, and other glass formulations (9). The commonly used filler particles currently used as reinforcing materials are quartz, colloidal silica, lithium aluminum silicate, and silica glasses containing either strontium or barium (10). Quartz was the most successful of the commercial fillers due to its index of refraction and inert nature, however, its hardness and large particle size made polishing difficult resulting with the transition to softer glass fillers (11). In addition to being radiopaque, the softer glass fillers facilitate easier polishing of the set composite resin and the production of fine filler particles for incorporation into the matrix. There is, however, a potential toxicity problem with barium glasses and the radiopaque glasses may be susceptible to degradation in water (12). Chemical processes may also be used to synthesize filler particles, such as the colloidal silicon dioxide pyrogenic particles (13). The colloidal silicon dioxide particles may be fabricated by burning silicon tetrachloride in the presence of an hydrogen and oxygen gas mixture. Particles ranging from 0.007 to 0.14 μm result. The small size of the colloidal silicon dioxide filler particle, when incorporated in the dispersed phase, allows the polishing of a resin-based composite to a smooth finish. However, the small filler particle size prevents high filler loading. This tends to decrease the filler fraction of resin-based composites manufactured with a colloidal silicon dioxide dispersed phase (Table 1).

Hydroxyapatite and amorphous calcium phosphate filler particles have been advocated for resin-based composites (15,16). The reported advantage of these fillers is the potential for remineralizing adjacent tooth structure.

Filler-Matrix Interface

Transfer of stress from the dispersed-phase filler particles through the ductile matrix phase should occur to improve mechanical properties. The bond between the dispersed filler phase and the organic matrix may be achieved by two different methods, chemically or mechanically. The mechanical retention of the dispersed phase is achieved by sintering particles or fibers together, or by etching away a phase of a glass filler particle leaving a porous surface. Monomer may then flow into the porous surface creating a mechanical interlocking. Chemical bonding to the dispersed

phase may be achieved by using coupling agents, such as an epoxy silane (17). Two of the silane agents are γ -glycidoxypropyltrimethoxysilane and γ -methacryloxypropyltrimethoxysilane.

Silane coupling may involve hydrolysis of the methoxy groups with bound surface water on the dispersed phase-filler particle or with aluminol or silanol groups of the dispersed phase filler particle. During polymerization of the composite resin, the unsaturated carbon double bonds are available to react with the matrix. *In vitro* tests suggest, that a general rule, as filler volume is increased, wear is reduced regardless of filler treatment (18).

PHYSICAL AND MECHANICAL PROPERTIES

Physical Properties

Wettability partially determines the marginal microleakage and surface staining of a composite. Wettability may be determined by the contact angle formed by a drop of water on the resin-based composite surface. Composite resins are considered hydrophilic because the advancing contact angle of water on composite surface is $\sim 65^\circ$. The water sorption value is 0.6 mg/cm^2 and water uptake of composites is a function of polar groups in the polymer structure. The thermal conductivity of composites closely matches that of dentin and enamel. The coefficient of thermal expansion usually averages $26\text{--}40 \times 10^{-6} \text{cm}/\text{cm per}^\circ\text{C}$ for the range of $0\text{--}60^\circ\text{C}$, and recently marketed composite resins even more closely match the values normally obtained for tooth structure. A composite resin with a thermal coefficient of expansion similar to tooth structure ($10 \times 10^{-6} \text{cm}/\text{cm per}^\circ\text{C}$) would theoretically suffer from less margin microleakage. When there is a difference in the values, composite resin restorations may expand or contract more than tooth structure during temperature changes resulting with gap formation between the two substances. Margin microleakage may then occur. Polymerization contraction (% by volume) for the typical composite resin averages 3.2–3.8%. The amount of contraction due to polymerization is effected by the types of oligimers used in the matrix phase and the filler volume. As the composite resin shrinks, it pulls away from the walls of the cavity preparation in the tooth. This polymerization contraction encourages the ingress of salivary contaminants and bacteria (microleakage). Not all studies have shown a statistical correlation between polymerization shrinkage and microleakage (19).

Methods have been employed to reduce the stresses associated with polymerization shrinkage. Pulse or two-step light activation for polymerization initiation has been recommended (20,21). Other methods include incremental filling, directed shrinkage, void incorporation, filler and matrix alteration.

Mechanical Properties

Virtually all composite resin manufacturer's spend considerable resources on testing their own and competitor's products for mechanical properties. Dentists are continually

bombarded with advertisements touting a composite resin's "compressive strength". It cannot be denied that mechanical properties are important for consideration. On the other hand, it is quite evident that clinical success may not be solely correlated with laboratory results or easily predictable. The oral environment is rather hostile to inorganic or foreign materials. Corrosion or degradation occurs with most metals and resins used by dentists. Composite resins demonstrate a change in roughness of the surface with laboratory aging suggesting degradation (22). Mechanical properties of the composite resins have improved considerably the last decade. Unfortunately, the exact relationship between mechanical properties and clinical success has yet to be determined.

The compressive strength of composite resins is greatly superior to their tensile strength. The clinical significance of this is unclear. It may be assumed that tensile strength is of major concern when placing composite resins in posterior teeth as a sliding tooth cusp will cause shear stresses (23). Many manufacturers claim that the compressive strength of their composite resins equal silver amalgam (silver filling material). However, the clinical relevance of

this high compressive strength is not known due to a lack of data demonstrating the minimum strength required to resist the forces of occlusion and mastication. The modulus of elasticity is an important factor to consider when a composite resin is used on a stress bearing area. A composite resin with a very low modulus will deform under occlusal stress and increase microleakage or transfer the stress to the supporting tooth. This does not mean that low modulus composites cannot be used when well supported by adjacent tooth structure (14).

Composite resins may be classified by the component materials that comprise each of the three phases. The matrix phase may be described as being either hydrophilic or, as in the case of some experimental resins, hydrophobic. The interfacial phase is not as amenable as the matrix phase to classification. It is possible to describe the coupling mechanism as being chemical (either polymeric or silane treated) or mechanical. However, the most appropriate basis for classification would appear to be the size and chemical composition of the dispersed phase (24). Composite resins may be classified into five main categories: traditional hybrid, microfill (pyrogenic silica),

microhybrid, packable, and flowable (25). Hybrid resin composites have an average particle size of 1–3 μ and are 70–77% filled by volume. They present with good physical properties compared to the microfilled resin composites. Some composite resins used softer, radiopaque glass fillers averaging 1–5 μ m (26). Microhybrid resin composites have an average particle size of 0.4–0.8 μ and are 56–66% filled by volume. Microhybrid resin-based composites generally have good physical properties, improved wear resistance, and relatively high polishability. Microfill composite resins utilize pyrogenic silicon dioxide with an average particle size of 0.04–0.1 μ , but due to the increase in viscosity associated with an unacceptably low filler fraction (35–50% by volume), a modified method of manufacture was developed. Microfiller-based complexes consists of prepolymerized particles (pyrogenic silicon dioxide mixed with resin matrix and cured) and resin matrix with an equal concentration of dispersed microfiller (pyrogenic silicon dioxide) as was in the prepolymerized particles. This formulation allows for an increased filler fraction without the difficulty in manipulation due to high viscosity. The microfiller composite resins exhibit high polishability (27). The smoother the surface of the composite resin, the less that surface wear occurs and plaque accumulates (28,29). Packable composites have an average particle size of 0.7–20 μ and are 48–65% filled by volume. Their higher viscosity is considered desirable in establishing interproximal contacts and is the result of a higher percentage of irregular, fibrous, or porous filler in the resin matrix. Flowable composites have an average filler particle size of 0.04–1 μ and are 44–54% filled by volume. Their reduced filler volume decreases viscosity to ease placement in thin increments or small cavity preparations. They are also more flexible, with a decreased modulus of elasticity, to absorb stress in certain applications (Table 2).

CLINICAL APPLICATION

Bonding is a general term that is used to describe the joining, uniting, or attaching of adhesives to an adherend (6). Bonding describes the attachment of two materials, but not the mechanism by which the bonding occurred. A bonded assembly may be attached together by mechanical means or by physical and chemical forces. The bond that

occurs between composite resin and tooth enamel is mechanical and is achieved by the process of acid etching. The acid-etch technique was developed by Buonocore in 1955 for use in dentistry (31). An 85% phosphoric acid solution was applied to the teeth of volunteer subjects and greatly enhanced the bond strength of an unfilled acrylic resin to the enamel surface. Retief demonstrated the effectiveness of a 50% phosphoric acid pretreatment of enamel for bonding and also the reversibility of the process by the saliva's remineralization of the enamel (32–35). Bonding is now universally accepted by the dental profession.

Enamel bonding ushered in the age of cosmetic dentistry and popularized the use of composite resins. It was also desirable to develop materials that would adhere to the second layer of tooth structure, the dentin. This is especially applicable in situations where the available enamel for bonding is minimal. Commercially available dentin bonding systems have recently been developed. Bonding may occur by two different means, micromechanically or chemically. Adhesion may be chemically established to either the inorganic or organic portions of dentin. The dentin bonding systems have improved considerably in a short period of time showing great promise for reducing margin microleakage and increasing restoration retention. Composite resins have rapidly established themselves as an important segment of a dentist's restorative armamentarium. Composite resins were initially used solely as a replacement for the unfilled acrylic resins and silicate cements. Use was limited to the incisors where esthetics were of paramount importance. Even then, many dentists considered all resins to be strictly temporary at best.

The patient was often advised to consider a permanent restoration that was metallic, such as a gold foil (placed by compaction of overlapping gold increments directly into the prepared cavity of a tooth). The failure rate of the early resins was considered unacceptable by many dentists and composite resins had to prove themselves "worthy".

The introduction of "bonding" reduced the severity and occurrence of microleakage with the composite resin restorations. Bonding also provided a conservative means to retain a composite resin restoration without substantial sacrifice of tooth structure (by cutting undercut areas into the tooth). Composite resins soon became useful in restoring traumatically fractured teeth (34–38). Malformed or hypoplastic teeth were reconstructed using composite resins and bonding (39,40). The pigments incorporated

Table 2. Classification and Physical Properties of Resin-Based Composites^a

Composite Type	Average Particle Size (Micrometers)	Filler Percentage (Vol %) ^b	Physical Properties ^b		
			Wear Resistance	Fracture Toughness	Polishability

^dVarying among the same type of resin-based composite.

into the composite resin matrix provide a wide range of natural shades. Additional tinted and opaquing resins are available that enable the dentist to achieve a life-like result closely mimicking enamel. The bonding of composite resins as a thin veneer to enamel was advocated for an aesthetic technique of restoring discolored teeth. Young discolored or malformed teeth could be given a natural appearance by covering the enamel surface with a thin "veneer" of the appropriately shaded composite resin (41,42). The public eventually became aware of dentistry's newest advancement and "cosmetic bonding" was "born".

Preventive dentistry benefited by the development and introduction of pit and fissure sealants. A pit and fissure sealant material is a BIS-GMA based resin that is introduced into the caries susceptible pits and fissures of teeth forming a barrier against the action of decay producing bacteria. Pit and fissure sealant resin is retained or bonded to the enamel surface of the teeth by the acid-etch technique. In the 1980s, a conservative cavity preparation that utilizes composite resins and bonding had been proposed by Simonsen (43). This technique involves the removal of only decayed tooth structure with the composite resin restoration bonded to the enamel surface sealing the pits and fissures from future decay. Simonsen termed this technique the "Preventive Resin Restoration" (43). Composite resins are also utilized as cementing or as luting agents.

Acrylic preformed laminate veneers were bonded with composite resins to discolored teeth as aesthetic restorations (44). Porcelain veneers have been bonded to discolored teeth with composite resins since 1983 (45). Composite resins have also been used to bond orthodontic brackets, and fixed partial dentures (Maryland Bridges) to teeth (46). Splints to stabilize periodontally or traumatically loosened teeth are constructed of composite resin. Restorations of decayed posterior teeth (molars) are more and more done with composite resins and bonding (47). A number of dentists and patients are reportedly concerned over the potential toxic effect of mercury, one of the constituents of silver amalgam filling material (48). Studies have shown that dentists with the highest exposure to silver amalgam also have the highest urinary mercury levels (49). The concern about mercury toxicity may yet be the necessary impetus to finally develop an ideal composite resin (50).

New low shrink composite resins consist of a bis-GMA matrix with a strontium glass filler of an average size of 1.1 μ . The composite is 86.5% filled by weight and has a compressive strength of 267.5 MPa. The composite has a volumetric shrinkage of 1.4%, which reduces the shrinkage stresses induced by polymerization. Also recently introduced have been the no-rinse conditioners (self-etching primers). No rinse conditioners are very convenient for the dentist and are very useful in patients with severe "gag" reflex (51).

The self-etching primer consist of a penetrating, polymerizable monomer and an acidic component. The pH of the self-etching primer is between 0.6 and 2, which is acidic enough to etch cut or prepared enamel (52). Several self-etching primers currently available will not etch unprepared enamel leaving resin extensions improperly bonded

(53). Self-etching primers that leave an acidic intermixed zone will demonstrate osmotic blistering (54). Osmotic blistering is the separation of the intermixed zone due to water penetrating the hydrophilic primers. Water is pulled from the dentin because of the high concentration of ionic species retained in the primer when no-rinse conditioners are used. The osmotic gradient from the ionic species and acid monomers creates pockets or blisters of water between the adhesive and composite resin. In addition, both the filler and the resin matrix may suffer degradation from the free acid radicals if the intermixed zone is left unbuffered. The shear bond strength of resin-based composite or sealants is reportedly less with the self-etching primers than the "total etch" technique, a pretreatment of both enamel and dentin with 32–40% phosphoric acid solution or gel (55). Immobilization of an antibacterial component into the resin matrix has also been achieved creating antibacterial composite resins. A new monomer, MDPB, has been produced by combining a quaternary ammonium with a methacryloyl group and incorporating it into the resin matrix for copolymerization with other monomers. The antibacterial effect is on contact only and does not dissipate by dissolution into the saliva (56).

RESPIRATORY MECHANICS AND GAS EXCHANGE

JAMES LIGAS
University of Connecticut
Farmington, Connecticut

INTRODUCTION

Respiratory mechanics applies the principles of solid and fluid mechanics to pressure, flow, and volume measurements obtained from the respiratory system. The utility of the resulting mathematical models depends on how well they guide clinical decisions and prove consistent with the results of new experiments. Although very sophisticated

models of respiratory system structure and function exist, our focus here is on simple concepts used for pulmonary function testing and mechanical ventilation.

RESPIRATORY SYSTEM STRUCTURE

The airways, or bronchial tree, conduct air to the small air sacs, or alveoli, which comprise the lung parenchyma. The upper, larger airways are lined with ciliated epithelium and mucus secreting cells to warm, humidify, and filter small particles from the inhaled gas. The heated and humidified air is ultimately exhaled, resulting in a water loss from the body of $\sim 1 \text{ L} \cdot \text{day}^{-1}$. When the upper airways are bypassed by tracheostomy or by intubation for mechanical ventilation, drying of the respiratory tract can result in inspissation of secretions and obstruction of the airways. Extracorporeal humidification of the compressed, zero-humidity gases used in mechanical ventilation is a necessity (1).

The cross-sectional area of the trachea is roughly the size of a United States quarter dollar (0.25¢). Alveolar surface area is about the size of a tennis court, so that over a very short distance the airways branch repeatedly to bring inhaled gases into contact with a large surface area for diffusion into the blood. The branching is generally dichotomous and asymmetric. The number of branches from the trachea to an alveolus varies from 6 to 30. Small nerve fibers coursing through the walls of airways cause glandular secretion and determine muscle tone. The blood vessels bringing venous blood to the alveoli for gas exchange follow a similar branching structure so that air and blood flow are closely matched for efficient exchange of gases (2).

The last generation of bronchioles ends in sprays of alveolar ducts and sacs. There are some 300 million alveoli, each $\sim 300 \mu\text{m}$ in diameter at full inflation, forming a network of interconnecting membranes. Within those membranes pass the smallest vessels, the alveolar capillaries. Microscopic studies show that the membrane consists of two parallel tissue sheets separated by a series of tissue posts, much like the deck of a parking garage. Red blood cells spend $<1 \text{ s}$ in this structure, and diffusion of respired gases occurs across the $0.3\text{--}3.0 \mu\text{m}$ barrier between air space and red cells in the capillaries. At low intravascular pressures, some parts of this network remain collapsed, yet can be recruited if the pressure in the pulmonary vessels increases. In addition, lymphatics also drain the interstitial space and follow the structure of the bronchial tree. They are capable of removing large volumes of extravasated fluid if necessary.

A thin membrane, the pleura, covers the outer surface of the lungs and is reflected to line the inside surface of the thoracic cavity. Between these two pleural surfaces is a space $6\text{--}30 \mu\text{m}$ in thickness. A very small amount of fluid is normally present, providing lubrication that allows the lungs to slide freely over the interior of the chest wall (3).

The thoracic cage itself consists of the spine, sternum, ribs, and associated muscles of the chest wall. The diaphragm separates the abdominal cavity from the thoracic cavity and is the major muscle effecting resting ventilation (4). As muscular contraction expands the thoracic cavity,

the lungs follow, filling with air. When the subject is at rest exhalation is passive. The muscles relax, the thoracic cavity decreases in volume, and air flows out of the lung.

In addition to the solid mechanics of these structures, analyses of fluid flows are important. The behavior of fluids spans many regimes: convection-dominated flows in the large airways, gaseous diffusion at the alveolar level, interphase diffusion through the capillary walls into the blood, and viscous flows in the alveolar ducts, capillary spaces, and intrapleural space.

STATIC MECHANICS OF THE RESPIRATORY SYSTEM

The simplest test of respiratory system behavior is to ask a subject to inhale or exhale to different lung volumes (Fig. 1). The tidal volume, V_T , is the volume of air that moves in and out of the lungs in a normal breath. At the end of a normal exhalation all the muscles of respiration are relaxed. With the glottis open, no forces are exerted on the respiratory system and atmospheric pressure exists both in the alveolar spaces and on the body surface. The lung volume under those conditions is called the functional residual capacity, or FRC. One can exhale beyond FRC by forcing more air out of the lung. The amount that can be forced out is called the expiratory reserve volume (ERV). Even at that point, there is still residual air in the lungs: the residual volume (RV). If one inhales maximally, the volume of air in the lung is the total lung capacity, or TLC. Similar to ERV, there is an inspiratory reserve available to us beyond our usual tidal volume: the inspiratory reserve volume, or IRV. The total amount of air that could be inhaled from FRC is called the inspiratory capacity, and the total amount that could be exhaled from TLC is called the vital capacity (VC). Figure 1 shows that quantities labeled "capacity" are the sum of two or more quantities labeled "volume". Together with statistical tables relating normal values to gender, age, and size, this data provides one measure of any muscular weakness or structural impairment that might limit the ability to move air into or out of the respiratory system.

Figure 1. Lung volumes and capacities.

Beyond simply measuring these volumes, one can ask how much force is required to change the volume by a certain amount. These experiments have been performed upon excised lungs and intact animals and subjects.

Parenchyma

Experiments that applied static pressure to an excised, air-filled lung supported in air showed that the relationship between lung volume and the applied transpulmonary pressure difference, that is, airway pressure minus pressure at the pleural surface, is dependent on the volume history of recent expansion (Fig. 2). To achieve any given volume, the required pressure difference is greater for inflation than for deflation. A large part of this behavior is due to surface tension at the gas-liquid interface in the alveoli and smallest airways (5,6). When the lung is degassed and then filled with and surrounded by saline, inflation pressures are reduced and much of the hysteresis is eliminated (Fig. 2). The surface-active agent, or surfactant, responsible for most of the hysteresis consists of a phospholipid protein complex secreted by certain cells found in the alveolar epithelium. Surface tension-area data from experimental systems utilizing films of surfactant indicate that surface tension varies over the range of $2\text{--}50 \text{ dyn} \cdot \text{cm}^{-1}$, decreasing markedly as the surface area of the film decreases, and is independent of cycling frequency. Surfactant lowers the surface tension below that for a pure water-air interface, and therefore decreases the pressure necessary to inflate the lungs and keeps alveoli from collapsing during exhalation. Infants born prematurely can lack surfactant, making respiration difficult. The development of an artificial surface-active agent delivered by aerosol was an important advance in neonatal care (7).

Because one often deals with changes about a specified lung volume, the elastic behavior of the lung is routinely described in terms of the tangent to the pressure-volume curve at that point, referred to as the *local compliance* (C_L) of the lung,

$$C_L = dV/dP \quad (1)$$

Figure 2. Pressure-volume curves for excised lungs filled with air and saline.

where P is the transpulmonary pressure (alveolar minus pleural surface pressure). Because of the nonlinear nature of the pressure-volume relationship, the compliance varies with lung volume. Thus the simplest model of lung elasticity is a single parameter derived from the transpulmonary pressure-volume curve of the liquid- or air-filled lung. The compliance for an air-filled lung will reflect both the mechanical properties of the tissue and the effects of surfactant.

Intrapleural Space

For spontaneously breathing subjects, the stresses generated by muscle contraction cause thoracic cavity expansion and are transmitted to the lungs through the intrapleural space. The thin fluid layer present between the membrane lining the lung (the visceral pleura) and the membrane lining the inside of the thoracic cavity (the parietal pleura) must in some way transmit those forces. Early models of this coupling postulated the concept of an intrapleural pressure (8). Because the minimal volume attainable at zero distending pressure for an excised lung (V_0) is below the residual volume of the intact subject, and because functional residual capacity is less than the volume of the thoracic cavity when the lungs are removed, the simplest model was that there must be a negative pressure, that is, a pressure less than atmospheric pressure in the pleural space (Fig. 3). In mechanical terms, any shear stresses in the minute amount of pleural fluid were neglected and the mechanics were modeled as a normal stress, the intrapleural pressure (P_{pl}).

Measurements of intrapleural pressure in intact animals or human subjects were traditionally made by placing

Figure 3. Lung-chest wall model. See text for details.

a catheter tipped with a small latex balloon into the thoracic esophagus. The balloon was partially inflated, but not stretched. The theory is that both the balloon and the esophageal wall are flaccid structures, and so pressure changes measured by this manometry system would reflect changes in intrathoracic pressure (9). These measurements were undertaken in intact animals and subjects to try to separate the mechanics of the chest wall from the properties of the lung itself.

Thoracic Cage

In a manner similar to the parenchyma, the chest wall was conceived of as an elastic structure and the slope of the pressure–volume curve for the relaxed chest wall was called the chest wall compliance. The active forces exerted by the muscles (ΔP_m) are conceived of as a normal force applied to change the intrapleural pressure. During inhalation, expansive chest wall forces decrease the intrapleural pressure, causing expansion of the lung. If the subject forcefully exhaled, or used the muscles to exhale to a volume below functional residual capacity, the intrapleural pressure would increase.

These were the simplest models for the static mechanics of the respiratory system. Pressure differences at various points in the system are related to volume changes, and the tissue properties were modeled as a simple elasticity although the compliance could be dependent on lung volume.

DYNAMIC EVENTS IN THE RESPIRATORY SYSTEM

Respiration requires the flow of gases into and out of the lungs. Many studies investigated the nature of the fluid flow, but early attention focused on a very simple model: that of a “resistance” to air flow. If a subject inhales to total lung capacity and then exhales to residual volume, the volume exhaled is the vital capacity. However, if performed with maximal expiratory effort, this experiment is called the forced vital capacity (FVC) maneuver (10). Mathematical analysis of the resulting data showed that the volume exhaled was almost exponentially related to time:

$$V = \text{FVC}(1 - e^{-kt}) \quad (2)$$

Where FVC was the volume eventually exhaled, t is time, and k was the constant in the exponential. Investigators acquainted with electrical analogues were quick to point out that this resembled the discharge of a capacitor C through a resistor R , with the time constant

$$k = 1/RC \quad (3)$$

The obvious analog was to equate C with the compliance of the respiratory system and R with the resistance to air flow. The pressure drop between the airway opening and the pleural surface was the driving force, so that the simple model for exhalation became:

$$P_{ao} - P_{pl} = R dV/dt + 1/CV \quad (4)$$

Where d/dt represents the time derivative, V the volume change of the lung, and C the compliance. The convention is

Figure 4. Maximum expiratory flow-volume maneuver at different degrees of effort.

that $dV/dt < 0$ represents exhalation. This equation fit conveniently with the classification of respiratory diseases into those that were restrictive and those that were obstructive. Restrictive diseases, such as muscle weakness, deformities of the chest wall, neurologic illnesses, and fibrosis of the lungs, were those that altered lung volumes and/or respiratory system compliance. Obstructive diseases such as asthma and bronchitis were those that interfered with the ability to quickly move air into, or especially out of, the lungs, leading to a high resistance.

Further support for these concepts came from the Maximal Expiratory Flow–Volume (MEFV) maneuver in which a subject performs the FVC maneuver while exhaling through a pneumotachograph. A plot of flow versus its integral (Fig. 4) has a straight-line portion, consistent with an exponential relationship, because if the pressure difference is constant the time derivative of equation 2 gives

$$dV/dt = kV \quad (5)$$

that is, a linear relationship between volume and flow rate. Once again, normal values are a function of race, gender, age, and size (11).

Equal Pressure Point Concept. Equation 4 would suggest that as the applied pressure difference is increased, the flow rate will increase indefinitely. However, the linear portion of the MEFV curve is relatively independent of effort. Beyond a certain point, trying to exhale more vigorously has no effect on increasing the expiratory flow. The idea of an “equal pressure point” was proposed to explain this flow limitation (12) (Fig. 5). If the subject closes the glottis, the pressure at the glottis will be equal to that in the alveoli because no flow occurs. Equation 4 shows that the pressure measured at the airway opening, or in this case just below the closed glottis, will be equal to the intrapleural pressure plus V/C . The quantity V/C is the elastic recoil force due to stretch in the alveolar walls. If the subject then performs a forced exhalation, intrapleural pressure

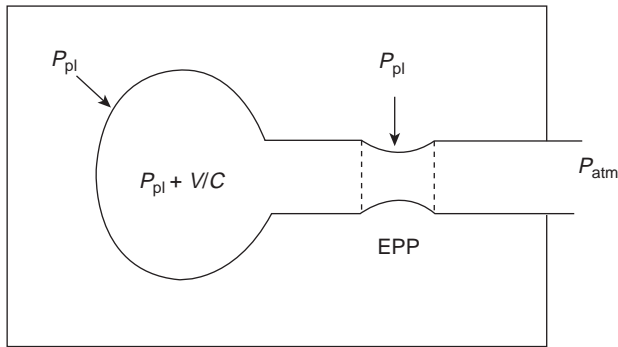

Figure 5. Equal pressure point concept. See text for details.

will be greater than atmospheric pressure and alveolar pressure is greater than this by V/C . Yet atmospheric pressure exists at the airway opening, so that at some point between the alveoli and the airway opening the pressure in the airway is equal to intrapleural pressure. This is the equal pressure point: The transmural pressure across the airway wall is zero, and if the EPP occurs in smaller airways unsupported by cartilage, they can collapse, impeding the flow. The model postulates that this occurs in such a fashion that the harder one tries to exhale, the more the airways are compressed, so that flow is limited. At a constant intrapleural pressure, as lung volume decreases during exhalation the equal pressure point moves toward the alveoli. Although the exact mechanism for flow limitation is undoubtedly much more complex (13,14), this model served as a simple explanation for the observed phenomenon. It also explained why flows would be reduced in patients with diseases such as emphysema, where airway obstruction from mucous and inflammation is not a major factor. In emphysema, fewer alveolar walls mean less elastic recoil, and so the equal pressure point occurs in smaller airways earlier in the exhalation.

MORE COMPLEX MODELS

These simple models underlie much of pulmonary function testing and mechanical ventilation. However, there is an extensive literature presenting more sophisticated analyses. Some of these are multicompartment versions of the simple models in that they postulate differing compliances and resistances in different regions of the lungs. Others propose nonlinear resistance and compliance elements, for example, a variable resistance representing the smaller, collapsible airways and a constant resistance for the more rigid upper airways (15). Some models are more consistent with physics in that they apply the principles of continuum mechanics, namely, conservation of mass, momentum, and energy, to the respiratory system. To do so, investigators have often had to restrict both the scope of the experiments and the portions of the respiratory system they model. Others have chosen to formulate input-output analyses without attempting to model the physical system (16). To date, none of these models has achieved wide acceptance or clinical utility.

THE PULMONARY VASCULATURE

Analyses of blood flow and mechanical changes in the pulmonary vasculature began with a concept analogous to airway resistance: the vascular resistance. The right ventricle pumps blood to the lungs, and the pulmonary veins return the blood to the left atrium. Measurements of mean pulmonary artery pressure (MPAP) and estimates of pressure in the left atrium (LAP) together with the determination of cardiac output (CO) allow the calculation of resistance as pressure drop is divided by flow:

$$\text{PVR} = (\text{MPAP} - \text{LAP})/\text{CO} \quad (6)$$

This is the clinically used model. Analyses of the “sheet flow” concept (17) have been used to explain the mechanics of blood flow through the lungs, but once again clinical applicability has been limited.

GAS TRANSPORT AND EXCHANGE

Although understanding the mechanical behavior of the respiratory system is important, ultimately one must both understand normal gas transfer, and then account for the effects of diseases on gas exchange. These concepts are among the most difficult to master in all of physiology. They bear detailed discussion because in practice physicians use the results of gas-exchange measurements to infer changes in mechanics rather than measure such changes directly. Once again, simpler concepts are used clinically although more complex and physically correct models do exist.

Respiratory control centers in the brain sense the partial pressures of carbon dioxide and oxygen in the blood and drive the respiratory muscles to move air into and out of the lungs. The amount of air that must move to the gas-exchanging alveolar surfaces each minute is known as alveolar minute ventilation, V_A . Some of the inhaled gas resides in the larger airways, where no gas exchange can occur. The volume of these airways is known as the anatomic dead space, V_D . If the gas were to flow in and out of the airways with no mixing, a concept known as “plug flow”, the total amount of air that is inhaled is composed of that which reaches the alveoli and that which is wasted in that it never reaches a gas-exchanging surface,

$$V_{\text{min}} = V_A + f V_D \quad (7)$$

Where f is the respiratory rate. Unless oxygen tensions are very low, carbon dioxide is the major driving force for respiratory effort. The partial pressure of carbon dioxide in the blood for normal people is ~ 40 Torr (5.320 kPa) and is closely regulated near that level.

The structure of the airways and blood vessels is such that local air flow and blood flow are closely matched: for the normal lung the ratio of ventilation to perfusion for any portion of the lung is nearly uniform even though different areas of the lung receive markedly different amounts of air and blood. The pulmonary vessels are capable of constriction in response to low oxygen tension, a process known as “hypoxic pulmonary vasoconstriction”.

This process tends to keep local blood flow well matched to local air flow (18). So, for the purposes of estimating gas transfer, one can lump all 300 million alveoli together and treat the normal lungs as if there were only one large alveolus receiving all the blood flow and all the air flow. One can then estimate (1) what level of alveolar ventilation would be required to maintain a normal partial pressure of carbon dioxide, and (2) what level of blood oxygenation would be expected for a given inhaled oxygen concentration.

Partial Pressures of Gases Related to Volume and Composition

It is molecules of gas that flow in the respiratory system, not volumes of gas. Pressure, volume, and the number of molecules are related by the equation of state:

$$PV = nRT \quad (8)$$

Where P is the pressure, V is the volume, n is the number of moles of gas, T is the temperature, and R is the gas constant. When physiologists speak of volume rather than moles, they must specify the pressure, temperature, and humidity at which that volume is measured. Two sets of conditions are used in respiratory physiology. The first is BTPS, or body temperature and pressure, saturated (with water vapor). Volumes given as BTPS are those that the gases would occupy if they were at 37 °C, standard atmospheric pressure (760 Torr or 101.080 kPa), and fully saturated with water vapor. The partial pressure of water vapor at 37 °C, the normal human body temperature, is 47 Torr or 6.266 kPa. Volumes given as STPD are standard temperature and pressure, dry, that is, at 0 °C, standard atmospheric pressure, with all the water vapor removed. The equation of state can be used to convert between conditions.

As an example, consider what would occur if an 80 kg human were to use glucose as the only fuel. A moderately ill person requires $\sim 25 \text{ cal} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ (104.6 J). The metabolism of glucose generates roughly $4 \text{ cal} \cdot \text{g}^{-1}$ (16.75 J) and consumes an amount of oxygen equal to the carbon dioxide produced:

To generate 2000 cal (8373.6 J) would require use of 500 g, or 2.8 mol, of glucose/day. This would in turn use 16.8 mol of oxygen and generate 16.8 mol of carbon dioxide.

Using the equation of state, or remembering Boyle's law, we know that 1 mol of gas at STPD occupies 22.4 L. During a day, our patient would use 376 L of oxygen and generate an equal amount of carbon dioxide. On a per-minute basis, oxygen consumption and carbon dioxide production would be

$$\dot{V}_{\text{O}_2} = \dot{V}_{\text{CO}_2} = 260 \text{ mL} \cdot \text{min}^{-1}$$

These are volumes at STPD. What would the volumes be at BTPS? At STPD,

$$n_{\text{O}_2} = (760 \text{ Torr})(260 \text{ mL})/R(273 \text{ }^\circ\text{C}) \quad (10)$$

These same molecules heated to body temperature and humidified would occupy a larger volume. Under these

new conditions, the pressure due to the dry gases is lower and the temperature is higher.

$$n_{\text{O}_2} = (760 - 47)V/R(310 \text{ }^\circ\text{C}) \quad (11)$$

The number of molecules is the same, so equating 9 and 10 yields

$$V = (760 * 260/273) * (310)/(760 - 47) = 314 \text{ mL} \quad (12)$$

For these calculations, glucose was the sole fuel used to meet the daily energy requirement. However, normally fat forms part of the fuel supply and because the units of a fatty acid chain lack the oxygen atom:

fat as an energy source consumes more oxygen per carbon dioxide produced, and therefore lowers the respiratory quotient (RQ). We generally estimate

$$\text{RQ} = \dot{V}_{\text{CO}_2}/\dot{V}_{\text{O}_2} = 0.8$$

when performing calculations, so that if

$$\dot{V}_{\text{O}_2} = 310 \text{ mL} \cdot \text{min}^{-1} \text{BTPS}$$

Then,

$$\dot{V}_{\text{CO}_2} = 250 \text{ mL} \cdot \text{min}^{-1} \text{BTPS}$$

Alveolar Minute Ventilation

With each breath, we inhale surrounding air with 21% oxygen. We do not use all of it (only about a quarter) and exhale the remainder. The amount of air we need each minute is usually determined by the need to rid ourselves of carbon dioxide. What volume of gas would have to reach the alveoli each minute to remove $250 \text{ mL} \cdot \text{min}^{-1}$ of carbon dioxide while keeping blood, and hence alveolar, carbon dioxide tension at 40 Torr?

The fraction of alveolar gas that is carbon dioxide must be

$$F_{\text{ACO}_2} = \dot{V}_{\text{CO}_2}/\dot{V}_A \quad (13)$$

But partial pressures are related to the proportion of the gas in the total mixture:

$$P_{\text{ACO}_2} = F_{\text{ACO}_2}(P_{\text{atm}} - P_{\text{H}_2\text{O}}) \quad (14)$$

Combining 12 and 13,

$$P_{\text{ACO}_2} = \dot{V}_{\text{CO}_2}/\dot{V}_A(P_{\text{atm}} - 47) \quad (15)$$

Some textbooks show P_{ACO_2} multiplied by a constant, 0.863, in this equation. In those books, CO_2 production is given at STPD and \dot{V}_A is at BTPS. The constant results from using the equation of state to convert \dot{V}_{CO_2} to BTPS.

Substituting standard atmospheric pressure of 760 Torr or 101.325 kPa, a desired alveolar CO_2 tension of 40 Torr (5.332 kPa), and CO_2 production of $250 \text{ mL} \cdot \text{min}^{-1}$ leads to the conclusion that alveolar ventilation must be

$$\dot{V}_A = 4.45 \text{ L} \cdot \text{min}^{-1} \text{BTPS}$$

If the inhaled oxygen is 21% of the respired gases and oxygen utilization is $310 \text{ mL} \cdot \text{min}^{-1}$, less than a one-third of the inhaled oxygen is consumed and the rest is exhaled. Alveolar minute ventilation is therefore usually determined by the need to exhale the carbon dioxide produced.

Expected Oxygen Tension

We next ask what degree of blood oxygenation we would expect if all the alveoli had the same ventilation/perfusion ratio, that is, if our assumption that the normal lung can be modeled as a single alveolus is correct. Consider the steps involved in inhalation:

1. Gas is brought into the nose and upper airways, heated to body temperature, and humidified.

The gases we inhale are almost completely composed of nitrogen and oxygen at the local barometric pressure. When water vapor is introduced, the partial pressure of oxygen is the fraction of oxygen inhaled times the sum of the partial pressures of the dry gases, which is barometric pressure minus the water vapor pressure:

$$P_{I_{O_2}} = (P_{\text{atm}} - 47)FI_{O_2} \quad (16)$$

Where the subscript I denotes inhaled.

2. This gas reaches the alveoli, where a certain amount of oxygen is taken up and carbon dioxide is added. Although not strictly true (the correction is relatively minor), the simplest approach is to consider how much oxygen is used compared to carbon dioxide delivered. The respiratory quotient can be used

$$V_{O_2} = V_{CO_2}/RQ \quad (17)$$

and an estimate of how much the alveolar P_{O_2} falls compared to the inhaled P_{O_2} becomes

$$P_{O_2} = PA_{CO_2}/RQ$$

giving

$$PA_{O_2} = PI_{O_2} - PA_{CO_2}/RQ$$

or

$$PA_{O_2} = (P_{\text{atm}} - 47) * FI_{O_2} - PA_{CO_2}/RQ \quad (18)$$

For an RQ of 0.8, normal CO_2 tension, and breathing room air (21% O_2) this gives

$$PA_{O_2} = 100 \text{ Torr or } 13.300 \text{ kPa}$$

Note that the calculations of alveolar minute ventilation and expected alveolar oxygen tension were based upon the hypothesis that for a normal lung, ventilation and perfusion are closely matched. Some 300 million alveoli were modeled as a single unit in terms of gas exchange. Miraculously, for the normal lung this turns out to work quite well. The difference between measured arterial oxygen tension (PA_{CO_2}) and calculated alveolar oxygen tension (PA_{CO_2}) is known as the alveolar-arterial oxygen gradient, or A-a gradient. In young normal subjects it is usually $<10 \text{ Torr}$ (1.330 kPa).

The Role of the Cardiovascular System

Blood delivered by the heart brings carbon dioxide to the lungs for elimination and oxygen to the cells of the body. Figure 6 shows the relationship between the partial pressures of the gases and the amounts of those gases in the blood. For simplicity's sake, these are shown as single curves although the amount of one gas present does affect the carrying capacity for the other somewhat (the Bohr and Haldane effects). The curves are very different. That for carbon dioxide is almost linear, while that for oxygen is sigmoid shaped. This difference is crucially important. Together with the fact that the major regulator of alveolar ventilation, is carbon dioxide, mismatches in the distribution of ventilation and perfusion caused by acute lung injuries will have less effect on carbon dioxide tension in the blood than they will on oxygenation, as we shall see below.

The cardiac output is $\sim 5 \text{ L} \cdot \text{min}^{-1}$. Blood with a hemoglobin content of $14 \text{ g} \cdot \text{dL}^{-1}$ exposed in the lungs to 100 Torr (13.330 kPa) partial pressure of oxygen will contain $\sim 195 \text{ mL}$ of O_2 per liter of blood. Therefore, 965 mL of oxygen will be pumped to the body every minute. If oxygen consumption is $310 \text{ mL} \cdot \text{min}^{-1}$, 655 mL of oxygen will return through the venous circulation unused. This translates to a venous hemoglobin saturation of $\sim 70\%$ with a venous blood oxygen tension of 40 Torr (5.320 kPa).

The carbon dioxide tension of arterial blood is regulated near 40 Torr (5.320 kPa). The arterial blood content of carbon dioxide is therefore $\sim 350 \text{ mL} \cdot \text{L}^{-1}$. If carbon dioxide production is $250 \text{ mL} \cdot \text{min}^{-1}$ and cardiac output is $5 \text{ L} \cdot \text{min}^{-1}$, $\sim 50 \text{ mL}$ of carbon dioxide will be added to each liter of blood, so that venous partial pressure of carbon dioxide is $\sim 46 \text{ Torr}$ (6.118 kPa).

During light to moderate exercise, or with a moderate illness, the normal response to increased oxygen utilization and carbon dioxide production is an increase in alveolar minute ventilation and an increase in cardiac output rather than an increase in oxygen extraction at constant

Figure 6. Carrying capacity of blood for carbon dioxide and oxygen.

cardiac output. If the cardiovascular system is impaired, oxygen extraction will increase.

RESPIRATORY MECHANICS IN DISEASE STATES

Several observations of mechanical behavior of the lung show that when diseases occur, the simple resistance-compliance model of the lung may cease to apply. The first concept relating to disease is that of dynamic compliance.

If a simple resistance-capacitor circuit is driven by a sinusoidal voltage, an analysis of voltage and current waveforms will give the same value for resistance and capacitance independent of the frequency of the sinusoid. However, attempts to calculate compliance from a diseased subject while varying the breathing frequency appeared to give a value for compliance that was dependent on the respiratory rate. This became known as “dynamic compliance”. The reason for this is that disease processes are seldom homogeneous. The inhomogeneity leads to varying mechanical properties, and a more appropriate model is then a sinusoidal driving force applied to several resistors and capacitors in parallel. In this case,

$$P \sin \omega t = R_1 dV_1/dt + 1/C_1 V_1 = R_2 dV_2/dt + 1/C_2 V_2 = \dots \quad (19)$$

Adding the equations above would give

$$aP \sin \omega t = (R_1 dV_1/dt + R_2 dV_2/dt + \dots) + (V_1/C_1 + V_2/C_2 + \dots)$$

where a is the number of parallel components. However, one measures only the total flow and total volume exhaled. Analyzing data obtained from an inhomogeneous lung using equation 4 would make the resulting R and C functions of all the resistances and compliances in addition to how the total volume and flow were distributed within the system, which itself would be a function of frequency. The term dynamic compliance is a misnomer: The existence of dynamic compliance is an indicator that a simple one-compartment model does not apply (19).

And as one would then expect, the MEFV curves from many subjects with obstructive lung diseases show that not only are the magnitudes of flows reduced, but the portion of the curve that was almost linear in normal subjects now has a definite curvature. This could result from having several compartments of different mechanical properties emptying at different rates.

These concepts fit well with observations of patients' breathing patterns. If increased airway resistance seems to be the issue, the patients breathe more slowly with a greater tidal volume, which might allow enough time for the slow compartments to empty. Equation 1 shows that complete emptying will require a time more than three time constants (RC). If retention of air is a problem because of loss of elasticity, such as in patients with emphysema and high FRC or with structural abnormalities lowering TLC, patients may breathe more rapidly with a smaller tidal volume. In addition, at times of increased airway resistance, some patients purse their lips while exhaling.

According to the Equal Pressure Point concept, creating a sharp pressure drop at the lips would raise the pressure throughout the airway system, moving the equal pressure point into larger airways that might not be so collapsible, and possibly allowing an increased expiratory flow rate. These patterns seem to be set by the respiratory controller in the brain in a way that may minimize the work and discomfort of breathing (20,21).

The simple dynamic models applicable to the normal lung have been extended in many ways to attempt to model the effects of disease processes. For example, investigators realized that at higher frequencies, such as those employed with jet ventilators or forced oscillatory ventilation in infants, the inertia of the fluid would play a role. They introduced the electrical analog of inertia, an inductance I , into their models. The models became more complex as investigators attempted to assign various components of the respiratory system their own electrical analog properties, and to allow these properties to vary in different areas of the lungs. However, measurements of lung volumes, compliance, and flows remain the mainstay of clinical pulmonary function testing and are based upon the simple concepts presented above.

EFFECTS OF DISEASE ON GAS TRANSPORT

In acute illnesses or acute exacerbations of chronic lung diseases, formal mechanical testing is usually not performed except in cases such as asthma, where abrupt and dramatic increases in airway resistance markedly reduce the expiratory flows. Clinicians draw conclusions about changes in mechanics from changes in arterial oxygen or carbon dioxide tensions. Understanding these changes is important for both assessing acute decompensations in ambulatory patients and for providing effective mechanical ventilation. These changes are perhaps the most misunderstood aspect of respiratory pathophysiology.

For the normal lung, ventilation and perfusion are matched to assure efficient gas transport. The elimination of carbon dioxide is the usual determinant of alveolar minute ventilation. Diseases affecting the respiratory system can decrease the total amount of air or blood delivered or disturb this matching. Although there are many different disease, the mechanisms are few. First, the membranes responsible for gas transport can be destroyed leaving fewer alveoli to do the job of gas transport, but without significantly affecting the matching. Second, the airways and/or the small blood vessels can become inflamed or blocked, either partially or completely, in a way that interferes with the normal matching of air and blood flows. This results in areas of the lungs with widely varying ventilation/perfusion ratios. Third, problems with the nervous system, with the musculature, or with the structure of the chest wall itself can limit alveolar ventilation. Interpreting the changes in blood gas tension using the simple model for the normal lung may lead to erroneous interpretations.

For example, consider what would happen if 50% of the blood flow went to alveoli, which were fluid filled or

Figure 7. Effect of a 50% shunt on oxygen delivery and partial pressures of carbon dioxide. See text for details.

collapsed (Fig. 7). In the normal person, cardiac output is $\sim 5 \text{ L} \cdot \text{min}^{-1}$. Venous oxygen tension is ~ 40 Torr (5.320 kPa), and at that pressure the hemoglobin is $\sim 70\%$ saturated. Venous carbon dioxide tension is ~ 46 Torr (6.118 kPa). Normally, the lungs would deliver oxygen, remove carbon dioxide, and the arterial blood would have a P_{aO_2} of 100 Torr (13.330 kPa) and a P_{CO_2} of 40 Torr (5.333 kPa). Because respiration is driven by the carbon dioxide tension, the brain would try to keep arterial P_{CO_2} at 40 Torr (5.320 kPa). But one-half of the blood passing through the lung would maintain its venous content of carbon dioxide, which has a venous partial pressure of 46 Torr (6.118 kPa). This means that the respiratory controller would increase alveolar minute ventilation to the functional alveoli, and alveolar partial pressure of carbon dioxide in those alveoli would fall to something like 32 Torr (4.256 kPa). If one measured the increase in alveolar minute ventilation, it would amount to some 10–15% increase. If one attempted to interpret this according to the one-compartment model, which applied to normal lungs, one might conclude that some of the alveolar ventilation was wasted, that is, that it went to areas of the lung that did not participate in gas exchange (that there was an increase in physiologic dead space). However, that is not what the figure above shows: It shows that blood flow goes to unventilated areas of the lung, not that ventilation goes to unperfused areas of the lung. The true situation is a shunt, whereas the model would predict an increase in dead space.

What would happen to oxygenation? The venous blood would not pick up any oxygen in the unventilated alveoli. Because of the shape of the oxyhemoglobin dissociation curve, very little extra oxygen could be delivered to the blood flowing through the functional alveoli even if the inspired oxygen concentration were increased to 100%.

Note the implications of this. Any condition that causes a mismatch between the amount of blood flow to given alveoli and the amount of air flow will affect oxygenation much more profoundly than it will affect carbon dioxide elimination. There are two major reasons for this: (1) chemosensors are very sensitive to increases in CO_2 tension and will increase alveolar ventilation to compensate; and (2) this compensation is possible for CO_2 and not for O_2 because of the different shapes of the gas content: partial pressure curves for the two gases.

MECHANICAL VENTILATION

The mechanisms by which diseases affect gas transport can be used to understand mechanical ventilation. Because the primary determinant of carbon dioxide tension is alveolar ventilation, adjustments in respiratory rate and tidal volume will allow control of carbon dioxide levels. Because oxygenation is dependent on the fraction of inspired oxygen AND upon how ventilation and perfusion are distributed, the FI_{O_2} is just one of the controls affecting oxygenation. Positive end-expiratory pressure (PEEP) can be applied to try to recruit alveoli that might be collapsed and responsible for the shunting of blood. That is, end-expiratory pressure at the mouth is held above atmospheric pressure to hold alveoli open. The price paid is that normal alveoli can become overdistended. Therefore the exact level of PEEP that should be used is still controversial (22,23).

Although there are many types of ventilators that perform many sophisticated functions, there are two basic ways to ventilate a human being. For adults, volume-cycled ventilators are usually used. A tidal volume is set, and pressures measured for safety reasons. For infants, tidal volumes are too small to accurately measure, so that pressure-cycled ventilators are used. In this case, a peak inspiratory pressure and PEEP are chosen, and the volume actually delivered depends on the mechanics of the ventilator and of the infant's respiratory system (24). In this case, tidal volume becomes a variable so that safe pressure limits are never exceeded.

Although there is much written about "barotrauma" from mechanical ventilation, that is actually a misnomer. Experiments on cells from the lungs show that when a cell is stretched beyond a certain point, inflammatory mediators are generated and the cell can die (25). The correct term is "volutrauma", but because we cannot measure cell stretch adequately, pressure limits are generally respected (26).

CONCLUSION

This article does not attempt to summarize the literature on continuum mechanics, statistical models, or tissue mechanics of the respiratory system. However, the simple concepts described above are essential for understanding pulmonary function testing, respiration, and patient support with mechanical ventilators. Once these concepts are mastered, the complex and often conflicting literature can be critically read and understood.

SAFETY PROGRAM, HOSPITAL

JOSEPH F. DYRO
Setauket, New York

INTRODUCTION

This article describes the broad scope of safety issues in the hospital and recommends ways in which hospitals should address these issues. Particular emphasis is placed on medical devices and instrumentation and how they interrelate with the hospital's environment, facility, patients, and device users and other personnel. Medical device safety depends in large part upon a comprehensive medical device technology management program, which includes elements ranging from technology assessment, evaluation, and procurement to device replacement planning and includes such components as user training, medical device incident investigation, and device quality assurance. The clinical engineer by education, training, and experience is shown to be ideally suited to implement and execute a technology management program and to lead in the effort to assure hospital-wide patient safety. Available resources are described including web-based training, distance learning, standards, publications, and professional organizations.

Innovative surgical techniques, improved invasive and noninvasive diagnostic procedures, advanced diagnostic and therapeutic medical devices, pharmacological processes continue to benefit the treatment of the sick; however, advanced technology has been a mixed blessing to recipients of these advances. Its positive impact on healthcare has been countered by the creation of problems engendered by an increasingly complex medical device and instrumentation environment. In the use of devices and techniques, misuse or procedural error can and does occur. Some level of risk is associated with everything that is done to care for the patient. Healthcare professionals must keep abreast of the advancing technologies, be aware of their limitations and risks, and manage them. The hospital safety program is an integral part of the system of risk reduction and can and should be broad in scope, not limited by undue attention to only one or two risk categories such as slips and falls or needle sticks. It should encompass means to address and control the risks of injury to patient and staff, risks that arise from all sources, not only those specifically related to medical devices, but those related to the performance of the individual healthcare giver.

THE PROBLEM WITH HEALTHCARE

The complexity and proliferation of the three components of technology (i.e., drugs, devices, and procedures) continues unabated. In the hospital complex, interrelationships exist among environment; facilities and utilities;

medical and nonmedical policies; and procedures, economics, ethics, and human performance. Inappropriate drugs, devices, and procedures; defectively designed, manufactured, and maintained medical devices; inappropriate staffing; inability to follow procedures, neglect of duties, inattention, and ignorance; and deficient education and training are among the factors that increase the risk of injury in the hospital.

The Institute of Medicine (IOM) of the National Academy of Sciences produced a report containing estimates as high as 98,000 deaths occurring annually in U.S. hospitals caused by medical errors (1). About 1 million medical injuries occur annually in the United States, with 200,000 involving some negligence (2). Such iatrogenic injury (injury caused by the physician, now more broadly defined as injury caused by giving care in a hospital) has been well documented (3). Medical devices used in delivering care have a finite probability of doing harm to the patient or to the person using the device (4) and are included as one source of iatrogenic injury. Estimates of the percentage of device-related incidents over all incidents vary from 1 to 11% (2).

Patient Safety Movement

The IOM report spawned a patient safety movement. Organizations, actively working to identify the weaknesses in the healthcare arena, are unified in their support of patient safety initiatives (5–7). The Institute of Medicine (9), in its sequel report, *Crossing the Quality Chasm: A New Health System for the 21st Century*, calls for a health care delivery system that is safe, effective, patient-center, timely, efficient, and equitable. Patient safety can be improved by implementing and executing effective hospital safety programs.

Safety Programs

Programs exist that address the overall safety concerns within a hospital. Under the umbrella of a *total hospital safety program*, there are various components, such as fire safety, infection control, medical device safety, and radiation safety. Guidelines for a comprehensive total hospital safety program incorporating all the various components are given below. Following this is presented a program that addresses medical device safety, in particular. Before elaborating upon these two safety programs, to obtain a clearer sense of the problem with health care the injurious forces and mechanisms present in a hospital are described and their interrelation with patients, staff, facilities, environment, medical technology are described.

Injurious Forces and Mechanisms

The hospital is a place where injury mechanisms abound. The nature of a hospital's business concentrates the injury mechanisms. For example, life-threatening situations demand rapid response by medical personnel often

utilizing a host of complex technologies. All components of the system must work for successful outcome. One element failure, for example, an error in device use, administration of the wrong drug, or inappropriate surgical technique, can produce disastrous results even though all other elements are working. Injury to patients, personnel, and visitors can arise from many different sources within a hospital. The following is a list of some of the many safety concerns and examples of hospital occurrences:

- Fire: Electrosurgical energy in an oxygen-enriched atmosphere has ignited a fuel source such as the hair of a patient resulting in a rapidly spreading, deadly conflagration.
- Air, medical gases, and vacuum: Crossed-medical gas pipelines have killed patients mistakenly given nitrous oxide instead of oxygen.
- Water: Water with inappropriate chemical content used in dialysis has injured patients.
- Chemicals, solvents, sterilizing agents, skin preparation solutions, anesthetic gases: Anesthetic gases can cause birth defects; ethylene oxide used in sterilization has caused severe skin lesions.
- Drugs: Administration of wrong or inappropriate amounts of medications have killed patients.
- Filth, microorganisms, vermin: Inadequately sterilized bronchoscopes have cross-contaminated hundreds of patients.
- Waste, bodily fluids, sharps (needles, scalpels): Improperly discarded needles have punctured hospital workers infecting them with human immunodeficiency virus (HIV).
- Sound, noise: Ambient noise levels have obscured audible alarms.
- Ionizing and nonionizing radiation [X-rays, laser, ultraviolet (UV), visible light, infrared (IR), microwave]: Interventional cardiologists have burned patients by using excessive X-ray exposure times during fluoroscopically guided catheter placement.
- Electricity: Lethal electric shock was delivered to a patient by improper connection of ECG leads to a power cord.
- Natural and unnatural disasters: Hurricanes have disrupted electrical power and back-up generators have failed to function.
- Mechanical stress: Static and dynamic forces on the body can result in injury. For example, excessive and prolonged mechanical pressure to parts of the body during surgery has resulted in pressure necrosis of tissue. Among the highest causes of injury are slips and falls and back strains.
- People: Human error, for example, administering the wrong medication or cutting-off the wrong leg, is the largest single cause of injury in the hospital. Abduction and elopement are also people-related safety concerns.
- Devices: A defectively designed check valve has failed preventing ventilation of a patient resulting in brain death.

From the above, it is clear that a hospital patient is exposed to a variety of risks many of which involve, in some way, medical devices and instrumentation. Human error resulting in patient injury often involves the use of a medical device in an inappropriate fashion. Such use may signify that the device was designed with inadequate attention paid to human factors considerations (9). A hospital safety program must pay due attention to the relationships among devices, people, places and things, and take a systems perspective on safety.

Systems Perspective on Safety

The hospital is a complex environment where medical devices and instrumentation utilized for diagnostic, therapeutic, and rehabilitative purposes interact with each other and with patients, staff, facilities, and the environment. A systems approach to understanding the mechanisms contributing to incidents and accidents aids in the development of programs to control and minimize safety risks (10). The efficacy and safety of the delivery of patient care depends, in general, on five main components: medical device; operator; facility; environment; and patient. The following is a description of these components along with examples of the contributions they can make toward creating hazardous situations.

Medical Devices

The device itself can be the sole cause of an iatrogenic injury. A medical device can be rendered injurious by the actions or inactions of the device inventor, designer, manufacturer, shipper, inspector, maintainer, or user. For example, the manufacturer may fail to properly assemble or construct an otherwise efficaciously designed medical device. The shipper who transports the device from the manufacturing plant to the hospital may damage a properly manufactured device. The inspector at the hospital may fail to properly inspect the device upon receipt, allowing a damaged or defective device to be placed into service. The maintainer may fail to keep the device operating within manufacturer's specifications by not adequately performing preventive maintenance and calibration procedures. The manufacturer may fail to provide adequate warnings and instructions. The user may abuse or misuse the device, rendering it hazardous to the patient. Finally, the device may not be retired when it has reached the end of its useful life and is subject to more failure modes and is not up to date with current medical practice.

Injury can result from the absence or failure to utilize medical devices that are accepted as the standard of care in the community. Physicians and nurses have an obligation to utilize technology that has been accepted as the standard of care, and liability is incurred if available technology is not used.

Definition

For an all-encompassing safety program, the definition of medical device adopted by the U.S. Food and Drug Administration (FDA) is recommended (11):

"The term device means an instrument, apparatus, implement, machine, contrivance, implant, in vitro

reagent, or other similar or related article, including any component part, or accessory, which is

1. Recognized in the official National Formulary, or the United States Pharmacopoeia, or as supplements to them.
2. Intended for use in the diagnosis of disease or other conditions, or in the cure, mitigation, treatment, or prevention of disease, in humans or other animals.
3. Intended to affect the structure or any function of the body of humans or other animals, and that does not achieve any of its principal intended purposes through chemical action within or on the body of humans or other animals and that is not dependent on being metabolized for the achievement of any of its principal intended purposes.”

All devices used in the hospital or provided by the hospital must be addressed whether they are purchased, donated, leased, or owned by a physician or are under evaluation. Technically, a safety program must include devices ranging from tongue depressors to magnetic resonance imaging (MRI) units. Both reusable and disposable devices must be considered. As medical device technology becomes more complex and new modalities are employed for diagnostic or therapeutic intervention, the hospital safety program must adapt to these changes. It was not that long ago that such issues as laser safety, magnetic field strength hazards, and nonionizing radiation hazards were unknown concepts. A hospital safety program must also include a way of dealing with devices used outside the hospital, such as devices provided by or through the hospital to enable ambulatory and home care or devices used in the transport of patients to or between hospitals. A hospital department such as clinical engineering that extends its services to other entities such as a doctor's office or clinic must adhere to the same principles that guide its in-house safety program such as regular preventive maintenance schedules.

Electricity

Medical devices that are electrically operated can pose risk to patients and staff of electric shock. Incoming inspection and periodic inspections thereafter can assess the safety of such devices. As with all electrically operated devices, care should be taken to ensure that surfaces that may be contacted by patients and operators are not energized because, for example, of poor design, manufacturing defect, or deterioration and inadequate maintenance and repair. Electrical safety of medical devices is but one aspect of safety as is shown below. Safety programs should not be obsessed with electrical hazards, shown to be a relatively minor contributor to death and injury in hospitals since first introduced several decades ago as a major problem (12).

Chemicals

Many potentially injurious chemical compounds are or have been associated with the operation of medical devices and instrumentation. For example, ethylene oxide gas used in hospital sterilizers poses a risk to operators and to

patients if improperly utilized (13). Iatrogenic complications can be introduced by infusion pumps, widely used for intravenous and intraarterial fluid and drug administration. Incompatibility of certain drugs with the plastics from which infusion pump administration sets are made is a source of risk. Nitroglycerin in solutions administered by infusion pumps has been shown to interact with certain formulations of poly(vinyl chloride) (PVC) tubing, ultimately decreasing the potency of the drug and making the administration of a known amount impossible to gauge. Other examples include allergic reactions to latex gloves, skin preparation agents, and contrast media and adverse reactions to implantable devices such as artificial joints and nerve stimulators.

Sound and Electromagnetic Radiation

A neonate's auditory system is particularly susceptible to injury from high sound levels as can occur in infant incubators. Diagnostic ultrasound units must be properly designed and maintained to ensure that output levels remain within acceptable limits recommended in safety standards.

The hazards of ionizing radiation became well known not long after the development and use of the X-ray machine. A good radiation safety program is essential to ensure that radiographic equipment and protective measures in radiographic suites meet acceptable performance and safety standards and that operators are appropriately trained and follow established safety procedures.

Nonionizing radiation is a significant health hazard in all hospitals and includes UV, microwave, and laser radiation. Ultraviolet therapy is employed in the treatment of some skin disorders. However, UV radiation can adversely affect the eye (keratitis) and the skin (erythema and carcinogenesis). Microwave radiation is commonly used in physical therapy for diathermy treatment of patients. Microwave effects are largely thermal, with the eye being the most susceptible organ (cataractogenesis). Surgical lasers are particularly hazardous since the beam can travel large distances with little attenuation and can reflect off surfaces in the room. The intensity of the beam is of necessity sufficient to burn body tissue as is required in surgical procedures. Momentary eye contact with the beam can cause severe eye damage. A laser safety program is recommended wherever lasers are used. Eye protection and restriction of the area to trained personnel are essential steps in the program.

Alarms

The Joint Commission on Accreditation of Healthcare Organizations identified appropriate attention to alarms as one of six patient safety goals of 2003 (14). Alarms are sometimes ignored, unheard, unnoticed, misinterpreted, or disabled. A life-threatening alarm that goes unattended can have disastrous consequences for the patient. Alarms are rendered ineffective for a host of reasons, some of which are listed here. Frequent false alarms cause the care givers to relax their guard to the point of ignoring a real alarm condition when it occurs. Doors to patient rooms, closed to give the patient some respite from the noise in the corridor

and in other rooms, can attenuate a bedside monitor alarm such that it is not heard by nurses on the floor. Medical staff members, either through inattention, lack of knowledge, or intent, can disable the alarm function on a device. Mechanical or electrical failures could occur that render the alarm circuitry ineffective. Artifact present can be interpreted by a monitor as a real physiological signal and can cause a monitor to fail to alarm when the patient's physiological signal exceeds limits.

Mechanics

Device design should account for motion, maneuverability, and impact resistance. A transport stretcher that is difficult to maneuver can strain the muscles of the transporter. Devices should be made of materials with strength adequate for their intended purpose. Device mountings and supports must have adequate load-bearing characteristics. Inadequately secured physiological monitors have fallen onto patients from overhead shelves. Latches, locks, protective covers, and restraints must be designed with appropriate attention to human factors and conditions of use to prevent inadvertent opening and loss of protection from falls or tampering. Patients of all ages have died from asphyxiation after becoming entrapped by bed rails. Connectors and couplings abound in the hospital environment. Blood line disconnections have resulted in deadly air embolisms; airway disconnections have resulted in death and brain damage from oxygen deprivation; and reversed connections to anesthesia vaporizers have resulted in deadly anesthetic overdoses.

Operator

Lack of knowledge concerning the operation of a device is the most common failing of the operator. A safety program must recognize that the rapid introduction and wide proliferation of complex medical device technology taxes the operator's ability to remain competent and must assure that adequate educational programs are in place to address this need. Educational programs and credentialing requirements minimize user error caused by ignorance of device operation.

Failure to correctly diagnose is a claim made increasingly more frequently in malpractice actions. Risks associated with diagnostic medical devices such as ECG telemetry systems or clinical laboratory analyzers often relate to device set-up, calibration, and operation and data gathering, manipulation, display, storage, and retrieval. The harm that people (e.g., doctors, nurses, technologists), can do to the patient can relate directly to the presence, quality, and limitations of diagnostic data obtained by the device (15).

Errors in the operator's use of devices are more likely when manufacturers do not provide instructions or provide ambiguous or misleading instructions, labels, indicators, or controls on the device. Manufacturers have a duty to communicate word to their customers of upgrades and product improvements that address design deficiencies in the products that they have sold.

The manufacturer may contribute substantially to the operator's failure by not understanding the limitations of

the operator and designing a device without adequately addressing human factors engineering. The FDA recognizing the important role sound human factors engineering plays in safe medical device design has spearheaded efforts to develop standards and guidelines in this area (16). The degree to which human factor problems contribute to safety risks and incidents is indeterminate largely because those reporting device problems often lack the understanding of how faulty medical devices and instrumentation design contributes to user errors (17).

Drug and medication errors constitute one of the major sources of hospital incident reports. Safety problems include adverse drug reactions and inappropriate dosage, drug, frequency of administration, and route of administration.

Economic pressures influencing staffing patterns and work requirements result in understaffed and overworked operators who do not adhere to policies and procedures, but rather take more expedient, albeit more risky, avenues. For example, an ECG telemetry central station, which by the manufacturer's instructions and hospital policy should be monitored constantly, may go unattended because of competing demands for personnel resources. A study of anesthesia claims over an 8-year period revealed that 14% of the claims alleged failure to monitor (18). Personnel who do not adhere to hospital or departmental policies and procedures pose safety problems for the patient. Policies and procedures also address such issues as patient care procedures or surgical procedures.

Facility

The hospital's physical plant and its facilities can have a substantial effect upon safety. Some of the major facilities of a typical hospital are listed below followed by some examples of how these facilities can affect patient and personnel safety (19):

- Heating, ventilation, and air conditioning (HVAC)
- Medical gases
- Water
- Electric power
- Sanitation systems
- Transport and space

Heating, Ventilation, and Air Conditioning

Air pollution can adversely affect the compressed air supply that is needed to provide respiratory support and to power pneumatic devices. Inadequate ventilation has resulted in hazardous concentrations of ethylene oxide gas used in the sterilization of heat-labile devices. Failure to control relative humidity has resulted in water condensing on wrappings of sterile surgical instruments and thus breaching the sterility barrier.

Medical Gases

Switched oxygen and nitrous oxide supply pipelines have caused patient deaths. Poorly designed and maintained medical gas and vacuum distribution systems can fail to

provide adequate pressures and flows for the proper operation of such devices as suction machines, pneumatically powered surgical instruments, ventilators, and anesthesia machines.

Water

A hospital must have an adequate supply of water (20). Because it is in direct contact (through a membrane) with a patient's blood, the water used in hemodialysis must be monitored and its components controlled. Numerous adverse reactions from untreated water have occurred (21). Components that can affect the dialysis treatment have been identified and include insoluble particles, soluble organics and inorganics, heavy metals, bacteria, and pyrogens.

Electrical Power

The performance of sensitive electronic medical devices can be adversely affected by irregularities in electrical power distribution systems. Line voltage variations, line transients, and interruption of power can all result in harm to the patient by adversely affecting the performance of such devices as physiological monitors, ventilators, electrosurgical units, and clinical laboratory analyzers.

Sanitation Systems

The safe disposal of solid, liquid, and gas waste constitutes a significant environmental concern to the hospital, its patients and personnel, and the community in which the hospital is situated (22). It is common for clinical personnel to be stuck by needles in the course of either injecting a patient or disposing of a used needle. Housekeeping personnel are victims of improperly discarded needles, scalpels, broken glass, and biohazardous and radioactive waste. Chronic low level exposure to inhalation anesthetics is associated with spontaneous miscarriage, liver disease, cancer, and other physiological disorders.

Hepatitis C, HIV, SARS, influenza, and other infection agents pose threats to patients and personnel who come in contact with infected patients or their bodily fluids and waste. To add to the problem, infectious agents have developed into virulent forms that are resistant to standard antibiotics.

Transport and Space

Elevators, escalators, doors, stairwells, and staff and patient care areas affect the level of hospital safety. A patient room that is too small results in crowding of medical devices, personnel, and patient. Crowding restricts rapid access to necessary devices and instruments and interferes with access to the patient. Poorly maintained and designed elevators delay a caregiver's access to a patient. Fire doors propped open or emergency exit doors propped shut pose serious hazards in the event of fire. Fire is particularly hazardous in an environment in which an individual's ability to evacuate is compromised by illness or disability. A closed door to a patient room may afford the patient some quiet from the noise from the outside, but it can also attenuate a bedside alarm to make it inaudible to the staff.

Environment

Those elements within a hospital environment that can influence the safe operation of a medical device include such things as medical and nonmedical devices that are not directly involved in a patient's care, people, electromagnetic interference, cleanliness, psychological factors, biomechanics, and natural and unnatural disasters. The environment in which medical devices are used has grown beyond the hospital to now include emergency vehicles, ambulatory care facilities, long-term care facilities, and the home. The hospital, to the extent that it furnishes devices for patient use, must assume the responsibility for ensuring that these devices are safe and effective.

Device-Device Interaction

The hospital has become a complex electrical environment where incompatibility can exist between medical devices (24). For example, electrosurgical units have obscured electrocardiographic traces on cardiac monitors, defibrillator discharges have damaged internal pacemakers, and electrical transients have modified patient ventilator rates.

Nonmedical Devices

An ever-increasing variety and number of nonmedical devices are often requested to be brought into hospitals by patients. Some of these devices include cell phones, space heaters, electric heating pads, televisions, electric shavers, electric guitars, and video games. A hospital safety program must specify what is not allowed to be brought into the hospital or into specific areas of the hospital, must detail the means of enforcement, and give guidance on making exceptions in unusual circumstances. Policies and procedures will vary with the institution, medical condition of the patient, and inspection capabilities of the hospital's clinical engineering resources.

Hospital staff often desire to bring in personal-use devices such as fans, electric space heaters, radios, and hot plates. Office equipment such as personal computers and radios also may be a source of risk and should be considered in a comprehensive safety program. Equipment used by housekeeping and plant engineers such as floor buffers, vacuum cleaners, and power tools are a source of risk.

People

Besides the operator described above (i.e., the patient's nurses, doctors, and technicians), other people in the patient's environment can pose safety risks. These include other medical staff not directly involved in the patient's care; other patients; nonmedical hospital personnel (e.g., housekeeping, maintenance, administrators, and security personnel); and visitors, salespeople, and interlopers.

Visitors have altered controls on life support equipment to the detriment of the patient. Housekeepers have disconnected life-support ventilators from wall outlets in order to plug in floor sweepers. Premeditated or nonpremeditated attack either on a patient or by a patient is a possibility. Abduction of infants or elopement of mentally deranged patients occurs.

Poor communication has an adverse effect upon a patient's treatment. For example, a care giver's order for a test or request for a report that goes unheeded can be detrimental. Not communicating what has already been done for the patient may at best result in unnecessary and costly repeat procedures or at worse the repeat administration of medications and resulting overdose.

Electromagnetic Interference

Electromagnetic interference (EMI) is the disruption of the performance of one device by electrical energy emitted by another device or by another source of radiation such as a radio or television transmitter. EMI is becoming more of a problem as the number of electronic devices in the hospital increases (24,25). The utilization of an ever increasing amount of the electromagnetic spectrum and the proliferation of devices that are intended and unintended emitters and receivers of electromagnetic energy require that hospitals pay due attention to compatibility and interference (26).

The high strength magnetic fields about MRI units have drawn in from the surrounding environment ferrous metallic objects resulting in death and injury when these objects collide with great force against patients and personnel.

Cleanliness

Infection is a major complication of invasive arterial, central venous, and pulmonary artery monitoring. Nosocomial (hospital acquired) infection can be spread by way of medical devices that have not been properly handled, cleaned, disinfected, or sterilized (27). Vermin, animals, fomites (bedding, clothes), food, and people are other vehicles for the spread of nosocomial infection. Dirt and dust can contaminate wound sites, can damage delicate electronic instrumentation and computer data storage devices, and can harbor pathogenic organisms.

Psychological Factors

Periontogenic (having its genesis in the surroundings) illness afflicts patients and staff. Such illness has its roots in the stresses engendered by the high technology surroundings and includes such syndromes as intensive care unit (ICU) psychosis, the adverse psychological impact of the ICU setting. Dehumanization of patients can lead to such neuroses and psychoses as depression, denial, and dependency.

Biomechanics

Thousands of patients each year are injured in slips and falls while attempting to get out of bed to make use of bathroom facilities. Back injuries to staff from lifting heavy equipment or positioning patients are not uncommon occupational injuries.

Natural and Unnatural Disasters

Major safety problems are associated with a wide range of natural disasters such as tornado, hurricane, and earth-

quake and unnatural disasters such as terrorism, and nuclear power plant meltdown. Disaster planning will minimize loss in these circumstances (28).

Patient

Failure of patients to exercise their duties and responsibilities can lead to their own injuries. Patients can contribute to their own injury by failing to use reasonable care in attending to themselves. Such examples include deliberate removal or tampering with support equipment, failure to follow instructions to remain in bed, tripping or falling over obvious obstacles in hospitals, and introduction of unauthorized items into the environment of the hospital.

Systems Analysis

The interaction of the above five components (patient, device, facility, operator, and environment) can be demonstrated by considering the example shown in Fig. 1. A neonate (the patient) is in an infant radiant warmer (the device) electrically powered from the wall receptacle (the facility). The nurse (the operator) prepares to connect the skin temperature sensor to the warmer's control panel. A nearby examination lamp and external influences of a bright sun and electromagnetic waves emitted by a local station are shown (the environment). All five elements of the system can interact and give rise to a situation resulting in patient injury. For example, electromagnetic radiation can interfere with the operation of the radiant warmer's heater control. The nearby examination lamp can add to the heat transfer to the neonate leading to hyperthermia. The skin temperature sensor could be incompatible with the temperature monitoring system, but its connector could permit it to be connected to the system only to give false reading and result in excessive radiant heat output. Interruption of electric power because of a damaged electrical receptacle could result in loss of heater output and subsequent hypothermia.

Figure 1. Systems approach to medical device safety.

TOTAL HOSPITAL SAFETY PROGRAM

As seen from the preceding section, the issue of total hospital safety encompasses human elements, machine elements, and environmental elements, all of which must be considered in a total hospital safety program (30).

JCAHO Recommendations

The *Comprehensive Accreditation Manual for Hospitals* (CAMH) (30) published by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) includes a chapter entitled, “*Management of the Environment of Care*”. The standards contained in this article require hospitals to manage seven areas by the development and implantation of appropriate plans:

- Safety
- Security
- Hazardous materials and waste
- Emergency
- Life safety
- Medical equipment
- Utility systems

Safety Committee

The safety management plan requires a hospital to identify “*processes for examining safety issues by appropriate hospital representatives*”, that is, the safety committee, now often called the environment of care committee. The JCAHO refers to the safety committee as “*a multidisciplinary improvement team*” and defines its activities and responsibilities as follows:

- Safety issues are analyzed in a timely manner.
- Recommendations are developed and approved.
- Safety issues are communicated to the leaders of the hospital, individuals responsible for performance-improvement activities, and when appropriate, to relevant components of the hospital wide patient safety program.
- Recommendations for one or more performance improvement activities are communicated at least annually to the hospital’s leaders.

The safety committee serves as a forum for reports from the seven environment of care areas. For example, the safety committee will receive reports as specified in the hospital’s medical equipment management plan, including performance monitoring data and incident investigation reports. Serving as a reporting forum is an essential part of the safety committee’s role. However, the great value of the safety committee is found in its ability to subject these reports to multidisciplinary analysis. Careful analysis from a representative range of perspectives will produce communications, recommendations, and performance improvement activities that enhance safety throughout the hospital. Hospitals may assign managers to oversee

the implementation of the management plans in the above environment of care areas.

Cooperation and Communication

The hospital safety program requires the conscientious participation and work of a wide range of committees, departments, and individuals with full cooperation and support of the hospital’s administration. It involves a set of policies and procedures that cut through departmental barriers. Interdepartmental cooperation, involving virtually every clinical and support service, is imperative to adequately address the wide range of issues that bear upon the safety of patients and personnel. Hospital safety programs are inherently difficult to implement as a consequence of the diversity of their component parts.

A total hospital safety program should include patient and employee, environmental, and medical device safety. Hospital-operated and physician-directed safety programs should be linked in a single system. The hospital and medical staff should pool their resources and direct all patient safety information to a central point. At that point, data analysis can identify problem areas before compensable events occur. The components of a total hospital safety program that are actively involved in hospital safety issues are committees, departments, and administration.

Committees

The committee is a means by which formal lines of communication can be exercised. A hospital has various committees that relate in some fashion to an overall hospital safety committee (environment of care committee). Each committee necessarily deals for the most part with rather narrow issues. Those committees that have the strongest influence on overall hospital safety are listed in Table 1. No two hospitals are alike and the names of the committees may vary from one institution to the next.

Participation of key individuals, representing the entire spectrum of services provided within the hospital, in the work of the safety committee as well as in the work of the other committees listed is an integral component of the hospital safety program. Formal communication channels must be created between these committees and the safety committee. Committee attendance is an aid to interdepartmental communication. Transfer of information in an informal setting in a face-to-face meeting before or after a committee meeting can often be more effective, rapid, and accurate than written or telephone communications.

Table 1. Committees Concerned with Hospital Safety

Radiation safety	Specialty medical services	Infection control
Quality assurance	Emergency resuscitation	Utilization review
Standards and evaluation	Medical board	Capital equipment
Continuing medical education	Operating room	Credentials and privileges

Table 2. Departments, Offices, and Authorities Concerned with Hospital Safety

Risk management	Staff development	Materials management
Plant and facilities engineering	Environmental health and safety	Fire marshall
Medical departments	Quality assurance	Information services
Radiation safety	Infection control	Clinical engineering

Departments

The departments, offices, and authorities that play important roles in the hospital safety program are shown in Table 2.

Risk management is a key element in any hospital safety program (31). It has become not only a moral, but a financial necessity to provide a safe environment for the staff and patients. It is the risk manager who must make recommendations, in the face of cost containment efforts, on the investment of capital in monitoring systems and modern equipment as a means of reducing risk. Risk management can determine a course of action aimed at reducing risk through, for example, increased surveillance of the patient by appropriate monitoring devices such as electrocardiographs, capnometers, blood pressure monitors, and pulse oximeters. Should an analysis show that the main problems lie in human error, clinical engineering and staff development might implement an educational program as a response. For example, human error, rather than equipment failure, appears to be the primary factor in most preventable anesthesia mishaps. Increased risk management initiatives can reduce these adverse incidents. Cost-effective anesthetic practices actually require using the most up-to-date and well-maintained equipment. The risk management component is central to controlling the costs of safety. Care must be taken to deploy risk management resources judiciously. A disproportionately large amount of attention has been focused on some relatively minor safety issues, such as electrical safety, while by comparison few resources have been commanded to address issues that pose greater risks to patient safety, such as slips and falls (32).

Materials management is generally responsible for the acquisition and distribution to patient floors of a wide variety of device accessories and disposable products. Prepurchase evaluation of these items should not be overlooked. Clinical engineering is often in a position to lend its expertise in device testing to the evaluation of new products proposed for addition to the hospital's standing inventory.

Environmental health and safety is concerned with such issues as fire safety; air quality; spillage, handling, and storage of chemicals and unidentified substances; and noise abatement.

Radiation safety is concerned with the protection of patients and personnel from the effects of ionizing radiation (33). The primary aim of radiological protection is to provide an appropriate standard of protection for humans without unduly limiting the beneficial practices giving rise

to radiation exposure according to the International Commission on Radiological Protection (ICRP) (34). The ICRP system of protection is based on the following three objectives:

1. To prohibit radiation exposure to individuals unless a benefit to the exposed individuals and to the society can be demonstrated, and be sufficient to balance any detriment.
2. To provide adequate protection to maximize the net benefit, taking into consideration economic and social factors.
3. To limit the dose (other than from medical exposures) received by individuals as a result of all uses of radiation.

Infection control identifies the means of growth, reproduction, and transmission of pathogenic organisms. Infection control advises on methods for eliminating or controlling the reservoirs of microorganisms, on appropriate sterilization, disinfection, and sanitation techniques, and on disturbing or eliminating the means of transmission. Where this means of transmission involves the medical device, close cooperation with clinical engineering is advisable.

Staff development has a substantial contribution to make in training staff and in periodically reviewing competence levels in device use and patient treatment techniques. Staff development typically develops suitable curricula with the assistance of clinical engineering.

Plant and facilities engineering maintains the facility, ensures satisfactory heating, ventilation and air conditioning, electric power, water supply, medical gases and vacuum, and sanitation. Facilities engineering keeps abreast of the building codes pertaining to construction and renovation (35).

The *medical departments* constantly review the quality of the care administered and remain alert to indicators of inappropriate diagnoses or therapeutic intervention. The medical staff's quality assurance programs are coordinated with each other and integrated with hospital programs under the office of the safety director.

Information technology departments are responsible for the computerized acquisition, storage, and retrieval of patient information of both an administrative and clinical nature. Timely, accurate, and conveniently displayed information reduces medical errors and the risks associated with providing treatment on the basis of clinical laboratory and other diagnostic data.

Administration

The hospital administration must support the safety program by allocating adequate personnel and financial resources and by enforcing compliance with policies and procedures and assigning responsibility to program implementation to a hospital safety officer.

Safety Officer

The key individual in a hospital safety program is the hospital safety officer. This position should be held by a

full-time hospital employee, especially in large, tertiary care, teaching hospitals. For small hospitals, community hospitals, and surgical centers the responsibilities of the safety officer's position can be exercised by an administrative staff member. The safety officer develops the administrative policies and procedures to address all aspects of safety within the hospital. Each department will have its own particular policies and procedures governing safety as will multidisciplinary committees.

Performance Improvement

A fundamental concept underlying all JCAHO standards is *performance improvement*, which is a continuous process of monitoring and evaluating performance to identify and realize opportunities for improvement. The performance improvement cycle links the safety committee, the safety officer, and the managers of the seven environment of care management plans into a framework for coordinating the many separate activities that constitute a hospital-wide safety program.

SAFETY PROGRAM: MEDICAL DEVICES AND INSTRUMENTATION

The focus in the past of most hospital safety programs on employee and device safety has changed to include a broader range of patient safety issues. The hospital safety program must address all the risks to which patients and staff are exposed. The duties and responsibilities of the hospital safety officer should reflect this broader safety perspective. Clinical engineering contributes to the hospital safety program principally through its management of medical device technology. A broadening of the clinical engineering department's perspective could be required in some cases, particularly in a hospital in which undue attention is placed on electrical safety issues.

Clinical Engineering

A medical device safety program can be administered in several ways: through an in-house clinical engineering (CE) department, either centralized and full service or departmentalized and partial service, through outside service provided by manufacturers' programs, or through an independent service organization (ISO) (36). The hospital personnel required to support such a program will range from one part-time worker when outside services are employed to 30–40 full-time workers when, for example, an in-house program is utilized in a major medical center (38).

Clinical engineering departments are concerned primarily with medical device performance and safety. The responsibility for servicing nonmedical devices and medical and nonmedical facilities may rest within or outside of clinical engineering; however, of overriding importance are the concepts that the hospital safety program should include all medical devices, medical device systems, utilities and facilities that may directly affect the safety of hospital patients or staff, and that the hospital should have in place a system that addresses all of these safety

issues. The clinical engineering department's responsibilities with regard to the hospital safety program should include the implementation and execution of a medical device technology management program.

Technology Management

Medical device technology management is the sound foundation upon which any safety program must be built. Technology management is the management of medical devices throughout their useful life and includes selection and acquisition and eventual replacement (38). Elements of technology management follow:

- Strategic planning (technology assessment)
- Acquisition (specification, evaluation, purchasing)
- Utilization and asset management (impact analysis)
- Medical device service (inspection, maintenance, repair and modification)
- Replacement planning

When a technology management program is run effectively, a hospital can be assured that the need for all medical devices has been ascertained; that medical devices have been properly evaluated, selected, purchased, inspected, and calibrated for optimal performance and safety; that all users of the devices are appropriately trained; that the devices will be maintained on a regular basis; that service will be provided promptly so that patient care will not be disrupted; that a system of tracking and identifying every medical device will be in place; that the device is retired from service at the appropriate time; and that device replacement planning ensures continuity of technological support. Documentation of all elements of the system is essential. A deficiency in any one of the above elements can increase the exposure of a hospital patient or employee to injury. From technology management flow all other aspects of a safety program.

Strategic Planning

The first step in minimizing the risk of medical device technology is strategic planning and technology assessment, determining what services will be provided and what technologies are appropriate for delivering those services.

Hospitals need to monitor changes in technology to enable sound strategic planning. For example, examination of the effects of new therapeutic or diagnostic modalities, such as magnetism in the case of MRI, would allow the hospital to circumvent incompatible or health-threatening situations. The hospital should maintain ready access to technological assessment reports such as those published by the National Center for Technology Assessment. A *chief technology officer* may be warranted for large, university-affiliated teaching hospitals. The acquisition of appropriate medical device technologies can be aided by the use of such tools as the Essential Health Technology Package developed by the World Health Organization (39).

Acquisition

Acquisition of adequate medical device technologies starts with a statement of clinical needs. Detailed specifications

are then written, accurately reflecting the needs expressed by the clinical staff. Prospective vendors are then selected and invited to demonstrate their products. Clinical and laboratory evaluation of these products will determine suitability to the hospital's needs and adherence to safety and performance standards. The evaluation will often involve a multidisciplinary approach so that all aspects of the device (e.g., life cycle cost analysis, clinical efficacy, safety, and engineering design) can be evaluated. A hospital standards and evaluation committee is a good mechanism to control the acquisition of a broad range of medical devices from infusion pumps to gauze pads. Purchasing documents should contain device performance specifications and conditions of sale such as withholding payment until all in-coming acceptance inspections are complete and the device is installed and operational. Other conditions include provision of operator and service manuals, vendor training, and warranty periods.

Utilization and Asset Management

At the initial (in-coming) inspection of a device entering the hospital, a record of that device (asset) is entered into the management system. Generally, affixing an asset management control number to the device enables the identification of that particular device and allows a computerized medical device management system to store and retrieve device histories. Computerized Medical Device Management Systems greatly enhance the acquisition and analysis of data and thus improve the management process (40). The unique control number points to a file containing information about the device that is essential to management of that resource. Such information as generic name of the device, manufacturer, location, and phone number of the manufacturer or authorized service representative, applicable inspection procedure to be used during scheduled preventive maintenance, and cost of the device are generally included in the medical device data base. The management system linked to a *medical device recall system* (see below) enables rapid determination of whether or not the hospital possesses devices that are subject to a recall.

Asset management data of the acquired medical device technology can support utilization and impact analysis enabling the hospital to reap maximum economic benefit (41). Improvements in utilization can positively affect a patient's care by maximizing availability of diagnostic and therapeutic services.

Medical Device Service

Periodic inspection, maintenance and repair are essential elements of medical device safety. Whether these functions are carried out by an in-house department or by an outside service organization, it is crucial that the service be performed in a timely manner so that there is negligible impact on the delivery of care for want of the necessary device or instrument. Several guides to developing maintenance and repair programs are available (42). Techniques for obtaining maximum support from vendors and outside service providers have been described (43).

Replacement Planning

All medical devices reach the point in their lives where replacement becomes necessary because of decreased reliability, increased downtime, safety issues, compromised care, increased operating costs, changing regulations or, simply, obsolescence. Healthcare organizations have limited funding for capital purchases with many under strict budgeting guidelines. Replacement based on anecdotal and subjective statements and politics create havoc related to finances, morale, and operations. Clinical engineering departments are impacted if they do not have a replacement plan when major repairs occur in older equipment.

The ideal healthcare technology replacement planning system would be facility-wide covering all clinical equipment, utilize accurate, objective data for analysis, be flexible enough to incorporate nonequipment factors, and be futuristic by including strategic planning related to clinical and marketplace trends and hospital strategic initiatives related to technology. The plan should encompass many factors related to cost benefit, safety, support, standardization, and clinical benefit (44).

Medical Device Recall System

A medical device recall system should be in place in all hospitals to receive recall notices, hazard bulletins, and safety alerts and to disseminate them to the appropriate authorities (45). The system should have a means for documenting any corrective actions required and implemented. The pharmacy typically operates a separate drug recall system. The *medical device safety officer* (see below) should manage the recall system. Close interdepartmental communication is required. All clinical departments, ancillaries, and support or service departments within the hospital are typically involved in medical device recall system. Virtually all types of medical devices are subject to recall: reusables or disposables, accessories and supplies, and capital equipment. Every medical device from tongue depressor to computed tomography (CT) scanner are included in the system.

Several publications contain hazard and recall notices including *FDA Enforcement Report*, *Biomedical Safety Standards Newsletter*, and *Health Devices Alerts* (see Reading List).

Incident–Accident Investigation and Reporting

The hospital safety program should encompass the mechanism to respond to an accident or incident in which a patient or staff member is injured (46). Incidents and accidents associated with medical devices and instrumentation fall within the purview of the clinical engineering department. The Safe Medical Devices Act of 1990 requires that the manufacturer of a medical device be notified within 10 business days if one of its devices contributed to death or serious injury. The manufacturer, under FDAs Mandatory Device Reporting (MDR) regulation, is required to report these incidents to the FDAs Center for Devices and Radiological Health. Manufacturers are required to report to the FDA when they receive information from any source which reasonably suggests that a

device they manufacture contributed to death or serious injury (47).

The clinical engineering department has the most familiarity with medical device performance and safety features and would be best qualified to serve as incident investigation coordinator of all medical device-related incidents. Many clinical engineers are ideally qualified by education, training, and experience to investigate incidents. When in-house clinical engineering expertise is unavailable or when an outside, unbiased investigation is required, hospitals make use of independent third-party investigators.

Medical Device Accident and Incident Investigation Methodology

Impoundment of devices after incidents is recommended. Control settings, dials, knobs, and switches should not be changed. Photographic evidence should be obtained. Disposable devices must be saved along with packaging material that can often be the only indication of lot number. Cleaning, disinfection, or sterilization of the item(s) involved could hinder further investigation and should be done only under the guidance of the incident coordinator. Policies should be written advising clinical staff to preserve all equipment involved in an incident, including disposable devices and associated packaging. Relative positions of devices in the room should be noted. Staff should record all relevant identifying information, such as the manufacturer of the device, date of use, location, serial or lot number, and hospital equipment control number if applicable.

Incidents and accidents often go unreported for fear of legal repercussions and from reluctance to admit that a procedural error may have been committed. An error in the use of a device may be related more to the human factors engineering failings of the device than to the carelessness of the operator. Only through aggressive reporting of medical device problems can the need for technological improvements be identified and the likelihood of similar incidents occurring be eliminated.

Quality Assurance

A means by which the CE department can measure the quality of its service is recommended (48). A departmental quality assurance plan should aim to identify problems or potential problems related to the safe, effective, and appropriate use of patient care equipment. Quality assurance indicators would include such items as the number of in-service education sessions, the number of device prepurchase evaluations, the average length of time required to restore damaged or defective equipment to working condition, the scope of department services, productivity, and proficiency. A computerized medical device management system is an invaluable aid in developing the necessary statistics for measuring departmental performance.

Information Technology

Clinical engineering and information technology are converging as an increasing number of medical devices become integrated into hospital information systems (49). Sensi-

tive patient information is contained in many medical devices and thus the security provisions of the Health Insurance Portability and Accountability Act (HIPAA) apply (50). Inappropriate use of medical information is a patient safety hazard. For example, reporting a negative HIV result to a person who is actually HIV positive could result in that person not taking appropriate steps to reduce the spread of the disease.

Education and Training

Developing a comprehensive education program in the use of medical devices is one of the principal goals of the hospital safety program (51). Changing legal attitudes in response to technological advances have resulted in additional responsibilities for nurses. Training to enhance the recognition of the day-to-day condition of devices, the need for in-service, and alertness to the signs of incipient device failures are essential components of a sound medical device safety program.

Tools

Professional organizations provide a good forum for the exchange of safety information. Keeping current with developments in medical device technology, patient and hospital safety, and regulatory issues by attendance at meetings of these organizations is recommended. The American College of Clinical Engineering (ACCE) is the only international professional organization dedicated exclusively to representing the interest of clinical engineers (53). Other biomedical engineering, facilities engineering, and medical instrumentation organizations support clinical engineering efforts at the national, regional, and local levels. These include the Engineering in Medicine and Biology Society of the Institute of Electrical and Electronics Engineers, the American Society of Hospital Engineers of the American Hospital Association, and the Association for the Advancement of Medical Instrumentation.

Numerous resource materials are available to assist the clinical engineering department in administering a safety and technology management program. The Reading List section includes texts that contain instructional material relating to technology management and patient safety. Teleconferences, workshops, and Internet also serve as good sources of information (53–55). Manufacturers, recognizing the need to provide informative material to the user to promote a better understanding of safety issues, often provide beneficial educational material.

Medical device standards, technology management recommendations, and safety guidelines are promulgated by several professional and trade organizations. Clinical engineers are encouraged to participate in standards-setting activities to contribute their informed user opinion on medical device performance and safety issues.

ENHANCING PATIENT SAFETY

The clinical engineer has many opportunities to design means to reduce the occurrence of medical errors and to

enhance patient safety through the application of engineering skills to solve problems of medical device selection, application, utilization, and safety (56,57). The proactive engineer will implement solutions to problems before they occur. Root-cause-analyses and failure modes and effects analysis (FMEA) will aid the engineer in determining what is wrong with the system and what needs to be fixed (58,59).

Medical Device Safety Officer

The medical device safety officer (MDSO) will one day be commonplace in hospitals. The clinical engineer is well suited to serve in this role and to manage the medical device safety program.

Postmarket Surveillance

Improved postmarket surveillance of medical device performance and safety is needed to provide more device problem feedback to the manufacturer, regulatory authorities, and to the hospital itself (60). Such feedback enables enhanced device design, revisions in standards, and improvements in educational programs with the ultimate goal of reduction in hazards. Improved methods are required to determine the prevalence, nature, and causes of medical device-related errors.

INTRODUCTION

Scoliosis deformity occurs in the spine quite frequently, especially in growing children. In spite of the attention given to this deformity over the past century, still very little is known about its etiology or progression mechanisms.

There are a number of health related consequences of a progressive scoliosis. In large scoliosis deformities there is impairment of respiratory and cardiovascular function. If progressive, the deformity produces thoracic compromise, pain, and degenerative changes in the spine. In large curves that have been surgically fused, there may be iatrogenic problems secondary to multisegmental arthrodesis. Although scoliosis is often perceived as having a minimal cosmetic impact, it has psychosocial consequences (1–3).

TERMINOLOGY AND GENERAL MORPHOLOGY OF SCOLIOSIS

Geometry of Scoliosis

Scoliosis literally means a lateral curvature of the spine, but as a deformity it includes overall asymmetry and lateral deviation of the trunk, as well as axial rotation of the spine and trunk. The total geometric description of scoliosis is of paramount importance and merits more detailed characterization than can be given by a single-plane X ray. Three-dimensional (3D) measurements of the complete spinal and thoracic geometry require complex techniques of radiographic and surface measurement. Some measurement techniques currently used in research may achieve clinical application in the future.

Frontal, Sagittal and Transverse Planes Components of Spinal Deformity

Frontal Plane. Scoliosis is strictly defined as a lateral curvature of the spine although the scoliosis deformity is a 3D abnormality of the axial skeleton. Scoliotic curves have been described as being primary or secondary, major or minor, or structural or compensatory. The structural curve is defined as having asymmetry not reversible in lateral bending. Usually, a compensatory curve is present to maintain the alignment of the body so that the head is over the pelvis. When two curves of the same spine are defined as structural, the resultant S-shaped deformity is called a double structural curve. The apex of a scoliosis curve is at the vertebra or disk that is the most laterally deviated from the vertical axis passing through the sacrum (base of the spine) (4).

The Sagittal Plane. The mid-sagittal plane is the plane that divides the left side of the body from the right. The terms kyphosis and lordosis (Fig. 1) are used to describe curvatures that exist normally in the sagittal plane, with the prefixes hyper- or hypo- describing abnormal curvatures. Curvatures in this plane interact with the abnormal lateral curvature of the spine in scoliosis. This interaction is termed coupling (see below).

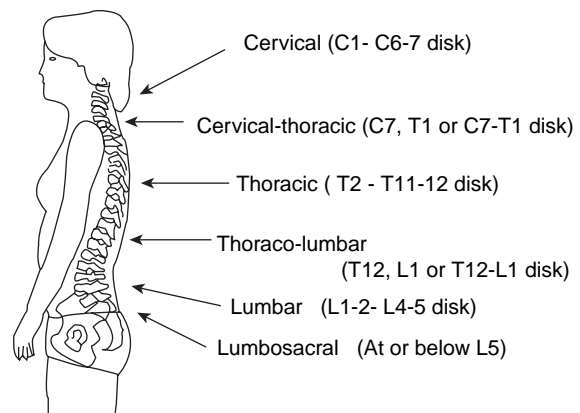

Figure 1. Lateral view of the spine defining regions of curvature.

Transverse Plane. Axial rotation of vertebrae accompanies the lateral deviation. The vertebral rotation can be measured from a frontal plane radiograph by grading the positions of the vertebral pedicles relative to the center of the vertebral body. Also, templates and formulas have been developed to convert these pedicle offsets into estimates of the rotation in degrees. The rotation can be measured more directly from transverse plane images obtained by computed tomography (CT) scanning or magnetic resonance imaging (MRI). The usual rotation of the vertebral bodies is to the convex side (5). Asymmetries of the vertebrae also develop, probably as a result of altered stress on these bones (6). The back surface rotates in the same sense, producing a “rib hump” (gibbosity). Back surface rotation correlates weakly with the scoliosis magnitude as measured by the Cobb angle (7), leading to the idea that curve magnitude could be measured topographically, without X rays. However, the back surface rotation is of lesser magnitude than the vertebral rotation (8), which in turn is of lesser magnitude than the Cobb angle, so this attenuation of the asymmetry as seen at the surface produces technical measurement difficulties.

Stereoradiography and stereophotogrammetry have been used to document the transverse plane deformity in patients with idiopathic scoliosis with simultaneous radiography to record the skeletal shape (9). The back surface rotation was reported to be greatest at the level of the apex of a lumbar scoliotic curve, but located as much as four vertebrae lower than the apex in thoracic and thoracolumbar curves (9). Thus the surface deformity is apparently augmented by the effects of the rib cage where the ribs point downward. In thoracic curves the radiographic rotation of vertebrae is reported to be greatest on average at the apex (defined as the most laterally deviated vertebra), but with a range of three vertebrae above to three below (9,10). In most of the lumbar curves the greatest surface rotation, the maximal vertebral rotation, and the apex coincides. The axial rotation of the surface had a variable relationship with the Cobb angle and in all cases was less than the Cobb angle (11). The amount of back surface rotation is less than the amount of axial rotation of the underlying vertebrae (9).

Coupling of Rotations. Coupling is the term used to describe the tendency of the spine while moving intentionally in one plane to produce secondary or coupled motion in another plane. Two kinds of coupling can be defined, orientation and kinematic. Orientation coupling describes the relationships between the linear or angular displacements of a single vertebra from its reference or nonscoliotic position. Kinematic coupling is defined as the association of two variables describing the relative motion of two vertebrae without regard to forces. Kinematic coupling has been described from *in vivo* measurements of normally curved spines (12–14). The relationship may be altered by adaptation of bone and soft tissue resulting from the scoliosis deformity.

Lateral bending of the healthy lumbar spine is accompanied by a rotation in the same direction as that seen in scoliosis (15); however, the coupling of axial rotation with lateral bending is in the opposite sense in the thoracic spine

(16). In normal spines, lumbar curves produced by lateral bending are associated with a vertebral body rotation toward the concavity of the curve (15). This is not the direction of the static rotation in a spine with scoliosis. The orientation coupling in scoliosis has the same direction as was noted in lateral bending of normal spines in extended positions.

In scoliosis, for each vertebra there are five orientation variables of interest: flexion–extension angle, lateral tilt angle, axial rotation angle, and lateral and anteroposterior deviations from the spinal axis. This leads to 10 possible coupling coefficients, which are ratios between pairs of these geometric variables. There is no reason *a priori* why orientation coupling in scoliosis and/or kinematic coupling coefficients in healthy spines should be related especially when ongoing growth complicates the relationship between different components of the deformity. However, after the end of growth, if a kinematic process governed by such coupling occurred during curve progression, then these relationships would be apparent.

Rib Cage and Back Surface Shape

The scoliosis deformity of the spine (curvatures and associated rotation) is associated with a complex pattern of rib cage deformity, evident as a thoracic rotation (rib hump). The rib hump becomes more subjectively evident in the back with scoliosis on forward bending of the trunk but its magnitude is in fact not increased (17). Thoracic rotation or rib hump can be measured on clinical examination in forward bending and recorded as the depression from the horizontal plane, or as the angular rotation from the horizontal (18) (Fig. 2). The balance of the torso or the extent to which the top of the spine deviates from being vertically above its base (sacrum). Several contacting and noncontacting (optical) methods are available to document the surface trunk deformity (reviewed below).

Classification of Scoliosis

Scoliosis is considered to exist if the Cobb angle is $>10^\circ$. The pattern of scoliosis can be classified by different criteria.

Figure 2. Rib hump seen in forward bend position.

Classification by Anatomical Region of the Curve. In classification of a curve by the location of the apex: the apex of a cervical scoliosis is between C1 and the C6–7 disk; cervicothoracic scoliosis between C7 and T1; thoracic scoliosis between T2 and the T11–T12 disk; thoracolumbar scoliosis between T12 and L1, lumbar scoliosis between the L1–L2 and L4–L5 disk spaces, and lumbosacral scoliosis below L5 (19).

Classification by Age. Scoliosis can be classified according to the skeletal age of the patient at diagnosis (not necessarily the same as the age of onset). Infantile scoliosis is diagnosed during the first 3 years of life, juvenile scoliosis between the ages of 4 and 10 years; adolescent scoliosis is a scoliosis diagnosed between ages 10 and 18 years, and adult scoliosis is diagnosed after age 18 years (19). A large percentage of infantile cases resolve spontaneously. These cases may be related to the position of the body in utero, but generally the likelihood of progression of the deformity is worse the earlier the age at which it develops, consistent with progression being associated with continued skeletal growth. Usually, skeletal maturation is complete after the age of 17 in females and after the age of 19 in males. For reasons that are unclear, in idiopathic scoliosis (81% of all scoliosis) the convexity is more common on the left side in lumbar curves and on the right side in thoracic curves.

Classification by Causation. In most instances, scoliosis can also be separated into one of the four major subgroups depending on the probable initial cause: idiopathic (spontaneous or unknown cause), neuromuscular (associated with disease of the neuromuscular system), congenital (associated with a prenatal developmental anomaly) (20), and iatrogenic (from radiation or thoracic surgery). Idiopathic scoliosis (for which no obvious cause is ascertained) represents 81% of the cases. There are biomechanical factors associated with scoliosis of any cause, since the deformity alters the biomechanics of the spine and trunk, and this in turn alters the processes of musculoskeletal growth, degeneration, and so on.

Classification by Curve Pattern. Classification systems are used to guide the management of scoliosis when a curve type can be consistently related to a different prognosis or management strategy. In surgical planning for the surgical management of adolescent idiopathic scoliosis, classification by radiographic measures is used to help decide on the extent of the arthrodesis. The King et al. classification (21) is probably still the most widely used in planning of spinal fusions, although it was originally developed to aid planning for Harrington instrumentation, that is seldom used now. It defines five thoracic scoliosis curve types, and an additional group called miscellaneous. The King et al. classification relies on subjective identification of the radiographic features that provide the measures used for classification. It may also require individual interpretation and memory of the classification criteria. As a result, there are numerous opportunities for variable implementation that produce inter- and intraobserver variability. A recent empirical study (22) of repeat curve-type classification

has demonstrated poor reliability. An algorithm (23) aims to overcome these problems by defining an objective classification procedure.

The Lenke (24) classification system was developed to provide a comprehensive and reliable means to categorize all surgical AIS curves, using postero anterior (PA), lateral, and side bending X-ray films. The three classification components are curve type (1–6), a lumbar spine modifier (A, B, C), and a sagittal thoracic modifier (–, N, +). The largest curve is considered to be the major curve, and minor curves are subdivided into structural and nonstructural types.

Axes and Coordinate Systems

The global coordinate system describes the positions and displacements of vertebrae relative to the whole body; regional coordinates systems employ a reference within a spinal curve or the entire spine, and local coordinate systems are fixed in a particular vertebra and aligned with its anatomic features are needed to describe motion between vertebrae (Fig. 3). The Scoliosis Research Society (SRS) (4,25) placed the origin at the center of the superior endplate of S1 for both global and spinal axis systems of patients with scoliosis. This is a commonly accepted convention. The ISO 2631 (VDI 2057) right-handed axis convention has x signifying anterior, y signifying left, and z signifying the cephalad direction. The global and spinal axis systems have the origin and sagittal plane defined by the pelvis, with the anterior superior iliac spines (ASIS) defining the transverse global (Y) direction. (This would normally be achieved by positioning the ASIS parallel to the X-ray film plane.) The other principal directions are aligned either with gravity (global system), or with spinal landmarks.

Plane of Maximum Curvature. The geometry of the spine can also be considered as a curved line in space with vertebrae positioned along this vertebral body line (4).

Figure 3. The hierarchy of four coordinate systems defining spinal geometry: (a) Local coordinates based on a vertebra. (b) Regional, curve-based coordinates defined by the end vertebrae of a curve or other spinal region. (c) Spinal coordinates, defined by the Z axis passing through the centers of the most caudal and cephalad vertebrae of the entire spine. (d) Global, whole-body-based coordinate system, with its origin at the base of the spine (S1), and the Z axis vertical (gravity line).

The vertebral body line in turn defines a plane of maximum curvature and best-fit plane (4,26), that lie in the mid-sagittal plane for an undeformed (symmetrical) spine, but are rotated from that plane when a scoliosis is present. In a straight, healthy spine the plane of maximal curvature is the sagittal plane, but in a scoliosis the maximum curvature is seen by viewing the spine from an intermediate angle that may be rotated from the sagittal plane by approximately the same number of degrees as the rotation of the apical vertebrae (27). In a purely geometrical sense, the trihedron axis system (28) provides the basis for 3D measurements, including the local curvature and the geometrical torsion of the vertebral body line. It also defines the osculating plane (local transverse plane), the tangent and normal directions, and the binormal. While providing a pure geometrical approach to defining spinal geometry (29), this approach has not been much used either in clinical or many research contexts.

Measurement of Curve Magnitude. The degree of the scoliosis deformity is most commonly measured clinically by the Cobb angle, which is the angle between lines drawn on the end plates of the most tilted vertebrae in the radiographic curve as shown in Fig. 4. The Cobb (30) measurement of a scoliosis is the sum of the angles of inclination in the frontal plane of the two end vertebrae. The end vertebrae are defined as those with the largest inclinations to the horizontal, and are typically close to the points of inflection of the curve. End vertebrae normally have no axial rotation. Reliability studies estimate the interobserver error of the Cobb measurement as 5° (23). The Cobb angle measurement summarizes curve magnitude, but ignores numerous important structural characteristics including the length of the curve (numbers of vertebrae in it), its flexibility, and the relative contributions of vertebral and discal wedging. While it is presently the major objective measurement used in planning management of patients with scoliosis, these shortcomings suggest that there is scope for improvements in clinical measurement.

Figure 4. The Cobb angle as used to measure scoliosis curve magnitude. It is defined as the angle between the lines drawn on upper and lower end-vertebral endplates, where the end-vertebrae are those having the greatest inclination to the horizontal.

FUNCTIONAL ANATOMY

Spine: Vertebrae, Disks, Facet Joints

The structure and function of the spinal column depends on a complex interaction between the vertebral bodies, the articulations between their posterior elements (facet, or zygoapophyseal joints), interconnecting ligaments and intervertebral disks, the rib cage and the trunk musculature. In a scoliosis the vertebrae become wedged and twisted, the intervertebral disks become wedged, and there is a variable degree of adaptive changes in the soft tissues (ligaments, muscles, etc.) that probably increase with age. The ribs are more sharply angled on the convex side, and this asymmetry, together with the axial rotation component of the deformity produces the rib hump or gibbosity that is the most evident outward indication of the deformity. Surgical treatment of adult scoliosis is more difficult in part because of the adaptive changes and the typically greater curve magnitude and cardiothoracic compromise.

The Spinal Motion Segment

The spinal motion segment is a structural unit of the spine consisting of two vertebrae and the intervening soft tissues. It is a valuable tool in spinal biomechanics because it is the basic element of the spinal column. Once motion segment behavior is defined, the behavior of the whole spine can be represented by a series of fundamentally similar components. In the absence of scoliosis, the motion segment can be considered as being symmetrical about the sagittal plane, thus right and left lateral bends, axial rotation and shear are theoretically symmetrical. The presence of the posterior elements (zygoapophyseal or facet joints and the ligaments) introduces differences between the flexion and extension behaviors. The presence of these posterior structures also produces a posterior displacement (relative to the disk center) of the effective structural axis of the motion segment. The stiffness of the lumbar motion segments has been described by a stiffness matrix, and by an equivalent beam structure (31).

Ribcage and Costovertebral Articulations

Motion of the thoracic spine is connected to that of the rib cage by the costovertebral joints. The ribs articulate with the transverse processes, as well as with the vertebral bodies of the corresponding vertebra and that immediately cephalad. Motion of the ribs has been described as consisting of both pump-handle and bucket-handle motion. Although not well defined, these terms imply rotations about the horizontal (mediolateral axis) and an axis joining the ends of the ribs, respectively. The complex interactions in chest wall mechanics during breathing are difficult to explain in terms of muscular recruitments that involve the diaphragm, as well as the intercostal musculature and abdominal musculature. Rib deformation is part of the scoliosis deformity, thus complicating the progression of thoracic curves as well as their surgical treatment (32) where costoplasty is sometimes considered. The biomechanical consequences of costoplasty were analyzed biomechanically by Aubin and co-workers (33,34).

KINEMATICS OF THE SPINE AS IT RELATES TO SCOLIOSIS

Very little is known about how a scoliosis deformity specifically affects spinal kinematics, with little information either from cadaveric specimens or intraoperative measurements. Studies of gait (35) suggest that asymmetrical spinal axial rotation motion is the main kinematic consequence of a scoliosis. After spinal fusion, the overall motion of the spine is reduced as expected, but with reduced motion also in unfused segments (36).

Range of Motion, Coupled Motion, Intervertebral Stiffness Matrix

The intervertebral articulations have six degrees of freedom (three translations and three rotations) each of which has a measurable stiffness. Traditionally, the load-displacement characteristics of these joints have been described by a stiffness matrix (37). This stiffness matrix has off-diagonal terms, as well as diagonal terms. The off-diagonal terms resulting from this tendency of certain degrees of freedom to be associated with each other (especially axial rotation and lateral bending) has been referred to as coupling. The pattern of motion that occurs between two vertebrae depends on the combination of forces applied, and the axis of rotation is not fixed. It is only possible to define an instantaneous axis of rotation.

Most experimental motion segment stiffness data are limited as they do not include all six degrees of freedom, were obtained by inverting flexibility data, and were obtained without physiological levels of axial compressive force. Physiological axial compression has been observed to increase lumbar motion segment stiffness by a factor of 2 or more (31,38). Janevic et al. (38) reported that the stiffening of the motion segment with preload was approximately linear with preload magnitude. With 2200 N preload, rotational flexibility decreased on average 2.6 times, and shear flexibility 6.16 times, the effects being even greater at 4400 N preload. The stiffening of the motion segment with preload appears to result from nonlinearities in the intrinsic material properties of the annulus fibers, as well as the more easily visualized engagement of the facet joints (31).

METHODS TO DOCUMENT TRUNK DEFORMITY

Plane Radiography, and Derived Measures

The PA radiograph is normally used for documentation of scoliosis to show the lateral curvature and some indication of the axial rotation. The anteroposterior (AP) radiograph delivers higher radiation dose to breast tissue, sternum, thyroid, and ovaries (39), whereas the PA projection gives a higher dose to posterior structures, including the marrow of the spine. Radiographs used to monitor a scoliosis deformity can involve a cumulative skin entry dose of 2–3 rems per year during the growth years, or ~10 times the annual background dose; however, most of the body receives a much lower dose. Radiation exposure can be minimized by such techniques as the Ardran method (40), by using experienced technicians to minimize retakes, by

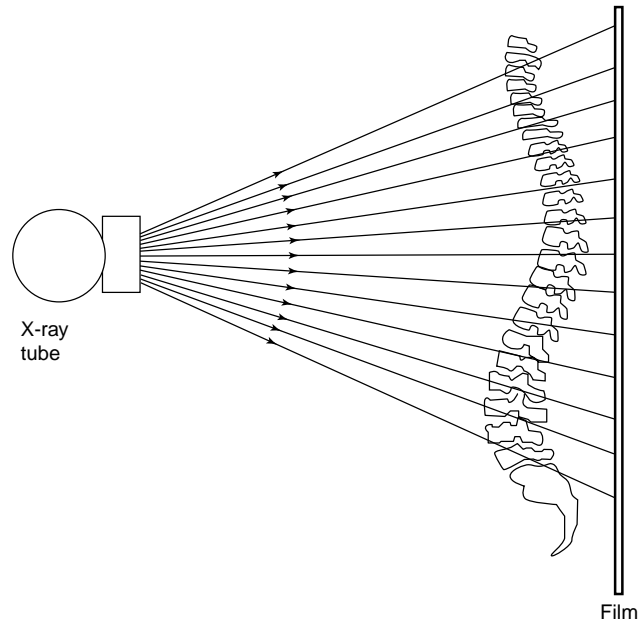

Figure 5. The distortion inherent in an X-ray image, due to the divergence of the X-ray beam relative to the object in the image, and the flat film plane.

proper collimation, and by proper monitoring of X-ray tube performance and filtration. Also, digital radiography with highly efficient X-ray detector arrays hold promise for further dose reductions relative to conventional passive systems with photographic films and intensifying screens.

Both PA and AP radiographs give a magnified distorted image because of divergence of the X-ray beam (Fig. 5). DeSmet et al. (41) compared the measurements of the Cobb angle using both AP and PA projections. There were small differences ($\sim 2^\circ$) in the lordotic lumbar region and kyphotic thoracic region. In the thoracolumbar region where the spine is more nearly vertical and the central X-ray beam is more perpendicular to the film, there was no difference between measurements in the PA and AP projections.

The frontal plane projections may also be used to estimate axial rotation of the vertebrae, based on the positions of the pedicles relative to the apparent center of the vertebral body (42). However, the exact relationship between rotation and this pedicle offset depends on the shape of vertebrae, which is a factor that can be taken into account by using statistical data for vertebral shape (43,44).

Multiview Radiography and 3D Reconstruction

In idiopathic scoliosis the standard frontal and lateral radiographs do not supply all the needed information to understand the 3D aspects of the deformities (e.g., intrinsic vertebral deformities, intervertebral disk wedging, spine torsion, rib cage and pelvis deformation, etc.). Computerized tomography and MRI can be used for 3D imaging, but these modalities have limitations. The image acquisition is normally done in the recumbent position (therefore not

Figure 6. Principles of stereo and biplanar radiography. Stereophotogrammetry principles are used to identify the 3-D positions of object points. The location of the object points can be visualized as the intersections of lines joining the X-ray sources to the corresponding image points.

documenting the standing, functional position). The CT scans can require high X-ray dose of radiation, and both CT and MRI may be incompatible postoperatively with surgical metallic implants. The cost and the image acquisition time are considerable.

Stereo or biplanar techniques (with PA and lateral views, or PA and oblique views) permit 3D reconstruction of selected spinal landmarks using photogrammetric principles (Fig. 6). In the reconstruction, the position of a selected anatomical point visible in both views can be calculated in 3D space (45), using an algorithm such as direct linear transformation (DLT) (46). Dansereau and Stokes (46,47) developed an iterative method for line reconstruction that they applied to the 3D reconstruction of the rib cage based on the images of ribs as seen in PA and oblique radiographs. The average error of these reconstruction methods is ~3 mm, depending on the nature of the landmark (some are more precisely identified than others)(48,49).

These 3D reconstruction methods require calibration to take into account the relative positions of the X-ray sources and film planes. A calibration object with object points in known positions is normally employed. This process was substantially facilitated by the DLT method (46,47), and a recently described self-calibration algorithm (50) relies on point-correspondences between two views of the same scene, without using a calibration object. *A priori* knowledge of typically shaped vertebrae and the pelvis can be used to enhance the anatomical detail, employing a database of geometrical templates in an atlas derived from statistical anthropometrical data from the literature (51,52).

Tomography

Computerized tomography provides several measures of vertebral and thoracic rotation in the transverse plane (53). However, this method has technical difficulties because of the need to select the orientation of the image plane correctly: usually a global transverse plane is used that is not coincident with the local or regional planes in the deformed spine. While this technique can obtain rotation both at the vertebral level and in the trunk cross-

section, it is an expensive procedure, and the radiation dose can be high. It may be used in planning complex surgical procedures for spinal reconstruction after trauma or in cases of severe congenital spinal abnormalities.

Back Surface Topography

The topographical reconstruction of the human trunk has been developed in an attempt to improve documentation of the scoliotic deformity, to eliminate radiation exposure, and to document the external cosmetic aspects of the deformity. These methods may have potential clinical application in detection of scoliosis progression in serial back shape recordings using an automated surface shape measurement system (54). These noncontacting, optical techniques include Moiré fringe photography (55), laser scanning (56,57), and Raster photography (9,58). The principle behind the Moiré fringe technique is shown in diagrammatic form in Fig. 7. The interference patterns, or fringes, represent the surface height or topography of the surface upon which a least one set of lines is projected. Raster techniques involve projection of a structured light pattern (usually lines or dots) on to the body surface, and viewing from an oblique direction (Fig. 8). With suitable calibration, the distorted pattern of the projected lines or points can be converted into the three dimensional coordinates of surface points.

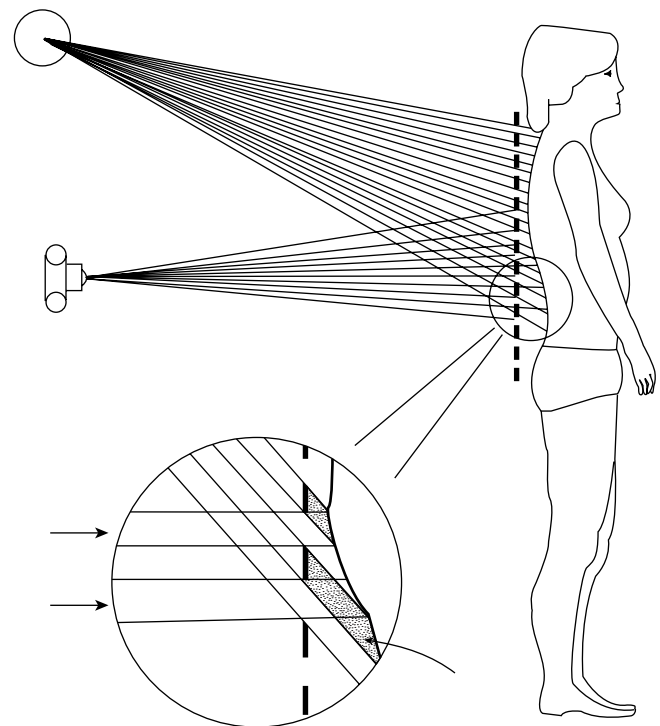

Figure 7. Principles of Moiré fringe photography for recording the shape of the back surface. The surface is viewed through a grid of parallel lines, through which also the surface is illuminated from a different angle. The Moiré fringe pattern results from the interference between the curved line shadows, viewed through the straight line grid.

Figure 8. Example of raster stereophotograph of the back surface of a person with scoliosis. The back surface is illuminated by a square grating pattern of lines. These lines appear curved when viewed from a different angle. This system can be calibrated (by a priori knowledge of the geometry, or empirically by measuring the distortion of the grid when projected on to a surface of known shape. This measurement technique is suitable for automatic measurement, for example, by computer analysis of a digital image.

Recent developments in surface topography include the 360° reconstruction of the trunk to analyze the overall external asymmetry with laser scanning or range sensing (56,57,59) (Fig. 9), and its combination with a neural network approach to identifying the optimal relationship between body surface shape and spinal asymmetry.

THEORIES OF IDIOPATHIC SCOLIOSIS ETIOLOGY

The exact biomechanical contributions to etiology and progression of idiopathic scoliosis deformities are not well understood. Scoliosis consists of a lateral spinal curvature, together with transverse plane rotations of the spine and rib cage, and any complete theory concerning its etiology should be able to explain the originals of this complex geometry. In the absence of clear mechanism explaining

the etiology, it is considered that the causation is probably multifactorial (59,60).

Biomechanical Aspects

Several biomechanical factors have been invoked to explain the biomechanics of scoliosis. These include intervertebral motion coupling, spinal tethering and buckling, and mechanical influences on growth. While in some forms of scoliosis, the initiating causes are relatively clear (e.g., muscle imbalance or weakness in neuromuscular scoliosis), the etiology of idiopathic scoliosis remains obscure. Somerville (62) emphasized the importance of sagittal plane curvatures and demonstrated with an articulated model how a spine with tight posterior ligaments, which is then forced into flexion will become unstable and develop a rotated, scoliotic deformity.

Coupling. Note that both lateral bending of the spine and scoliotic deformities involve transverse plane rotation, but it appears unlikely that coupling of rotational motion in intervertebral segments controls the development of vertebral rotation in scoliosis. The normal kinematic relationships between lateral bending and axial rotation produce a different spinal shape than that seen in scoliosis (16,63,64). In particular these changes do not explain the pattern of deformity that develops in scoliosis with maximal vertebral rotation at the curve apex. Spinal tethering by posterior structures of the spine (62) has also been invoked to explain the spinal shape in scoliosis and its etiology. There are several parts to this theory. Tethering is thought to prevent flexion of the spine and lead to a hypokyphotic or lordotic shape, which then has a greater tendency to instability. Secondly, the tether is thought to maintain a straighter alignment of the posterior elements than of the vertebral bodies, thus the anterior part of the spine (the vertebral bodies) become more laterally deviated, producing the rotation of the vertebrae.

Buckling. The fact that sagittal plane curvature of the spine is flattest in the early teen years supports the idea that this shape places the spine at risk for development of scoliosis. The shape of the spine in scoliosis is reminiscent of a buckled beam, but buckling may not explain the development of lateral curvatures since buckling of the ligamentous spine first exaggerates the sagittal curvatures (64).

Nonbiomechanical Factors

Despite several recent promising developments concerning genetic (65–67) and systemic (68,69) anomalies in patients with AIS, the origin of the initial spinal asymmetry remains unknown. While the regulation of growth and development produces random distributions of right–left asymmetry that are commonly centered around a mean of perfect symmetry (called fluctuating asymmetry), the spine is apparently subject to a higher tendency to spontaneous development of right convex thoracic asymmetry, possibly linked to developmental or mechanical instability. There is some evidence of subtle disturbance

Figure 9. Range sensing topographic scanner (two of the six cameras that surrounds the subject are shown on left panel) and biplanar X-ray system (middle panel) for concurrent surface and spine imaging, showing typical superimposed 3D torso spine model (right panel).

of systemic growth factors (70), abnormal collagen synthesis (71), and abnormalities of muscles and neuromuscular control (72). Recently, Moreau et al. (73) reported that bone cells of patients having surgery for idiopathic scoliosis had an abnormal response to melatonin, implicating a dysfunction melatonin signaling in these patients. However, all these empirical findings have not yet been incorporated into a coordinated theory of the cause of idiopathic scoliosis.

BIOMECHANICS OF SCOLIOSIS PROGRESSION DURING GROWTH

Scoliosis progression is associated with the rate of skeletal growth (74,75). In the progression of a small deformity to a large one, it has been proposed that a small lateral curvature of the spine would load the vertebrae asymmetrically (76), leading to asymmetrical growth in the vertebral growth plates. This acceleration of the deformity associated with mechanically modulated growth has been termed a vicious cycle (77) starting after a certain threshold of spinal deformity has been reached. This theory of spinal growth sensitivity to loading asymmetry must, however, explain why the normal spinal curvatures (kyphosis and lordosis) in the sagittal plane do not progress into hyperkyphosis and hyperlordosis by the same mechanism, although progressive deformity in Scheuermann's kyphosis has been attributed to a similar mechanism (78). This concept of a biomechanical mechanism of progression of deformity is attractive intuitively, and has been incorporated into the rationale for brace and surgical treatments (79). However, it cannot be quantified without better knowledge of the normal spinal loading and the alteration of loading in scoliosis, and better understanding of the sensitivity of growth to the time course of mechanical load

and its magnitude. It is known that bone growth, including that of vertebrae, is modulated by sustained altered stress (increased stress slows growth). However, the mechanism of growth of intervertebral disks, and its possible modulation by altered mechanical conditions is unknown (80). Notably, there does not appear to be any sudden change in disk matrix synthesis at the time of skeletal maturity (81), although scoliosis progression slows considerably after cessation of growth (82).

Scoliosis progression by alteration of bone growth has been investigated both experimentally (83) and analytically. By using heuristic (84) or empirical (85) estimates of spinal loading and growth plate response to altered stress it has been possible to demonstrate the plausibility of the vicious cycle theory of mechanically modulated vertebral growth in progressive scoliosis. In these incremental analyses the asymmetrical forces acting on vertebrae are estimated, and a small increment of spinal growth is applied to the vertebrae, modulated by the applied load. Then the spinal geometry is updated, loading asymmetries recalculated, and the process is repeated until the simulated adolescent growth is achieved. Results are sensitive to numerous assumptions about the initial geometry, the prevailing loading of the spine, as well as the extent to which growth is modulated by chronically altered stress.

BIOMECHANICS OF CONSERVATIVE TREATMENT

Treatment for patients with scoliosis aims to reduce not only the lateral deviation of the axial skeleton, but also the cosmetic deformity that is associated with the axial torsion of the trunk. All the common treatment methods are mechanical in nature, yet the mechanical aspects of the treatment have only recently been studied. The magnitude, area of application and balance of the forces, and their

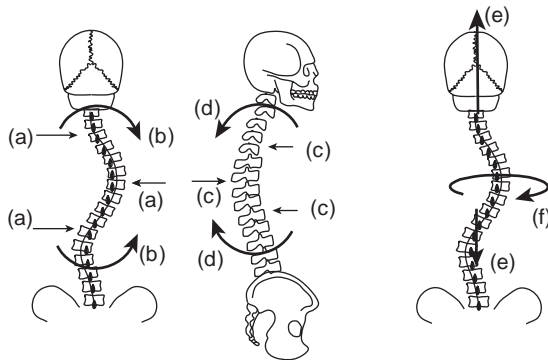

Figure 10. Possible correction force components applied by surgical instrumentation to the spine. Lateral force (a); coronal moment (b); sagittal force (c); sagittal moment (d); distraction force (e); axial moment (f).

moments about the spine are all important to the end result. The types of force applied to the spine for correction are shown in Fig. 10. These forces may either come from an external passive system (i.e., brace) or from an internal active mechanism (i.e. muscles control to shift the trunk away from the pressure areas of the brace).

Braces, Exercises, Electrical Stimulation

A brace is an orthosis that is used to prevent an increase in, or even to reduce, the curvature while waiting for the patient to reach skeletal maturity. The Boston brace, introduced in 1971 by Hall et al. (86) is widely used to treat moderate scoliosis. It has a plastic body envelope with pressure cushions adjusted in the back with straps. Its predecessor, the Milwaukee brace, is made of a neck ring extended by two metal bars and corrective pads. Braces are tailored specifically for each patient and are adjusted by the orthotist. Appropriate positions of the brace's pressure pads are determined from radiographs and clinical examination. Braces use a three- or four-point pressure principle (87), with pads placed generally over the posterolateral part of those ribs that connect to the apex of the thoracic spine deformity, and in the lumbar region, at the level of the scoliosis apex. The strap tension is determined empirically by the orthotist or the orthopedic surgeon (88).

Braces can improve the natural history of scoliosis according to case studies (87), a meta-analysis of published literature (89) and multicenter randomized and controlled studies (90). However, in 81% of the cases the correction is partial or the brace is not sufficient to stop the progression, which cast some doubt on the usefulness and efficacy of braces (91). Clinical studies may be biased by including patients having scoliosis curves that are not likely to progress, with the brace thereby erroneously deemed as effective. Also, it is apparent that many patients do not wear the brace as much as is prescribed (poor compliance), which may reduce the documented effectiveness of bracing. Physical exercises can also be recommended to strengthen back muscles and to improve the spine's stability as well as to reduce back pain. However, these exercises have not been proven to correct nor prevent the progression of

scoliosis deformity and should be used along with a more effective treatment like bracing.

Electrical stimulation of the back muscles has been used in the 1970s for the conservative treatment of scoliosis, but has not been found to be effective (90).

Biomechanical Evaluation of Brace Function

The mode of action of a brace is indirect, since it does not apply forces directly to the spine (92). Many factors influence brace efficiency, including the flexibility of the spine, the shape and stiffness of the brace shell, the location, size and thickness of the brace pads (or of the voids inside the brace), the strap tension adjustment, the biomechanical properties of trunk and thorax tissues, and the duration of the brace forces (93,94).

Analyses made using 3D reconstruction of the spine and rib cage of patients with scoliosis who were treated with the Boston brace have revealed that the brace produced immediate significant curve correction of the spinal deformity in the frontal plane at the expense of a significant reduction of thoracic kyphosis in the sagittal plane and without significant effect on the rib hump, vertebral rotation or frontal balance (95). Coupling mechanisms between the applied forces on the rib cage and the coronal deformity of the spine may explain partially the lack of effect in these planes (32).

The forces generated by braces have been evaluated by measurement of pressure distribution between the brace and the patient's torso (Fig. 11) (94,96) High force zones (20–113 N) are mostly located on both sides of the pelvis, on the lower anterior part of the abdomen, on the posterolateral part of the right thoracic zone, and on the lateral part of the left lumbar zone. However, in some cases unfavorable forces were measured on the left thoracic or on the right lumbar parts of the torso, which can explain some of the negative results of bracing. Correction of curves was not solely dependent on the level of force applied by the brace (96) and some patients with the greatest curves achieved little correction despite significant levels of applied force. Jiang (68) found that although high strap forces are necessary to ensure lateral and derotational forces on the spine, they also cause undesirable forces that induce lordosis. Large variability (8–81 N) was measured in the prescribed tension in the thoracic and pelvic straps of the brace (93), and significant relaxation of strap tension also was found a few minutes after adjustments had been made.

Computer Modeling of Bracing

Biomechanical finite element models simulating the orthotic treatment have been developed to analyze brace biomechanics. In the analyses, forces representing brace pads were applied to models representing specific patients' trunk geometry. The traction force applied by the mandible support of the Milwaukee brace was found to be of relatively minor importance in the correction of scoliotic curves, whereas the lumbar pad significantly affects correction in a lumbar curve and thoracic pad often completely dominates the nature of the correction produced (98). The best correction of scoliotic curves could be obtained using

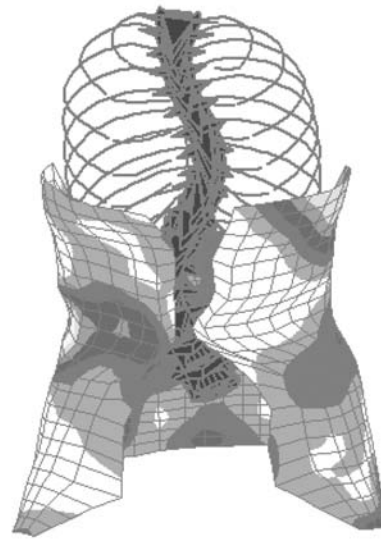

Figure 11. Analysis of brace effectiveness using a flexible matrix of 192 pressure sensors (at the brace-torso interface) and force cells (to measure strap tension). The right side panel shows a typical pressure distribution generated by a brace that is mapped onto a surfacic model of the brace envelope, and superimposed over the three-dimensional reconstruction of the spine and rib cage.

a thoracic pad without lumbar or subaxillary counterpad for thoracic curves, and a lumbar pad with a thoracic counterpad for lumbar curves (99). Application of passive primary forces on the convex side and counter forces on both thoracic and lumbar concave sides of a thoracic scoliotic curve had a substantial corrective effect on the Cobb angle and lateral alignment, as well as do active muscle forces (100). The Boston brace system also was modeled and the brace mechanisms investigated (96,101). An optimization approach of the Boston brace treatment of scoliosis showed that the optimal (most effective) brace forces were mostly located on the convex side of the spinal curves (102). However, the optimal configuration only achieved overall correction of 50% on average.

In previous models of bracing, the action of the brace was represented as force generators instead of passive deformable systems that interact with the flexible torso. Also the complex mechanical action of the brace on the entire torso was not completely addressed. Current modeling efforts are oriented toward the detailed explicit representation of the brace-torso interface (103) (Fig. 12) to improve their simulation of the complete brace system's interaction with the patient, and to optimize the brace design parameters.

BIOMECHANICS OF SURGICAL TREATMENT

In the case of severe spinal deformities (Cobb angle $> \sim 50^\circ$), surgical spinal fusion with metallic implants is often performed. The goals of surgical treatment are to prevent further worsening in the scoliosis, and if possible to straighten the spine. This is normally achieved through arthrodesis (bony fusion) of a region of the spine that spans one or more scoliosis curves. Implants used in surgical treatment of spinal deformities have two complementary mechanical roles. The first is to apply forces to

correct or reduce the spinal deformity intraoperatively and to maintain correction subsequently. The second is to create the correct mechanical environment for spinal fusion to occur by immobilizing the spine until bony fusion has occurred.

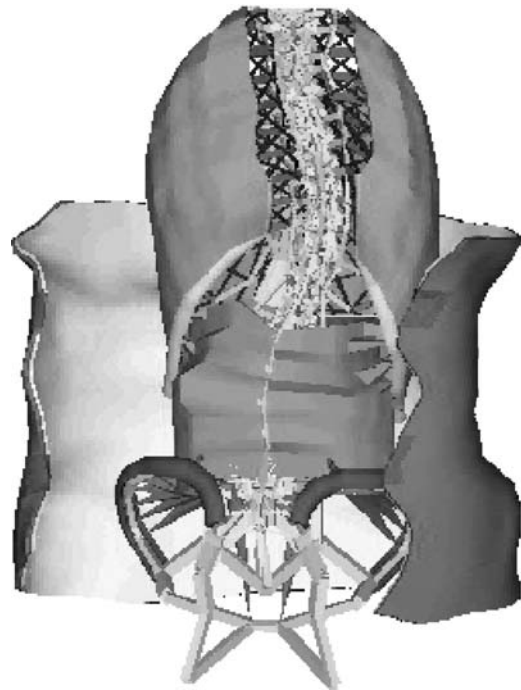

Figure 12. detailed finite element modeling of the brace-torso interface (pelvis not shown). The opened brace is first introduced onto the spine and rib cage model. When the brace is closing (when the opening forces are released), contacts are established at the brace-torso interface and reaction forces are generated. Strap tightening is further generating additional forces.

Types of Spinal Instrumentation and Surgical Planning

The Harrington instrumentation system was introduced in the 1960s, with many subsequent advances, including segmental instrumentation (attached to numerous vertebrae) and anterior spinal instrumentation systems (attached to the front of the spine). The main components of the Harrington instrumentation are hooks, rod with ratchets and cross members. An outrigger could be used to provide some predistracted and stretching of ligaments before the actual distraction rod is implanted on the concave side of the spine deformity. A second rod in slight compression can be installed on the convex side of the spine curve. The main disadvantages of this instrumentation are its limited number of attachments to the spine; consequently, it mainly corrected the deformity in the frontal plane and occasionally resulted in back flattening (104). In the mid-1980s, the 3D nature of scoliosis deformity was becoming more widely recognized and surgical systems were developed that addressed correction of the deformity in 3D. Luque (105) advanced the use of wires passed around the neural arch of vertebrae (sublaminar wiring) to provide multiple connections between a profiled (curved) rod and the vertebrae. The first 3D system was developed by Dubousset and Cotrel (106). It had a curved rod system that was rotated during surgery. A precontoured rod, to account for the deformity and a final kyphosis, is loosely attached to the hooks and then rotated $\sim 90^\circ$ and tightened. The belief is that the deformity in the frontal plane is rotated 90° to provide a natural kyphosis in the sagittal plane. Subsequent developments included pedicular screws that provide stronger anchorage to the vertebrae than simple hooks. With screws, direct derotation of the apical vertebra can be applied before securing the screws on the rods. Instead of additional hooks, sublaminar wires may be used to attach the spine to the rod.

Surgical release of anterior structures and fusion of adjacent vertebral bodies are sometimes necessary in conjunction with posterior fusion to prevent the crankshaft phenomenon. This occurs due to the continued anterior growth in skeletally immature patients. A completely anterior approach and fusion to correct scoliosis was first

introduced by Dwyer and Schafer (107) and was popularized with the Zielke instrumentation in the 1980s (108). Anterior fusion is considered controversial (e.g., because of risks to anterior structures including nerves and major blood vessels), so posterior instrumentation with fusion is still considered the gold standard.

Staples applied between adjacent vertebrae are a promising minimal invasive technology to correct spinal deformities (109) (Fig. 13). Compression staples are used on the convex side of a spine curve to reduce growth while distraction staples are placed on the concave side to accelerate growth.

Testing of Spinal Instrumentation (Construct Design)

Much of the understanding about results of spinal instrumentation and fusion is empirical, based on follow-up studies. Biomechanical principles should be able to provide additional information. The use of surgical instrumentation has a direct mechanical effect on the fused part of the spine, and an indirect effect on the unfused region. It remains as a challenge to biomechanics to further our understanding of the interactions between the spine, the instrumentation, and the muscular and other forces. The muscles, and their control presents the greatest difficulties, since CNS (central nervous system) control of trunk balance is so poorly understood.

There are three basic types of spinal implant construct testing: tests of individual implant components (hooks, screws, rods etc.), tests of the connections between an implant, and the spine and tests of complete instrumentation assemblies. All can be tested in simulations of *in vivo* conditions to evaluate their performance. Laboratory testing of a spinal construct (consisting of a test instrumentation applied to a standardized spinal specimen) can provide information about its flexibility, strength, and fatigue life. Components, such as pedicle screws, may be tested in pull-out (110) or bending. The challenge in all these tests is to establish conditions that are representative of the *in vivo* situation. Both strength and stiffness are desirable properties of instrumentation, and fatigue testing is important to establish whether instrumentation will mechanically fail

Figure 14. Mechanical test of spinal instrumentation construct, (a) with a pure moment imposing flexion-extension by means of a couple (equal parallel forces). (b) with offset compression loading.

or the conditions will lead to pseudoarthroses (failure to fuse this spine segment completely) with repetitive loading over a period of time.

In a typical construct test, instrumentation is applied to a spine specimen, which is then loaded. The resulting deformations are measured. Alternatively (but rarely), a construct can be tested by applying a displacement, and measuring the necessary forces: a flexibility test, which is the inverse of the stiffness test. In a typical stiffness test, a pure moment is applied via a couple consisting of two equal parallel forces. Alternatively, offset compression loading (Fig. 14) is intended to be more physiologically realistic by compressing the spine axially at the same time as creating a bending moment. Most reports then give the resulting rotations about the same axis as the applied torque, or collinear with the applied load. If additional rotations or displacements about other axes are recorded, these provide information about the coupled (as opposed to direct) stiffnesses. The motion is typically recorded by mechanical or opto-electronic methods, or by magnetic sensors of position and orientation.

Some information about *in vivo* loading of internal fixators has been provided by means of telemetry of signals from force transducers built into the instrumentation (111). These show forces on the order of 250 N and moments on the order of 6 Nm transmitted through the instrumentation during walking, but this constitutes an unknown proportion of the total load carried by the spine and the instrumentation.

Many instrumentation tests are performed with animal spines because human spines representative of the target population (of people requiring implants) are hard to obtain. Furthermore, human spinal specimens are more variable in their mechanical properties than animal spines of similar ages, taken from animals of the same breed. Bovine calf and pig spines have been shown to be a reasonable choice based on similar vertebral dimensions and flexibility properties.

Standardized instrumentation testing protocols (112–114) should be advantageous to facilitate comparisons between tests performed in different labs. However, standardization is difficult. In addition to defining the exact conditions for the tests, standardization has to take into account the difficulty of obtaining suitable human cadaveric material or the appropriateness of using animal spines. Standardization has been elusive, and to date only

the testing of instrumentation systems attached to plastic blocks (corpectomy model) has been provisionally standardized by the ASTM (111).

It remains unclear how to interpret the information in reports of stiffness and strength testing of spinal implants, in terms of how to select an instrumentation system and adapt it to the individual needs of a particular patient. It appears that stiffer instrumentation is better, providing the instrumentation size is not excessive. Given that there are six degrees of freedom possible in a stiffness test, it is not known which components of rotation and translational stiffness are the most important. An important aspect of the instrumentation is how easy it is to apply, with minimum blood loss and risk of injury, for example, to neural and vascular structures. Also, the ability to achieve the desired realignment of the spinal column is important. Biomechanical information can be used in conjunction with other information in making surgical decisions, and biomechanical testing ought to be used with the goal of reducing the need for empiricism in the development of knowledge about the outcomes of different surgical strategies.

Analytical Simulation of Surgical Maneuvers

Segmental instrumentation offers surgeons many variables and multistep maneuvers to adapt to individual patients' needs. Biomechanical modeling offers the possibility to explore these options in advance, and to assist in decision making. In theory, if the mechanical properties of both the spine and the instrumentation were understood completely, then biomechanical models could be built and be used to predict the outcome of surgery. However, the complexity of the surgical choices creates many unknown inputs for the biomechanical analyses, and difficulties in validation of model predictions. To simulate the procedures of the Cotrel–Dubousset instrumentation (Medtronic Sofamor–Danek, Memphis, TN), for example, the surgical maneuvers for the concave-side rod of a segmental instrumentation can be represented as four steps: (1) install the rod passively to the end hooks, then approximate the intermediate hooks to the rod; (2) displace the hooks along the rod to their final positions (hook distraction); (3) rotate the concave-side rod; (4) lock the hooks to the rod and relax the applied torque (spring-back). It has proven very difficult to quantify the required magnitude and direction of all these displacement inputs in the simulation. Another difficulty in using a mechanical deterministic model to predict the outcome of surgery for an individual patient is the unknown flexibility of each motion segment and of the rib cage.

Another possibility offered by analytical modeling is the ability to calculate stresses at selected sites in the spine and instrumentation. Finite element analyses were used to estimate stresses in internal fixation devices (115,116). These models have provided estimates of the change in bone stress for different vertebral injury situations, with inclusion of instrumentation components such as plastic washers in the construct, and after incorporation of bone graft. Biomechanical analyses have also been used to investigate the consequences of surgical variables such

as angulation of pedicle screws on the rigidity of the construct (110,117).

Most biomechanical models simulating surgical procedures have employed finite element models. A finite element model of the spine and rib cage (118) was adapted to investigate the biomechanics of Harrington instrumentation (119). The hooks were connected to the instrumented vertebrae (with rotation allowed along vertical axis), while the rod distraction maneuver was modeled as a thermal expansion of the rod to reach its final shape. The biomechanics of Cotrel–Dubousset instrumentation also was studied with this model, in an idealized geometry (120). This study was extended by simulating the surgical maneuvers on fifteen surgical cases (121,122). Each model's geometry was personalized to each patient's 3D skeletal geometry, built from preoperative stereo X rays, and results were compared with documented post-surgical geometry. The simulations of surgical maneuvers showed generally good agreement (on average) with measured effects of surgery in the frontal plane. However, in the sagittal and transverse planes, the response was dependent on model's boundary conditions, motion segments' mechanical properties and instrumentation variables.

A kinematic model including flexible elements to represent each motion segment and kinematic joints and sets to model the instrumentation (flexible multibody approach) was developed by Aubin et al. (123,124). This was intended to overcome limitations of finite element structural modeling that occur when there are large differences in the structure's stiffness (the surgical construct has properties of a mechanism as well as of a structure). Fig. 15 shows preliminary results of this modeling approach for 1 of 20 cases. In the simulations, geometric indices such as Cobb angles showed trends similar to those observed during surgery: gradual correction during surgical procedures and partial loss of correction after hooks/screws lock-up, when the strains induced by the correction maneuvers and stored in the noninstrumented part of the spine were released. To complement this kind of surgical simulation, a spine surgery simulator and a virtual reality training simulator (Fig. 16) currently are under development (125).

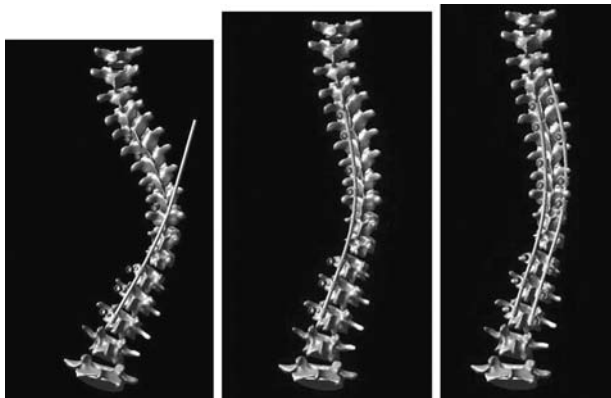

Figure 15. Biomechanical simulation of a spinal instrumentation procedure. The left and central panels show the attachment of the first rod, while the right panel shows the installation of the second rod.

Figure 16. Virtual reality spine surgery simulator. The left panel shows one part of the virtual surgery room with the operating table, the patient and the exposed spine, as well as the radiographs and a magnification of the selected vertebra. The right panel shows an operator that is performing a virtual reality surgery (using stereo stereoscopic glasses and a 3D mouse).

Once validated, these combined tools will allow surgeons to test various surgical options before the real surgery and determine the best scenario for each patient's spinal deformity.

Simulation of the mechanical action of various designs of costoplasties (operations to change the shape of the ribs) by Grealou et al. (33) and Carrier et al. (34) is another recent development. They analyzed different procedures (side, location, length, and number of ribs to resect or to graft), to investigate the biomechanical effect on the spinal and thoracic shape, and to test the idea that spinal deformity can be treated by operations on the rib cage alone.

CONCLUSION

Scoliosis is a costly problem in terms of both healthcare resources and human suffering. Many cases have unknown etiology, and there may be a genetic component in their causation that is modified by environmental factors.

Mechanical analyses of scoliosis as a buckling phenomenon have not been very illuminating, possibly because they are single plane models and do not incorporate rotation or other coupling. The interactions between biomechanical factors and spinal stability during growth are probably important in most scoliosis deformities, irrespective of their initial cause. Biomechanical factors including motion segment coupling, spinal length and slenderness, muscle asymmetry, and postural sway, are apparently relevant in the development and progression of these deformities.

Geometrical aspects of scoliosis can be better documented and understood with 3D measurement including low dose 3D X-ray techniques. These provide a more complete picture of the deformity than the relatively inaccurate single plane Cobb angle measurement. Noninvasive surface measurement techniques show promise, but there is still a need to establish their relationship to radiographic measurements, especially during progression of a curve.

Although many experimental and biomechanical models of scoliosis have been developed, the mechanisms behind the spinal deformity process and its treatment

are not yet clear. Developing a better understanding of the mechanical aspects of the deforming scoliotic spine will lead to a more selective and appropriate means of treatment, especially if the mechanisms that produce the deformity are confirmed to be reversible. Certainly, the empirical evidence from successful brace or stapling treatments suggests that this is the case. Early detection and treatment by mechanical methods show promise for prevention of progression of the deformity.

SCREEN-FILM SYSTEMS

ZHENG FENG LU
Columbia University
New York, New York

INTRODUCTION

Projection radiography generates the majority of the imaging volume in a typical hospital-based radiology department. Figure 1 illustrates the basic geometry for projection radiography. As shown, an X-ray beam incidents upon and transmits through the patient. Differential attenuation occurs as X-ray photons interact with tissues in the patient. Consequently, an altered X-ray distribution pattern is generated behind the patient. This altered X-ray pattern can be recorded by an image receptor placed underneath the patient.

Film has been utilized as an image receptor since the very beginning of radiographic imaging. The first radiograph of a living hand was exposed by Roentgen in 1895 using a photographic plate (1). Film is sensitive to both X rays and light photons. However, the sensitivity of film to direct X-ray exposure is low. In order to overcome this problem, the fluorescent screen was developed shortly after the discovery of X rays to be combined with the film as an image receptor. Fluorescence, as used in radiography, refers to the phenomenon that the absorption of X rays by crystals of certain inorganic salts (called phosphor) is followed by the emission of light photons (2). The emitted light photons are then utilized more efficiently to expose the film that is sandwiched between the screens (see Fig. 2). These fluorescent screens are also called intensifying screens. Initially, calcium tungstate was the phosphor of choice for screens in radiography (3). Over the years, especially since early 1970s, more efficient phosphor materials have been developed, such as rare earth phosphors (2,5–7). The “rare earth” elements are found in a row of the periodic table of the elements with the atomic numbers 57–71. The most common rare earth phosphor currently available is gadolinium oxysulfide (4). Phosphors, other than rare earth types, are used as well, such as yttrium tantalate (5–7).

Figure 1. Illustration of the basic geometry for projection radiography.

Figure 2. X-ray photons are absorbed by the intensifying screens and the emitted light photons from the screens expose the film to form the image.

Despite numerous improvements made in technology since the discovery of X rays, screen-film systems had remained, for a long period of time, as the main recording image receptors for radiography until recently. Since the 1980s, the essential role of the screen-film system has been challenged by the new invention of computed radiography (CR) and digital radiography (DR) (8). In comparison to screen-film systems, the CR and DR system has a much larger dynamic range. It has been reported that a linear response over more than four orders of magnitude of radiation exposure is achievable (2). This allows CR and DR systems to have a high tolerance for variations in radiation exposures. Therefore, the repeat rate due to underexposure or overexposure is significantly reduced. While the CR and DR systems provide tremendous potentials in image manipulation associated with digital imaging, their current spatial resolution is usually inferior to that of the screen-film systems (9,10). This explains the fact that the last stronghold of the screen-film system is in mammography, where the spatial resolution is on high demand. However, the digital technology continues to evolve, and the results of several large clinical trials of digital versus screen-film mammography suggest that the diagnostic accuracy of the digital mammography “is similar to” that of the screen-film mammography (11). In recent years, more and more radiology departments moved toward “filmless” with picture archiving and communication systems (PACS) (8). It is expected for DR and CR to become more widely available, and even replace screen-film systems completely in the near future (12).

In this article, we will outline the physical and photographic properties of intensifying screens and film. The steps for film processing will be delineated. Performance evaluation of the screen-film system will be discussed in relation to image quality and patient radiation dose. Finally, quality assurance and quality control testing will be described for the applications of screen-film systems in radiology.

INTENSIFYING SCREEN

Since only a small percentage (2–6%) of the X rays can be absorbed by the emulsion of the film, the sensitivity of the film alone is very low (2). With the screen-film combination,

X rays are absorbed more efficiently by the intensifying screen. After absorption, the screen furnishes a light image converted from the X ray image. The light image is then recorded on the film with much higher sensitivity. The main purpose of using the intensifying screen with a combination of film, instead of film alone, was to raise the sensitivity of this image receptor in order to reduce the radiation dose to patients. A factor of 50–100 dose reduction is achievable. This dose reduction is often depicted by the intensification factor that is defined as the ratio of the X-ray exposure required to produce a film density (e.g., 1.0 o.d. net density) without screens versus the exposure required to produce the same film density with screens (2):

$$\text{Intensification factor} = \frac{\text{exposure required without screen}}{\text{exposure required with screen}} \quad (1)$$

Also, lower exposure required by screen-film systems can be achieved by using a shorter exposure time that has the added benefits of minimizing patient motion artifacts and reducing X-ray tube heat capacity. However, these advantages are gained at the cost of a decrease in spatial resolution and an increase in noise on the image.

Physical Properties of Intensifying Screen

As shown in Fig. 3, an intensifying screen is composed of four layers (2): a base, a reflecting coat, a phosphor layer, and a plastic protective coat. The total thickness of a typical intensifying screen is ~ 0.3 – 0.6 mm.

The base is the screen support. The materials to make the screen base may be high grade cardboard or polyester plastic (2). The thickness of the base varies among manufacturers. The approximate range is 0.2–0.3 mm.

As described by Curry et al. (2), the reflecting coat is made of a substance, such as titanium dioxide (TiO_2), and is spread in a thin layer (~ 30 μm in thickness) between the phosphor layer and the base. Because light from the phosphor is emitted in all directions, including the direction away from the film, this reflecting coat acts to reflect those light photons back toward the film so that they may also contribute to the exposure on film. Although this increases the sensitivity of the screen, it also increases the blurring effect due to light spreading (shown in Fig. 3). Therefore, some manufacturers choose not to include a reflecting coat in the screen in order to improve image sharpness. This is normally the case for those screens that emphasize spatial resolution, such as those for bone imaging. Consequently, more X-ray exposure is needed to compensate for the loss in

Figure 3. A cross-sectional view of an intensifying screen.

the reduced intensification factor of the screen if the reflecting coat is not added.

The phosphor layer, the key component of the screen, contains phosphor crystals that generate fluorescence. It is used to absorb X-ray photons and convert the absorbed X-ray energy into light photons that expose the film. The thickness of the phosphor layer varies in a range 0.05–0.3 mm, depending on the desired screen intensification factor. Usually, a thicker phosphor layer leads to a faster screen and a thinner phosphor layer leads to a slower screen.

The outmost layer consists of a protective coat that is applied over the phosphor crystals. This protective coat serves three major functions as outlined by Curry et al. (2): (1) it protects the delicate phosphor crystals; (2) it provides a surface that can be cleaned; (3) it helps to prevent static electricity that may generate image artifacts. This layer is usually made of very thin plastic.

Absorption Efficiency and Conversion Efficiency

The process of screen intensification is twofold. First, X-ray photons are absorbed by the phosphor, quantified by the absorption efficiency. Second, the absorbed X-ray energy is converted into light photons that expose the film, quantified by the conversion efficiency. The overall efficiency of a screen is the product of the absorption efficiency and the conversion efficiency, which leads to the intensification factor of the screen mentioned in equation 1. Raising either the absorption efficiency or the conversion efficiency or both can increase the screen intensification factor; thus raising the speed of the screen-film system.

The absorption efficiency, describing how efficiently the phosphor crystals absorb the incident X-ray photons, is a function of the X-ray photon energy and varies with the phosphor type (2–7,13–14). As we learn from the X-ray interactions with matter, X-ray photons are most likely to undergo the photoelectric effect when the X-ray photon energy is just slightly greater than the K-shell binding energy. This forms an abrupt increase in the X-ray photon absorption above the K-shell binding energy, called the K-edge. Obviously, it is desirable to have the K-edge of the phosphor coincide with the effective energy of the X-ray beam so that a high percentage of X-ray photons may interact with K-shell photoelectric effect. The effective energy of an X-ray beam is usually one-third to one-half of the peak in kilovolts. Most X-ray beams commonly employed in diagnostic radiology are operated in a kVp range of 50–120 kVp. Therefore, majority photons incident upon the image receptor are <60 keV. As a result, screen phosphors with K-edges <60 keV may have improved absorption efficiencies. As shown in Table 1 (7,13,14), the K-edge of the conventional calcium tungstate is 69.5 keV, above the energy of majority photons in a typical diagnostic X-ray beam spectrum, especially those X-ray beams with low kVp settings. In contrast, the K-edges of the others are <60 keV. Consequently, the calcium tungstate screen does not absorb X rays as efficiently as those screens with lower K-edges. Other factors that change the absorption efficiency are the thickness of the phosphor layer, the composition of the phosphor crystal, and

Table 1. Physical Properties of Some Common Phosphors^a

Phosphor	Atomic Number of Heaviest Element	K-Edge, keV	Conversion Efficiency, %	Light Emission Spectrum
Calcium tungstate, CaWO ₄	74	69.5	3.5	Blue (340–540 nm)
Barium strontium sulfate, BaSO ₄ :Eu	56	37.4	6	Blue (330–430 nm)
Barium fluorochloride, BaFCl:Eu	56	37.4	13	Blue (350–450 nm)

grain size. A thicker phosphor layer will result in greater absorption efficiency. However, the disadvantage of doing so is the reduction in spatial resolution because light diffuses laterally as it propagates through the screen phosphor layer. The thicker the phosphor layer, the wider spread the light diffusion will be. For a single-screen single-emulsion system, the film is placed closer to the patient prior to the screen (shown in Fig. 2). This arrangement is based upon the fact that X-ray interaction with the phosphor reduces exponentially with the depth. Therefore, the majority of the X rays are absorbed in the top most region of the phosphor layer. Placing the intensifying screen underneath the film ensures a shorter light diffusion path. Consequently, a better spatial resolution is achieved.

The conversion efficiency is also increased from a calcium tungstate screen to a rare earth screen. As defined, the conversion efficiency is the fraction of absorbed X-ray energy converted to light energy for exposing the film. As shown in Table 1, the conversion efficiency varies according to the composition of the phosphor material.

An increase in conversion efficiency results in a greater intensification factor. However, since fewer X-ray photons are involved in image formation, an increase in conversion efficiency also results in an increase in quantum mottle in the image. Quantum mottle is the image noise caused by statistical fluctuation of the finite number of X-ray photons that form the image on film (2). As the conversion efficiency increases, the number of the X-ray photons detected by the intensifying screen reduces; thus the quantum mottle increases due to the reduced number of X-ray quanta that form the image. Unfortunately, an increased quantum mottle is associated with a decrease in low contrast detectability.

FILM

Physical Characteristics of Film

Figure 4 illustrates the cross-section of a film. The film base is to support the fragile photosensitive emulsion. Several conditions for film base materials have been outlined by Curry et al. (2) and include the following: (1) It must be transparent to visible light so that when a developed film is viewed (e.g., on a light box) the base will not interfere with the visual pattern (e.g., the image) recorded in the emulsion layer. (2) It must be strong enough to endure the film

developing procedure, and, yet at the same time, be flexible and easy to handle. (3) It must be physically stable, that is, the shape of the film base must not distort during the developing process and over the long period of film storage. Historically, glass was utilized for film base. Although it was transparent, glass was too fragile and difficult to handle. In 1914, cellular nitrate was adapted to replace glass for X-ray film. But cellular nitrate was flammable and caused possible fire hazards. Later in 1924, less flammable cellulose triacetate base was developed to replace cellular nitrate (2). In 1960, polyester plastic was first introduced to make the X-ray film base. Thereafter, film base has been made of a thin, transparent sheet of plastic; the thickness of the base being ~0.2 mm.

Firmly attached to the base through adhesive substances are photosensitive emulsion layers. Because the emulsion materials are delicate in nature, a supercoat layer is used to prevent damages to the emulsion. If emulsion layers are coated on both sides of the base, the film is called double-emulsion film. Sometimes, such as in mammography, only one side of the base is coated with emulsion. Thus, the film is called single-emulsion film. Intuitively thinking, the single-emulsion film would be less sensitive than the double-emulsion film because it has only one emulsion layer. However, it gains in spatial resolution. The thickness of the emulsion layer is usually very thin, ~10 μm.

The emulsion, the key component of the film, consists of two major ingredients: gelatin and grains made of silver halide. The gelatin is used as the binder for the silver halide grains in order to keep them well dispersed. Because the gelatin is stable in nature, it provides protection and stability for the film emulsion layer before and after the film development process that we will discuss in detail in the section Film Processing. Also, the gelatin allows easy penetration for the film-processing solutions (13).

Figure 4. A cross-sectional view of an X-ray film.

Figure 5. Photomicrographs of flat, tabular-shaped grains with the crystals orientated with the flat side parallel to the film base (a) and three-dimensional (3D) silver halide grains (b). (Courtesy of Dr. R. Dickerson of Eastman Kodak Company.)

The light sensitive silver halide is in the form of small crystals whose sizes vary in the order of 0.1–1.0 μm in diameter (15). The grain sizes, size distribution, and their shapes play a major role in determining the film speed and contrast. Generally, the larger the grain size, the greater the film sensitivity will be. This may be changed if the grain shape varies at the same time. Figure 5 shows photomicrographs of two types of crystals in the film emulsion. One contains flat, tabular-shaped grains, and the other contains the conventional, 3D silver halide crystals. As explained by Dickerson (16), the use of tabular grains increases the ratio of the surface area to volume, which leads to a significant improvement in the film sensitivity. Also, the tabular grains provide better image sharpness by reducing the light “crossover”, which refers to the light emitted not by the screen in contact with the film emulsion, but by the screen opposite the film emulsion and passed through the film base. Newer technologies in 1990s developed a zero-crossover system that the film emulsion on one side of the film base was isolated from the film emulsion on the other side of the film base by adding a light-stopping dye to the film base (16,17). Obviously, the added dye must be removable during the film processing so that it will not be visible on the developed film.

Silver halide crystals can be grown in a variety of sizes and shapes by choice of emulsion precipitation conditions. Details of emulsion making were described by Wayrynen (15) and Dickerson (16). The film designers vary the emulsion grain morphology to meet various needs in film speed, resolution, contrast, and latitude.

The silver halide consists of, predominantly, silver bromide (AgBr) and a very small fraction of silver iodide (AgI) or silver chloride (AgCl), added as a sensitizer. All ions are bonded to form a cubic crystalline lattice.

Latent Image Formation

The silver halide crystals in the film emulsion also contain silver sulfide (AgS) molecules randomly distributed on the crystal surface, which tend to trap free electrons from the bromide ion during X-ray exposure. The trapping site is called the sensitivity speck. This is the location where the latent image formation begins. The mechanism of latent image formation was initially described by the Gurney-Mott theory and has remained a topic of research by many over the years (18). The Gurney-Mott theory is accepted as incomplete, but basically correct. The theory describes the latent image formation as two steps: an electronic excitation and an ionic migration. First, a visible light photon interacts with a bromide ion, forming a bromide atom and releasing an excited mobile electron:

The bromide atom, Br, then migrates out of the crystal into the gelatin while the free electron becomes subsequently trapped at a sensitivity speck. The trapped electron (negatively charged) at the sensitivity speck attracts a mobile silver ion, Ag^+ , (positively charged), and the two combine to form a silver atom, Ag, at the sensitivity speck:

This single silver atom then acts as an electron trap for subsequent freed electrons. There is a continued accumulation of silver atoms at the sensitivity speck following repeated trapping of electrons and their neutralization with silver ions. At least 3–5 silver atoms must be accumulated at the sensitivity speck in order to form a valid latent image center that can become a clump of the silver atoms after the film is developed. The film darkening is produced by the accumulated silver atoms.

Comparison of two films using light sensitometry

Figure 8. A comparison of two films using their H&D curves obtained by light sensitometry.

logarithmic scale, and the film density is plotted along the vertical axis. Figure 7 shows an example of the H&D curve of an X-ray film using light sensitometry, where relative exposures are utilized instead of actual exposures, because, in practice, the relationship between two exposures is often more important than the actual exposure. The H&D curve illustrates how much the optical density may change corresponding to the exposure change. As outlined by Bushberg et al. (4), the curve has a sigmoid shape, beginning with the base plus fog for no exposure, which cannot actually be plotted on a logarithmic scale, and the “toe” for the low exposure region. In the “toe”, the film density rises very slowly as the exposure increases. This region corresponds to “underexposed” film regions, such as the mediastinum on a chest radiograph. Beyond the “toe”, the film density escalates linearly to the increase of logarithmic exposure. This is called the “linear region” or the “straight-line portion” of the H&D curve. In this region, the film contrast is at its best and the film density fits in the useful density range as shown in Table 2. Ideally, a radiograph image should be exposed with proper technique to have densities within this region. Further beyond the “linear region”, the curve flattens out. This region is called the “shoulder”. It corresponds to the “overexposed” region where the film contrast is compromised.

Film Contrast and Latitude

The image contrast in film radiography is shown as the difference in film densities at various locations on the image. It is contributed by both the subject and film contrast. The subject contrast is determined by the difference in X-ray intensity after transmitting through various regions of the patient. It is primarily determined by the differential attenuation of tissues. For example, a solid tumor may attenuate more X rays than its surrounding tissue; thus leaving a lower X-ray intensity behind the tumor. The subject contrast relies on factors such as kVp,

differences in patient part thickness, atomic number, and density of tissues. Film contrast represents the ability of the film to manifest the subject contrast into the image contrast on film. Choosing the correct film will enhance the subject contrast on the final image. The film contrast is determined by the slope of the H&D curve: a steeper slope leads to a higher film contrast. For a given H&D curve, the slope is a function of film density, being low in the toe region, peaking in the straight-line portion, then being low again in the shoulder region (shown in Fig. 8). Based upon the H&D curve, the film contrast is often quantified by two commonly used parameters: gamma and average gradient. Gamma is defined in the straight-line portion by the maximum slope of the H&D curve:

$$\gamma = \frac{D_2 - D_1}{\log E_2 - \log E_1} \quad (5)$$

where D_2 and D_1 outline the straight-line portion of the H&D curve and E_2 and E_1 are exposures needed to produce the film densities of D_2 and D_1 . The average gradient is often calculated over a density range of 0.25–2.0 O.D. both above the base plus fog, because such a density range is considered the useful density region:

$$\text{Average Gradient} = \frac{D_S - D_B}{\log E_S - \log E_B} = \frac{1.75}{\log E_S - \log E_B} \quad (6)$$

where D_S is 2.0 O.D. above the base plus fog and D_B is 0.25 O.D. above the base plus fog. The parameters E_S and E_B are exposures needed to produce the film densities of D_S and D_B .

Very often, a special term called “latitude” is also cited for film photographic characteristics. The latitude is usually defined as the exposure range that produces a certain density range over which a usable image can be made on film (20). If this density range is between the upper and lower optical density limits on an image, then the corresponding exposure range is also called the

“dynamic range”. Obviously, the film latitude changes inversely with the film contrast. Films with wide latitude exhibit lower film contrast than films with narrow latitude. Sometimes, a wide latitude is preferred in spite of compromising the film contrast. For example, in chest imaging, wide latitude films are desirable because of the large dynamic range needed to cover areas behind lungs as well as mediastinum. In other words, a wide latitude film is capable of keeping the lung regions below the shoulder and the mediastinal region above the toe. With the new inventions of digital imaging (e.g., CR, DR), the wide linear dynamic range of these technologies has proved to be advantageous and ultimately solve the conflict between the film latitude and contrast.

The characteristic curves are often employed to compare films regarding various properties including speed, contrast, base plus fog, and maximum density. Figure 8 shows the characteristic curves of two films. The H&D curves are shown in solid lines and the film contrasts as functions of the film density are shown in dashed lines. The graph has dual vertical axes with the left axis for the film density and the right axis for the film contrast. The graph demonstrates Film B has a faster speed, but a lower contrast than Film A. Both have similar base plus fog. Film A can reach a higher D_{\max} than Film B. Note that the characteristic curves shown in Fig. 8 are from light sensitometry. A device called a sensitometer is utilized to expose the film in a “step” fashion with a range of constant light intensities that each differs by a factor of the square root of 2 (i.e., 0.15 increment on the logarithmic exposure scale of the H&D curve). The sensitometer simulates the light emitted from the intensifying screens. Nevertheless, because the simulated light is not the same as the emitted light from screens, the response of film to the sensitometer may differ from that to the actual light from the intensifying screens caused by X-ray exposure. Special cautions are needed when comparisons are made based upon the light sensitometry (21).

The contrast of the image receptor of the screen–film system, as a whole, is primarily dependent on its film contrast; although there are exceptions, such as Kodak InSight asymmetric film–screen systems, of which the contrast can be varied by changing the intensifying screens (16,17).

Spectral Emission and Spectral Sensitivity

Obviously, the wavelength of light emitted by an intensifying screen should correspond closely with the spectral sensitivity of the film used with the screen. Otherwise, the total photographic effect is decreased, and the patient has to suffer more radiation exposure to get the proper film density. Usually, the sensitive spectrum of the film is matched to cover all the wavelengths emitted by the screen in order to maximize the speed of the screen–film combination. Shown in Fig. 9 is a spectral match of blue sensitive X-ray film with the calcium tungstate spectral emission that is continuous with a peak in the blue region (16). The invention of rare earth phosphors made the intensifying screen more efficient in both absorption and conversion of X-ray photons. However, the luminance from the majority

Figure 9. Relative spectral match of Kodak X-Omat K film with ultraviolet (UV) and blue-emitting screens. (Courtesy of Dr. R. Dickerson of Eastman Kodak Company.)

of the rare earth screens was changed to the color green, which made it necessary to change the spectral sensitivity of X-ray films accordingly. The extension of the film spectral sensitivity to longer wavelengths was achieved by adding spectral sensitizing dyes absorbed by silver halide (13). Figure 10 shows a spectral match of green sensitive X-ray film with the spectral emission of a rare earth intensifying screen. Note that, in Fig. 10, despite the fact that the screen emission spectrum was beyond the green region, the film spectral sensitivity was topped at the green region in order to have a safelight zone in the color red. The safelight in the darkroom is for the convenience of handling the film without film fogging. For many years, amber safelights were utilized to handle blue sensitive X-ray films. As the upper limit of the film spectral sensitivity moved up from the blue region to the green region, the

Figure 10. Relative spectral match of Kodak T-Mat G film with Kodak Lanex regular screens. (Courtesy of Dr. R. Dickerson of Eastman Kodak Company.)

darkroom safelight was necessary to change from the amber to the red safelight.

Speed and Resolving Power

The speed of a film, also known as the system sensitivity, is defined in the unit of $1/R$ as the inverse of the exposure that produces a net film density of 1.0 O.D. above the base plus fog. Because film is utilized in combination with intensifying screens, the speed commonly quoted is actually the speed of the screen–film system. Although with a faster film, the speed of screen–film system may be increased accordingly, the determining factor for the speed of a screen–film system is in the screen not in the film. For a screen–film system, the speed can be compared by examining the location of the H&D curve along the horizontal logarithmic exposure scale at a net density of 1.0 O.D. above base plus fog. In general, when a horizontal line is drawn at 1.0 O.D. above the base plus fog, the curve that appears toward the left on the exposure scale has faster speed than those that appear toward the right (see Fig. 8). Apparently, this speed depends on a number of variables, especially kVp and film processing conditions. The American National Standards Institute (ANSI) has published guidelines to standardize the method for measuring the speed of screen–film systems (22). The standard method is rigid in defining the exposure and the controlled film–processing conditions. Unfortunately, such absolute measured results are not widely available. In practice, a concept of “speed class system” has been commonly accepted for comparing the relative speeds among various screen–film systems (2). The specified speed class differs in value by $\sim 25\%$, which is similar to the camera speed class adapted in photography. For example, the sequence of the numbers in speed class starting from 100 is 100, 125, 160, 200, 250, 320, 400, 500. A great number in speed class means a fast screen–film system.

A faster screen–film system is mainly due to a greater intensification factor in the screen, which is often achieved by utilizing a thicker screen phosphor layer that leads to a reduction in resolving power. A general comparison of screen speed and resolving power is shown in Table 3.

Reciprocity Law

The relationship between the optical density and the X-ray exposure depicted in the H&D curve is usually not dependent on the exposure rate. The film density remains the same as long as the amount of the X-ray exposure received by the screen–film system is the same for a wide range of exposure rates. This phenomenon is known as reciprocity law. It allows the X-ray technique to vary in tube current

milliamperes (mA) and exposure time as long as the product of milliamperes and exposure time is constant.

However, the reciprocity law has been known to fail at very short (i.e., the exposure rate extremely high) or very long exposure (i.e., the exposure rate extremely low) with screen–film systems. For example, the film speed is observed to be reduced in mammography where very long exposure time (>2 s) has to be utilized for large or dense breasts (23). The reciprocity law failure can be explained by the latent image formation mechanism described earlier as the Gurney and Mott theory (18). In the case of extremely low exposure rate, the rate of photon absorption is too low to allow the gathering of enough silver atoms at the sensitivity speck to make it stable. Only one or two silver atoms at a sensitivity speck may disintegrate; thus the latent image may disappear before enough silver atoms can be gathered. Therefore, the speed is reduced at the extremely low exposure rate. In the opposite case, where the exposure rate is extremely high, the production of free electrons is too fast for all the silver ions to migrate to the proper sensitivity specks. Therefore, a fraction of the silver ions may not be utilized in forming silver atoms. This also leads to the reduction in film speed. For X-ray units, the automatic brightness control (ABC) on the system, or sometimes referred to as the phototimer, is a feature designed to maintain the consistency in film density regardless of the patient thickness. It is also designed to compensate for the reciprocity law failure.

The reciprocity law failure applies only to screen–film systems, but not to direct exposed film systems.

THE SCREEN–FILM CASSETTE

Figure 11 shows images of two screen–film cassettes. The double emulsion film is sandwiched between the two intensifying screens. In some applications, such as mammography, a single emulsion film is utilized with only one intensifying screen in the cassette. The front of the cassette is X-ray transparent usually made of materials with low atomic numbers, while the back of the cassette often includes a sheet of lead to reduce backscattering. The cassette is light tight so that the film, once being shut into the cassette, will not be exposed to ambient light. Opening or closing the cassette has to take place in a darkroom or other dark environment. The screens are usually mounted on layers of compressible foams so that when the two cassette halves close, air is expelled from the space between the screens and the film. This is to ensure good image quality by having a firm film screen contact without air trapping in between.

FILM PROCESSING

After a latent image is formed on the film by X-ray exposure, the film is subjected to a sequence of chemical processes in order to make the latent image visible to human eyes. This is film processing or film development (21).

Films had been developed manually in the darkroom until the first automatic film processor was introduced in 1956 (4). An automatic film processor (see Fig. 12) consists

Table 3. Physical Characteristics of Screen–Film Systems.

Type of screen–film system	Speed Class	Resolving Power, lp–mm ⁻¹
Film alone		~ 100
Fine detail	<100	$\sim 10\text{--}15$
Par-speed	100	$\sim 8\text{--}10$
Regular	200–400	$\sim 6\text{--}8$
High speed	~ 800	$\sim 4\text{--}6$

Figure 11. Pictures of the screen–film cassettes: (a) a double-screen double-emulsion cassette; (b) a single-screen single-emulsion cassette.

of three tanks: developer, fixer, and water to wash off the chemicals from the film. The film is then dried in a drying chamber and ready for reading at the drop slot. A standard cycle takes ~ 90 s for film processing. There are rapid cycles that take less time and extended cycles that need longer time. Rollers are utilized to transport the film along the circuitous path through each of these tanks. These rollers need to be serviced periodically to prevent roller transport processing artifacts (24). Film artifacts refer to those features on the image that do not reflect the true subject being imaged. The film artifacts are highly undesirable because they distract or even mislead readers. Although artifacts may be generated by factors other than the film processing such as X-ray equipment, patient positioning, film storage and handling, and so on, the film-processing artifacts are among the most commonly seen artifacts in routine clinical images. Details of the film artifacts, and how to battle against these artifacts, can be found in Ref. 21 Chapt. 6.

As the film enters the developer tank, the developer acts as the reducing agent that selectively reduces those

Figure 12. A picture of an automated daylight film processor.

exposed grains to silver. For those silver halide crystals that have been exposed to photons, latent image centers have been formed, each center having at least 3–5 silver atoms, and typically having 10 or more silver atoms. These silver atoms act to catalyze the further reduction of the silver in the presence of the reducing agent which, in this case, is the developer. After development, those exposed silver halide crystals become dark silver grains. One sensitivity speck can be converted to $\sim 10^9$ silver atoms, which gains an enormous amplification (16). They contribute to the O.D. of the film. A great O.D. region has a high concentration of such silver grains; a light O.D. region has a low concentration of such silver grains. An ideal developer should have only the exposed grain developed and unexposed grain washed out. But realistically, unexposed silver halide grains that do not contain latent images may also be developed. This causes “fog”.

The film developing time and temperature of the developer must be optimized because the film speed and the film contrast are directly affected by both factors. Usually, the speed and the contrast increase, up to a certain degree, by the increase of the development time. Then the speed and the contrast reach a plateau or may even decrease with further increase of the development time. Similar effect is observed for the development temperature on the speed and the contrast. Also, note that film fog increases with the increasing development time or temperature, which is not desirable. Therefore, it is important to optimize these film-processing conditions in order to achieve a reasonable compromise among film speed, contrast, and fog.

A fixer is used to terminate the development process and dissolves unexposed silver halide grains without damaging the image formed by metallic silver already developed by

the developer. An incompletely fixed film is easily recognized because it has a "cloudy" appearance. This is a result of the dispersion of transmitted light by those very small silver bromide crystals that have not been removed by the fixer.

Washing the film thoroughly with water is necessary. Otherwise the chemical residues left on the film will turn the film into brown as it ages. This is the function of the water tank after the developer and the fixer.

The last step for film processing is drying. Warm air is blown over both surfaces of the film when it is transported by rollers through the drying chamber. Finally, the dried film is delivered at the drop slot of the automated film processor.

QUALITY ASSURANCE AND QUALITY CONTROL (QA/QC) FOR SCREEN-FILM SYSTEMS

There are many aspects of QA/QC protocols for screen-film system maintenance and film processing. We will briefly discuss several important tests for routine QA/QC in the clinical environment.

The film processor needs day-to-day quality control in order to ensure consistent performance. The major concern in film processing is the instability due to wet chemistry variation and temperature fluctuation. The film sensitometry is a method to evaluate and monitor the performance of a film processor on a daily basis. As an important step in film processor QC, a light sensitometry strip (see Fig. 13) is made by a sensitometer and charted in the morning before any patient images are processed. Needed for film sensitometry are a sensitometer, a box of control films that are identical so that variations among films are negligible, and a densitometer to measure the film density. In addition, a thermometer is utilized to measure the developer temperature to ensure the optimal temperature according to the manufacturer's guideline. Three basic concerns for film sensitometry are (1) the base plus fog; (2) the speed

index; (3) the contrast index. The base plus fog is often measured at an unexposed area of the sensitometry film. For the speed index, a step is often designated with a mid-gray film density such as a film density of no less than, but close to 1.2 O.D. for mammography (19). For the contrast index, two steps are designated with one step of high film density, such as a film density ~ 2.20 O.D. and the other of low film density such as a film density of no less than, but close to 0.45 O.D. (19). The difference in density between these two steps is called the contrast index. The aim values of these three indexes are established over a period such as 5 consecutive days to smooth out normal day-to-day variation at the initial film processor installation or after a thorough preventative maintenance and calibration on the film processor. Day-to-day observation compares the measured indexes with the aim values. Figure 14 demonstrates sensitometric data for a film processor within one month. Records like these allow the tracking of the performance trends. The purpose is to eliminate problems in processor performance before those problems affect patient images. In mammography, 0.10 O.D. variation from the aim value triggers the action level for further monitoring and correction, and 0.15 O.D. variation demands immediate corrective actions before patient films can be processed (19).

There are certain screen-film cassette maintenance issues. First, the intensifying screens need to be kept clean. Artifacts may appear on images in the presence of dust on the screens. In mammography, screen clean-up is required at least once a week (19). In general radiography, screens are recommended to be cleaned at least on a quarterly basis. The cleaning procedure involves a solution containing an antistatic compound and a detergent. With a soft lint-free cloth, the screen surface should be wiped very gently with the solution. Then the cassette should be left open to air-dry. Another important issue of the screen-film cassette maintenance regards screen-film contact. A good screen-film contact is essential to prevent loss of spatial resolution. A simple method for testing the screen-film contact is to image a piece of wire pattern such as a mesh phantom placed on the top of the cassette. The sharpness of the wire pattern in all regions of the filmed image should be examined. If the screen-film contact is poor in certain areas, fuzziness or slightly increased density will be observed at those locations.

Finally, an important routine QA/QC test in a film-based imaging environment is related to darkroom fog. The darkroom fog degrades the image quality unnecessarily and should be prevented. Remedies to eliminate darkroom fog are straightforward, involving sealing the darkroom from light leaks (e.g., the door frame, the film processor, the film pass-box and any openings into the room) and following instructions on safelight type, bulb wattage and safelight positioning (19,25,26). Such easily preventable problems are often unnoticed or neglected (26). Therefore, it needs to be emphasized to have the darkroom fog tested during the initial film processor installation and monitored thereafter periodically (e.g., semiannually). To measure the darkroom fog, we may expose a film with a phantom that would produce a mid-gray film density when the film is developed (19). In the darkroom before

Figure 13. An example of a film sensitometry strip made by a sensitometer.

Figure 14. A chart of a film processor through a period of 1 month using the sensitometry method.

processing the film, place the film on the darkroom counter and bisect the latent image by using an opaque paper so that one-half of the film is protected from and the other exposed to any possible fogging sources in the darkroom. The covering line should be parallel to the anode-cathode direction of the X-ray tube in order to prevent any density difference due to the heel effect. Turn on the safelight in the darkroom. After 2 min of such fogging exposure, develop the film. The density difference of the two portions of the film near the covering line determines the darkroom fog. Usually, the darkroom fog should not exceed 0.05 O.D. (19).

SEXUAL INSTRUMENTATION

KIRK A. BRUNSWIG NEWRING

 WILLIAM O'DONOHUE
 University of Nevada
 Reno, Nevada

INTRODUCTION

From the annals of measurement comes an item of lore on the origins of measurement, occurring when two male

hominids were urinating side by side arguing over whose was bigger. More recently, it is told in the pubs of Ireland that the yardstick was invented in Dublin to settle such disputes.

As Semmlow (1) stated in the first edition of this Encyclopedia, sexual instrumentation is a rapidly evolving science. (*Note:* This article does not endorse an instrument or instruments. None of the authors have received compensation from a manufacturer of any of the products described in this work.) Many early developments in the arena of sexual instrumentation relied on “nonspecific responses associated with increased activity in the sympathetic nervous system”, such as heart rate and blood pressure. However, more recent investigations have turned to more specific physiological responses, generally focusing on the physiological responses of the genitals. While the scope of this entry prohibits a full description of the history and developments in the assessment and interventions related to the human sexual response, interested readers are welcome to refer to the works of Kinsey and Masters and Johnson for a more detailed review of the history of human sexuality research.

The need for and sophistication of measurement of human sexual behavior has improved dramatically over the years; however, there are still several scientific, methodological, and statistical challenges facing those researching the measurement of human sexual behavior. The current entry will review these measurements along with instruments and procedures related to female and male sexual behavior. Within each sex, the measures related to assessment and diagnosis of sexual concerns are reviewed first, followed by a review of devices used in treatment.

INSTRUMENTS AND MEASUREMENT OF FEMALE HUMAN SEXUAL BEHAVIOR

Formal research into physiological aspects of female sexual behavior was spurred in a large part by the work of Masters and Johnson in the 1960s. They highlighted the importance of genital vasocongestion as an indicator of sexual arousal. Later researchers explored the multidimensional nature of female arousal, often ascribing three necessary aspects: physiological, cognitive, and emotional. That is, physiological arousal is a necessary condition for sexual arousal, though it alone is often insufficient; however, early research into women's sexual behavior focused almost exclusively on the physiological aspects; detailing the physiological changes across the human female sexual response of arousal, plateau, orgasm, and resolution. The absence of an integrative research approach toward the assessment and treatment of female sexual response is discouraging, as this is a necessary condition for sexual arousal, and it seems to be a common problem among women. Estimates range from 1 in 3 to 1 in 5 women between 18 and 59 years of age complain of a lack of interest in sex.

A series of studies in the 1980s evaluated the normative aspects of human sexuality research volunteers. Through

these studies, it became clear that both male and female university-based research participants were decidedly different than their college peers. Typically, participants were more likely to participate in human sexuality research if they were to remain clothed. Also, those who were willing to participate were more likely to masturbate, to have had early and more frequent exposure to commercial erotica, to have less sexual fear, and (for female participants) to have a history of being sexually abused. Thus, for the early research studies listed, restraint should be used when extrapolating the findings discussed to dissimilar populations. More recent research has employed intent-to-treat and wait list control approaches in community-based research. These approaches have increased the ecological validity of this line of research, and this trend should continue as researchers increasingly use more ecologically valid methodology.

FEMALE SEXUAL BEHAVIOR ASSESSMENT

Internal Devices

In the late 1960s and 1970s, several devices were constructed to assess physiological components of female sexual response. One early device measured vaginal blood flow using two thermistors mounted on a diaphragm ring (please refer to later section on thermistor clip for the use of temperature measurement in female sexual behavior for more information). Other early devices included those intended to measure vaginal pH, temperature, and genital engorgement and blood flow properties via photoplethysmography. Common to all of these early instruments was a lack of standardization. Of these instruments, photoplethysmography received the most empirical attention.

Vaginal Photoplethysmography. Hatch's 1979 (2) review of vaginal photoplethysmography (VPPG) provides a description of the device as well as the issues and controversies surrounding its use at the time. The VPPG is described as a cylindrical probe approximately the size and shape of a menstrual tampon which is easily inserted into the vagina by the subject. A light source contained within the clear acrylic probe is directed at the wall of the vaginal lumen. A photoelectric transducer is also situated on the probe in such a position that it detects only that fraction of the incident light which is reflected from the vaginal tissue and the blood circulating within it. Changes in blood volume within the vagina produce changes in the amount of the incident light backscattered to the light detector, because of the large difference in transparency between blood and bloodless tissue. Changes in blood volume can therefore be easily recorded as changes in the output of photoelectric transducer (p. 358) (Figs. 1 and 2).

Hoon et al. (5) provide a description of a VPPG (including construction, instruction, recommended calibration procedures, and diagrams) and note there is a lack of standardization among VPPG, indicating that differences in probe size may have impacted cross-study comparisons, as larger probes are thought to reduce movement at the expense of

Figure 1. Vaginal photoplethysmograph similar to that originally designed by Sintchak and Geer (3) using a single light source and photodetector. (Courtesy of Farrall Instruments, Inc., Grand Island, NE.)

possible tissue stretching, blood supply occlusions, reduced sensitivity, and decreased acceptability by women.

One of the challenges with VPPG is the choice of current: alternating current (ac) or direct current (dc). Direct current coupling is used to assess slowly developing changes in vaginal blood volume (VBV), which is suggested as reflecting the pooling of blood in the vagina. Alternating current coupling is used to assess vaginal pulse amplitude (VPA), which is the observation of the arrival of the pulse wave at the observation point on each cardiac cycle. While some researchers approach the ac/dc issue as an either/or issue (2), more recent research (5) has measured both VBV and VPA. In reviewing the controversy surrounding the sensitivity of VBV and VPA, Hatch concludes, "there is some evidence suggesting that VPA is the more sensitive variable in the sense that it has been shown to significantly discriminate among responses in various types of erotica in some cases where VBV has not" (Ref. 2 p. 359).

Geer et al. (6) presented one of the earlier reports on the use of VPPG to demonstrate differential vaginal states following exposure to erotic and nonerotic visual stimuli. In their study, VPPG assessed VBV and VPA. However, they were one of many research groups to find that physiological arousal did not necessarily correlate with subjective ratings of arousal. Similarly, van Dam et al. (7) used VPPG to compare women with and without amenorrhea. The authors theorized and found that women with

Figure 2. (a) Vaginal plethysmograph featuring a circularly symmetrical source/detector pattern. (b) Automatic baseline offset circuit. (From Ref. 4 © 1978, IEEE. Figures courtesy of the authors.)

amenorrhea had decreased vaginal blood flow as assessed via VPPG in contrast with “normals” under equivalently rated conditions of sexual arousal. Again, there was a negligible correlation between physiological and subjective ratings of arousal. Vaginal photoplethysmography VPPG has also been used to assess hematological function pre- and postoperatively for a variety of procedures.

Notably, both VBV and VPA are measured via polygraph. This results in the use of millimeters of deflection or change scores as the dependent measure in such measure-

ments. This often results in within-study consistency, with cross-study inconsistency. Furthermore, some researchers use deviation from baseline (average over the length of preintervention assessment), while others use deviations from time-specific baselines (e.g., average of 10 s prior to next condition, which can be erotic or nonerotic).

Other problems with the use of VPPG include the reliance of the measurement on blood oxygen saturation, temperature, and response time of the light indicator. Hoon et al. (5) also discuss the relative difference of pre- and postmenopausal status, as well as sleep cycle status, as it relates to basal blood flow. Each of these affects the ability of the VPPG to reliably detect a difference within and across subjects over time. Furthermore, genital engorgement during the time of ovulation has been reported as much greater than during the 10th day of the cycle (2), suggesting hormonal levels may influence baseline genital hematology through the menstrual cycle. Notably, variations in hormone levels through both menstrual cycles and entire lifespans are related to vaginal blood flow. Similarly, increases or decreases in naturally occurring agents, such as prolactin and androgens, can change the basal levels of vaginal blood flow and alter the rapidity and duration of genital engorgement. Finally, external agents, such as SSRIs and oral contraceptives can interfere with genital blood flow. However, arousal responses appear to be minimally reliant upon the woman's hormonal levels relative to other variables, such as type of stimulation (e.g., fantasy, film, audiotape) or activity (e.g., watching a film versus masturbating).

Beck et al. (8) highlighted some of the above-mentioned problems with VPPG, emphasizing the measurement concerns related to temperature, response consistency, and drift. They assert that, at the time of publication, no devices seemed sufficient in measuring female sexual arousal.

Several recent studies have explored the relationship among parasympathetic nervous system arousal, genital arousal, and subjective arousal. Early returns suggest parasympathetic arousal may facilitate sympathetic activation in female sexual arousal. Vaginal photoplethysmography has been used to distinguish between vaginal blood flow related to sexual arousal versus sexual anxiety. The ability to differentiate anxiety-induced blood flow versus arousal-based blood flow can be quite helpful, depending on the issue being assessed. Further, sexually dysfunctional women often report significantly less autonomic arousal. One possible extension of these data would be to include treadmills and exercise bikes as potential sexual response enhancement devices, as physical exercise often leads to parasympathetic arousal.

Perhaps surprisingly, the gross differences within and across vaginas has not been shown to introduce confounds in experimental research. Given the changing shape of the vagina during sexual response cycle, researchers have found a fair degree of reliability is possible, even when the VPPG shifts or is repositioned within the vagina. However, researchers and practitioners need to heed the inherent measurement artifact introduced due to movement within subjects and differences across subjects.

Another problem in comparing VPPG study is the use of arousing stimuli, and the induction of arousal in a

laboratory setting. Several researchers have commented on the challenge to ecological validity when having volunteer undergraduates insert an acrylic tampon in a university research laboratory to assess sexual response. One improvement on this variable has been the development of a portable data collection augment to the VPPG to enhance validity. This provides for a greater sense of ecological validity, in that the research volunteers are able to pursue their sexuality in more naturalistic settings, such as their bedroom or dormitory room.

Further confounding is the type of activity employed to induce arousal in these settings. Some researchers use visual material, such as video depictions of heterosexual and homosexual congress, including oral, anal, manual, and vaginal. There is empirical, marketing, and anecdotal evidence that women are less responsive to visual erotica than to other media. Some researchers have instead employed audiotaped erotica, while others direct the subjects to engage in fantasy.

Some have used the VPPG to assess responding to male-versus female-produced sexually explicit videos. In addition to these variations, other studies have included the request to digitally masturbate, use a vibrator on the vulva and clitoris (without penetration), and to attempt or achieve orgasm, or some combination of all of these. Thus, it is difficult to compare the findings across studies using the VPPG to assess arousal, as there has been so little uniformity in the experimental procedures.

Several researchers have noted that physiological arousal and subjective arousal are not synonymous. One of the few studies to demonstrate a link among physiological and subjective arousal involved the use of VPPG in postoperative male-to-female transsexuals (9). Notably, they found postoperative male-to-female transsexuals demonstrated male-typical category-specific sexual arousal patterns following sex reassignment surgery. Their study included both genital and physiological responding, and discussed some of the physiological differences among natal women and sex-reassigned women, as the later may also include penile erectile tissue.

While relatively few in comparison to male sex offenders, female sex offenders appear to be receiving more attention in judicial and forensic settings. Due to their small numbers, there are few studies assessing female sexual arousal patterns using the VPPG. However, there are case studies in this area, with results likening the utility of the VPPG with the penile plethysmograph (described below).

The VPPG has its strengths and weaknesses relative to other assessment devices. Compared to self-report measures, it is more invasive, cumbersome, and difficult to use. However, it typically provides reliable and valid data that is otherwise unknown. It appears to have fallen out of favor in large scale randomized clinical trials, though is still popular for use in smaller scale and individually based studies.

Vaginal Electromyography. Engman et al. (10) used pelvic floor muscle surface electromyography (EMG) to assess for partial vaginismus (involuntary contractions of the muscles of the outer third of the vagina such that

Figure 3. The EMG transducer with associated detector and recording instrumentation for monitoring the contractile activity of the pubococcygens muscle. (Courtesy of Farrall Instruments, Ins., Grand Island, NE.)

intromission is painful or impossible) and vulvar vestibulitis (a specific form of vulvar pain). They conclude that EMG is not a useful method to distinguish between asymptomatic women and women with partial vaginismus and vulvar vestibulitis. However, other researchers have found EMG to differentiate women with vaginismus from those without during basal and induced vaginismus conditions. Others have used EMG to demonstrate differences between ejaculatory and nonejaculatory orgasmic women. Electromyography has been used successfully in several studies researching etiology, treatment, and bio-feedback for urinary incontinence. While this approach appears promising, there does not appear to be a consensus on the utility of this approach relative to other approaches (e.g., Vulvalgesimeter, discussed below) (Fig. 3).

Thermistor Clip and Vaginal Temperature. In a series of studies, Henson et al. (11) tested for a relationship between labial temperature and subjective ratings of arousal. They began by developing a thermistor-clip to measure changes in labial temperature, and found that labial temperature rose in response to erotic stimuli, while other measures of body temperature were unaffected. In assessments throughout the sexual arousal cycle, VPPG data and labial temperature variation were found to show corresponding variations up to the point of orgasm. The temperature remained relatively constant during orgasm, but began to rapidly decrease during the resolution phase. A follow-up study by another group using a portable vaginal temperature gauge found variation in vaginal temperature over the course of the day. These researchers hypothesized that the variations may be concomitant with circadian temperature changes, with temperature decrease in arousal being perhaps related to vaginal wall edema or a change in the position of the uterus. While Henson and colleagues made strong arguments for the use of temperature as a meaningful measure, later researchers have not followed-up on their early works.

External Measurement Devices

Vulvalgesiometer. Pukall et al. (12) introduced a new instrument for the assessment of pain in vulvar vestibulitis syndrome (VVS), which is a common form of dyspareunia in premenopausal women. Given the lack of standardization in the cotton-swab test for diagnosing VVS, Pukall et al. (12) developed a simple mechanical device, the Vulvalgesiometer, to standardize genital pain assessment. The device consists of a set of pen-like devices, each holding springs with varying resistance. The bottom of the device holds a Q-tip-type cotton swab, which is pushed down on the area being tested for pain. The pain threshold is measured by how much pressure can be exerted (or by how far the spring is compressed). The researchers reported that subjects endorsed similar pain experiences with the Vulvalgesiometer in comparison to intercourse pain. Furthermore, the authors contend that practitioners will be able to assess change over time more reliably with the Vulvalgesiometer. While still relatively new to the field, this approach shows promise as it appears relatively easy to use for both practitioner and client, as well as both reliable and valid for the assessment of vulvar pain (Fig. 4).

Vaginal Fluid Production. Levin (13) reviews the early work in the assessment of human female genital function. In his review, he discusses the measurement of vaginal pH, pO_2 , blood flow, motility, fluid and its ionic concentrations, electrical activity, and amino acid concentrations in both arousal and basal states. Other researchers have evaluated the prevalence and elements of female ejaculate. The measurement of vaginal lubrication has been assessed through the weight gain of preweighed filter papers. Research in this area has demonstrated the correlation between vaginal lubrication and other physiological measures of arousal. Thus, while not a device *per se*, it is a measurement approach to an aspect of female sexuality. However, the lack of uniform methods of assessment and relative difficulty in obtaining the data appear to have impeded additional research in this area.

Figure 4. Figure of vulvalgesiometer.

Imaging

Duplex Doppler Ultrasonography. Munarriz et al. (14) reported on the use of duplex doppler ultrasonography (DDU) to assess genital engorgement. They used ultrasonography combined with the Doppler effect to assess clitoral and corpus spongiosum diameter, as well as clitoral and corpus spongiosum peak systolic and end-diastolic velocity. The Doppler effect can show whether blood is flowing toward or away from the device, while the ultrasound helps for visualization. They concluded the use of ultrasonography appears to be a less invasive and a consumer-friendly approach to assess genital engorgement in comparison with VPPG. Others have used DDU to assess changes in clitoral engorgement in a study of Alprostadil. Relative to other approaches, such as self-report, DDU is more time and cost-intensive and less invasive than VPPG.

Magnetic Resonance Imaging. Rosen (15) reports on the promising developments in the use of magnetic resonance imaging (MRI) to assess genital engorgement and response in human sexuality. However, there are few published studies in this promising area in the assessment of human female sexuality. Like the DDU, it is anticipated that with additional research, the MRI will be rated as more consumer-friendly than VPPG, and will likely be more cost-intensive than self-report measures of sexual arousal and genital engorgement.

FEMALE SEXUAL BEHAVIOR TREATMENT

Devices and Instruments

Vaginal Dilators. Vaginal dilators are generally a set of graduated glass tubes or cylinders, 2–5 cm in diameter and 15 cm in length. Typically, vaginal dilators are used for the treatment of vaginismus, which is the involuntary muscle contraction of the outer third of the vagina.

With the advent of plastics, nonbreakable dilators are preferable. Furthermore, while vaginal dilation had historically been conducted under general anesthesia, it is now being offered as an outpatient referral for self-administration at home. A recent study using vaginal dilators for in-home use lists their instructions as: These dilators are to relax the muscles around the entrance to the vagina and to gently stretch the area. You should start using the smallest of the dilators, which should be inserted for 10–15 min·day⁻¹ and preferably for two episodes per day of 10–15 min, passing the dilator downward and backward into your vagina. Light lubrication with K-Y jelly or similar is advised. After 1 week you should increase the size of the dilator to the next biggest and increase the size by one every week until you are using the largest of the dilators or you feel comfortable to resume intercourse, whichever happens first. The time that the vaginal dilator should spend in the vagina is the same on each occasion (i.e., 10–15 min).

They also note: “Sometimes it was necessary to help the patient insert the first dilator in the clinic explaining the need to relax her pubococcygeal muscles while advancing the tube during muscle relaxation” (16) (Fig. 5).

Figure 5. Vaginal dilator (17). (Courtesy of www.vagenemus.com.)

Several researchers have noted the benefit of pairing muscle relaxation exercises, and specifically pelvic floor muscle relaxation, as a beneficial adjunct to vaginal dilator therapy. Weiss (18) describes the use of dilators in the treatment of vaginismus. She presents a case study in which, due to economic circumstances, an assortment of vegetables was substituted successfully in the treatment protocol, with positive long-term results. Dilators appear to be one of the most commonly used treatment approaches for vaginismus. For more on the etiology, diagnosis, and interventions related to vaginismus, please refer to Koehler (19). Dilators have also been used in several cases of vaginal construction or reconstruction. However, there is some variability in practice using dilators in this way.

Clitoral Vacuum. Billups et al. (20) introduced the Eros clitoral vacuum for the treatment of female sexual dysfunction. The device is a small battery-powered device designed to enhance clitoral engorgement, increase blood flow to the clitoris, and ultimately to work toward increased sexual arousal and response. It looks a bit like a computer mouse and has a small suction cup to be placed over the clitoris. In follow-up studies, this device was shown to increase genital and clitoral engorgement. Participants self-reported improved libido, arousal, lubrication, orgasm, and satisfaction, as well as decreased pain. Gynecological exams revealed improved mucosal color and moisture, vaginal elasticity, and decreased ulceration and bleeding (Fig. 6, Ref. 21).

Clitstim and Vibrotactile Stimulation. Riley and Riley (2003) (23) present a small study on the use of a finger-cot

Figure 6. The Freund phalloglethysmograph: (1) glass cylinder, (2) plastic ring, (3) metal tube with threads, (4) lock nut, (5) rubber cuff, (6) flat, soft sponge rubber ring. (From Freund et al. (22). Copyright 1965 by the Society for the Experimental Analysis of Behavior, Inc. Reprinted by permission.)

shaped device (sometimes called a vibrotactile genital stimulator) designed to increase digital clitoral stimulation when worn on a finger. The device is similar in nature to a nonmedical clitoral vibrator, but its unobtrusive design was created with the hopes that it would be more socially acceptable. Based on their results, the researchers conclude that the device may be of assistance in anorgasmic or slow-to-orgasm women.

Over-the-counter vibrotactile devices (e.g., vibrators) are the most commonly used sexual instruments for anorgasmic and slow-to-orgasm women. Vibrotactile devices have also been developed for use with men, though the literature in this area is sparse.

IUD with Danazol. Cobellis et al. (24) report on the successful use of an IUD loaded with danazol for the treatment of dysmenorrhea, pelvic pain, and dyspareunia associated with endometriosis. Danazol had previously been used as an oral treatment for these ailments, however, this route of administration led to side effects. Cobellis et al. (24) found that the release of the danazol through the IUD eliminated these side effects (only adding a common IUD side-effect of first-month spotting). They reported 6 month duration of benefit with generally favorable consumer satisfaction.

Treatment Articles. There are several articles reviewing the treatment of sexual dysfunction in the human female without the use of specific instruments or devices. These include the use of botulin toxin for vaginismus, the role of fantasy training, androgen therapy, and cognitive-behavioral therapy including progressive muscle

Table 1. Female Sexual Behavior Assessment

relaxation and meditation. Many of the more recent treatment outcome studies limit their dependent measures to self-report, often ignoring the physiological assessment that some researchers see as necessary and vital. Beck (25) reviewed the theories of etiology, prevalence estimates, and theories related to hypoactive sexual desire disorder. She concluded that a lack of valid, reliable, and consumer-satisfactory dependent measures impede scientific progress in this area.

Self-Report. For a review of self-report measures of female sexual function and behavior, please refer to Althof et al. (26) (Table 1).

INSTRUMENTS AND MEASUREMENT OF MALE HUMAN SEXUAL BEHAVIOR

Erectile Dysfunction and Sexual Deviance

The measurements of and devices related to male sexual behavior typically fall into one of two categories: erectile dysfunction and deviant sexual arousal. Coleman (27) reviews the scientific literature on the etiology and intervention for Erectile Dysfunction (ED), which is defined as the persistent inability to achieve or maintain an erection sufficient for satisfactory sexual activity. It is estimated that > 50% of men of 65 years-of-age experience ED. Meuleman and Van Lankveld (28) note that with the increasing availability of pharmacological interventions for ED, male hypoactive sexual desire disorder may be commonly misdiagnosed. They conclude, "HSDD is more common in men than in women. In public opinion and in medical practice, HSDD is often misinterpreted as ED, and treated as such. There is a need for physicians and patients to be educated, and for the development of reliable clinical tools to assess this aspect of male sexual function (294). The tools used for the assessment and treatment of ED are described below.

The second area of assessment and intervention is toward deviant sexual interest and arousal: most notably, pedophilia. For the assessment of sexual interest, researchers have often turned away from face-valid self-reports and

looked to physiological data. However, as with the women discussed above, it has been shown that physiological arousal is not uniformly correlated to emotional or cognitive arousal.

An area of concern in this topic is the limits to ecological validity inherent in university- or medical-center-based research on male sexuality. Just as the women above are presumed to rarely masturbate with photoplethysmographs inserted, it is presumed that most men do not wear penile Strain Gauges or plethysmographs when engaging in sexual activity (see Ref. 29 for more in this area). Again, more recent researchers have adopted intent-to-treat or wait-list controls to enhance the ecological validity of their research.

MALE ERECTILE DYSFUNCTION

Assessment

Circumferential versus Volumetric Assessment. The early research on male erectile response typically used volumetric assessment. Volumetric assessment usually involves the placement of a flaccid penis in an airtight cylinder with a monitored release valve. Engorgement leads to displacement of air out the valve, leading to an indication of volume displacement due to erection.

Circumferential assessment often involves the placement of a mercury-filled rubberized band around the shaft of the penis near the base. Engorgement typically leads to expanding girth, resulting in millimeter displacement as measured by an accompanying graphing device (Figs. 7 and 8).

In a comparison of volumetric and circumferential measures of penile erection, Wheeler and Rubin (30) found that the circumferential method was preferable for several reasons. While both measures showed a correlation, the authors contend the volumetric approach produced more artifacts, was more difficult to use, and was no more sensitive than the easier-to-use circumferential method. However, a rapid change in length may result in a net decrease in girth, at least temporarily. Taken together, information on the length and width of penile tumescence are consistent with recommendations to take measures over time to assess the level, course, and trend of the observed response.

Figure 7. Barlow-type strain gage for monitoring penile tumescence. (Courtesy of Farrall Instruments, Inc., Grand Island, NE.)

Figure 8. Measuring graphing device for expanding girth.

The assessment of ED often involves the use of a snap gauge, which is an application of multiple circumferential measures (there are several brands and types available, e.g., Dacomed's Snap Gauge, the RigiScan). In essence, this measures a sample of volumetric expansion, which allows for the assessment of both rigidity and circumference. Snap gauges often involve the placement of a band or sleeve around the shaft of the penis, with two or more expansion-specific snaps placed along the length of the gauge. Thus, as the penis expands from the base to tip, the snaps are presumed to snap in sequence dependent on the length of turgidity.

A common assessment avenue for ED is the use of a snap gauge during sleep. Typically, adult males enter REM stage three to four times per night, achieving at least one erection during each REM stage. The sleep-related erections are termed nocturnal penile tumescence (NPT). Presence of NPT is suggestive of psychogenic ED, while an absence of NPT is often inferred as organic ED.

Libman et al. (31) discussed the issues and problems with the reliance on NPT and snap gauges to assess for erectile dysfunction. These authors emphasize the growing body of research indicating waking erectile capacity is not directly related to NPT, concluding there may be different processes underlying NPT and erotically induced erection. Further, Libman noted several subjects balked when presented with the notion of "snap" and "penis" in the same sentence. They altered the description of the procedure to impotence testing and expansion tape. In their study, they confirmed that NPT, as assessed by a snap gauge, did not constitute a valid measure of daytime erectile ability in their sample. However, they provide recommendations to enhance the utility of the assessment, including assessment during waking and sleeping states, as well as a multimodal approach.

The Snap Gauge (Dacomed Inc.) is described by Diedrich et al. (32): A commercial device, which, according to the manufacturer, can be used for the determination of organic impotence. The Snap Gauge consists of nonstretch-

able fabric band that is fastened around midshaft of the penis by Velcro straps. Three plastic snap elements are attached to the device such that they break in sequence if an erection of sufficient circumferential expansion and local hardness is obtained. A male using the device may break none, one, two, or three of these elements corresponding to the sufficiency of his erection.

It is possible to judge a person's ability to reach sufficient tumescence for intercourse by looking at how many snaps remained intact. With all three intact, no intercourse would be possible. With all three unsnapped, the erection would be insufficient for intercourse. If two snaps remain, it is questionable whether the subject has reached sufficient rigidity (Fig. 9, Ref. 32).

Nobre et al. (33) found a similar discordance between physiological and subjective ratings of arousal. Generally, they found men in their sample to underreport their arousal in relation to physiological measures of tumescence. Notably, in their study, participants were unable to manually or visually assess their erections. The researchers noted that positive affect facilitated arousal and was predictive of subjective and physiological arousal estimate concordance.

Strain Gauge. The measurement of human penile tumescence was one of the first review articles describing the construction and measurement issues associated with the armamentarium for the assessment of male sexual arousal. Rosen and Keefe (34) recommend volumetric assessment when precision is important (e.g., specific research question) and circumferential assessment for efficiency and ease of use. They cite the mercury-in-rubber as an optimal tool for the measurement of circumference.

Strain Gauge measurement (a component in PPG) is often conducted via a method involving millimeter displacement as a percentile of maximum erection. In this procedure, the participant places the gauge on the flaccid penis. They are then directed to self-stimulate to a full erection. The point of maximum tumescence is then taken as 100% erection, with later erections being taken as a proportion. Notably, this procedure allows for erections of >100%. There is also an inherent floor effect, in that the lab setting allows for a measurement of flaccidity that does not measure any aversive or deroxing responding (33).

The Dacomed Snap Gauge was evaluated by Diedrich et al. (32) using both mechanical and human subject tumescence. In the biomechanical procedure, a device was manufactured that allowed for the incremental increase in circumference (1mm intervals). The Snap Gauge was placed on the mechanical device, as well as a mercury Strain Gauge. With the human participants, a mercury gauge was placed near the base of the penis, with the Snap Gauge at mid-shaft. Participants were able to manually and visually assess their erections, and were asked to report as the Snap Gauge snaps broke, as well as to report their sufficiency for penetration following the presentation of sexually explicit videotape. The authors noted that the Snap Gauge appears to be lacking in validity based on three problematic deficiencies: the lack of erection uniformity, lack of placement uniformity, and lack of uniform rigidity. The authors direct practitioners to proceed

Figure 9. Snap Gauge (Dacomed Inc.).

with caution when diagnosing ED based upon Snap Gauge data, as in their analysis, the Snap Gauge was subject to both false positives and negatives.

In comparison studies of the RigiScan and Snap Gauge in the assessment of penile rigidity, researchers have concluded the Snap Gauge is more cost-effective than and as reliable as the more complicated RigiScan. They recommend the use of The Snap Gauge primarily, with the RigiScan being recommended for clients when The Snap Gauge is inconclusive or when assessment that is more detailed is necessary (e.g., per research protocol).

Stamp Test. One of the simplest, least expensive, and perhaps oldest tests for ED is known as the stamp test. The stamp test is used to assess NPT. In this procedure, the subject fastens postage stamps around the base of the penis, similarly to where the snaps would be found on a snap gauge. The NPT is likely to displace the stamps. The stamp test was developed before the widespread use of self-adhesive stamps and instead used the moisture-catalyzed

gumming adhesive. Moreover, while this is relatively inexpensive, the published reports provide two false positives and one false negative in a rather small sample.

Electromyography. Da Silva et al. (35) found that EMG could be useful in the differential diagnosis of ED. In this clinician-administered procedure, EMG inserts electrode needles into the muscle, and when the subject is asked to move that muscle, the EMG gives a general picture of the muscle activity by showing the action potentials occurring in the specific surrounding muscle cells. This makes it possible to see whether the dysfunction is indeed physiological. However, few researchers have completed follow-up studies on this promising work.

Imaging

Near-Infrared Spectroscopy. Burnett et al. (36) compared near-infrared spectroscopy (NIS) with color duplex ultrasonography, Strain Gauge circumference measure,

penile tonometry, and clinical assessments. They found NIS to be a safe, inexpensive, and easy-to-use device that provides for quantitative measurements of vascular physiology in erectile assessment, by measuring the percentage of blood volume reaching the penis, and monitoring the circulation. Again, few researchers have continued in this line of research.

Self-Report. A review of self-report measures for the assessment of male sexual behavior can be found at Berman et al. (37) and Kalmus and Beech (38).

THE TREATMENT OF ED

Devices and Instruments

With the advent and marketing of several pharmacological agents for the treatment of ED, some authors have questioned the utility of mechanical devices and surgical interventions. There have been several cases of adverse responses from pharmacological interventions, and there are several conditions for which these medications are contraindicated. For these individuals, surgical or mechanical intervention may be their only hope for a reliable and useful erection.

Vacuum Constrictive Device. The vacuum constrictive device (VCD) typically includes an acrylic cylinder into which the flaccid penis is inserted. The VCD has a manually squeezed bulb pump for the forced suction of air out of the cylinder (up to 250 mmHg, 33.33 kPa), which in turn leads to increased engorgement. A constrictive band is then placed at the base of the penis, with the intent of maintaining the engorgement through the completion of the sexual act by reducing, not preventing, penile venous outflow. Some pumps allow for the placement of the constrictive band (similar to what is sometimes called a “cockring”) while the pump is in place; others involve the removal of the pump and the placement of the band prior to detumescence. A device similar to the VCD (albeit satirized) played a supporting role in the first of the Austin Powers films. Wylie and Steward describe a homemade device for ED, for use when pharmacotherapy is contraindicated (39). In their case study, a 65 year old client fashioned his own VCD for the effective creation of erections (Fig. 10, Ref. 40).

Several researchers have commented on the utility of the VCD, with successes reported with diabetic and neuropathic populations, as well as with psychogenic ED.

Researchers have also found that the device is generally more effective when it is combined with couples’ therapy. However, several complications have also been discussed. Some men have complained of feelings of demoralization, discouragement, and confusion with the device, while others reported frustration when their spouses were not supportive or helpful when using VCD. Furthermore, some men report that even though they can create an erection, they are not necessarily emotionally aroused. Lastly, as the VCD involves the restriction of blood flow out of the penis, possible problems include hemotoma, skin irritation, and in at least one reported case, penile gangrene. This com-

Figure 10. The vacuum constrictive device (VCD) sucks air out of a cylinder to increase penile engorgement.

plication underscores the need for proper instruction and compliance with the device.

Penile Prosthetics. Penile implants were some of the earliest treatments for ED. While practitioners now recommend nonsurgical interventions (e.g., pharmacological or the VCD treatment), there are still some clients for whom a prosthetic implant is preferable. Penile prosthetics have also been used successfully in the creation of neophallus in sex reassignment surgery, and in reconstructive surgery following injury.

Penile prosthetics are typically either malleable or inflatable. Malleable implants are basically permanent, semirigid tubes placed within the penis. When an erection is desired, the man (or partner) positions the penis into the desired direction. Inflatable prosthetics often involve two or more components. A fluid-filled pump reservoir is implanted in the scrotal sac, with hollow tubes (initially one, now two or more in connection) placed within the penile shaft. When an erection is desired, the man or partner squeezes the pump, leading to an outflow of fluid from the reservoir into the tubes, resulting in an erection. Surgically, the procedure can involve the removal of cavernous tissue. With the placement of prosthetic, it may result in fibrous involvement, scarring, or both. These complications can result in difficulty changing implants if needed, and preventing future “natural” erections. A fenestrated implant has been successful in the sparing of cavernous tissue and spontaneous erections.

Follow-up studies on penile prosthetics show high rates of consumer satisfaction, with occasional problems with

Table 2. Erectile Dysfunction

Device	Function	Reference
Snap Gauge	Measures penile rigidity and circumference	32
Strain Gauge	Measures penile circumference via displacement	34
EMG	Tests for physiological penile dysfunction	35
NIS	Measures penile blood volume	36
VCD	Treats ED by increasing engorgement	39
Penile Prosthetics	Surgical treatment for ED	

leakage, breakage, infection, and stretching due to over-use. A common partner complaint is the lack of girth; other complaints have included spontaneous deflation, a cold penis, and that intercourse felt unnatural. Malleable implants are reputed to be easier to install, with inflatable prosthetics typically rated higher by consumers and their partners (Table 2).

Summary. Several researchers have explored the effectiveness, advantages and disadvantages of pharmacological, psychotherapeutic, surgical, and mechanical treatment of ED, and in combinations of these. Taken together, there is no clear gold standard for the treatment of ED; rather, there are several tools available to the clinician and consumer that may be appropriate given the client's physiology, psychology, and context.

DEVIANT PHYSIOLOGICAL AROUSAL

Assessment

The second major area of inquiry into male sexual behavior relates to physiological changes related to deviant sexual arousal. The following section describes the use of the penile plethysmograph (PPG), visual tracking (VT), and pupillometry (PM) to assess differential arousal in response to presentation of varied stimuli. The bulk of this work centers on deviant sexual arousal, typically with adult males being shown or presented videotapes, still images, or audio recordings. The stimuli typically depict age-appropriate as well as age-inappropriate stimuli, and may include other challenges, such as sadistic themes, adult rape themes, fetishes, bondage or sadomasochistic themes, or both, and control conditions with no intended sexual content.

While in Freund's early phallometry work (41) PPG typically assessed volume, the bulk of the last half-century's research using PPG seems to be reliant upon circumferential assessment. Bancroft et al. (42) describe the construction, provide schematics, and a photograph of a simple transducer for measuring penile tumescence. The device is a mercury and rubber strain gauge, which they describe is inexpensive, portable, easy to apply, and unobtrusive in use. They contrast the simple strain gauge with the more complex volumetric PPG used by Freund

(described earlier, please refer to earlier figures of penile plethysmography devices).

Penile Plethysmograph. A PPG is a strain gauge (a stretchable band filled with mercury that is fitted around a subject's penis, discussed earlier in this article), connected to a video screen and data recorder, which records changes in the penis with different stimulus. While PPG can assess both volumetric and circumferential changes, PPG using measures of circumference changes appears to be more widely used. Advances in technology have led to the advent of computer-based assessment and scoring in penile plethysmography. O'Donohue and Letourneau (43) concluded, "there does not appear to be a standardized penile tumescence assessment, but rather there is a family of procedures that share some common aims and features (p. 126)." The 17 potential sources of variation in the assessment that O'Donohue and Letourneau described have not been satisfactorily addressed in most recent reviews. Still, some researchers use an average of pen deflection; some use a sampled interval average, while some use maximum response and percentage of maximum response. Further, as measurement is often less reliable at the ends of the metric, there was some discussion about the reliability and validity of PPG at large expansions.

Kalmus and Beech (38) reviewed the self-report and physiological assessment of male sexual response. They noted that PPG is still the most common method for such assessment, though to acknowledge it is prone to a number of possible artifacts, including faking or intentional suppression. Other clinicians have noted a possible retest habituation effect, which may be an artifact of attempts at standardization. However, some authors contended the PPG is useful in repeated assessments, provided the stimuli are varied and content matched to reduce habituation.

Golde et al. (44) assessed participants' ability to suppress penile responding under audio-only and audiovisual stimulus conditions. They also included measures common to the polygraph (discussed in a later section polygraph), galvanic skin response (GSR), and finger pulse amplitude (FPA). The authors found participants were able to suppress penile arousal while not providing indicators of deception as measured through GSR and FPA. Both naïve and experienced participants were able to suppress, and arousal was less pronounced in audio-only conditions. These data suggest the PPG is susceptible to faking through suppression, especially in the audio-only presentation.

Other evidence of altered penile tumescence comes in treatment studies using the PPG as a dependent measure. Rosen and Kopel (45) demonstrated that with multiple sessions of biofeedback, penile tumescence to undesired sexual stimuli was reduced with lasting effects. The authors contended the result was not due to habituation or generalized suppression. Follow-up data indicated the case study subject had been deceptive in his self-report and had renewed the targeted sexual behavior. This research vignette highlights the oft-noted weakness of deception when using self-report data.

In a study comparing adult males alleged to have sexually offended against children and "normal controls",

Haywood et al. (46) assessed the relationship between physiological arousal as measured by PPG and subjective arousal assessed through self-report. The alleged sex offenders showed more subjective arousal to children, with nonincest offenders reporting higher subjective arousal than incest offenders. Notably, both alleged offenders and normals reported subjective arousal without physiological responding, and subjective repulsion, despite showing penile responding. The authors recommend for the continued use of subjective and physiological measures in the assessment of sexual response.

Other concerns with the PPG include the ethical use of such a device in correctional or forensic settings, including the use of PPG as a treatment device for the challenging of sexual offenders reported responses and arousal patterns. There are also cautions against the use of PPG for predictive purposes, or for reasons beyond which it has been demonstrated to be reliable and valid.

Recent work has explored the use of portable circumferential PPG. Rea et al. (47) found the data taken inside the lab to generally correspond with data taken outside the lab. Not surprisingly, there appeared to be an inverse relationship between penile tumescence and proximity of researcher.

Finally, Mathews et al. (48) reviewed the arguments and problems with the use of PPG in legal settings. They discussed the Frye and Daubert standards of evidence as it relates to the PPG. These standards describe requirements of a measure before it is considered acceptable in evidentiary purposes. A description of these standards can be found in the O'Donohue and Levensky edited collection, *The Handbook of Forensic Psychology* (49). Given the above findings indicating the PPG can be suppressed, and be subject to false positives and negatives, Mathews et al. (48) contended the PPG should not be admitted as evidence for forensic purposes.

Pupillometry. Pupil dilation is indicative of arousal, including sexual arousal. Pupillometry uses a magnified video recorder to track a subject's pupil changes when presented to different stimuli. While the results using pupillometry originally seemed promising, the research has been criticized for a variety of methodological problems, and appears to have lost favor as an avenue of inquiry.

Viewing Time. In viewing time studies, participants are presented visual stimulus materials and allowed to view the materials. The instructions vary across studies as to how long and how much liberty the participant has to view the materials (e.g., in some, the participants are allowed to choose display times, while in others, visual field is tracked). The principle behind this approach is that participants will view images that hold more sexual interest to them for longer periods than those without such appeal.

Abel et al. (50) reported on the development of the "Abel Screen", also known as the Abel Assessment for Sexual Interest (AASI). This device is reported to correspond well with the more intrusive volumetric assessments, and to be more efficient. Laws and Gress (51) review the multiple criticisms of this specific instrument, although they also

acknowledge the benefit of VT-based assessments. The Affinity [Glasgow et al. (52); Kalmus and Beech (38)] is a VT device designed for use with learning-disabled offenders. While there are minimal data to support its use, the existing data are promising.

The Abel Screen [cf. Gaither (53)] was created in response to some of the criticisms of plethysmography. The Abel Screen is different in that it measures attention (as opposed to tumescence or vasocongestion) as measured by tracking visual focus on stimulus objects. The Abel Screen was developed in part to eliminate the need for nude slides as stimulus materials. By using the Abel Screen, clinicians are able to assess the focus of the respondent's attention, and the duration of that attention. Further, the Abel Screen is less time intensive, and less intrusive than plethysmography. While Abel and colleagues report that visual reaction time is a reliable (alphas 0.84–0.90 across stimuli) and valid means of assessing interest, Gaither's data was mixed in an analogue study using undergraduate students. Other researchers have criticized VT studies for their clear face validity, which makes the VT vulnerable to faking. The device consists of a questionnaire, which tests for things such as deviant and inappropriate sexual behaviors, and a program on a computer, in which the participant is to rate the slides on a seven-point Likert scale from "highly sexually disgusting" to "highly sexually arousing". The computer tracks how long it takes for the subject to rate the slide and advance to the next slide, thus tracking how long the subject looks at the slide. Abel and colleagues also state that measures have been taken to identify offenders attempting to conceal their offenses (abelscreen.com) (54), and even with deniers Abel and colleagues contend device is able to detect 88% of sexual abusers.

Laws and Gress (51) reported on the development of computer-generated images in a standardized assessment using PPG, VT, and Choice Reaction Time. They posited this approach as a stopgap measure in the advancement of the inclusion of new technologies to assist in the assessment and monitoring of deviant sexual arousal. They argued that developments in virtual reality might provide avenues of worthy inquiry by posing more realistic challenges to relapse prevention plans while addressing community safety and privacy. With increases in technology and privacy regulations, many researchers are turning to computer-generated composite images to further enhance and clarify sexual arousal patterns. In doing so, researchers may be able to provide for individually based stimulus materials that would maximize the likelihood of deviant arousal and more realistic virtual reality scenarios to provide therapeutic challenges for sex offender treatment skills application.

In a comparison of Abel's visual reaction time (VRT) and PPG with audiostimuli, Letourneau (55) revealed interesting data: both identified offenders against young boys, and neither reliably identified offenders against adult women. Visual reaction time identified offenders against young girls (although not reliably), and surprisingly, PPG data indicated men with female child victims produced significantly lower levels of arousal than men in other offence categories.

Thermistor, Temperature, and Photoelectric Surface Blood Volume. Temperature measurements, indicative of penile and groin blood flow, have not been supported as valid and reliable measures of arousal due to the latency involved in tumescence and detumescence (38). Previous reviews discussed the possibility of telemetric temperature dissipation assessment as an avenue of physiological arousal assessment, however, there are few publications promoting its use in this way. While photoelectric blood volume research is the basis for VPPG in women, it has not born fruit in assessment of male sexual response (38).

Electroencephalogram Movement. Cohen (56) presented one of the few research projects in which the sex organ between the ears was assessed. Their preliminary results suggested an electroencephalogram (EEG) can be used to assess sexual arousal, and that responding was different based on stimulus modality. Although limited, a promising area of inquiry is the EEG measurement of contingent negative variation. Researchers in this area noted a presumed difficulty in faking EEG response. However, given the limited data in this area, caution is warranted in using this approach in the assessment of sexual preference (38).

Galvanic Skin Response. The relatively few studies in this area suggest galvanic skin response (GSR) may be a useful augment to PPG in assessment in which the respondent is showing minimal response or is hypothesized to be faking or suppressing a response. Typically, research in this area is based on the concurrent use of PPG and polygraph.

Polygraphy. Oksol and O'Donohue (57) provided a thorough review of the use of the polygraph in a forensic setting. In their review, they described polygraphy as the evaluation of physiologic reactions that purportedly occur in response to the emotions of fear or conflict, or are in some other way associated with lying. The polygraph measures a number of subtle and involuntary changes in physiological functions, such as heart rate, skin resistance, and blood pressure. By amplifying and recording autonomic functions on a multichannel instrument, the polygraph detects the changes in these functions. It is so named because it has many (poly) pens, with each pen measuring and recording (graphing) a different physiological response. Some of these physiologic responses are recorded on a polygraph chart and the polygrapher interprets these changes to be indicative of truthfulness or deception.

Over the years, there have been many settings in which polygraph examinations have played an important role. These settings include criminal investigations of suspects accused of theft, rape, murder, or lesser crimes. Recently, a number of criminal justice and treatment professionals have been advocates of the increased use of polygraph tests to assess child sexual abuse allegations and have implemented polygraph testing in their practices or treatment programs. For example, polygraphers have been called to assess the verity of a subject's self-reported masturbation patterns, fantasy content, and truthfulness in treatment.

Contrary to lay opinion, there is no such thing as a "typical polygraph test". In reality, the polygraph exam-

ination varies immeasurably from operator to operator. From formulating the questions that will be asked of the suspect to scoring the results of the physiological responses, polygraph techniques are not standardized. Rather, each polygraph administration is a complex and highly variable conglomerate of choice points and interview situations. Polygraphers choose from at least eight different question formats of lie detection, with each having its own psychometric properties (e.g., accuracy rates, reliability).

Oksol and O'Donohue (57) highlighted the multitude of problems facing the forensic use of the polygraph. Most problematic are the lack of uniformity in the procedures, the lack of reliability, and the lack of validity, in that the polygraph has not been able to reliably demonstrate that it assesses what its proponents argue the polygraph assess.

TREATMENT OF SEXUAL DEVIANCE

There are not any accepted devices or instruments for the treatment of sexual deviance, other than the assessment devices described above. For a review of the issues, controversies, and methodology in the treatment of sexual deviance, please refer to Sbraga (58) (Table 3).

Summary. There are several devices and instruments available to the clinician assessing and treating human sexual function. A common theme throughout the measures of human sexuality is the lack of concurrence among physiological and self-report data. It seems as though self-report measures are more satisfactory to the consumer, and perhaps have better psychometric properties. As a result, more and more outcome studies are relying on self-report data for their ease of use and psychometric superiority to physiological devices and instruments.

While there are several reliable, valid, and useful devices and instruments for the assessment and treatment of human sexuality issues, there are some shortcomings that limit the use of these tools. A common theme in review articles is a lack of uniformity in the psychophysiological assessment of human sexual behavior. This lack of uniformity is likely one component in the relatively lower reliability in comparison with self-report data. In addition, many of the research studies in this area have used

Table 3. Deviant Sexual Arousal

Device	Function	Reference
PPG	Measures circumference changes with different stimuli	43
Pupillometry	Tracks pupil dilation with different stimuli	
Abel Screen	Tracks visual tracking with different stimuli	59
EEG Movement	Assesses sexual arousal stimuli	56
GSR	Measures skin response with different stimuli	
Polygraphy	Measures subtle physiological changes associated with lying	57

volunteers, which is problematic due to the demonstrated differences among human sexuality research volunteers and normals. However, some gains have been made in increasing the ecological validity of human sexuality research. Taken together, the above data are consistent with the recommendation for a multimodal assessment, addressing the physiological and psychological (cognitive and emotional) components of human sexuality. Consumer satisfaction with medical devices and instruments appears to be driven by ease of use, partner support, and effectiveness. Technological advances may increase the precision with which the assessment and treatment of the above concerns can be made; however, a lack of cohesiveness in the field may serve to perpetuate the aforementioned problems.

SHOCK, TREATMENT OF

SABIN DECAU
COLIN F. MACKENZIE
University of Maryland,
School of Medicine
Baltimore, Maryland

INTRODUCTION

Assessment and treatment of shock is based on understanding of circulatory system physiology and cellular metabolism. Shock is defined as inadequate supply of oxygen and nutrients due to inadequate capillary perfusion to the cells. This definition is not always correct, as in severe shock some cells cannot metabolize oxygen even with adequate perfusion. In addition, the removal of metabolites is equally important or even more crucial over time, since accumulated metabolites will cause cell injury.

Deficient capillary perfusion triggers a host of metabolic changes in every organ and tissue, which affects whole body homeostasis and circulation. Ideally, one should evaluate the cellular metabolism, but this assessment can be done only indirectly by measuring the acid–base balance in the form of blood gas and pH. This arterial or venous blood test does not give any information about the regional metabolic alterations. For evaluation of the circulatory function, indirect measurements are used including heart rate, blood pressure, and urinary output. Invasive hemodynamic monitoring devices, such as the pulmonary artery catheter are also used for cardiac function assessment. To effectively reverse shock requires monitoring of the pathophysiological state of hypoperfusion. Various devices are used for this state to be monitored directly or indirectly, continuously and intermittently, so that the patient response to therapy can be determined and treatment adjustments made.

ETIOLOGY

There are three common types of shock: loss of blood volume (hypovolemic shock), abnormal blood distribution (e.g., septic shock), and cardiac pump failure (e.g., cardiogenic shock). In practice, these three types of shock do not occur independently, but are frequently mixed with a similar final pathway, irrespective of the circulatory or cardiac state that may have been the precipitant (1).

Heart

The critical event in the development of cardiogenic shock is severe impairment of heart muscle contractile performance. Cardiac performance is primarily determined by four factors: preload, afterload, strength of contraction, and heart rate. Preload is defined as the force exerted on myocardium at the end of ventricular filling. If the filling is inadequate (low preload), cardiac output will be reduced. This finding is best exemplified by extracardiac obstruction, such as pericardial tamponade (blood in the pericardial sac that surrounds the heart) or by the reduction of venous return to the heart caused by high thoracic pressure (such as occurs with a pneumothorax, which is air under tension between the ribs and lung). Afterload is the resistance to emptying of the ventricles with myocardial contraction after the opening of the pulmonary and aortic valves. A rapid increase in afterload as in valvular stenosis leads to decreased volume of blood ejected from ventricles and decreased cardiac output. Contractility is most affected by loss of heart muscle as a result of myocardial infarction (heart attack). In the acute setting of myocardial ischemia, loss of at least 40% of left ventricular heart muscle results in severe depression of cardiac performance and shock.

A similar picture may also result from myocarditis (an inflammation of the heart muscle) and with prolonged cardiopulmonary bypass during cardiac surgery. In addition, myocardial stunning may occur following reversible myocardial ischemia. If the heart rate is too fast as in ventricular dysrhythmias, this may compromise ventricular filling and decrease cardiac output. If the rate is too slow, cardiac output may be insufficient, and shock may ensue. Both high and low heart rates are common complications of myocardial infarction (1–3).

Loss of Volume

Hypovolemic shock is caused by a reduction in intravascular circulating volume to a point where compensation is no longer possible, by constriction of venous capacitance vessels, to maintain cardiac filling. The loss of circulating volume may result from hemorrhage, dehydration, or leakage from the circulation into the body tissues. Trauma and gastrointestinal bleeding are common causes of rapid blood loss and lead to a reduction in preload and cardiac output. However, the oxygen (O_2) carrying capacity of blood is not severely impaired except in massive blood loss causing a decrease in hemoglobin concentration. Dehydration results in intravascular volume reduction with an increase in O_2 carrying capacity, since the number of red blood cells per unit of volume will increase, but the cardiac output is decreased.

Abnormal Distribution

Maldistribution of blood flow occurs with widespread vasodilation usually caused by infectious agents (septic shock) but vasodilation with low systemic vascular resistance may be caused by other mechanisms including endocrine disease, anaphylaxis (severe systemic allergic reaction), and neurogenic shock.

PATHOPHYSIOLOGY

The underlying result of shock of any etiology is hypoperfusion at the cellular level due to an inability to provide the cell with adequate oxygen, glucose, and other nutrients necessary to maintain normal functions. Consumption is calculated by the Fick equation, where cardiac output = O_2 consumption % (arterial-mixed venous O_2 content). If the cardiac output is low, the tissue blood flow is reduced.

Hypoperfusion and hypovolemia due to blood loss decrease the blood pressure and cardiac output. With the loss of up to 15% of total blood volume, no detectable changes in heart rate and blood pressure may be found because venous capacitance vessel constriction compensates for hypovolemia and maintains cardiac filling pressures. If fluid loss is 15–30% of blood volume, that is, 750–1500 mL in a 70 kg male, heart rate will increase tending to maintain cardiac output. Pulse pressure (the difference between systolic and diastolic blood pressure) decreases due to a rise in vascular resistance mediated by circulating catecholamines. The systemic vascular resistance (SVR) increases by constriction of arterioles, which tends to maintain an adequate arterial pressure. However, an increase in SVR raises arterial pressure, but unless it is accompanied by an increase in cardiac output, it has no effect on tissue blood flow. The relationship between flow and pressure is as follows: flow = pressure/resistance, and can be applied to the entire circulatory system, or to a single organ or even an electric circuit (Ohms law).

If the heart produces a constant flow per unit time (cardiac output), then the tissue blood flow (perfusion) will be inversely proportional to the vascular resistance. Therefore, in the case of shock, capillary perfusion should be globally reduced. However, this is not the case, as different organs have variable blood flow and oxygen utilization. The kidneys have high blood flow and little O_2 extraction, whereas the heart has relatively low blood flow (because it is contracting) and high O_2 extraction (Fig. 1) (4). In shock, vasoconstriction occurs preferentially in certain regions (skin, muscle, viscera), diverting the blood flow from these high vascular resistance organs to more vital organs with low resistance, such as heart and brain. If blood loss continues beyond 30–40% of total blood volume, the compensatory mechanisms fail and the blood pressure will fall, accompanied by marked tachycardia, changes in mental status, and decreased urinary output (1).

In the first stage of shock, arterioles are constricted and the amount of oxygen available to tissues may be insufficient for their metabolic needs. The global oxygen consumption will decrease after O_2 extraction from hemoglobin has been maximized (from a normal of 25% of the O_2 carriage to up to 70%). When O_2 consumption falls below a critical level, local metabolism becomes anaerobic, which leads to an increased production of lactic acid by the cells. Later on, this metabolic acidosis causes relaxation of the precapillary sphincters while the postcapillary venules are still constricted. Therefore, the capillaries become overfilled with blood and the hydrostatic pressure

Figure 1. Venous oxygen saturations of blood leaving various organs are shown on the left side and blood flow expressed in mL/min and as a % of total cardiac output (Q_t) are shown on the right side of this figure. Note that the heart and brain with low blood flow relative to their oxygen requirements (e.g., coronary blood flow and carotid artery) have low venous oxygen saturations. In comparison, an organ such as the kidney has high blood flow, but little oxygen requirement and contributes relatively more to the final mixed-venous O_2 saturation of 75% in the pulmonary artery than does the much smaller venous blood flow from the heart and brain. For this reason, a normal pulmonary artery oxygen saturation is not a good indicator of adequate shock resuscitation of the brain or heart.

increases such that there will be loss of plasma into the interstitial space, further depleting the circulating volume. Hemoconcentration occurs and the blood viscosity is increased, causing slowing of the blood flow through the microcirculation. A vicious circle is established, where slow flow causes an increase in viscosity, which in turn leads to a decrease in flow, and so on.

In the latter stages, capillaries are filled with a sludge of red blood cells, which impairs the local flow. In addition, there is further reduction in tissue exchanges by shunting of blood through arteriovenous anastomoses so the functional flow is nearly zero. Therefore, cells lack O_2 and anaerobic metabolism will proceed to a point where cells are no longer able to survive. If a significant number of cells die, the organ function will be compromised. The lung is the first organ to fail, approximately 3–7 days after the primary shock event. The condition that results is called adult respiratory distress syndrome (ARDS) and is characterized by an increase in physiologic shunting and refractory hypoxemia. Kidney involvement is apparent within 2–5 days with acute renal failure due to ischemic tubular necrosis, followed by electrolyte disturbances and metabolic acidosis. Clearance of creatinine by the kidney approximates glomerular filtration rate and when this falls <25 mL/min, there is early onset of renal failure that is still

potentially reversible (5). If liver failure occurs, the first sign is jaundice, but the most significant evidence of failure is abnormal hepatic metabolism, with impaired protein synthesis and an inability to process available energy substrates. Gastric hemorrhage may occur as a late manifestation and is usually precipitated by coagulopathy, a common event in shock. The immunologic response is depressed leading to an increased susceptibility to infections. The syndrome in which all these events occur—multiple organ system failure—is a terminal event common to all types of shock (3).

SHOCK ASSESSMENT

Assessment and management of a patient in shock are accomplished simultaneously. Since evaluation of cellular metabolism cannot be done directly, the physician must rely on surrogate clinical findings such as blood pressure (BP), heart rate, skin temperature, urinary output and mental status, and on data obtained by using various monitoring devices.

Measurement of BP is routine in shock patients. The systolic blood pressure measure (SBP) is not a good indicator of blood loss, as up to 30% of circulating volume may be lost without any change in SBP. Instead the diastolic blood pressure (DBP) is more sensitive and is usually elevated in shock due to peripheral vasoconstriction. Therefore, mean arterial pressure defined as $MAP = DBP + 1/3$ pulse pressure ($SBP - DBP$) seems to be more useful for BP monitoring. Blood pressure measured by auscultation is inaccurate in patients with low peripheral blood flow. Invasive measurement using an intra-arterial catheter inserted into radial, brachial, axillary, or femoral arteries is more precise and provides continuous monitoring and easy access for blood gas and pH analysis.

Change in heart rate occurs with increasing blood loss, values >100 /min in adults are detectable before any change in SBP. Pulse pressure is usually low due to increased DBP. Another clinical monitor is capillary refill time, which is the time for return of blood flow after compression of the nail beds until blanching occurs. It is prolonged >2 s in severe peripheral vasoconstriction. Skin temperature correlates well with peripheral blood flow and a difference of 3–6 °C between toe and rectal temperature reflects severe peripheral vasoconstriction (2). The ability of commonly used clinical parameters to quantify acute hemorrhage is shown in Fig. 2 (6). Base deficit, mean arterial pressure, serial hemoglobin, and serum lactate are related to blood loss.

Preload is assessed by measuring central venous pressure (CVP), which correlates with right atrial pressure, with a catheter inserted in the superior vena cava via the jugular or subclavian veins. Normal CVP is 5–12 cm of H_2O and values <5 are generally found in hypovolemic states and indicate the need for assessment of reserve cardiac function by rapid fluid administration together with assessment of changes in CVP. However, CVP does not always correlate with fluid requirement because an increase in pulmonary vascular resistance (hypoxia, acidosis, increased intrathoracic pressure) may be associated

Figure 2. Commonly used clinical and laboratory values compared to quantity of acute hemorrhage. Graphs show predicted versus actual blood volume reductions for six representative parameters. Solid black lines represent an individual animal ($n = 10$). Gray bar represents the ideal in which predictions equal actual blood volume reductions. For mean arterial pressure, predictions at large volume hemorrhage were more accurate than predictions with small volume bleeds. Models such as heart rate and lactate both showed significance variability before hemorrhage among animals and flat slopes (e.g., mixed-venous PCO_2) indicated fixed-volume predictions regardless of actual degree of hemorrhage. (Reproduced with permission from Waisman Y et al. *J. Appl. Physiol.* 1993;74:410–519.)

with high CVP, reflecting right ventricular failure, even when there is considerable blood loss.

Fluid Challenge

Reserve cardiac function is assessed by means of a fluid challenge until CVP pressures are elevated at least 2 mmHg above the baseline for 10 min after fluid infusion ceases. There are four possible outcomes when 250 mL boluses of fluid are given over 5 min (Fig. 3). Outcome No. 1: Filling pressures rise with the challenge and continue to rise even after fluid infusion ceases. If cardiac output is measured (see below), there is no increase with elevation of filling pressures and the heart has limited reserve function and is not able to deal with the increased fluid load by increasing contractility by the Frank–Starling mechanism (this mechanism describes the property of heart muscle increasing its contraction in proportion to fiber length, up to a maximum point when contractility decreases and cardiac failure occurs). Further fluid infusion (when this response occurs) is expected to produce cardiac failure. The therapeutic indication this response dictates is to restrict

Figure 3. The possible responses to rapid (50 mL/min for 5 min) administration of a fluid is shown schematically. The vertical axis shows the change in cardiac filling pressure (could be either CVP or PAQP) in response to fluid. Time is on the horizontal axis. Fluid infusion ceases after 5 min and the filling pressures are remeasured (and cardiac output measured if available). Fluid challenge in outcomes 3A and 3B should be repeated until filling pressures increase and remain elevated for 5 min after ceasing fluid infusion (outcome No. 2). (Reproduced with permission from Mackenzie CF et al. *J. Neurosurg.* 1985;62:843–849.)

fluid infusion and reduce myocardial depressant agents. If the trend continues, inotropic agents are required to increase cardiac contractility and reverse myocardial depression. Outcome No. 2: Central venous pressure or pulmonary capillary wedge pressure (PCWP) rise 3–4 mmHg, but then falls to a level 2 mmHg above baseline, indicating myocardial contractility is adequate for the increase in cardiac preload. Management should be to infuse fluids and maintain cardiac filling pressures within this range for optimum cardiac output and oxygen transport for the prevailing vascular tone. In outcome No. 3, filling pressures either rise briefly (3A) or do not rise at all (3B) with the 250 mL fluid challenge indicating that the patient has considerable reserve cardiac function and a greater fluid load could be tolerated. If the patient has low urine flow, has evidence of poor tissue perfusion, such as acidosis or low mixed venous oxygen tension, inotropic agents, or diuretics should not be given. Rather, fluid infusion should continue at the same rate until outcome No. 2 is obtained. In fact, because filling pressures have not increased in outcome No. 3, it is unlikely that myocardial fiber length would increase and, therefore, cardiac contractility would not have changed by the Frank–Starling mechanism. Outcome No. 4 is seen in ~5% of cases and results in a fall in filling pressures when fluid is infused rapidly. The two most likely explanations are either that rapid fluid infusion has a vasodilator effect on peripheral vasculature and reduces left ventricular afterload, increasing cardiac output, or alternatively, it may be related to a reduction in heart rate seen when fluid is infused in the hypovolemic patient. The decreased heart rate allows more

time for myocardial perfusion, which occurs mostly during diastole or cardiac relaxation. Cardiac output increases and the Frank–Starling function curve shifts to the left due to improve myocardial oxygenation (7).

Cardiac Catheterization

Catheterization of pulmonary artery (PA) is a method of hemodynamic monitoring that can be used to assess right and left ventricular function as well as quantitate the proportion of blood shunting and to calculate tissue delivery and O_2 extraction. Catheterization is usually reserved for chronically ill patients with heart disease or shock refractory to conventional therapy, because it requires an invasive flow directed, balloon tipped catheter to be floated in the blood stream through the right side of the heart into the pulmonary artery. Such heart catheterization has complications including infection and cardiac rhythm irregularities. It provides data on PA pressure, PCWP, vascular resistances, cardiac output (commonly by a thermodilution technique), and also allows blood sampling from PA, for measurement of mixed-venous saturation (SvO_2) and calculation of intrapulmonary shunting of blood.

Equations

Normal SvO_2 is ~75% (Fig. 1), and it reflects the ratio between oxygen delivery [arterial O_2 content (CaO_2) \times cardiac output (Qt)] and oxygen extraction [ratio of O_2 consumption (VO_2) and O_2 delivery]. Consumption is calculated by the Fick equation, where cardiac output = O_2 consumption % (arterial mixed-venous O_2 content). If the cardiac output is low, the tissue blood flow is reduced.

Blood gas and pH analysis give a rough estimate of oxygen utilization and cellular metabolism by calculation of bicarbonate and base deficit. A low arterial pO_2 (hypoxemia) may accompany shock and be found before any clinical sign due to ventilation–perfusion inequality and increased venous admixture by shunting (see above). The causes of hypoxemia include hypoxic hypoxemia (low inspired O_2), anemic hypoxemia (low hemoglobin for carrying O_2) stagnant hypoxemia (low cardiac output for delivery of O_2), and histotoxic hypoxemia (poisoning of the enzyme systems used to offload O_2 from hemoglobin at the tissues). Blood lactate is an indicator of tissue hypoperfusion and anaerobic metabolism and is elevated in patients with low cardiac output. Lactate is a clinically useful marker of the amount and duration of shock. Sustained reduction in elevated lactate is an important clinical marker of recovery. Arterial pH can be high or normal despite metabolic acidosis, because of low pCO_2 due to increased respiratory rate and alveolar ventilation, common in patients with low cardiac output (1,3,8).

Real-Time Noninvasive Measures of Systemic Perfusion

Sublingual capnometry (measurement of sublingual pCO_2 – $PsICO_2$) is a new technique for assessment of systemic perfusion failure. It is based on elevated pCO_2 in tissues with low blood flow due to intracellular buffering of

hydrogen ions by bicarbonate. Elevated $PsICO_2$ correlates well with increased blood lactate and low mean arterial pressure (MAP), markers of tissue hypoperfusion. $PsICO_2$ has the advantage of prompt indication and continuous monitoring of tissue flow reversal, unlike lactate whose clearance presents significant delay. A threshold value of 70 mmHg for $PsICO_2$ has been identified that is predictive of both the severity state and survival. A $PsICO_2$ >70 mmHg is highly predictive of circulatory failure whereas readings <70 mmHg are highly predictive of survival (9). A similar technique to sublingual capnometry is gastrointestinal tonometry, which measures gut mucosal pCO_2 . Calculation of intramucosal gut pH is possible (pHi) using the Henderson–Hasselbach equation: $pHi = 6.1 + \log (HCO_3^- / \alpha^* \text{ tonometer } pCO_2)$, where α is the solubility of CO_2 in plasma ($\alpha = 0.03$) Values of pHi <7.32 define mucosal hypoperfusion and are associated with high mortality rates (10).

Brain Perfusion

Brain perfusion monitoring is technically difficult and inaccurate. Clinically, signs of confusion, altered sensorium, agitation, and decreased consciousness give a rough idea about cerebral hypoperfusion. Jugular venous oxygen saturation ($SjvO_2$), transcranial cerebral oximetry, and brain tissue oxygen tension ($PbtO_2$) monitoring are the methods of monitoring brain oxygenation. Measurement of $SjvO_2$ is performed using a catheter inserted in the jugular bulb, the upper part of the internal jugular vein. Continuous monitoring of venous saturation without blood sampling is possible by using intravenous oximetry. This type of device has been used in patients with head injury and during anesthesia for neurosurgery. It provides only global brain oxygenation monitoring and is susceptible to errors. Cerebral oximeters using near-infrared spectroscopy seem to be a promising alternative. They can evaluate regional ischemia, hemoglobin saturation, and even concentration of oxygenated and reduced hemoglobin. However, these monitors can only assess trends, where each patient is their own control. There are no normative data for comparison and the boundaries of monitored brain tissue cannot be precisely defined. Brain tissue oxygen tension is measured with small catheters inserted directly into the brain tissue during a craniotomy or via a burr hole. These catheters measure pO_2 , pCO_2 , pH, and temperature. Some studies suggest a normal value for $PbtO_2$ of ~35 mmHg, whereas cerebral ischemia is usually defined as a $PbtO_2$ < 8 mmHg. These data were obtained in patients with traumatic brain injury, but their usefulness should be confirmed by further studies (11,12). Extra cellular glutamate and aspartate measures (obtained by microdialysis) are closely related to outcome after head injury (13). These markers were also related to the type of head injury and suggest that excitatory amino acids play a role in the evolution of brain injury.

SHOCK MANAGEMENT

Treatment of shock should be directed to its underlying cause. However, establishing an exact diagnosis can be

time consuming, so management is focused on simultaneously stabilizing the patient and proceeding with diagnostic tests to identify the cause of shock.

For cardiogenic shock, the goal is an increase in cardiac output by acting to change preload, afterload, contractility, or heart rate. Therapy is tailored using information provided by a PA catheter. Various drugs are given to increase contractility and to relieve pulmonary congestion. In unresponsive cases, additional measures may be considered, such as urgent myocardial revascularization in acute myocardial infarction, intraaortic balloon counterpulsation, and anatomic defects repair (ruptured valves). In extracardiac compression, relieving the pressure of pericardial tamponade by pericardial puncture or insertion of a chest tube for increased intrathoracic pressure due to pneumothorax is the treatment of choice, when these are the causes of impaired cardiac filling and decreased cardiac output.

In case of septic shock (the most common form of distributive shock), large quantities of fluids are administered to fill the vascular bed and maintain perfusion pressure. Cardioactive drugs are used only if cardiac output declines. At the same time steps are taken to identify and control the source of infection (3).

Hypovolemic shock requires initial rapid expansion of circulating volume. Fluid resuscitation is initiated with administration of crystalloid or colloid solutions through large-bore intravenous lines. Rapid infusion devices can be used to pump large amounts of fluids in <10 min. A potential adverse effect resulting from resuscitation with large amounts of fluid, when using rapid infusion devices, is a drop in body core temperature. Levels <35 °C are associated with impaired coagulation and depressed cardiac contractility (14). Covering the patient with inflatable warming blankets can prevent this complication, but the most effective method for rewarming is an extracorporeal countercurrent warmer through femoral artery and vein cannulation, which can elevate temperature ~6 °C in <30 min. During fluid infusion, hemodynamic parameters are continuously monitored and signs of instability (persistent SBP <90 mmHg) imply there is ongoing blood loss or shock has not been reversed. Classically, a hemoglobin (Hb) level <10 g/dL with continuous loss requires blood transfusion, but recent studies have demonstrated that this level can be as low as 7 g/dL without adverse effects in the majority of the population (15). Those with cardiac or cerebrovascular disease should be transfused at higher hemoglobin concentrations.

THE FUTURE OF SHOCK DIAGNOSIS AND MANAGEMENT

Future trends in shock diagnosis and management include identification of mediator's released in shock states and blockage of the release of harmful mediator factors while facilitating release of those with benefits. The field of proteomics, defining protein expression with shock, will

provide many future treatment and diagnostic opportunities. Genomics may identify some individuals or disease states susceptible to adverse outcomes from shock. These future findings could lead to improved outcome, particularly from septic shock, which has a high mortality and morbidity.

SKIN SUBSTITUTE FOR BURNS, BIOACTIVE

ROBERT H. DEMLING
LESLIE DeSANTI
Harvard Medical School
Boston, Massachusetts

INTRODUCTION

A body burn is a complex injury process resulting in local changes in skin integrity as well as profound systemic changes in fluid and electrolyte balance, metabolism, and immune defenses. Severe psychosocial changes also occur in addition to long-term, often permanent changes in skin function. Major advances in care have resulted in a marked decrease in mortality and also morbidity, especially with massive burns. In addition to survival, the current focus in burn care is on improving the long-term function and appearance of the healed or replaced skin cover as well as quality of life.

This focus on quality has generated a significant interest in the use of skin substitutes to be used to improve wound healing, to control pain, to more rapidly close a burn wound, to improve functional and cosmetic outcome, and, in the case of massive burns, to increase survival.

To more effectively address these new roles, the new generation of skin substitutes are developed to be biologically active. The concept behind providing bioactivity is that the wound healing process can be substantially improved as compared with a simple synthetic barrier-type dressing. It remains to be seen just how much better this new generation of products will impact the burn wound. To date, the new products to be discussed have not displaced the more inert standard burn wound dressings, but rather are used in conjunction and for quite specific indications.

The skin substitutes are initially classified according to whether they are to be used as a temporary wound covering to decrease pain and augment healing or a permanent skin substitute to add to or replace the remaining skin components.

The ideal properties and indications for these products will be better clarified after a discussion of the function of normal skin and the effect of a burn on skin integrity.

THE NORMAL PROPERTIES OF SKIN

Normal skin is a very complex bilayer organ with a wide variety of properties mainly protective barriers, which are critical to survival (1–5). Loss of these protective barrier functions occurs with a skin burn. Restoration of skin structure and function become the necessary properties

of temporary and permanent skin substitutes. The skin is a bilayer organ with each layer having specific functions. But both layers are needed for proper skin function. An outer thin epidermal layer covers an inner thicker dermal layer.

Epidermis

The outer thinner layer known as the epidermis is composed mainly of epithelial cells or keratinocytes (1–3). The deepest epidermal cells are immature cells and are continually dividing and migrating toward the surface, to replace lost surface cells; keratinocytes. The same types of regenerating epidermal cells are found in hair follicles and other skin appendages, which are anchored in the dermis. As the cells mature and migrate to the surface, they form keratin, which becomes an effective barrier to environmental hazards such as infection and excess water evaporation.

Stratum Corneum. The stratum corneum is the “outermost” layer of the epidermis consisting of several flattened layers of dead keratinocytes as well as keratin. This layer protects against entry of bacteria and toxins. The epidermal layer regenerates every 2–3 weeks, but regeneration requires the structure and functional components of the dermis.

Skin Functions: Epidermis (Outer Layer).

- Protection from drying.
- Protection from bacterial entry (infection).
- Protection from toxin absorption, like chemicals on the skin.
- Fluid balance: avoiding excess evaporative water loss that would cause dehydration.
- Neurosensory (touch, pain, pressure, sensation).
- Social-interactive (visible portion of the body covering).

The epidermis is firmly anchored to the dermis by the rete pegs, which are ingrowth of epithelial cells interdigitating into the upper dermis like the teeth on a saw.

Dermis

The dermis (1,4,5) is the deeper skin layer responsible for skin durability, and the barrier functions of controlling body temperature, and flexibility and barrier function. The nerves for touch and pain, blood vessels, and hair follicles are present in the dermis. The dermis is responsible for orchestrating the formation of the epidermis.

Skin Functions: Dermis (Inner Layer).

- Regulation of body temperature avoiding hypothermia and hyperthermia.
- Properties of elasticity and durability necessary for movement.
- Epidermal regeneration.

The imbedded epidermal cells can multiply and re-form an epidermal structure under the direction of growth

factors and cell signals found in the dermis (6). The dermal signals are richest in the upper third of the dermis known as the papillary dermis. The deeper dermal layer is less able to regenerate epidermis and itself, therefore the thinner the thickness of remaining dermis in a wound, the less likely it is that the skin can regenerate. More scar will develop to replace the lost skin. If the dermis is totally destroyed, a burn cannot heal by itself and a skin graft or permanent skin substitute is required.

Of extreme importance is the psychological impact in the quality of healed or replaced skin, as this organ has a major role in human communication and helps define the individual. One of the key objectives, of the newer skin substitutes, is to restore some normalcy to the new skin cover.

BURN INJURY

A skin burn is the damage to the structure and function of skin, caused by heat or other caustic materials (7,8). Severity is based on the degree to which the outer epidermis and the inner dermis are destroyed or damaged. The most immediate and obvious injury is one due to heat. Excess heat causes rapid protein denaturation and cell damage (9,10). The depth of heat injury is dependent on the depth of heat penetration. In addition, the body's response to the burn in the form of inflammation and inflammatory mediator release, especially oxidants, results in further cell damage. The damage to skin caused by a burn is therefore a very dynamic process starting with a heat or chemical insult, and then evolving with time, especially in the deeper higher risk burn insult. The initial thickness of the skin is also a major factor as to severity as the thinner the initial skin the more severe will be the burn for the same heat insult. Children and the elderly have very thin skin (7,8).

Burn severity is determined by the depth of the burn, the burn size relative to the percent of total skin burned, and the location. The greater the function (e.g., hands) or cosmetic importance (e.g., face) the more severe the burn. Other factors include age and status of overall health. The very young and very old are at a greater risk with a burn due to an impaired ability to tolerate severe bodily trauma as well as thinner skin. The body response and postburn complications, especially infection, add to severity (7–10).

Burn Size

Burn size is defined as the percent of the persons body skin burned. In the adult, the "Rule of Nines" assessment is commonly used. Each area is considered 9% of total body surface (TBS), each leg 18%, back 18%, front torso 18%, and head being 9% of total. The palm of the patients' hand is considered to be 1% of that persons body skin surface area.

Burn Depth

Burn depth is defined by how much of the two skin layers are destroyed (Fig. 1). Burns can be categorized by degree:

- First degree: confined to the outer layer only.
- Second degree: also involves part of the dermis.
- Third degree: destruction of both layers of skin.

Figure 1. Schema describing burn depth with terminology.

More recent terminology is

Partial thickness: a second degree burn consisting of injury to part of the dermis.

Full thickness: a third degree burn consisting of necrosis to both layers.

Partial thickness or second degree is further divided into superficial-confined to epidermis and upper dermis and deep: when most of the dermis is destroyed.

Full thickness is further categorized as burns involving destruction of the skin alone and burn extending below skin into (e.g., muscle). The latter is often referred to as a fourth degree burn.

Superficial Second Degree

Involves the entire epidermis and no more than the upper third of the dermis is heat destroyed. Rapid healing occurs in 1–2 weeks because of the large amount of remaining skin and good blood supply. Scar is uncommon. However, in young children and the elderly, with an already thin dermis, a burn of this type actually extends to mid-dermis increasing the healing rate with an increasing risk of scarring, especially if re-epithelialization takes >3 weeks.

Initial pain is the most severe of any burn, as the nerve endings of the skin are now exposed to the air. Protection of the burn wound surface from desiccation, inflammation, and infection is necessary to optimize healing. Temporary skin substitutes are used, especially in children, to protect the wound and relieve the pain while it re-epithelializes beneath (11,12).

Deep Second Degree (Deep Partial Thickness) Burn

Most of the skin is destroyed except for small amount of remaining dermis. The wound looks white or charred indicating dead tissue. Pain is much less as the nerves are actually destroyed by the heat. Usually, one cannot distinguish a deep dermal from a full thickness (third degree) by visualization. The presence of sensation to touch usually indicates the burn is a deep partial injury rather than full thickness. There is a high risk of infection due to decreased blood flow and impaired local immune defenses (1,2). This burn typically takes several months to re-epithelialize due to few remaining epidermal cells. The quality of the epithelial covering is typically poor, being thin and friable. Wound scar is usually severe with healing (13).

Table 1. Mean Survival Rate after Burns in Burn Centers,^a age versus Burn Size

Burn size, % of total skin ^b	Age (years)						
	0–1	2–4	5–34	35–49	50–59	60–74	>75

90–100	20	20	20	15	0	0	0

^aSee Refs. (10) and (14).

^bThe body surface burn is the combined second and third degree area relative to total body surface (TBS) (adapted from current literature).

Typically this depth of burn is managed by early surgical excision of the dead tissue and coverage with a skin graft (or permanent skin substitute) (11,12,14).

Third Degree (Full Thickness) Burn

Both layers of skin are completely destroyed leaving no cells to heal. Any significant burn will require skin grafting. Small burns will heal with scar. There is typically no initial pain as nerve endings are destroyed. Because of the high risk of infection and inability to heal primarily third degree burns are typically managed by early excision of the dead burn tissue and skin grafting (or permanent skin substitute) (11–14).

Survival Rate

As can be seen from Table 1, many young patients with massive burns now survive in burn centers, increasing the need for both temporary and permanent skin substitutes.

Note that survival is very high for even massive burns (<75% of the body) in older children and in the young adult. Survival decreases in the elderly due to the presence of pre-existing disease and inability to withstand severe stress. Survival is also less for babies and toddlers for the same size (14).

Burn Scar and Pain Relative to Depth

The initial problems of pain and later problems of scar relate to burn depth and healing time (Table 2) (13,15,16).

Pain is a major problem with superficial burns. Temporary skin substitutes markedly decrease initial pain. Scarring is a result of loss of a large amount of dermis and a resulting prolonged wound healing period (13–17). The wound healing process includes an initial inflammation followed by an increase in wound fibroblasts, new vessels, and epithelial cell proliferation (if the burn is superficial). By 7 days, the fibroblasts are producing increased amounts of collagen, which persists until the wound has healed or is closed. Wound inflammation persists as long as the wound is open.

In superficial burns, epidermal regeneration will be relatively rapid, if the wound environment is optimized. The injured dermal elements are usually covered by new epithelium within 2 weeks if protected from environmental insults. Only modest amounts of collagen are deposited. The wound usually becomes relatively pliable with time and minimal to no wound contraction is seen. Cosmetically, the superficial second degree burn, which heals in 2 weeks, results in very minimal to no long-term scarring (15–17).

The histology of the wound bed, however, changes dramatically if it has not been re-epithelialized by 3 weeks, as would be the case with a deeper dermal burn (13–17). Fibroblasts and macrophages become the predominant cells. Large numbers of myofibroblasts also enter the wound. Besides leading to contraction, these cells continue to deposit large quantities of collagen and glycosaminoglycans. Later, closure of this wound by re-epithelialization or

Table 2. Etiology and Prognosis Relative to Burn Depth^a

Second degree (partial thickness)	Cause	Appearance	Pain	Healing	Scar
Superficial	Hot liquid, short exposure	Wet, pink blisters	Severe	10–14 days	Minimal
Mid-dermal	Hot liquid, hot grease, or flash flame with longer exposure	Less wet, red ± blisters	Moderate	2–4 weeks	Moderate
Deep dermal	Chemicals, direct contact with flames	Dry, white	Minimal	8–16 weeks	Severe, usually needs skin graft
Third degree (full thickness)	Chemicals, flames, explosion with very high temperature	Dry, white or char	None	Needs skin graft	Mild to severe, depending on timing and type of graft

^aThe short- and long-term impact of a burn is described relative to depth.

grafting does not eliminate the stimulus for ongoing scar formation. The components produce a harder, less pliable wound shortening the scar and causing fusion of the collagen fibers in the contracted site. The process of wound contraction will lead to joint contractures.

Also, there are typically no finger like structures called rete pegs produced if healing time exceeds 4–6 weeks and the epidermis is not well anchored such that blistering is common (13,16).

The risk of hypertrophic scar formation increases with the healing time of deeper burns. Hypertrophic scar is an excess scar formation leading to a red, raised, itchy, nonpliable skin cover (13,15,16).

ROLE OF BIOACTIVE SKIN SUBSTITUTES

Outcome is defined both in terms of survival, the quality of the healed or grafted skin, and the degree of morbidity from the burn. The final objective of burn management is achieving survival as well as minimizing the morbidity such as loss of muscle and strength, maintaining quality of life, minimizing scarring, and optimizing the healing process (7,8).

The major stimulus for advances in skin substitutes is to improve the quality of the closed burn wound and avoid poor quality skin (18–20). As can be seen in the table describing burn survival, there are now many massive burns that survive necessitating the use of skin substitutes. Remaining nonburn skin is not sufficient to close these massive burns (11,12,14).

A superficial burn involves the epidermis and very little of the dermis, and the dead tissue peels off, in the form of blisters, leaving a viable wound bed that must be protected. Temporary skin substitutes can improve the healing while decreasing pain (16,17). With deeper burns involving some or all of the dermis, the dead tissue, remains adherent to the wound. The dead tissue known as the burn eschar, will then cause an inflammatory response producing both local and systemic effects. The systemic effects include a profound increase in metabolic rate with a marked increase in muscle wasting, and impairment in immune defenses (1,2). Controlling this systemic response, by earlier removal of the dead burn tissue and closure of the wound, has markedly decreased overall mortality morbidity (11–13). Skin substitutes are used to temporarily or permanently close the excised burn, especially in large burns where there isn't enough remaining skin to use for skin grafts (18–21).

The addition of biological activity to the skin substitute, is intended to improve the healing process with the intention of more rapidly healing a superficial burn and restoring valuable dermal components in a deeper burn wound bed thereby minimizing scarring and optimizing function (18–21). As stated before, the impact of the added bioactivity in burns is yet to be firmly established. A list of the noncellular components of dermis, used in available skin substitute, is shown below (22–26) (Table 3). Epidermal and dermal cells are usually also added to dermal elements in permanent skin substitutes in addition to these dermal components.

Table 3. Components of Dermis that Are Involved in Healing and Used in Skin Substitutes

<i>Dermal Components Stimulating Healing^a</i>	
Structural component or scaffolding	
Biologically active component stimulating all phases of healing	
Collagen (protein)	Scaffold for cell migration and matrix deposition Cell guidance
Elastin (protein)	Tissue elasticity
Fibronectin (protein)	Cell-to-cell adherence Contact orientation for cells Increases epithelial cell division, migration Chemo attractant for fibroblasts, macrophages
Growth factors (proteins)	Stimulate all phases of wound healing
Glycosaminoglycan (glycosylated protein)	Cell adherence properties Conduit for healing factors Deactivator or proteases Scaffold or foundation for dermal elements
Hyaluronic acid (complex carbohydrate)	Maintaining matrix hydrated Decreases inflammation Stimulates healing Proper cell alignment

^aSee Refs. (22–26).

AVAILABLE BIOACTIVE SKIN SUBSTITUTE

A list of skin substitutes, categorized by biologic make-up, is presented below (Table 4). All have some degree of biologic activity for improving the wound-healing environment. A disadvantage of all of these skin substitutes is the absence of active antimicrobial activity. However, early effective wound closure does decrease the risk of infection.

Skin substitutes can also be categorized as to use and indication into temporary or permanent.

Table 4. Available Skin Substitutes Are Categorized Based on Composition

<i>Available Biologically Active Skin Substitutes</i>
Naturally occurring tissues
Cutaneous allografts
Cutaneous xenografts
Amniotic membranes
Porcine small intestinal submucosa
Composite Synthetic-Biological
Collagen based dermal analogs
Integra
Culture-derived tissue
Bilayer human tissue
Cultured autologous keratinocytes
Fibroblast seeded dermal analogues
Epithelial seeded dermal analogue

Skin substitutes can also be categorized as to use and indication into temporary or permanent.

Table 5. Ideal Properties of a Temporary Skin Substitute^a

<i>Ideal Properties of a Temporary Skin Substitute</i>
Rapid and firm adherence properties for closure of the wound
Relieves pain
Easily applied and secured
Does not incite inflammation
Stimulates wound healing
Barrier to microorganisms
Avoids wound desiccation
Optimizes healing environment
Does not cause hypertrophic tissue response
Hemostatic
Prevents evaporative water loss
Flexible yet durable
Easy to remove when
Wound has re-epithelialized
Wound ready for grafting
Cannot transmit disease
Inexpensive
Long shelf life
Does not require refrigeration

^aThese properties are then sought when developing new skin substitutes.

Temporary skin substitutes are used to help heal the partial thickness burn (or donor site) and close the clean excised wound until skin is available for grafting. There are typically no living cells present.

Permanent skin substitutes are used to replace lost skin providing either epidermis or dermis, or both and to pro-

vide a higher quality of skin than a thin skin graft. Most permanent skin substitutes contain viable skin cells as well as components of the dermal matrix.

Temporary Bioactive Skin Substitutes

The purpose of a temporary skin substitute is twofold (Table 5). Temporary skin substitutes are typically a bilayer structure. There is an outer epidermal analog and a more biologically active inner dermal analogue (18–21). The first objective is to close the wound, thereby protecting the wound from environmental insults (18,19,27–29). The second objective is to provide an optimal wound healing environment by adding dermal factors that activate and stimulate wound healing (18–29). Biologically active dermal components naturally are typically provided to the inner layer, which is then applied to the remaining dermis in a partial thickness burn or to an excised wound. Below is a list of the commonly available dermal matrix elements present in these products, and their actions.

The currently available products are listed in Table 6.

Human Allograft (Cadaver Skin)

Human allograft is generally used as a split-thickness graft after being procured from organ donors (30–32). When used in a viable fresh or cryopreserved state, it vascularizes and remains the “gold standard” of temporary wound closures. It can be refrigerated for up to 7 days, but must be stored frozen for extended periods. It is also used in a

Table 6. Available Bioactive Temporary Skin Substitutes^a

Product	Company	Tissue of Origin	Layers	Category	Uses	How Supplied
Human allograft	Skin bank	Human cadaver	Epidermis and dermis	Split thickness skin	Temporary coverage of large excised burns	Frozen in rolls of varying size
Pig skin xenograft	Brennan Medical St. Louis, MO	Pig dermis	Dermis	Dermis	Temporary coverage of partial thickness and excised burns	Frozen or refrigerated in rolls
Human amnion	On site procurement	Placenta	Amniotic membrane	Epidermis Dermis	Same as above	Refrigerator
Oasis	Healthpoint, LTD San Antonio, TX	Xenograft	Extracellular wound matrix from small intestine submucosa	Bioactive Dermal like Matrix	Superficial burns Skin graft donor sites Chronic wounds	Room temperature storage Multiple sizes 3×3.5 cm 7×20 cm
Biobrane	Dow Hickam/Bertek Pharmaceuticals	Synthetic with added denatured bovine collagen	Bilayer product outer silicone Inner nylon mesh with added collagen	Synthetic epidermis and dermis	Superficial partial thickness burns, Temporary cover of excised burns	Room temperature storage 15×20 in. 10×15 cm 5×15 in. 5×5 in.
Transcyte	Smith and Nephew Wound Management Largo, FL	Allogenic dermis	Bilayer product Outer silicone Inner nylon seeded with neonatal fibroblasts	Bioactive dermal matrix components on synthetic dermis and epidermis	Superficial to mid-partial thickness burns Temporary coverage of excised burns	Frozen in 5×7.5 in. sheets

^aThe names and properties of available temporary skin substitutes, with some biological activity are described. Also listed are the indications of the various products.

Table 7. Advantages and Disadvantages of Allograft Skin as a Skin Substitute

Allograft Skin

Advantages
 A bilayer skin providing epidermal and dermal properties
 Revascularizes maintaining viability for weeks
 Dermis incorporates into the wound

Disadvantages
 Epidermis will reject
 Difficult to obtain and store
 Risk of disease transfer
 Expensive Need to cryopreserve

nonviable state after preservation in glycerol or after lyophilization: however, most existing data describe best results when it is used in a viable state. The epidermal component provides a barrier until rejected by the host in 3–4 weeks. The dermis revascularizes and incorporates.

Homograft, another term for human allograft, can only be obtained from a tissue bank as strict protocols are required for harvesting and storage. Donors must be rigidly screened for potential viral and bacterial disease to avoid any transmission of disease. The product is in limited supply and very expensive.

The primary indication for use is to cover a large excised burn wound until an autogenous skin or a permanent skin substitute becomes available. Allograft is also used to cover a wide meshed skin graft, sealing the interstices during the healing process (Table 7).

Xenografts

Although various animal skins have been used for many years to provide temporary coverage of wounds, only porcine xenograft is widely used today (33,34) (Table 8). The epidermis of the porcine xenograft is removed and the split thickness dermis is provided in rolls. Split-thickness porcine dermis can be used after cryopreservation, or after glycerol preservation. It effectively provides temporary coverage of clean wounds such as superficial second degree burns and donor sites (33,34). Porcine xenograft does not vascularize, but it will adhere to a clean superficial wound and can provide excellent pain control while the underlying

Table 8. Advantages and Disadvantages of Xenograft as a Skin Substitute

Xenografts

Advantages
 Good adherence
 Decreases pain
 More readily available compared to allograft
 Bioactive (collagen) inner surface with fresh product
 Less expensive than allograft

Disadvantages
 Does not revascularize and will slough
 Short term use
 Need to keep the fresh product frozen

Table 9. Advantages and Disadvantages of Human Amnion as a Skin Substitute

Human Amnionic Membrane

Advantages
 Acts like biologic barrier of skin
 Decreases pain
 Easy to apply, remove
 Transparent

Disadvantages
 Difficult to obtain, prepare and store
 Need to change every 2 days
 Disintegrates easily
 Risk of disease transfer

wound heals. In general, xenograft is not as effective as homograft but is more readily available and less expensive. Primary indications are for coverage of partial thickness burns during healing and used burn wounds prior to skin grafting.

Human Amnion

Human amniotic membrane is used in many parts of the world as a temporary dressing for clean superficial wounds such as partial-thickness burns, donor sites, and freshly excised burns (35,36). Amniotic membrane is generally procured fresh and used after brief refrigerated storage. It can also be used in a nonviable state after preservation with glycerol. Amnion does not vascularize but still can provide effective temporary wound closure. The principal concern with amnion is the difficulty in screening the material for viral diseases. The risks of disease transmission must be balanced against the clinical need and the known characteristics of the donor (Table 9). The primary indications are the superficial burn and the excised wound.

Oasis Wound Matrix

This product is made of the submucosa of the porcine small intestine found between the mucosa and muscularis, in the wall of the porcine small intestine (37,38). The freeze dried acellular natural matrix retains its natural collagen and matrix structure and contains most of the bioactive matrix proteins found in the human dermis (Table 10).

Table 10. Advantages and Disadvantages of OASIS as a Skin Substitute

Oasis Wound Matrix

Advantages
 Excellent adherence
 Decreased pain
 Provides bioactive dermal like properties
 Long shelf life, store at room temperature
 Relatively inexpensive

Disadvantages
 Mainly a dermal analog
 Incorporates and may need to be reapplied

The submucosal layer is ~0.2 mm in thickness, but is quite durable. The product is freeze-dried removing the cells. The product is sterile, porous, biocompatible and nonimmunogenic. It has a long shelf life and can be stored at room temperature. The OASIS is incorporated into the wound bed over ~7 days and needs to be reapplied if the wound has not yet healed. The outer-barrier function is diminished with incorporation.

The primary indication is for use in difficult to heal nonburn wounds. It's use in burns is for the partial thickness burn and the skin graft donor site.

Biobrane

This product is a two-layer membrane (39,40). The outer epidermal analog is constructed of a thin silicone film with barrier functions comparable to skin. Small pores present in silicone allow for exudates removal and has permeability to topical antibiotics.

The inner dermal analogue is composed of a three-dimensional (3D) irregular nylon filament weave upon which is bonded type I collagen peptides. The surface binding of inner membrane is potentiated by collagen-fibrin bonds as well as fibrin deposition between the nylon weave. A thin water layer is maintained at the wound surface for epidermal cell migration maintaining moist wound healing. Excellent adherence to the wound significantly decreases pain in the superficial partial thickness burns. The silicone and nylon weave provides flexibility. The biobrane is removed once the partial thickness wound has re-epithelialized or the covered excised burn wound is ready for grafting. However, if left in place for >2 weeks the product is difficult to remove as tissue grows into the inner layer. Biobrane L contains a nylon fabric woven from monofilament threads that provide a less dense matrix and less adherence, preferred (e.g., on a donor site). There is likely very little direct bioactivity from the collagen peptides (40). The product has a long shelf life and can be stored at room temperature. It is also relatively inexpensive (Table 11).

The primary indication is for closure of the clean superficial burn or the excised burn wound.

Transcyte

This product is also a bilayer skin substitute (41,42). The outer epidermal analogue is a thin nonporous silicone film

Table 11. Advantages and Disadvantages of the Use of BIOBRANE as a Skin Substitute

Biobrane

Advantages

- Bilayer analog
- Excellent adherence to a superficial burn
- Decreases pain
- Maintains flexibility
- Easy to store with long shelf life
- Relatively inexpensive

Disadvantages

- Has very little direct bioactivity
- Difficult to remove if left in place >2 weeks

Table 12. Advantages and Disadvantages of TransCyte as a Skin Substitute

Transcyte

Advantages

- Bilayer analog
- Excellent adherence to a superficial to middermal burn
- Decreases pain
- Provides bioactive dermal components
- Maintains flexibility
- Good outer-barrier function

Disadvantages

- Need to store frozen till use
- Relatively expensive

with barrier functions comparable to skin. The inner dermal analog is layered with human neonatal foreskin fibroblasts that produce products, mainly collagen type I, fibronectin, and glycosaminoglycans.

A subsequent cryopreservation destroys the fibroblasts, but preserves the activity of fibroblast derived products on the inner surface. These products are then anticipated to stimulate the wound healing process (Table 12). A thin water layer is maintained at the wound surface for epidermal cell migration.

The nylon mesh provides flexibility and excellent adherence properties significantly decrease pain in the partial thickness burn. The product is peeled off after the wound has re-epithelialized.

The Transcyte must be stored at -70°C in order to preserve the bioactivity of the dermal matrix products. The primary indication is for closure of the clean superficial to mid-dermal burn, especially useful in children. Transcyte is also indicated for the temporary closure of the excised wound prior to grafting. Tissue ingrowth tends to be less of a problem even if the product is kept in place for >2 weeks.

Permanent Skin Substitutes

The purpose of these products is to replace full thickness skin loss as well as to improve the quality of the skin, which has been replaced after a severe burn (20–23).

As opposed to the bilayer concept of the ideal temporary skin substitute, permanent skin replacement is much more complex.

This area can be arbitrarily divided into two approaches (21–23). The first approach is the use of a bilayer skin substitute, with the inner layer being incorporated into the wound as a neodermis, rather than removed like a temporary product. The outer layer is either a synthetic to be replaced by autograft (epidermis) or actual human epithelial cells. If the outer layer is composed of epithelial cells that will form epidermis barrier function is not sufficiently developed at placement to act immediately as an epidermal barrier.

The second approach is the provision of either just an epidermal or a dermal analog or simply a coculture of cells containing elements of both. These products are technically not permanent skin substitutes (Table 13) upon initial placement as there is no bilayer structure until the product

Table 13. Components of Permanent Skin Substitutes**Permanent Skin Replacement**

Bilayer structures with biologic dermal analog and either synthetic or biologic epidermal analog

Skin components

- Epidermal cells alone
- Dermis alone
- Coculture of epidermal cells and fibroblasts

Rapid incorporation

Cannot transmit disease

Good functional and cosmetic result

Inexpensive

^aAs yet, the ideal skin does not exist.

evolves once placed on the wound. Both approaches will be discussed as will the ideal properties (Table 14).

The ideal property would be that of a bilayer structure.

The currently available clinical products are listed below (Table 15). There are a number of permanent skin substitutes in the development stage, which will not be listed.

Table 16. Advantages and Disadvantages of the Use of Apligraf As a Skin Substitute**Apligraf****Advantages**

- Bilayer skin containing human neonatal cells
- Not requiring patients skin biopsy
- No lag time for production
- Contains epidermal and dermal functions (eventually)
- Does not need to be frozen

Disadvantages

- Made in small pieces and not practical for large burn
- Cannot be stored for over 24 h
- Relatively expensive

Apligraf

The dermal analog is made of fibroblasts from neonatal foreskin populated in a bovine type I collagen matrix. This layer incorporates into the excised full thickness wound adding a dermal component. Epithelial cells (keratinocytes) are also obtained from neonatal foreskin. No Langerhans cells at present so rejection does not occur. The epithelial cells divide, migrate and form an epidermis, which will eventually provide biologic barrier function. Donor foreskin is screened for viruses, which could be transmitted. The product is indicated mainly for chronic wounds. It's use in burns is currently off label (44,45). Apligraf is typically provided as a 7.5 cm diameter disk that is 0.75 mm thick. The advantages are that the product is already made and does not depend on obtaining the patients own cells (Table 16). However, the product must be shipped the night before use in a polyethylene bag in agar nutrient medium and a 10% CO₂ content and stored at room temperature until used (within 24 h).

Table 15. Properties and Uses of the Currently Available Permanent Skin Substitutes

<i>Available Permanent Skin Substitutes</i>						
Product	Company	Tissue of Origin	Layers	Category	Uses	How supplied
Apligraf	Organogenesis, Inc and Novartis Pharmaceuticals Corp	Allogenic Composite	Collagen matrix seeded with human neonatal keratinocytes and fibroblasts	Composite: Epidermis and dermis	Chronic wounds, often used with thin STSG Excised deep burn	7.5 cm diameter disk 1/pack
OrCel	Ortec International Inc.	Allogenic Composite	Collagen sponge seeded with human neonatal keratinocytes and fibroblasts	Composite: Epidermis and Dermis	Skin graft donor site, chronic wounds	6 × 6-cm sheets
Epicel	Genzyme Tissue Repair Corp	Autogenous keratinocytes	Cultured autologous keratinocytes	Epidermis Only	Deep partial and full thickness burns >30% TBSA	50 cm ² sheets in culture medium
Alloderm	Life Cell	Allogenic dermis	Acellular Dermis (processed allograft)	Dermis only	Deep partial and full thickness burns, Soft tissue replacement, Tissue patches	1 × 2–4 × 12 cm
Integra	Integra Life Science Corp	Synthetic	Silicone outer layer on collagen GAG dermal matrix	BioSynthetic Dermis	Full thickness soft tissue defects definitive "closure" requires skin graft	2×2 in. 4×10 in. 8×10 in. 5/pack

Table 17. Advantages and Disadvantages of Orcel as a Skin Substitute

<i>Orcel</i>
Advantages
Eventual bilayer skin
Not requiring patient's cells
Does not need to be frozen
Disadvantages
Bilayer structure requires 14 days to develop once applied
Not indicated for excised burns
Short storage time
Relatively expensive

Orcel

The product is produced as a coculture of keratinocytes and fibroblasts (neonatal foreskin) in a cross-linked bovine collagen sponge (46). The donor tissue is screened for viruses. The nonporous side of the sponge is seeded with the keratinocytes and the porous side with fibroblasts. After application, a neodermis forms. Once applied the epidermis and an epidermal barrier requires 14 days to develop as the keratinocytes migrate and divide on the surface (Table 17).

The product is indicated mainly for chronic wounds but is also indicated for coverage of split thickness skin graft (STSG) donor sites. This product is not currently indicated for use on excised burn. The purpose for the STSG is to provide a better functional and cosmetic outcome compared to a healed donor site. It is shipped in a package filled with its culture medium which is stored at room temperature until used, usually within a few days.

Epicel

This product, used mainly for very large burns is composed of the patients skin epithelial cells and referred to as cultured epithelial autograft (CEA). Therefore, only the epithelial layer is provided (47–49). The product is made from a small biopsy of normal skin (2×2 cm) from the burn patient. The epithelial cells are extracted and cultured. Use of a cell culture technique allows the keratinocytes to be grown in a thin sheet 10,000 times larger than the initial

Table 18. Advantages and Disadvantages of Epicel as a Skin Substitute

<i>Epicel</i>
Advantages
Patients own keratinocytes expanded several thousand fold
Small skin biopsy required
Can cover very large surfaces with reasonable graft take
Used in large burns
Disadvantages
2–3 week lag time for production
Provides only the epidermal layer
Epithelial layer can be quite fragile for some time
Needs to be used immediately on delivery
Very expensive

biopsy. This process does require 2–3 weeks from the time of biopsy. Often the burn wound is excised and covered with homograft (allograft) until the cells are ready to be transplanted. The CEA is then applied to the clean excised (or allograft covered) wound.

The CEA is supplied in sheets 2–6 cells thick on small pieces of petroleum gauze (50 cm²), which are bathed in culture medium. Immediate application is necessary. The CEA grafts are very fragile and easily rubbed off for at least several weeks. The backing is removed in several weeks as the CEA thickens and adheres. Graft take ranges from 30 to 75% of total epithelium applied. The epithelium gradually thickens but has a low resistance to shear forces for some time. Application of allograft dermis, prior to CEA grafting appears to improve skin quality.

The primary indication is for very large burns.

Alloderm

This product is basically treated human allograft with the epidermis removed (50–52). The dermis is treated to produce a copreserved lyophilized allodermis, which incorporates. The product is used as a dermal implant. Therefore application of a thin epithelial autograft is required.

Primary indication is for use in the replacement of soft tissue defects. This product is not commonly used in large burns. Typically the alloderm is applied to an excised wound and then a split thickness skin graft is placed on top of the alloderm (Table 19). The product has a long shelf life in its lyophilized form. It requires rehydration prior to use.

Integra

This product is composed of a dermal analog made of a biodegradable bovine collagen-glycosaminoglycan copolymer matrix. The collagen and glycosaminoglycan is cross-linked to attempt to maximize ingrowth of the patients own cells (53–55) (Table 20).

The epidermal analog is a thin silicone elastomer providing temporary barrier protection. After the dermal analog incorporates and the surface revascularizes, at ~2–3 weeks, the silicone layer is removed and replaced with a very thin skin graft from the patient (or CEA cells). The Integra needs to be carefully immobilized for the first 2 weeks as movement will cause devascularization and loss of the product. The primary indication is the treatment of large deep burns as well as reconstruction procedures. The

Table 19. Advantages and Disadvantages of Alloderm as a Skin Substitute

<i>ALLODERM</i>
Advantages
Easy to store, an off the shelf product
Does not require skin bank
Comes in large and small pieces
Disadvantages
Requires thin skin graft to provide epidermis
Two procedures required to achieve bilayer skin
Relatively expensive

Table 20. Advantages and Disadvantages of Integra as a Skin Substitute**Integra****Advantages**

- Provides thick dermal analog
- Reasonable shelf life
- No risk of transmitting viruses
- Relatively inexpensive
- Used in large burns

Disadvantages

- Need to provide epidermis from the patient
- Dermal cells must come from the patient requiring product incorporation
- Two procedures required to achieve bilayer skin

incorporated neodermis appears to improve the function of the final skin once the epithelial graft is applied. The product is provided in a number of sizes and sheets stored in 70% isopropyl alcohol. Shelf life is very good.

SUMMARY

The scientific principles and practical approaches, to replacing skin either temporarily or permanently are advancing at a rapid rate. Much of these advances can be attributed to both advances in the field of bioengineering as well as increasing interest in optimizing the outcome of the burned skin.

The ideal properties of a bioactive temporary and a permanent skin substitute have been well defined. As expected, the properties of temporary skin substitutes are more concrete, easier to categorize and determine efficacy. A bilayer structures is the current standard with the dermal component being bioactive. Permanent skin replacement on the other hand is much more complex. A variety of approaches are being used which can be loosely categorized as either use of bilayer products (usually the outer layer to be replaced by epidermal autograft) or replacement of either dermal or epidermal elements separately. The terminology of the latter approach is difficult because these component products are really not permanent skin substitutes on initial application but become so only when all the elements are in place.

An understanding of the properties of each product is essential for the user to optimize outcome.

MAMMALIAN RESPONSE TO INJURY

Scale of Functional Deficit

Medical treatment options for the loss of normal organ or tissue function depend heavily on the scale of the defect, either macromolecular- or organ-scale. Since antiquity, macromolecular-scale defects have been treated with chemical therapeutics such as herbs and potions. More recently, pharmaceuticals, vitamins, hormones, and antibiotics have been used to treat a vast array of medical maladies that are caused by a macromolecular defect; these treatment regimens have been used successfully to replace or correct a missing function on the molecular scale. Organ-scale defects present a significantly larger wound site and require considerably different treatment practices.

Large-scale failures of a tissue or organ are created primarily by disease or by an acute or chronic insult; injury or damage of this type typically results in wound sites on the scale of a millimeter or centimeter, as opposed to the nanometer scale of a molecular defect. This type of damage cannot be treated with drugs because the problem is the failure of a mass of tissue, including a large number of cells, soluble proteins and cytokines, and insoluble extracellular matrix. The typical organismic response to an injury at the organ-scale is cell-mediated wound contraction and synthesis of nonphysiologic tissue (scar); this process is termed repair. Regeneration of lost or damaged tissue describes a process marked by synthesis of physiologic (normal, functional) tissue in the wound site. There are a few notable exceptions to the rule that the mammalian response to organ-scale injuries is repair. The epithelial tissues of the skin, genitals, cornea, and gastrointestinal tract all regenerate spontaneously, and the liver has shown the ability to synthesize a substantial organ mass without recovery of the original organ structure, but also without contraction or scar synthesis (1). Despite these few notable exceptions, the mammalian response to the loss or damage of a tissue or organ is almost exclusively repair, an irreversible

response resulting in the formation of scar tissue that lacks the structure and function of the damaged organ or tissue.

Regeneration Versus Repair

As previously noted, there are two possible outcomes of the mammalian healing process following acute or chronic injuries: regeneration or repair. Regeneration is characterized by synthesis of a replacement tissue in the anatomical wound site that is structurally and functionally similar to the original tissue. Repair is characterized by synthesis of scar tissue (nonphysiological tissue) to replace the normal tissue lost due to injury. In addition to synthesis of new, nonphysiologic tissue, contraction of the wound site is also observed during repair. Cell-mediated contraction of the wound site has been observed in many different species to varying degrees at different wound sites (1).

Wound closure following severe injury occurs by one or more of three distinct processes. The initial wound area can close by contraction (C), scar formation (S), and/or regeneration (R). The process of wound closure can be represented quantitatively by the defect closure rule: $A_C + A_S + A_R = 100$ ($A_X \equiv$ percentage wound area closed by process X); these three processes are the only mechanisms by which wound closure takes place. In adult mammals, chronic and acute injuries have a common clinical outcome because the repair processes responsible for wound healing close the wound through contraction and scar formation only ($A_R = 0$). With the exception of a certain class of injuries, such as injuries to epithelial tissues in select organs, the ability to regenerate tissues and organs is lost in mammalian adults. Spontaneous regeneration (regeneration without external stimulation) is observed in very specific tissues in adult mammals following minor injuries such as a small skin scrape or a first or second degree burn, while more severe injuries such as a deep skin wound or third degree burn result in contraction and scar formation. A review of the available data comparing cases of regeneration with those of repair has led to the proposal of antagonistic relationship between contraction and regeneration; in cases of adult healing where contraction occurs, regeneration is not observed, and regeneration is observed when wound contraction is blocked (1–3).

Mammalian Response to Injury

While the mammalian adult responds to severe injury by repair processes resulting in the formation of scar ($A_C + A_S = 100$; $A_R = 0$), the mammalian fetus is able to regenerate the lost tissue spontaneously ($A_C, A_S \ll A_R$) (4,5). For the sake of this article, the fetal classification refers to all mammalian fetuses that respond to injury with regeneration processes while the adult classification refers to all mammals (adult as well as juvenile) that respond to injury with repair processes. Modifying the adult mammalian wound healing response to more closely resemble that observed with the fetus has been an area of extensive study. In addition to understanding the differences between the fetal and adult healing processes, analogs of the extracellular matrix (ECM) have been used as templates for a variety of tissue engineering related disciplines

toward the goal of inducing regeneration of tissues damaged by severe injury where the organism would normally respond to injury with repair processes.

The extensive study of the mammalian response to injury has focused on understanding the mechanism and timing of the transition from regeneration to repair processes during the fetal–adult transition of development and whether regeneration can be induced in the adult mammals once the initial transition has taken place. For mammals, the transition from wound closure by regeneration to wound closure by scar synthesis and contraction takes place during the third trimester of gestation (1,4,5). While certain classes of amphibians have been studied extensively throughout metamorphosis from tadpole to young adult (6), there is for the most part much less information available about higher mammals. A detailed study of wound closure mechanisms of the amphibian frog during larval development was based on measurement of the fractional extent of wound contraction, scar formation, and regeneration during development. With increasing fetal development, wound closure depended increasingly less on regeneration and correspondingly more on contraction. Once metamorphosis to the young adult frog was complete, regeneration was not observed while contraction and synthesis became the predominant mechanisms for wound closure (7). These and several other observations support the conclusion that there is an antagonistic relationship between regeneration and wound contraction. To date, while the causes for the transformation in the mode of mammalian response to injury from the fetus to the adult are not known, adult mammals are known to be unable to regenerate tissue lost due to severe injury and close severe wounds by contraction and scar formation.

There are three tissue layers that are grouped together in sequence in all organs, namely, epithelia, the basement membrane, and the stroma (1,8). This sequence has been termed the tissue triad. A pattern has been observed as a result of examinations of the structure and tissue-specific response to injury of the three tissues that to date have been induced to regenerate: skin, peripheral nerves, and conjunctiva. Understanding of the response of each member of the tissue triad to injury aids in shedding light on the process of regeneration and has suggested methodology for inducing regeneration in tissues that do not regenerate spontaneously. A layer of epithelial cells (epithelia) covers all surfaces, tubes, and cavities of the body; this layer is totally cellular with no ECM component. The epithelia is completely cellular, avascular, and is the only member of the tissue triad that does not contain an extracellular matrix. Developmental and functional similarities between epithelial cells and tissues from a variety of different tissues and organs such as the skin and peripheral nerves have been observed; these observations have suggested that the tissue triad can be used as a more general tool to understand organismic response to injury (1).

The basement membrane (also termed basal lamina) is a continuous layer of tissue separating the epithelial layer from the stroma. In all tissues, the basement membrane is acellular, and no blood vessels pass through the basement membrane layer. The stroma contains connective tissues as well as the blood supply, and provides a reservoir for

Figure 1. Schematics of the tissue triad structure observed in mammalian tissue. Top: Tissue triad of skin and peripheral nerves. The basement membrane is a thin extracellular matrix tissue located between the cellular and nonvascular epithelia (epidermis, myelin sheath) and the cellular, vascularized stroma (dermis, endoneurium). Bottom: Diagram of the distribution of epithelial, basement membrane, and stromal tissues in the mammalian system. Examples of stromal tissues are bone, cartilage, and their associated cell types as well as elastin and collagen. Examples of epithelial tissues are those covering the surface of the genitourinary, respiratory, and gastrointestinal tracts as well as surfaces of the mesothelial cells in body cavities, muscle fibers, fat cells, and endothelial cells in the cardiovascular system (1).

nutrient uptake to and waste removal from the basement membrane and epithelia. Figure 1 provides a basic diagram of the organization of the tissue triad in the adult mammalian system.

Using the tissue triad as a guide, we can identify similarities among the three tissues. In skin, peripheral nerves, and the conjunctiva, there are tissues that spontaneously regenerate (the epithelia and basement membrane) and a tissue that does not (the stroma). The regenerative capacity of epithelial tissue and the basement membrane as well as the irreversible (repair) nature of stromal wound healing have been extensively reported (1,9–13). Specifically, the stroma has been repeatedly observed as nonregenerative in skin, peripheral nerves, blood vessels, lung, kidney, and pancreas (1,3,14–18). It has been suggested that the mechanism for the irreversibility of injury (nonregenerative response) is entirely dependent on disruption of the stromal architecture, and

that proper replacement of the stromal layer is critical for any regeneration to occur.

Methods to Treat Loss of Organ Function

While a molecular scale defect can often be treated with the use of pharmaceuticals, an organ-scale defect requires more extensive treatments. Significant loss of function in the affected tissue or organ, also referred to as the “missing organ” (19), can lead to a number of significant consequences such as lack of social acceptance in the case of severe burns and facial scars, loss of mobility and sensory function in the case of neuroma, or life-threatening symptoms in the case of a cirrhotic liver, large-scale severe burns, and ischemic heart muscle.

Six basic approaches have been used to treat the problem of the missing organ: transplantation, autografting, implantation of a permanent prosthetic device, use of stem

cells, *in vitro* synthesis of organs, and induced regeneration. The last three techniques have been grouped together and are known by the moniker “tissue engineering” (20). All six techniques will be discussed in the following sections.

Transplantation. Transplantation, the transfer of an organ or a fraction thereof from a donor to a host, is widely utilized as a therapeutic strategy to replace complex tissues and organs. Since the introduction of transplantation in the early twentieth century (21), it has been used in increasingly complex organ systems such as the skin, cornea, kidney, liver, lungs, and heart. Patients have exhibited extraordinary survival characteristics even with the simultaneous transplantation of multiple organs (22–27).

While transplantation of tissues at a few immune-privileged sites such as the eye and testis can occur without rejection, the most significant challenge facing modern transplantation is the immunological barrier for transplantation of tissues from donor to host, where the donor organ is attacked and rejected by the host’s immune system upon transplantation; this response is termed host-versus-graft disease where the host’s (patient’s) immune system recognizes the antigens expressed on the graft tissue as foreign and attacks and destroys the tissue. The primary clinical method for preventing rejection of the transplanted tissue is the use of drugs to suppress the immune system of the host. Immunosuppression therapy often is necessary for the remainder of the host’s life to prevent transplant rejection; however, immunosuppression also presents a significant hazard to the host, as the immunosuppressed host becomes vulnerable to infections (28). Significant efforts have been mounted to develop technologies that allow for local rather than whole-body immunosuppression, such as the development of cells that can express a protein (i.e., Fas ligand) to induce immune cell apoptosis and the use of natural and synthetic polymers to encapsulate heterologous cells to mask their antigens (24,28–31).

The major obstacle in using human donors for transplantation has been the difficulty in finding immunocompatible donors and the shortness of supply of suitable organs because the supply is greatly exceeded by the demand (32). A more recent area of research has focused on developing a transgenic pig model to be used as an immunocompatible donor for humans for a procedure known as xenotransplantation. Development of this area of transplantation has been slowed by evidence that pig viruses are capable of infecting human cells and producing unique viral infections in the host (33–35).

Autografting. With autografting, the donor and the recipient are the same individual; a fraction of the tissue or organ is harvested from an uninjured site and grafted at the nonfunctional site (25). Autografting offers a technology that removes the danger of organ or tissue rejection due to a host-versus-graft response, but is relatively limited in its scope of application. Autografting necessitates the creation of a second wound site (donor site), subjecting the patient to a second severe trauma. Therefore, autografting is utilized only when the loss of functionality at the sec-

ondary wound site is outweighed by the loss of functionality or morbidity at the primary wound site. This procedure is obviously limited by the availability of functional tissue that can be transplanted without additionally harming the patient. Major clinical uses of autografting have been associated with skin grafting in massively burned patients (36), the use of the sural nerve to bridge a severe peripheral nerve injury, primarily in the case of hand injuries (37–41), and the use of autologous vein graft to bypass a restricted artery (42).

Permanent Prosthetic Device. The implantation of a permanent prosthetic device to replace the functionality of lost or damaged tissues offers a number of advantages and disadvantages. Typical examples of prosthetic devices are artificial hips and knees (43), cardiac pacemakers (44), heart valves (45), stents (46), cochlear implants (47), and contact lenses (48). Prosthetic devices are typically fabricated from biologically inert materials such as metals, ceramics, and synthetic polymers. Hence, these devices do not provoke the immune response problems inherent to transplanted tissues and organs and can also be manufactured on a mass scale. Even though these devices are fabricated from bioinert materials, interactions with the biological environment surrounding the prosthesis lead to a number of unfavorable physical and biological manifestations. Specific examples of negative biomaterial–tissue interactions are the formation of a thick, fibrous scar tissue capsule around a silicone breast implant (49,50), stress-shielding due to the implantation of a relatively stiff (compared to the host bone) hip prosthesis that eventually leads to a loss of bone mass (51), platelet aggregation to implanted surfaces, also known as biofouling (52–55), and the accumulation of polyethylene particles in the lymph system as a result of wear of an orthopedic implant (56,57). The spontaneous remodeling process of the surrounding tissues can also be significantly altered, negatively or positively, by the presence of the prosthetic device (58). The often-serious side effects that appear as a result of interactions between nonbiological materials and the surrounding tissues illustrate the difficulty of replacing bioactive tissues with bioinert materials with drastically different material and mechanical properties.

Stem Cells. Stem cells present an exciting possibility for replacement of lost or damaged organs and tissues. The pluripotential nature of stem cells offers the possibility for the synthesis of tissues from the least differentiated cells in the body (59,60). Current efforts in stem cell research have focused on identifying protocols to harvest stem cells, expand them in culture, and reimplant them at a site of injury, as well as to develop technologies to introduce genes into stem cells so that when reintroduced to the patient, they will synthesize the required proteins *in vivo*. Currently, mesenchymal stem cells (61), epithelial stem cells (62), and neural stem cells (63) have been grown *in vitro* and studied. While few advances in the use of stem cells for replacement of damaged tissues have been made to this point, stem cell technologies present a new area of scientific study for future exploration with a great deal of promise.

In Vitro Synthesis. *In vitro* synthesis requires the growth of a functional replacement tissue using an *in vitro* culture environment to replace a lost or damaged organ or tissue. Traditional *in vitro* synthesis techniques have utilized both cell culture systems and culture systems based on interactions between cells and an extracellular matrix analogue. *In vitro* synthesis allows for total control over the culture environment, specifically the inclusion or exclusion of soluble regulators (i.e., growth factors, cytokines), insoluble regulators (i.e., extracellular matrix proteins), and a variety of cell culture media and conditions; the complexity of biological systems, specifically their cytokine and growth factor needs, and the necessity for developing an efficient method for providing nutrients and cell–cell signals to the site of the developing tissue have to date precluded the formation of complex tissues *in vitro* (1,64).

Early successes with *in vitro* synthesis were encountered using cultured epithelial cells to produce a physiological epidermis (65). In these studies, keratinocyte sheets were grown *in vitro* from skin explants; these keratinocyte sheets were implanted into skin wounds, and induced the formation of a fully mature, stratified epidermis, the uppermost tissue layer that makes up skin (66,67). Later study found that keratinocyte sheets could be grown *in vitro* starting from disaggregated epidermal cells and could then be implanted into a skin wound, inducing the development of a mature, fully stratified epidermis as well (68). This technique has been used to prepare autologous sheets of keratinocytes to treat skin wounds in severely burned patients (69–77). Known as a cultured epithelial autograft (CEA), this technology will be discussed in greater depth later in this article as one of the five major techniques that lead to at least partial regeneration following severe skin injuries. *In vitro* synthesis of more complex tissues and organs began with work aimed at developing an epithelial–mesenchymal bilayer in order to produce a material that could be implanted to replace damaged skin. The fabrication of a “living skin equivalent” (LSE) involved culture of fibroblasts within a collagen gel, followed by introduction of keratinocytes in order to produce an immature skin equivalent; this bilayer was implanted into a skin wound and was observed to lead to the formation of a mature, stratified epidermis as well as an immature neodermis (78–82). This technology will also be covered in greater detail later in this article.

In vitro synthesis of increasingly complex tissues has necessitated the development of technologies for culturing cells in three-dimensional (3D) scaffolds known as ECM analogs and modifying the surface chemistry of these scaffolds to control cell–substrate interactions (20,48,83–86). Synthetic polymer meshes have been used as an ECM analog for culturing keratinocytes and fibroblasts as a potential skin replacement that has been used clinically in the treatment of severe burns and ulcers (87–94). This technology (Living Dermal Replacement, LDR) will be described in greater detail later in the article as one of the major techniques utilized to treat severe skin wounds. *In vitro* synthesis using ECM analogs as a culture environment has also been studied using hepatocytes in an attempt to synthesize a functioning liver (95–97), and chondrocytes in an attempt to synthesize a cartilaginous

network (98–101). Continued exploration of *in vitro* techniques to synthesize tissue replacements has been hampered by the complexity of biological systems and an inability to provide the proper nutrient cocktails (i.e., cytokines, growth factors), the structures necessary to deliver these nutrients (i.e., arteries, veins, and capillary systems), and the correct mechanical environments (ECM analog structures) for complex tissue and organ growth outside of the organism.

Induced Organ Synthesis *In Vivo* (Regeneration). Induced organ synthesis *in vivo* relies on the healing processes that are inherently active in a wound site to regenerate lost or damaged tissue. In this method, an analog of the ECM is implanted in the wound site and combined with the biological processes in the wound induce synthesis of a physiologic replacement tissue. Induced organ synthesis was first identified following the development of fabrication techniques that allowed for synthesis of ECM analogs with a well-defined macromolecular structure, specifically controlling the ECM specific surface, chemical composition, and degradation rate (102–106).

The first application of induced organ synthesis was in the fabrication of an ECM analog able to induce skin regeneration, the dermal regeneration template (DRT). The DRT showed very high biological activity when implanted into a full-thickness skin wound and was capable of inducing regeneration of the underlying dermal layer of skin as well as the epidermal and basement membrane layers (3,103,107–113). The speed of this regeneration process was significantly increased when the DRT was further seeded with autologous keratinocytes prior to implantation (3,111,112,114–116). This technology will be covered in greater detail later in the article as one of the major tissue engineering techniques utilized to treat severe skin injuries.

Induction of organ regeneration, first observed in the study of skin regeneration, has also been observed in other tissues and organs with the use of other specialized ECM analogs. Regeneration of peripheral nerves has been achieved using a tubular device that incorporates an ECM analog as a filling, known as the nerve regeneration template (NRT) (1,117–120). The long-term morphological structure and electrophysiological function of nerves regenerated using the NRT has been observed to be at the level of an autografted nerve, the current gold-standard for peripheral nerve injury treatment (121,122). In addition, the DRT was implanted into a conjunctiva stromal wound model, where induced regeneration of the conjunctival tissue structure was also observed (123).

In vitro synthesis and induced organ regeneration (*in vivo* synthesis) currently constitute an area of study termed tissue engineering (20). For the remainder of this article, we will focus on studies on the structure and function of ECM analogs for use in tissue engineering and on an overview of the tissue engineering approaches that have been utilized to treat skin wounds.

Basic Parameters of the Living Environment During *In Vivo* Synthesis

The process of *in vivo* regeneration of lost or damaged tissue can be modeled as if the entire process was taking

place within a “bioreactor” that is surrounded by a reservoir with constant properties, representing the entire organism with its complex homeostatic mechanisms. The “bioreactor” itself has a defined anatomical and physicochemical environment (environment of the wound site); parameters include the temperature, the pH, the structure of a template within the “bioreactor”, and the flow rate and composition of the exudate. The flow of exudate entering the “bioreactor” starts almost immediately following the creation of the wound site, while the structure in the wound bed is provided by implantation of an analog of the ECM. The ECM analog, and any cells that may be seeded within, constitutes the exogenous stimulus provided to the wound bed. During the remainder of the healing process, the reservoir (surrounding organism) is considered to maintain the “bioreactor” environment: temperature, pH, as well as cytokines, growth factors, and cells present in the exudate. While these factors are considered standardized in a wound bed, it is the ECM analog that provides the variable structure and ECM components (proteins) that are critical for inducing regeneration. If no active ECM analog is present or if its structural features are changed, the reaction sequence within the “bioreactor” is observed to follow almost completely normal repair processes that result in wound contraction and scar formation. In contrast, when the appropriate ECM analog is introduced into the “bioreactor” normal repair mechanisms are replaced by induced regeneration, also referred to as *in vivo* or *in situ* regeneration (1).

Experimental study of *in vivo* regeneration is complicated by a lack of reproducibility between different reaction sites (anatomical sites); unless the wound site is standardized, it will be impossible to accurately study differences between ECM analogs when implanted into wound models and results obtained in independent laboratories will not be statistically significant. Billingham and Medawar (124,125) introduced the concept of an anatomically constant wound for the study of massive skin injuries. For skin injury models, the entire thickness of the skin (epidermis, basement membrane, and dermis) was consistently excised down to the layer of the underlying muscle and fascia. Except for edge effects, this model standardized the wound environment from one animal to another, making it possible to obtain statistically significant results from a study with several animals. For the remainder of this article, all animal results that are discussed will be from this wound model. In clinical cases, the nature of the wounds is different; such issues will be discussed in greater detail later in this article.

Mammals possess a small, quite limited, ability to spontaneously regenerate damage inflicted to most of their tissues and organ systems. The epidermis and basement membrane in the skin regenerates spontaneously, provided that there remains an intact, underlying dermal layer (1). In another example, a small, cylindrical defect (<1 cm in diameter) in mammalian long bones is spontaneously refilled with normal bone (126), and a gap <5 mm in a transected rat sciatic nerve can be spontaneously regenerated to a moderate extent (127–131). In these cases, regeneration is observed without the implantation of any active ECM analog. More specifically in the case of skin

injuries, the epidermis and basement membrane have been observed to spontaneously regenerate to form fully mature tissue, but the adult mammal is unable to spontaneously regenerate the dermis (1,124,125,132). In studies of induced regeneration using grafting techniques, it is important to first understand the fundamentals of behavior of the tissues involved, specifically the type of tissue that can be spontaneously regenerated, in order to understand the effectiveness of the graft. Regeneration of tissue that has resulted from the exogenous graft will be referred to as induced regeneration. In the case of studies of skin regeneration, the presence of new dermis following grafting of a full thickness skin wound with an appropriate device will be considered induced regeneration.

CHARACTERISTICS OF EXTRACELLULAR MATRIX ANALOGS THAT DEFINE BIOACTIVITY

Fundamental Design Principles for Tissue Regeneration Scaffolds

Porous scaffolds are utilized in the study of tissue regeneration; the term active extracellular matrix analogs (bioactive analogs) refers to scaffolds that induce regeneration of normally nonregenerative tissues following severe injury. Bioactivity is observed in only a limited number of scaffold variants, and is measured by the scaffold’s ability to prevent irreversible repair behavior while inducing regeneration. With a bioactive scaffold, the cells, cytokines, and biological exudate in the wound site interact with the scaffold such that the mechanisms and kinetics normally associated with spontaneous wound closure by wound contraction and scar synthesis (repair) are modified leading to the induced regeneration response. Bioactivity of tissue regeneration scaffolds has been observed to depend on the structural characteristics of the scaffolds, notably the chemical composition, the template pore structure, and the template residence time (1). These characteristics, and any governing models to describe cellular behavior in regeneration scaffolds, will be discussed in the following sections.

Template Residence Time

The residence time of an implanted scaffold is a critical variable that helps to define the bioactivity of the scaffold. For physiologic tissue to be synthesized in the wound bed, the scaffold must degrade in such a way that it does not interfere with the production of physiologic tissue. Empirical evidence supports a requirement for the implanted active ECM analog to be capable of isomorphous tissue replacement, that is, degradation of the active ECM analog at a rate of the same order as the rate of synthesis of new tissue (1).

These considerations are consistent with a model that defines a scaffold residence time with both an upper and a lower bound. Using the isomorphous tissue replacement model, the appropriate time period for scaffold residence is approximately equal to the time period required to synthesize a mature tissue at the specific site by regeneration. A reasonable approximation of the time for regeneration is the time period observed for the conventional healing

process of a wound that involves wound contraction and scar formation at the anatomic site of interest. In the case of a full-thickness skin wound, the healing time is ~ 25 days (1,3,133). As the intact scaffold cannot diffuse away from the wound bed, the simplest method for achieving isomorphous tissue replacement requires the macromolecular scaffold structure to be degraded by enzymes in the wound bed into low molecular weight fragments that are able to diffuse away. In a model of template degradation characteristics, the lifetime of the scaffold in the wound bed can be defined by the time constant for degradation (t_d) and can be compared to the time constant for a normal healing process of a wound at the anatomic site of interest (t_h). For isomorphous tissue replacement:

$$\frac{t_d}{t_h} = O(1)$$

The isomorphous tissue replacement hypothesis has been supported by observations made with different implanted devices that were studied in the context of *in vivo* synthetic processes. When the ratio of t_d/t_h was much >1 , the scaffold remained in the wound bed virtually as a nondegradable implant, and dense fibrotic tissue similar to scar was observed to be synthesized underneath the scaffold (1,133). As the ratio became considerably <1 , the initially insoluble scaffold became rapidly degraded and did not induce a regenerative healing process in the wound bed; instead, wound bed healing was marked by scar synthesis similar to the healing process observed in an ungrafted wound (109).

Satisfying the principle of isomorphous tissue replacement requires adjustment of the structure of the ECM analog such that the biodegradation time constant of the scaffold (t_d) closely matches the healing time constant (t_h). In the case of collagen-based ECM analogs, degradation of the scaffold in the wound bed is accomplished primarily by collagenases present in the wound site. Reduction of the biodegradation rate of collagen scaffolds has been achieved both by introducing glycosaminoglycans (GAGs) into the collagen mixture and by cross-linking collagen fibers to one another: scaffold resistance to degradation is increased with an increase in the density of cross-links (103,105,108,117,134). For collagen-GAG scaffolds, precipitating the two polymers together under an acidic pH mixes the glycosaminoglycan and collagen components, and the scaffold is fabricated from the coprecipitate. Cross-linking of the collagen fibers can be accomplished by a variety of different techniques, both physical and chemical.

Dehydrothermal (DHT) cross-linking is a physical technique that has been often utilized for cross-linking collagen and collagen-copolymer scaffolds, and allows for the creation of a variety of cross-linking densities. Dehydrothermal cross-linking involves exposure of the scaffold to a high temperature (90–120 °C) under vacuum (i.e., 95 kPa), leading to removal of water from the scaffold. When the water content in the ECM analog is removed below $\sim 1\%$, drastic dehydration of the scaffold leads to the formation of inter-chain amide bonds through condensation (135). This cross-linking reaction is a condensation reaction involving carboxylic groups from glutamyl/aspartyl residues on collagen

polypeptide chain P_1 and the amino groups of lysyl residues on an adjacent P_2 chain to yield covalently bonded collagen fibers. In addition, graft copolymers of collagen and GAG are formed by dehydration, leading to cross-link formation by condensation of amine groups on collagen chains (denoted P_1 and P_2 below) with carboxylic groups of glucuronic acid residues on GAG chains (104).

The density of cross-links formed through DHT cross-linking depends on the temperature as well as the length of exposure, with higher temperatures and longer exposure lengths producing a higher density of cross-links (104,105). Ultraviolet (UV) treatment is a second physical cross-linking technique that can create cross-links between collagen fibers (136–138). Additionally, cross-linking can be induced chemically by introduction of glutaraldehyde (GT) (104) or with 1-ethyl 3-(3-dimethylaminopropyl)carbodiimide (EDAC) (139). These chemical cross-linking techniques are considerably more powerful than the previously noted physical methods and lead to a much higher cross-link density and a much longer time constant of degradation (t_d). Chemically cross-linked scaffolds must be extensively washed to remove all trace of the cytotoxic cross-linking chemicals prior to use in the wound bed; in addition to concerns regarding washing away the excess chemical, some chemical cross-linkers function by having all or a portion of the chemical compound becoming part of the cross-link. In this case, slow degradation of the scaffold could result in the release of potentially cytotoxic agents into the wound site (1,3).

By using both physical and chemical methods, the cross-linking density of a particular collagen or collagen-GAG scaffold can be effectively adjusted to create a wide range of enzymatic degradation rates. These cross-linking tools can also be applied to a multitude of other scaffolds, fabricated from both natural and synthetic materials. As different wound sites and the same wound sites in different species have been observed to exhibit very different time constants for healing (t_h), it is necessary to adjust the degradation rate of the ECM analog to the characteristics of the specific wound bed site and species in order to satisfy the principle of isomorphous tissue replacement and to induce regeneration.

Critical Cell Path Length

Migration of cells into the active ECM analog (regeneration template) is critical for the synthesis of new tissue. The use of porous templates allows for more rapid incorporation of cells into the template. While the effect of the structural characteristics of the template will be discussed in the following sections, there is another important characteristic to consider: an adequate source of metabolites (i.e., oxygen, nutrients) available to the cells. There are two mechanisms available for transport of metabolites to and

waste products from the migrating cells: diffusion to and from the surrounding wound bed or transport along capillaries that have sprouted into the scaffold as a result of angiogenesis. While angiogenesis becomes the limiting factor for long-term cell survival and growth, significant angiogenesis is not observed for the first few days after implantation of the template. Therefore, early cell survival inside the scaffold is completely controlled by the diffusional mode of transport of metabolites from the wound bed.

A simplified model of cellular metabolic requirements and nutrient diffusion characteristics can be utilized to describe the critical cell path length (L_c) for cellular migration into a scaffold; the model assumes a totally diffusion-based mode of metabolite transport. Beyond the critical cell path length, diffusional transport will not provide for cellular survival; this model is important for predicting the initial “take” of a graft, as diffusional transport, along with prevention of graft rejection or infection, will be responsible for initial cell survival and graft “take”. Such a model simplifies the cell’s metabolic requirements by defining a “critical” nutrient that is metabolized by the cell at a rate of R mol/cm³/s. This nutrient is transported to the scaffold from the wound bed, where there is a constant concentration of nutrient, C_0 , that remains essentially constant due to resupply from the organism that acts as an infinite source. The transport processes are modeled by the diffusivity of the nutrient through the scaffold, D , with units of square centimeters per second (cm²/s) and a length of diffusion, L , with units of centimeters. The *cell lifeline number*, S , is a dimensionless number that is derived from these variables by dimensional analysis to express the relative importance of the consumption of an essential nutrient by the cell and the diffusion of the nutrient from the wound bed into the scaffold:

$$S = \frac{RL^2}{DC_0}$$

The magnitude of the cell lifeline number describes three distinct cases of cellular migration into the scaffold in the absence of angiogenesis. For $S \gg 1$, the rate of consumption of the critical nutrient exceeds the supply provided through diffusion processes, resulting in the death of cells that have migrated that distance L into the scaffold. For $S \ll 1$, the supply of the critical nutrient by diffusion exceeds the rate of consumption, resulting in cell proliferation and migration further into the scaffold. The steady-state condition, $S = O(1)$, describes the state where the value of L becomes the critical cell path length, L_c . L_c describes the longest distance from the wound bed edge that a cell can migrate while depending solely on diffusional processes as the source of metabolites before angiogenesis begins. In the case of many common nutrients with a low molecular weight, L_c can be predicted using this model on the order of 100 μm (109). This estimation of L_c indicates that there needs to be close contact between the wound bed and the scaffold immediately after grafting in order for the initial migration of cells into the wound site to take place prior to angiogenesis and suggests that very stiff ECM analog grafts will show inferior results. A stiffer scaffold will be unable to conform to the wound bed, thus reducing the

effective distance that cells can migrate into the scaffold and be metabolically supported prior to angiogenesis, eventually reducing overall graft “take”. Unfavorable values of the scaffold-tissue surface tension can also prevent close contact.

Chemical Composition

The chemical composition of an ECM analog plays a critical role in defining the bioactivity of the device. In order to design a suitable device for use in wound healing that will induce regeneration rather than repair mechanisms, it is important for the device to keep the wound edges apart and to drastically modify the healing processes in the wound bed to yield physiologic tissue rather than scar. At the outset, the chemical composition defines the ligands that are displayed on the scaffold surface. Cellular activities such as binding, migration, and contraction are all mediated by interactions between the integrins expressed by a specific cell type and the ligands available on the scaffold surface. The design of a scaffold to be used for tissue engineering purposes must accordingly be fabricated in such a manner and using such specific materials as to allow for appropriate binding between cell and scaffold. The specific cell–matrix binding that appears to be required in cases of induced regeneration is that which blocks contractile cells from implementing their program of wound contraction (1).

A number of different materials have been used for the production of scaffolds for tissue engineering. Several synthetic nondegradable polymers, such as poly(dimethyl siloxane), have been utilized; these polymers, which parenthetically violate the principle of isomorphous tissue replacement, have not exhibited the ability to induce regeneration. Degradable synthetic polymers, such as poly(lactic acid), can be fabricated to satisfy isomorphous tissue replacement and the surfaces can be modified to properly induce cellular binding, but have not been shown to prevent contraction and scar formation. A chemical composition that has been used successfully to induce regeneration has been a graft copolymer of type I collagen and a sulfated GAG (1). These natural polymers are capable of facilitating cell binding in part due to their expression of natural ligand-binding sites.

Template Pore Structure

Although the chemical composition is a critical component in defining the biological activity of the scaffold, it is not the sole characteristic. The biological activity of a particular ECM analog also depends significantly on the architecture of the three-dimensional (3D) network. Having migrated into the scaffold, the cell interacts with the structure that defines the porous scaffold, making use of its cell surface receptors (integrins) to bind to specific ligands on the scaffold surface. The first critical components of the scaffold pore structure to consider is the open- or closed-cell nature of the scaffold and its relative density: A tissue engineering scaffold must possess an open-cell pore structure with a relative density below a critical value. Three-dimensional porous structures can possess an open- or a closed-cell pore structure; in a closed-cell structure, each

individual pore is separated from adjacent pores by membrane like faces while open-cell pore structures exhibit interconnectivity between adjacent pores. Interconnectivity is critical for cells to be able to migrate through the 3D structure. The most important structural feature of porous scaffolds is the relative density (R_d): the density of the scaffold divided by the density of the solid from which it is made. The porosity of a scaffold, or pore volume fraction, is defined as $(1 - R_d)$. The relative density defines the amount of solid material available for cells to bind to; when the pores are closed or when the relative density is too large, cells are not able to migrate through the scaffold, a significant impediment for using such a scaffold for a tissue engineering application. Such structural aspects also suggest that in designing scaffolds for tissue engineering applications, there is a critical number of cells required for scaffolds to appear bioactive. There must be a large enough area available for cells to bind to in order to support a large enough population of cells within the scaffold; the existence of a critical density of cells has been hypothesized as a result of a number of experiments studying cell-scaffold interactions (1).

The development of a highly detailed model, describing the number of receptors utilized per bound cell and the nature of the binding and receptor sites, is required to describe even a simple interaction between a cell and a generic scaffold surface. However, a more generic explanation can be used to indicate both the complexity of the cell-scaffold interaction and the significant influence the scaffold pore structure has on scaffold bioactivity. In particular, we will examine the affect of another critical factor on scaffold bioactivity: mean scaffold pore size.

The structure of a porous scaffold is defined by the pore volume fraction, mean pore size, and pore orientation in the scaffold. All of these characteristics have been shown to significantly affect the bioactivity of the scaffold. The pore volume fraction and the mean pore size together define the specific surface area of the scaffold, the total surface area of pore walls available for cellular binding. Increasing the mean pore size while keeping the pore volume fraction constant decreases the specific surface area of a scaffold. Decreasing the pore volume fraction and keeping the mean pore size constant increases the specific surface area (140). It has been estimated that a 30-fold increase in pore diameter leads to a 27-fold decrease in specific surface (2). A change in the specific surface area of the scaffold significantly changes the area available for cells to bind to. More specifically, the surface density of bound cells (Φ) in a 3D dimensional porous scaffold is a function of both the density of bound cells in the scaffold (ρ) and the specific surface of the scaffold (σ):

$$\Phi = \frac{\rho}{\sigma}$$

This calculation suggests the significance of the specific surface of the scaffold in defining the scaffold bioactivity. If the specific surface is too small due to large pores, an insufficient number of cells will be able to bind to the scaffold and the cells that remain free will contribute to the spontaneous repair mechanism. There is a minimum pore size as well, defined by the characteristic dimension of

the cell, $\sim 10\text{--}50\ \mu\text{m}$ for most cell types. When the scaffold pore size is smaller than this critical dimension, cells will be unable to migrate through the porous structure, and will be unable to infiltrate and bind to the template. These upper and lower bounds of the scaffold pore diameter, mediated by cell size and specific surface requirements, have been determined experimentally for each cell type for tissues where regenerative templates have been used (3,141); however, future work is necessary to develop a better understanding of cell adhesion and its relation of scaffold structure.

The shape of the pores that make up the porous scaffold must also be considered; slight changes in the mean shape of the pores can result in significant variations in the mechanical properties of the scaffold (140). In addition, changes in mean pore shape may also play a role in defining the areas of the scaffold available or unavailable for binding and in defining available directions for cell migration. The template pore structure plays a very significant role in defining the overall bioactivity of the scaffold and the open or closed-cell nature, the mean pore size, relative density, and pore shape and orientation all are critical components to consider.

TISSUE ENGINEERING OF THE SKIN

Structure and Function of Skin

Mammalian skin is a stratified tissue made up of three distinct layers of tissue: the epidermis, the basement membrane, and the dermis. Each tissue displays unique structural and functional properties as well as distinctive responses to injury or damage. These tissues, an epithelial layer (epidermis in skin), a basement membrane layer, and a stromal layer (dermis in skin) make up the previously described tissue triad for the skin (1,8,142). Using the tissue triad to model a generic tissue, the epithelia covers all body surfaces, tubes, and cavities, and is separated from the underlying stroma by a continuous basement membrane layer. As the basement membrane is totally acellular and is not penetrated by the vascular system, the survival of the epithelia depends on diffusion of metabolites, nutrients, oxygen, and waste products across the basement membrane to and from the stroma. The stromal layer contains the vascular system and other supporting tissues (connective tissues) that serve to nourish and anchor the basement membrane and the epithelia. In addition, while both the stromal and the basement membrane layers contain an extracellular matrix structure, the epithelial layer does not. In the following sections, the structure and function as well as the response to injury of each of the layers of the tissue triad that constitutes adult skin will be described in detail.

Morphology and Function of the Epidermis

The epidermis is the exterior layer of tissue that makes up the skin. The epidermal layers act as a physical barrier to protect the organism against microorganisms; prevents organismic dehydration; and protects the organism from mechanical, thermal, chemical, and UV insults. It is a

stratified tissue, consisting of five distinct tissue layers (strata) that form a tissue ~0.1 mm thick. These layers represent a cell-maturation gradient along which cells move, from the interior to the most exterior layers; cells become increasingly mature and keratinized during this migration process. The most interior layer is the basal cell layer, known as the *stratum malpighii* or *stratum germinativum*. The next layer is the prickle cell layer, also known as the *stratum spinosum*, describing the prickly morphology of the cells. The granular layer, also known as the *stratum granulosum*, is the next layer consisting of keratohyalin granules (intracellular granules) that contribute to the process of keratinization. The *stratum lucidum* is the fourth epidermal layer, found only in the very thick skin associated with the fingertips, palms, and soles of the feet. The most exterior layer is the cornified or horny layer, the *stratum corneum*, made up of flattened cell remnants that are fused together forming a compact layer of keratin, the fibrous protein that makes up the external armor of the epidermis (142). The cell-maturation gradient observed in the epidermis starts with immature cells (keratinocytes) in the basal layer; these cells undergo mitosis and migrate through the cell layers toward the cornified layer over a period of 25–50 days. Along this path, the cells become increasingly keratinized, until they reach the cornified layer where the dead cells are desquamated. This stratified tissue is avascular, relying on the underlying dermis for a nutrient supply.

The five cell layers and the individual keratinocytes within each layer are bound together by desmosomes; keratin filaments, a meshwork of filaments inside the keratinocyte cytoplasm (also known as tonofilaments), anchor neighboring cells to one another. Additional mechanical stability is provided to the epidermis by its attachment to the underlying dermis; bonding at the epidermal-dermal junction is mediated by the basement membrane. Hemidesmosomes, located inside the cell membrane of basal cells, attach to the epidermis and to the basement membrane by means of tonofilaments via junctions on the subbasal plates (142). This construct forms a stratified, mechanically stable keratinized epithelium able to withstand the thermal, mechanical, chemical, and UV insults to which the body is continuously exposed.

Morphology of the Basement Membrane

The basement membrane, also known in the literature as the basal lamina, is found in many different tissues as an acellular, avascular layer between the avascular, cellular epidermis (no ECM) and the cellular, vascularized dermis (developed ECM). The basement membrane performs a number of significant duties; notably, it provides a secure and adhesive layer to facilitate a strong connection between the epithelia and stroma, serves as a boundary that can regulate cell and molecular movement, provides a scaffold to facilitate repair following injury, and facilitates differentiation and growth of the epithelial and stromal layers (9,143–146).

The basement membrane is an acellular, avascular stratified tissue made up of three distinct strata that are, in total, ~100 nm in thickness. The basement mem-

brane structure is often observed under light microscopy as having only a single layer, termed the *lamina densa*; electron microscopy of the basement membrane reveals the *lamina lucida* and the *fibroreticularis* (142). The first layer of the basement membrane, sitting adjacent to the basal cell layer of the epidermis, is termed the *lamina lucida*, an electron-lucent membrane ~20–40 nm in thickness that consists primarily of the glycoprotein laminin. The middle layer of the basement membrane, termed the *lamina densa*, consists predominantly of type IV collagen, is ~40–50 nm in thickness, is significantly more electron-dense than the *lamina lucida*, and is the region visible under light microscopy. The final layer of the basement membrane is located adjacent to the underlying dermis and is termed the reticular layer, also known as *fibroreticularis*. This electron-lucent layer is composed primarily of type VII collagen fibers and is responsible for fixing the basement membrane to the underlying dermis by anchoring fibrils attached to specific anchoring plaques that are embedded in the underlying dermis (147,148). While the primary components of the basement membrane are type IV and type VII collagen, the basement membrane also contains significant amounts of chondroitin sulfate, heparin sulfate, fibronectin, tenascin, nidogen, enactin, thrombospondin, and 1-microglobulin (149). When viewed from a more macroscopic scale, the topography of the basement membrane surface appears as an undulating line between the dermis and the epidermis, significantly increasing the surface area between these two structures. This undulating structural feature, termed rete ridges, will be discussed in greater depth in the next section describing the dermis.

Morphology and Function of the Dermis

The dermis is the final component of the skin tissue triad, lying below the basement membrane and above the underlying muscle and fascia. The dermis, considered anatomically to be a single layer, actually consists of two zones: the papillary dermis and the reticular dermis. The papillary dermis is the upper zone adjacent to the basement membrane and consists primarily of loosely packed collagen fibers. The papillary dermis forms the upward projections of the dermis into the epidermis that define the rete ridges; these projections are filled with capillary loops responsible for providing metabolites, nutrients, and oxygen to the epidermis. In addition, the papillary dermis contains fine axonal connections of unmyelinated sensory nerves that extend up to the basement membrane. The bulk of the dermis, termed the reticular zone, is found below the papillary dermis. The reticular zone is comprised of thicker and more closely packed collagen fibers as well as a significant content of elastin fibers that are interlaced with the collagen fibers to form an isotropic, collagen-elastin network. While collagen fibers are highly crystalline microfibrils that have a limited stretching ability and provide the strength to a tissue, elastin fibers are considerably thinner and amorphous (noncrystalline), providing the ductile strength (stretching without yielding) of a tissue (1). While the strength of the dermis is defined by the collagen content and the ability of the dermis to bend and deform without

permanent damage is defined by the elastin content, it is the combination of collagen and elastin fibers that is responsible for the robust nature of the dermis.

The dermis has two major functional roles: providing mechanical stabilization for and metabolic support to the epidermis. The combination of mechanical strength and deformability gives the dermis the ability to provide a stable base for the epidermis that is able to withstand the substantial shear, tensile, and compressive forces associated with ordinary activities that would cause an unsupported epidermis to fail. In addition, the undulatory nature of the dermo-epidermal junction allows for the intimate presence of an extensive dermal vascular system that provides metabolic support (providing nutrients and oxygen while removing waste products) to the avascular epidermis. The rete ridges also provide increased surface area for attachment of the epidermis to the basement membrane and the basement membrane to the dermis, increasing the strength of the dermo-epidermal connection and enhancing the surface area available for the capillary loops to provide metabolic support to the epidermis. In addition to the two zones that make up the dermal layer, hair follicles, sweat glands, and oil-secreting glands originate in the dermis and extend through the basement membrane and epidermis to the skin surface. The dermis also provides tactile sensation through the unmyelinated sensory nerves that extend through the dermis up to the dermo-basement membrane junction, and allows for thermoregulatory control (1,142).

Current Treatment of Massive Skin Loss

Traditional treatments of a severe skin wound have focused on developing a temporary technique or product that serves to close the wound, preventing infection and dehydration (important for large skin wounds) (1). Historically, attempts have been made to treat severe wounds and burns dating back almost 3500 years, and have included a wide variety of temporary devices such as membranes of organic and synthetic polymers, skin grafts from animals (heterografts or xenografts), skin grafts from human cadavers (homografts or allografts), and skin grafts from the patient (autografts) (133). Allografts are used as a temporary covering for excised (cleaned) wounds prior to autograft, where the allograft is removed and the permanent autograft is placed into the wound. Xenografts are typically taken from the pig due to the great affinity between human and pig skin. Like the allograft, xenograft skin is a temporary wound dressing used until autograft. Temporary dressings immediately reestablish the skin barrier, decrease inflammation and risk of infection, decrease fluid loss, and reduce patient mortality. More recently, the need to develop technologies suitable for treating severe skin injuries over large areas has increased, increasing the requirement for a material to rapidly close a severe skin wound. The fundamental reasons for such a change are that an increasing percentage of patients survive the acute phase of the injury due to improved medical care and that the widespread use of early escharectomy (complete debridement of the wound immediately after injury) requires immediate coverage of large wound areas. It is often not

possible to harvest enough autograft tissue to cover a large wound. In these cases, the graft is perforated and then stretched to cover much more space than the original tissue; this meshing process decreases the quality of regeneration, but increases the area that can be treated and will be discussed in greater detail later in this section. There are also a number of problems related to the use of temporary dressings such as allografts and xenografts. Especially in cases of severe burns over large areas of the body, the xenograft or allograft may need to remain in place for a significant period of time until autografting or other treatments are possible. In transplantation of donor tissue, histocompatibility becomes an issue; typically, xenografts and allografts are rapidly rejected, usually within a month of transplantation. This phenomenon illustrates the concept of host-versus-graft disease, where the patient's (host's) body mounts a host defense that ultimately destroys the implanted tissue (graft). Histocompatibility antigens expressed in the transplanted tissue are identified as foreign by the patient's immune system, leading to an inflammatory and immune response that destroys the grafted skin; such problems are also seen in transplantation of almost all other organs and tissue in the body (i.e., liver, kidney, heart, lungs, bone marrow). Patients with allografts or xenografts can be immunosuppressed using a variety of drugs to prevent host-versus-graft disease and prolong the viability of the transplanted tissue (150); however immunosuppression introduces a variety of complications such as a decreased ability to fight infection, a prime concern for people with severe skin injuries.

Polymeric membranes used as temporary dressings often lack biological activity due to the chemical composition and structure of the membrane; these membranes often have to be removed after only a few days due to lack of formation of physiological structures and incidence of infection (133). Often a temporary graft, such as a synthetic or organic polymeric membrane, xenograft, or allograft, is useful in early management of a wound while an autograft site is prepared. Permanent treatments for massive skin loss have traditionally been focused on the autograft technique.

Despite the presence of other grafting techniques, the autograft is the current clinical standard; it addresses both the urgent need to cover an exposed wound and results in an adequate long-term result. Under ideal conditions and in the case of small wounds, when full-thickness skin wounds are treated with an autograft, an almost fully functional skin has been observed to regenerate. However, the skin replaced via the autografts has been observed to lack hair follicles and other adnexa. Despite these missing components, this skin replacement remains functional for the remainder of the patient's lifetime. Two major problems complicate the use of autografts to treat full-thickness skin wounds: the creation of a second wound (donor site), and the requirement for large autografts in the case of massive skin injury. The removal of the autograft results in a secondary full-thickness skin wound that eventually becomes reepithelialized, but considerable scar formation and contraction are observed at the donor site. This factor coupled with the usual need for large amounts of autograft

tissue due to the typical size of severe skin defects in humans has resulted in the surgical meshing procedure, where a small amount of autograft tissue is harvested, then passed through a device to cut a pattern of slits in the autograft tissue; this tissue is then stretched, greatly increasing the area of coverage and thus decreasing the amount of harvested tissue needed to cover the wound. This technique is not without problems as scar synthesis is observed in the areas of the wound not covered by the stretched autograft mesh, resulting in a pattern of scar that greatly reduces the value of the autografting procedure. Due to clinical attempts to minimize the size of the autograft wound, meshing is used almost exclusively to treat skin wounds. This results in adequate coverage and closure of the wound, but the coverage is marked by considerable scar synthesis and contraction, reducing the aesthetic and functional value of the treatment.

It is this inability to utilize the autograft without considerable scar formation as well as the requirement for the creation of a secondary wound site that have provided the stimulus to investigate alternative dressing options that could potentially lead to regeneration of physiologic tissue rather than healing by contraction and scar formation. The resulting technologies will now be discussed in detail in the following sections.

TECHNOLOGIES FOR REPLACEMENT OF THE SKIN

A number of technologies have been developed in an attempt to induce regeneration of skin following injury, both in conjunction with or without the use of an autograft. These technologies have met with differing levels of success. There are five main technologies for treating massive skin wounds by grafting that will be discussed in this article: sheets of epidermis cultured *in vitro* (Cultured Epithelial Autograft, CEA), cell-seeded nylon scaffolds (Living Dermal Replacement, LDR), a 3D living bilayer first cultured *in vitro* with dermal and epidermal cells (Living Skin Equivalent, LSE), a collagen scaffold that was either seeded with keratinocytes or implanted as an acellular construct (DRT), and a naturally derived collagen matrix (NDCM, Alloderm). These distinct procedures will now be discussed in detail, describing the design and manufacture of each device as well as the attendant experimental and clinical results.

Cultured Epithelial Autograft

Cultured epithelial autografts have been studied in both experimental and clinical settings as a possible treatment for massive skin injuries. This technique uses an epidermal graft that is grown *in vitro* and then implanted into the wound site to cover the skin defect. While initially used to provide immediate coverage of the wound site to prevent excessive fluid loss and infection, the CEA has also been studied in models to assess its potential as a permanent skin replacement graft. In the literature, the CEA technology has also been referred to as a keratinocyte sheet, cultured epithelia sheets, or cultured autologous keratinocyte sheets. This technique to culture keratinocyte cells to form an epithelial sheet was utilized because keratino-

cytes make up ~90% of mammalian epidermal cells (1). There are three major sources for keratinocytes that have been used in cultivating keratinocytes sheets: keratinocytes from disassociated cells, keratinocytes from epidermal explants, and suspensions of pellets of disaggregated keratinocytes (65).

The CEA technology relies on culturing keratinocytes isolated from the patient to produce a graft of autologous tissue, removing any immune complications observed in the case of xenografts or allografts; additionally, since the epidermis can spontaneously regenerate, epidermal tissue harvested from the patient will regenerate without further scarring. Therefore, development of a successful CEA relies upon the development of *in vitro* methods for rapid, serial cultivation of human keratinocytes from a disaggregated cell suspension; these techniques allow for expansion of the (small) harvested cell population by >10,000-fold in 3–4 weeks, a rate necessary to culture the volume of cells required to rapidly produce a keratinocyte sheet large enough to cover a wound site in a clinically acceptable time period (76,77,151,152). In a clinical setting, keratinocytes are typically isolated from skin biopsies; the biopsy tissue is then treated enzymatically to allow removal of the dermal tissue and to dissociate the remaining epidermis. This sequential process prevents contamination of the keratinocyte cell line with dermal cells (mainly fibroblasts). The keratinocytes can then be cultured using a defined *in vitro* process (73,76,77). All of these techniques can be utilized to culture the requisite cell expansion.

Using these established cell culture techniques, an intact, coherent sheet of stratified epithelium can be produced *in vitro* that is on the order of four to six cell layers thick and is bound together by the desmosomes seen in the normal epidermis. Similar to normal epidermis, sparse keratin fibers are observed running parallel to the long axis of the flattened keratinocyte cells in this new epithelial layer. While keratinization is not always observed, the maturity of this newly formed neoepidermis is moderately high. The epithelial maturity can be acutely affected by the identity of the substrate on which the CEA sheet is grown. When the stratified neoepithelium is grown on collagen gels, hemidesmosomes are not synthesized; however, the use of a surface formed from reconstituted basement membrane led to synthesis of hemidesmosomes and a more mature epidermis (1,148,153).

Studies of CEA development have indicated that a partially mature epidermis can be synthesized *in vitro* starting from disaggregated keratinocytes. There is no requirement for the presence of any dermal component or for fibroblasts in the synthesis of a neoepidermis. However, there is a temporary requirement for a nondiffusible substrate onto which the cells are grown in order to develop stratified and keratinized cell layers. While contact with specific connective tissue surfaces can induce formation of the mature neoepidermis, it is still possible to develop a less mature epidermal layer with culture on plastic or glass surfaces (1).

In the clinical setting, keratinocytes are harvested from the patient via a biopsy; the cells are then dissociated, cultured, and expanded *in vitro* for ~3 weeks to form a neoepidermis. At the end of this period, the mature,

keratinizing epidermal layer that forms *in vitro* is then implanted directly into the wound site. One major drawback to the use of the CEA is that due to its extreme friability, handling and grafting the CEA into a wound bed require extreme care. Additionally, the grafted site must be kept immobile so that the CEA can remain in place and not break apart. After implantation, the epidermal cells continue to multiply and spread, covering the entire wound. Clinically, the success of the CEA treatment depends significantly on the condition of the skin wound. The adhesion (take) of the CEA was very different depending on whether the CEA was grafted onto a full-thickness or a partial-thickness skin wound. In the case of partial-thickness wounds, the *take* of the graft has been very good and the CEA has been used to cover significant areas as large as half of the total body surface, making the CEA a life-saving, although temporary graft (133). *Take* was considerably inferior in the case of full-thickness skin wounds, where there was no underlying dermis to support the neoepidermis; in particular, one persistent problem was the formation of blisters under large areas of the graft (avulsion). Regardless of whether the graft was placed upon a partial- or full-thickness skin wound, the resulting CEA graft exhibited mechanical fragility due to a lack of three specific structural features present in normal, adult epidermal and basement membrane that serve to tether these layers onto the underlying dermis: the 7-S domain of type IV collagen, anchoring fibrils, and rete ridges (154). These structures are required for the formation of a physiological dermo-epidermal junction, and CEA grafts have failed to induce formation of these structures, a collagen fiber architecture, or the elastin fiber network that are all observed in the normal, adult dermis (133). Without these structures, the CEA cannot be used as a permanent skin replacement; instead, the CEA is often used as a temporary coverage as part of a larger treatment regimen. The CEA also exhibits high vulnerability to cytotoxins and bacterial proteases, as the CEA does not behave as a full-thickness graft in preventing infection. During the initial period after grafting, the CEA is extremely sensitive to the effects of bacterial or fungal infections of the wound bed: a full-thickness graft such as the autograft can tolerate infections that result in a near or complete loss of the CEA.

Living Dermal Replacement

The LDR was developed to be a more permanent treatment for severe skin injuries. While the CEA relied upon developing a stratified epidermal layer *in vitro* that could be used to permanently treat injuries to the epidermis and basement membrane and to temporarily treat full-thickness skin injuries, the LDR was developed in an attempt to utilize a structure that could permanently treat full-thickness skin injuries. The LDR technology used an acellular scaffold cultured with both fibroblasts and keratinocytes *in vitro* prior to implantation. In addition to introducing a cell population to the wound site, the scaffold structure was included to provide an immediate 3D architecture for both structural and cellular support that could be synthesized and implanted rapidly into the wound site. The acellular LDR scaffold consists of a copolymer of glycolic acid (90

wt%) and lactic acid (10 wt%), termed polyglactin-910 surgical mesh (PGL). The PGL fibers, $\sim 100\ \mu\text{m}$ in thickness, were knitted into a mesh that exhibited a pore structure with a characteristic dimension of $280 \times 400\ \mu\text{m}$. This mesh structure presented a large-weave structure to the cells, relative to the characteristic cell dimension of $\sim 10\ \mu\text{m}$, allowing rapid cell incorporation into the mesh as well as diffusion of an ample supply of nutrients to support cell activity. The polyglactin mesh was cultured with fibroblasts until all of the pores in the mesh were covered with cells; the confluent cells were observed to have begun to synthesize several important ECM components *in vitro*. Immediately prior to grafting, the upper surface of the polyglactin scaffold that was confluent with fibroblasts was seeded with keratinocytes in an attempt to form a bilayer graft that would mimic the structure of skin. Once the keratinocytes reached confluence on the surface of the PGL mesh, the entire structure was grafted into the wound site (88,92).

The LDR was studied as a stand-alone graft to be used temporarily prior to eventual, permanent closure by an autograft, primarily in a mouse model where the device was grafted into full-thickness skin wounds (1,133). A thin, fragile epidermal layer developed initially by 10 days postgrafting and it became cornified as early as 20 days postgrafting. In addition, by 20 days the nylon scaffold degraded completely with minimal inflammatory response. While the interface between the graft and the wound bed stained positive for laminin, consistent with the synthesis of a lamina lucida layer, no other component of the basement membrane was synthesized. In addition, rete ridges were not synthesized and a thick fibrotic tissue layer characterized by a large fibroblast population and vascular in-growth was observed below the newly synthesized epidermal layer. Additionally, the cellular component of the LDR was critical in achieving these results. When fibroblasts were not seeded into the scaffold, the mesh rapidly separated from the wound bed and fibrovascular in-growth did not occur; the presence of keratinocytes in the graft was required to prevent contraction of the wound site (88,92). While the LDR showed the ability to induce regeneration of a neoepidermis, the LDR did not exhibit the ability to induce regeneration of a complete basement membrane or a dermal layer.

Living Skin Equivalent

Preparation of the LSE graft utilized a novel approach for producing a full thickness graft with 3D architecture. While the LDR consisted of an acellular, synthetic scaffold that was cultured *in vitro* with dermal cell then seeded with epidermal cells immediately prior to implantation, the LSE approach utilized dermal cells to create a cellular, organic structure *in vitro* that could be then seeded with epidermal cells and implanted into the wound site as a cellular, bilayer neotissue (78–80,82). The skin equivalent was formed by populating a collagen lattice with heterologous fibroblasts that *in vitro* contracted the lattice and synthesized additional extracellular matrix proteins that were incorporated into the base lattice. After this contraction period, the upper surface of the neodermal

layer was then seeded with a suspension of epidermal cells, primarily keratinocytes. Once seeded, the epidermal cells attached to the collagen scaffold, proliferated, and differentiated to form a multilayered, epidermal structure within 1–2 weeks. At this point, the collagen scaffold populated by fibroblasts with a neomature epidermis upper structure was then grafted into the wound site. This technology requires a significant culture period, necessitating temporary treatment of the wound for patients during the *in vitro* culture period if this technology were to be used in the clinical setting.

Detailed studies have been made of the structure of the LSE following *in vitro* culture but prior to grafting. The keratinocytes that were seeded onto the contracted collagen scaffold formed a multilayered, partially keratinized epidermis *in vitro* that included tonofilaments, keratohyalin granules, and desmosomes (82,155). The intercorneocyte lipid lamellae that were synthesized in the *stratum corneum* of the neoepidermis did not have the same repeating pattern of narrow and broad electron lucent bands that are responsible for the epidermal barrier properties in the normal, adult epidermis. As a result of this structural abnormality, the LSE has an increased water permeability compared with normal skin, and hence a greater chance for wound site dehydration (156). Although short segments of the lamina densa were observed along the dermo–epidermal convergence, the LSE did not exhibit a complete basement membrane layer at the end of the *in vitro* culture period (157,158). Rete ridges and skin appendages were also consistently absent. Continued structural and biological changes were observed in the LSE following grafting, indicating that remodeling was taking place (1,133).

The LSE was tested experimentally in full-thickness skin wounds in a rat model; the bilayer graft exhibited remodeling in both the neodermal and neoepidermal layers. A functional, fully differentiated epidermis was observed as early as 7 days following grafting, and by 14 days a vascularized subepidermal layer with many of the structural characteristics of normal dermis, such as a “basketweave” collagen fiber pattern, was present. While a pattern of collagen fibers was observed in the subepidermal layer, the fibers were much thinner and much more tightly packed than those fibers observed in physiologic dermis, and no rete ridge structure was synthesized (155). When the LSE was implanted into a mouse model, similar remodeling effects were observed in both the epidermal and subepidermal layers. A mature epidermal layer and basement membrane were synthesized *in vivo*, with only anchoring fibrils missing from these tissue structures. The subepidermal layer again exhibited densely packed collagen fibers, but a physiologic dermis was not observed, and rete ridges again failed to form (159). Experimental results across these animal models and a number of experimental trials were consistent in indicating that the LSE was able to induce regeneration of a mature epidermis and basement membrane, but a mature dermal layer was not observed and the dermo–epidermal junction remained flat, without any sign of rete ridges (1).

The results observed in experimental trials of the LSE led to a series of clinical trials for the LSE graft that focused

on its potential use for treatment of severe burn patients. Full-thickness skin wounds that covered >15% of their body surface area were grafted with the LSE. Extensive lysing of the graft was observed as early as 2 days post-grafting, and after 2 weeks only one patient showed any significant amount of *take* (~40%). The investigators concluded that the LSE was not appropriate to use as a permanent treatment to replace the autograft for burn patients (160). Additional clinical studies were performed on patients who had skin tumors removed where these acute wounds were not full-thickness skin wounds. While acceptable *takes* and no evidence of graft toxicity or rejection were observed in these trials, wound contraction by 10–15% was also observed; wound contraction to this extent was significantly larger than what is observed after grafting with an autograft. A biopsy taken from the graft site showed evidence of scar formation, and the authors hypothesized that the LSE was replaced by host tissue through more traditional modes of injury response (i.e., contraction and scar synthesis) (161).

A final series of clinical trials involving the LSE used the graft to treat chronic wounds due to venous ulcers, a chronic skin defect that has been observed to be of variable depth. Patients were diagnosed as having chronic ulcers when their wounds remained open for at least 1 month prior to LSE implantation, although the median duration of the ulcers for these patients was ~1 year. No information on the initial depth of each of the ulcers was reported, so it is not clear whether these were full- or partial-thickness skin wounds. In these studies, the use of the LSE was compared to a standard clinical treatment for such ulcers: bandaging with a compression regimen. Following a 6 month study, it was concluded that the time to wound closure was significantly shorter for patients treated with the LSE compared to those treated with standard bandages. However, observations from both experimental (animal models) and clinical trials indicated that while the LSE displayed a significant ability to regenerate both mature epidermal and basement membrane layers, dermal regeneration was not observed and normal skin architecture (i.e., collagen fiber architecture, rete ridges) was lacking in both animal and human models (1,162,163). More recent animal experiments utilizing the LSE have indicated that once implanted, the graft is rapidly incorporated into the host tissue and began to undergo remodeling; basic dermal organization, the appearance of specific ECM constituents such as type I, III, V, and VI collagen as well as elastin, and the gradual disappearance of contractile myofibroblasts occurred by 1-year postimplantation. However, complete regeneration of the tissue triad (epidermis, basement membrane, dermis) was not observed. The LSE possesses the adequate environment to remain bioactive >1 year post-implantation and provide a platform for long-term *in situ* therapy studying wound healing (164). While the LSE is used clinically to treat chronic (nonclosing) venous leg and diabetic foot ulcers and significantly increases the rate of wound closure and the likelihood of wound closure compared to conventional treatments (debridement followed by the application of a synthetic dressings), the LSE has yet to be able to replace the wound with normal, physiological skin.

Dermal Regeneration Template

The DRT is the fourth major paradigm investigated to treat massive skin injury. Like the LDR and the LSE, the DRT utilized a 3D scaffold as the basis for an implant to be grafted into a severe skin wound. But unlike the cell-seeded, synthetic, acellular scaffold of the LDR and the cell-seeded, organic, cellular LSE where the focus was not on developing a specific scaffold structure, the DRT was an acellular scaffold fabricated from primary components of the extracellular matrix (i.e., collagen, proteoglycans). The focus was on fabricating a bioactive ECM analog that presented a 3D architecture that induced the endogenous cell population in the wound site to regenerate the lost tissue (1,3). The DRT device sequentially performs two separate tasks during the wound healing process: prevent wound dehydration and infection while modifying the healing response to induce regeneration. The first task addressed by the DRT is the management of the acute phase of the clinical healing process; the graft must protect against severe fluid loss and prevent massive infection as a result of the open skin wound. The second task for the DRT to modify is the chronic phase of the wound healing process; in the chronic phase, wound contraction and scar synthesis take place, leaving a mechanically, functionally, and aesthetically inferior tissue compared to normal skin (repair mechanism).

The DRT is a two-stage device with a top layer of poly(dimethyl siloxane), a silicone elastomer, bonded to an active ECM analog beneath. The active ECM analog was designed to induce synthesis of new, physiological dermal tissue while the silicone elastomer was designed to prevent flow of exudate outside the defect, acting as a barrier to control moisture permeability and to shield the wound site from bacteria (109). The top silicone layer was designed so it would be easily removed after an initial healing period (Stage 1 of the healing response) so that a keratinocyte sheet could be grafted on top of the newly synthesized dermal bed, producing a stratified epithelial tissue on top of the neodermis. This grafting procedure was developed based on observations that the epidermis regenerates spontaneously provided that there is an underlying dermal structure, while the dermis does not. The graft design is also compatible with a view of the active ECM analog (template) as a structure that prevents contraction and scar formation, while the silicone elastomer layer protects the wound site from dehydration and infection. In the clinical setting (107), the silicone layer was replaced by a thin autoepidermal graft harvested from the patient once initial regeneration of the dermis occurred (~10–15 days). Following the introduction of a keratinocyte sheet, a mature epidermal and basement membrane layer forms on top of the regenerated dermis.

The DRT structure was optimized in studies utilizing animal models where it was observed that skin regeneration did not occur unless the ECM analog effectively delayed wound contraction. Preliminary optimization of the structural features of the ECM analog was quantitatively based on comparing the delay in the onset of contraction. The structural characteristics of an active ECM analog were individually studied to determine the optimal

chemical composition, template residence time, and template pore structure needed to create a bioactive scaffold that prevented contraction and induced regeneration (1,3,134).

The ECM analogs that were used successfully to induce skin regeneration are graft copolymers of type I collagen and chondroitin-6-sulfate, a GAG, with a collagen:GAG weight ratio of 98:2 (3). The porous structure of the DRT was produced using a freeze-drying process. The collagen-GAG (CG) copolymer was produced in slurry form from microfibrillar collagen, an aqueous glycosaminoglycan solution, and acetic acid. The slurry was frozen to a final temperature of -40°C and then sublimated [pressure <100 mtorr (13.3 Pa), temperature = 0°C]; after freezing, an interpenetrating network of ice crystals that is surrounded by collagen and GAG fibers has formed. The sublimation process converts all of the ice crystals formed in the frozen slurry into vapor and generates empty pores, creating a collagen-GAG scaffold formed from interconnected sublimated pores (3,165). The scaffold structure (pore size, specific surface) can be adjusted by varying the temperature of freezing of the CG slurry prior to sublimation; a lower temperature of freezing increases the frequency of nucleation of ice crystals in the slurry and decreases the rate of material transport within the slurry. These two processes result in the formation of smaller ice crystals, and therefore smaller pores after sublimation, for lower temperatures of freezing (3,166,167). In addition to being able to adjust the composition and the pore structure, the template residence time can be adjusted by changing the cross-link density, allowing the fabrication of scaffolds with specific degradation rates (3,105). Both chemically (i.e., glutaraldehyde or carbodiimide based cross-linking) and physically induced (i.e., dehydrothermal crosslinking) covalent bonds between collagen fibers (cross-links) can be introduced; as the scaffold becomes more highly cross-linked, it is increasingly difficult to degrade through enzymatic digestion. Adjustment of the severity of cross-linking (increasing the chemical exposure time or increasing the heat and/or exposure time to a dehydrating environment increases the severity of cross-linking) allows for adjustment of the scaffold cross-link density and therefore degradation rate (3,120). Previous research has determined that crosslinked collagen scaffolds degrade at a rate that monotonically decreases with increasing crosslink density (105). Systematic use of the contraction inhibition criterion was used to select the average pore diameter and biodegradation rate of the DRT that results in an optimal regeneration result. The speed of contraction of a wound site was measured using the wound half-life criterion, the time it took for the wound to decrease in area by 50% from its original size.

The kinetics of contraction of full-thickness skin wounds in the guinea pig were used to separate CG copolymer grafts into three classes: Class 0, I, or II (Fig. 2). The guinea pig model was employed during early studies because of the vigorous contraction observed in skin wounds; this rapid and significant contraction was used to identify templates that were active in preventing contraction and inducing regeneration (108). While the skin of most mammals is securely tethered to the underlying fascia and skin wounds

Figure 2. Schematic representation of wound healing kinetics in the adult guinea pig. A full-thickness skin wound was either ungrafted, grafted with the DRT, or grafted with a keratinocyte-seeded DRT, leading to three classes of wound healing: class 0, class I, or class II, respectively. *Top:* The ungrafted defect closed rapidly by contraction and formation of a characteristic “stellate” scar (class 0 healing). The ungrafted defect exhibited a half-life of 8 ± 1 days, and the wound contracted to $<10\%$ of the original area within 20 days. *Middle:* Grafting with a cell-free DRT led to a significant delay in wound contraction, and synthesis of a small mass of dermis and epidermis was observed. In the guinea pig wound model, however, the wound eventually closed by wound contraction (class I healing), but the resulting scar was more rounded than the “stellate scar”. The unseeded DRT exhibited a half-life of 27 ± 2 days, but the wound contracted to $<10\%$ of the original area within 40 days. *Bottom:* Grafting with a keratinocyte-seeded DRT led to delay in wound contraction, followed by the complete arrest of contraction and expansion of the defect parameter due to synthesis of new, physiologic skin (class II healing). The keratinocyte-seeded DRT exhibited a half-life of 22 ± 2 days, and as a result of synthesis of new skin the wound edges reached a steady-state condition by 200 days after grafting that was $72 \pm 5\%$ of the original wound area (1).

close by contraction, but mainly scar synthesis, the skin of the guinea pig is not nearly as well tethered and skin wounds close almost entirely by contraction with very little scar synthesis and no regeneration (Fig. 3) (1,3,133). Class 0 healing, attained by grafting either no scaffold or a biologically inactive scaffold in the guinea pig model is characterized by a wound half-life of ~ 1 week (8 ± 1 day); the wound was observed to contract to $<10\%$ of the original area within 20 days. Class I healing, attained by grafting a bioactive, cell-free scaffold into the full-thickness wound, is characterized by a significantly longer wound half-life (27 ± 2 days); however, the wound is still observed to contract to $<10\%$ of its original area after ~ 40 days. While this implant in the guinea pig still shows significant contraction of the wound site, in other animal models that more closely mimic human skin contraction kinetics, class I devices with the guinea pig prevented significant wound contraction (1). The final mode of guinea pig wound healing (class II) was observed when the wound was grafted with a bioactive scaffold seeded with cells (keratinocytes); this healing was characterized by an extended wound half life (22 ± 2 days) compared to class 0 healing. After ~ 200 days, the wound was observed to have stabilized at $\sim 72 \pm 5\%$ of the original wound area. Due to the more secure attachment of the skin to the underlying fascia with humans,

Figure 3. Kinetics of wound closure of full-thickness skin wounds (mediated primarily by contraction) in guinea pig and swine animal models. Each time point represents the change in defect area relative to the original wound dimensions on the indicated day after wounding. The guinea pig exhibits much more robust wound contraction compared to the swine model, arriving at a significantly smaller asymptotic wound area (1).

both class I and class II healing devices are useful clinically. The scaffold that led to these two healing modes was identified as having maximal biological activity, termed the DRT.

A homologous series of ECM analogs, varying in scaffold pore diameter from ~ 10 to $1000 \mu\text{m}$, was used in the above studies to determine the optimal pore diameter necessary to prevent class 0 contraction (Fig. 4). Maximum delay of wound contraction half-life, up to 27 ± 3 days, was observed when the average pore diameter was in

Figure 4. Identification of the optimal pore diameter for a bioactive extracellular matrix analog designed to induce skin regeneration. The range of maximal contraction-delaying activity for collagen-GAG scaffolds was observed when the average pore diameter of the scaffold was between 20 and $120 \mu\text{m}$. The limits to the area of maximal activity are indicated by broken lines and correspond to the range where contraction was most delayed (13).

Figure 5. Identification of the optimal degradation rate for a bioactive extracellular matrix analog designed to induce skin regeneration. Contraction delaying activity of the collagen–GAG scaffold was observed when the device degradation rate was maintained between the two levels indicated in the figure. The degradation rate is expressed in units of standardized collagenase solution (*in vitro* assay). When the degradation rate was <2.5 enzyme units or >100 units, scar synthesis and contraction were observed. The limits to the area of maximal activity are indicated by broken lines, and correspond to the range where contraction was delayed the most (13).

the range between a lower limit of $20 \pm 4 \mu\text{m}$ and an upper limit of $125 \pm 35 \mu\text{m}$ (3). The lower limit in pore diameter is on the order of two cell diameters, suggesting that the scaffold pore size must be large enough to maintain space for dermal fibroblasts, the major cellular constituent of the dermis, to migrate from the wound bed into the DRT. The upper limit has been hypothesized to be as a result of an apparent requirement for attachment of a minimal number of cells onto the surface of the scaffold (167). Another homologous series of ECM analogs, where the scaffold degradation rate was varied, was also studied to match the degradation rate of the scaffold with synthesis of new physiologic tissue, as outlined in the section discussing the isomorphous tissue replacement rule (Fig. 5). A significant delay in wound contraction was observed when the degradation rate was $<115 \pm 25$ enzyme units; the enzyme units used here are arbitrary units based on an *in vitro* assay using bacterial collagenase to degrade the scaffolds and then correlating these results with the ability of each device to prevent wound contraction in the guinea pig model (3,103,105). The upper limit in degradation rate is consistent with a lower limit for the time of biodegradation of the scaffold, indicating that the scaffold needs to be present for a specific amount of time in the wound site when the contractile response is active in order to prevent contraction ($\sim 2\text{--}3$ weeks in humans) (1).

The knowledge obtained from the series of experiments used to determine the optimal chemical composition, degradation kinetics, and pore structure that each prevented wound contraction were required in order to interpret the unusual biological activity of this specific ECM analog, termed the DRT. These characteristics are appar-

ently required to block contraction for the entire period that contraction was active in the healing wound bed. Host fibroblasts were observed to migrate into the DRT from the wound edges at a speed of $\sim 0.2 \text{ mm/d}$, making the endogenous cells able to cross the entire 0.5-mm thickness of the DRT within a few days, provided the appropriate contact with the wound bed was available. With a calculated critical cell path on the order of $100 \mu\text{m}$, a distance that is filled largely with wound exudate, growth factors and serum nutrients, it was expected that fibroblasts from the host (surrounding) tissue were able to migrate readily into the DRT, multiply, and differentiate, leading to the synthesis of a physiologic dermis (1,3).

In addition to inducing the synthesis of a physiological dermis using the silicone-covered DRT, it was necessary to induce formation of a mature epithelial layer if the DRT was to be used as a permanent treatment. In the case of small wounds, keratinocytes can migrate from the wound edges across the top of the regenerating dermis. Once the keratinocytes migrate over the entire surface of the new dermis, the keratinocytes multiply and differentiate, creating a mature, stratified epidermis and basement membrane (3,133). This process was termed sequential regeneration because regeneration of the dermis had to occur prior to keratinocyte migration from the wound edges across the top of the regenerating dermis to form the neoepidermis. For larger wounds, the cells can only migrate into the edges of the wound due to their average migratory speeds of $0.2\text{--}0.5 \text{ mm/d}$, and are unable to cover the surface of the DRT rapidly enough to create a functional epidermal layer over the entire wound surface. In this case, it is necessary to supply an exogenous source of keratinocytes. Two distinct techniques have been utilized to overcome this shortcoming. The first utilizes uncultured autologous epidermal cells that are harvested using a skin biopsy from the patient and are then seeded into the DRT prior to implantation. This procedure results in the formation of a confluent epidermis after ~ 2 weeks provided that a large enough amount of cells were seeded originally ($>5 \times 10^4$ epithelial cells/ cm^2 area of DRT); this modified process has been termed simultaneous regeneration (133). A second procedural option for introducing keratinocytes to the wound can be performed when the silicone elastomer is removed (after $\sim 2\text{--}3$ weeks). When the silicone is removed, a thin autoepidermal graft is applied to the surface of the regenerating dermis (107). Approximately equivalent final results have been observed when utilizing either of these techniques for creating a mature epidermal and basement membrane layer over the regenerating dermis (1,3,133).

The quality of regeneration using the DRT was determined through immunohistochemical analysis of the regenerated tissue and comparing these results to those seen in normal skin (Fig. 6). The regenerated skin was observed to have the three tissue layers present in normal skin (tissue triad): an underlying dermis, the stratified epidermis, and a basement membrane layer between the two. For all of the following images, observations, and analyses discussed in this paragraph, the DRT treatment utilized was the DRT seeded with autologous keratinocytes prior to implantation into a full-thickness skin wound in a

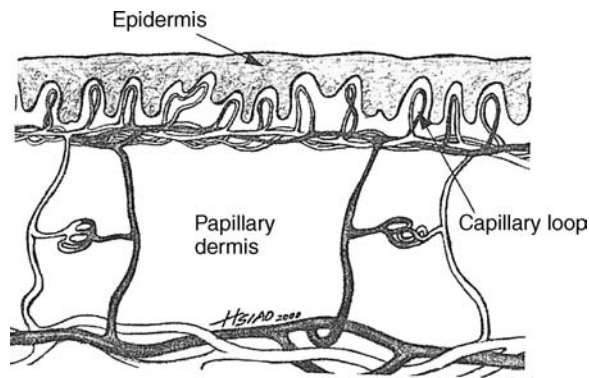

Figure 6. Diagram of normal skin showing the characteristic rete ridges at the dermo-epidermal junction and the vascular network (capillary loops) that populates the subepidermal region (1).

porcine model. As early as day 12 postgrafting, anchoring fibers were observed in the regenerated basement membrane (Fig. 7). By day 35 postgrafting, a rete ridge structure had formed, complete with vascular loops (Fig. 9), and a confluent hemidesmosomal staining pattern was observed at the dermo-epidermal junction (Fig. 8). All of these immunohistochemical results indicated that the regenerating skin was taking on all of the structural properties observed in the epidermis, dermis, and basement membrane of normal skin, except for skin appendages such as sweat glands and hair follicles (115).

Clinical studies of the DRT initially emphasized treatment of massively burned patients while later studies have focused on patients who elected to have plastic and reconstructive surgery. In both patient populations, the primary defect is severe, traumatic skin loss down to the underlying muscle and fascia. In studies with burn patients, burns were excised down to muscle fascia prior to grafting with DRT. Wound closure was accelerated greatly by removing the silicone cover after ~2–4 weeks and grafting the newly

synthesized dermis with an ultrathin autoepidermal graft, nominally 100 μm in thickness, that was free from dermal components (107,168). In a detailed histological study of the resulting new organ the endogenous cell population degraded the DRT structure; remodeling then occurred and the newly synthesized collagen fibers became coarser and a distinction between papillary and reticular layers of the dermis appeared. Scar synthesis was not observed either at a gross or at a histological level at any time during the course of healing. In contrast to studies with the swine in which rete ridges had clearly formed (115), rete ridges were not reported in this study with humans and skin appendages were absent from the human as they were from studies with swine and rodents (169). A related immunological study showed a very small rise in immunological activity in patients' sera for the components of DRT: bovine skin collagen and chondroitin 6-sulfate. The overall conclusion from the clinical studies was that DRT presents few, if any, immunological problems to patients (170). In other clinical studies of DRT, the focus was on follow-up of massively burned pediatric patients over a 6- or 10-year period (171–173). It was reported that the new integument did not restrict joint function, suggesting the absence of crippling wound contraction and that the new skin had the ability to grow and mature long after grafting even when children were treated with the DRT (171,173). The DRT has also been used to treat patients with purpura fulminans (174), to release skin contractures (175), and to resurface scarred areas resulting from full-thickness burns (176,177); in all cases, regeneration of a functional epidermis, basement membrane, and dermis was observed.

Naturally Derived Collagen Matrices

Separate from the development of a series of scaffold materials for use to treat severe skin injuries, a separate technology has been developed to utilize naturally derived collagen matrices (NDCM) to treat skin injuries. Instead of relying on technologies to fabricate a 3D scaffold structure

Figure 7. As early as 12 days after grafting a full-thickness skin wound with a keratinocyte-seeded DRT, anchoring fibrils were observed in the regenerating basement membrane (arrow). The basal surface epithelium and the periphery of the epithelial cords are labeled with type VII collagen immunostaining, identifying the anchorage structures at the dermo-epidermal interface. Bar: 150 μm . Reprinted with permission from Reference (115).

Figure 8. As early as 35 days after grafting a full-thickness skin wound with a keratinocyte-seeded DRT, a confluent hemidesmosomal staining pattern is observed at the dermo-epidermal junction (arrow) by immunostaining for the $\alpha_6\beta_4$ integrin. The pattern observed in the regenerating skin is identical to that observed in physiologic skin. Bar: 100 μm . Reprinted with permission from Reference (115).

from either synthetic or natural materials (i.e., CEA, LSE, LDR, or DRT), this technology uses decellularized dermal tissue as a scaffold structure. The most analogous treatment to the NDCM that has already been discussed in this article is the allograft and xenograft; the NDCM is a decellularized version of an allograft. The NDCM is designed to serve as a scaffold to support normal tissue remodeling following severe injury, thereby inducing regeneration.

The NDCM is produced through a three-step process. The epidermal tissue is completely removed from full-thickness autograft tissue, leaving both the dermal tissue and the basement membrane. The dermal cells are then removed using detergent washes. The decellularized tissue is then freeze-dried to preserve the NDCM structure and to maintain the bioactivity of the dermal matrix. The main advantage of the NDCM over the homograft and xenograft are that owing to decellularization, the antigenicity of the scaffold is significantly reduced. Reducing the antigenicity

reduces the immunological response of the patient to the graft and reduces the chance of implant rejection. To treat a severe skin wound, the NDCM can be rehydrated in saline solution then be implanted directly into a wound site in the same manner as a tissue autograft. The NDCM has been used primarily to treat full-thickness burns and burns to areas of the skin where contraction and scar formation would inhibit functionality (i.e., feet and hands). AlloDerm, a product of the LifeCell Corp., is a common NDCM available for experimental and clinical trials.

The NDCM is implanted into full-thickness skin wounds and is often covered by a thin autograft of the patient's own epidermis to speed the healing process. This treatment typically results in a high percentage of graft take; additionally, the thin autograft of epidermal tissue significantly decreases the time for complete reepithelialization of the graft and reduces the number of complications due to infection. Patients showed normal range of motion, grip strength, motor control, and functionality following

Figure 9. A full-thickness skin wound grafted with a keratinocyte-seeded DRT was observed to regenerate many of the structure observed in normal skin. Immunostaining for Factor VIII 35 days after grafting revealed that capillary loops had formed in the rete ridges of the regenerated dermis (arrow) similar to those observed in physiologic skin. Bar: 75 μm . Reproduced with permission from Reference (115).

treatment (178,179). The NDCM technology demonstrates the use of a naturally derived material in tissue engineering applications. A major restriction on the use of an NDCM such as Alloderm is the same as that faced by allografting: a limited supply of donor tissue available for grafting.

DISCUSSION AND CONCLUSIONS

Future improvements in treating injuries to various tissues and organs, including skin, via tissue engineering protocols will eventually depend critically on theoretical developments that explain the mechanism of tissue and organ replacement, thereby suggesting novel experimental studies and new paradigms for inducing regeneration. The goal of this article was to discuss the process of wound healing following injury, specifically the response of the skin to severe injuries and to discuss a number of paradigms that have been investigated in an attempt to alter the organismic (contraction-mediated) response to severe injuries. Evidence has been introduced to support the conclusion that contraction is the main engine for wound closure both in skin and peripheral nerve wounds, that scar formation is a byproduct of contraction, and that there is an antagonistic relationship between contraction and regeneration. Regeneration of skin and peripheral nerve requires selective blocking of contraction, but not blocking of other aspects of the healing process. The structural requirements for bioactive regeneration templates were also discussed in the light of this theory, and a number of distinct paradigms using very different scaffold structures were studied to determine the experimental and clinical outcomes of their use. This article concludes with a detailed discussion of the mechanism of regeneration after implantation of the DRT into severe wound sites.

The empirical evidence described here is consistent with the conclusion that synthesis of an organ *in vivo* (induced regeneration) requires grafting of an appropriate scaffold that has or has not been seeded with epithelial cells from the desired organ. In this approach, there is no requirement for addition of exogenous reactants such as mesenchymal cells (i.e., fibroblasts) or for addition of cytokines. These empirical findings appear to have direct relevance for the future selection of tissue engineering protocol based on both *in vitro* and *in vivo* environments.

INTRODUCTION

Skin, the body's largest organ, accounts for about 16% of an average adult's body weight and occupies a surface area of

Figure 1. Layers of skin (left) and view of rete ridges (right) (1).

approximately 2 m^2 . It has multiple essential functions: It provides the inner organs and vasculature with a protective barrier against injury or invasion by microorganisms; it prevents water loss; its sensory nerves can sense contact, pain, pressure, heat, and cold; and it plays an important role in maintaining normal body temperature via the function of sweat glands.

Structurally, the skin consists of two principal layers—epidermis and dermis—and various sublayers (Fig. 1). The epidermis is the thinner outer layer, composed of stratified squamous epithelium organized in four or five layers. The main cells in the epidermis are keratinocytes, which are generated by continuous divisions of stem cells that form the basal layer of the epithelium. As keratinocytes migrate to the surface of the epidermis, they grow and differentiate, synthesizing large amounts of a cytoskeletal protein called keratin. This protein builds into 10 nm filaments that gradually come to occupy 80% of the cell volume.

The epidermis is 0.07–0.12 mm in thickness over most of the body surface. It has no blood vessels and thus relies on the dermis for nutrients. The dermis is a supportive layer beneath the epidermis, composed of fibroblasts, fibrocytes, collagen, elastic fibers, glycosaminoglycan (GAG) matrix, blood vessels, and nerves. It is about 0.5–2.5 mm thick. The dermis has two distinct layers: papillary dermis (about 20% the overall thickness) and reticular dermis. The papillary layer is a loose connective tissue, containing large blood vessels, interlacing elastin fibers and bundles of collagen fibers. In contrast, the reticular dermis is a dense, irregularly arranged connective tissue containing interlacing bundles of type I collagen fibers and coarse elastic fibers.

The interface between the dermis and the epidermis varies from region to region. In thick skin, such as that found on the plantar aspect of the foot, the epidermis–dermis interface has the configuration of rete ridges (downgrowths of epidermis and dermis). The upper dermis exhibits a pattern of primary ridges separated by deep primary grooves (Fig. 1). Rows of conical dermal papillae project upward into the conforming concavities between the ridges in the deep surface of the epidermis. Tethering fibers connecting dermis and epidermis to the base membrane keep the dermis and epidermis from separating. In thin skin (e.g., facial skin), the dermo-epidermal junction is much simpler. The dermal papillae in thin skin are shorter, wider, and fewer and not arranged in the pattern of ridges and grooves as observed in thick skin.

Beneath the dermis is a subcutaneous layer (also called the hypodermis) consisting of areolar and adipose tissues. This layer is sometimes considered a third layer of skin. Collagen fibers from the dermis extend down into the superficial fascia and anchor the skin to the subcutaneous layer, firmly attaching it to underlying tissues and organs. The superficial fascia provides the skin's loose flexible connection with the other internal soft tissues, whereas the upper layers (epidermis and dermis) protect skin from injuries.

MECHANICAL PROPERTIES OF SKIN

Microstructure of Skin

The mechanical properties of skin have long interested dermatologists and bioengineers (2–11). Studies of the mechanical properties of skin could provide objective information related to skin and the changes it undergoes with age and disease. For instance, knowledge of the skin's mechanical properties is of potential use in assessing conditions of connective tissue disease, skin aging, wound healing, and scarring.

Like any other material, the mechanical properties of skin are determined by those of its structural constituents. Major structural components of skin are elastin fibers, collagen fibers, and the ground substance. The individual mechanical and structural properties of collagen fibers, elastin fibers, and their interaction with the ground substances in skin form the basis of mechanical properties of skin.

Collagen. Collagen, the body's most abundant and common protein, represents approximately 72% of the dry weight of dermal tissue. There are now more than 19 known collagen types, each of which is a genetically distinct product. The collagen of adult dermis is mainly type I (85–90%), with 8–11% of type III and 2–4% of type V collagen. In all connective tissues, collagen exists as fibers made up of crimped fibrils. Depending on the tissue, a collagen fibril varies from 50 nm to 300 nm in diameter. Collagen fibers in skin are randomly oriented in layers or lamellae, which give skin large extensibility and resiliency under stress. This arrangement contrasts with that found in the tendon and ligament, where the parallel alignment of collagen fibers gives these tissues higher values of tensile strength requirement.

Collagen fibrils are stabilized and strengthened by the formation of covalent cross-links. These cross-links are formed by lysine and hydroxylysine residues. The intermolecular cross-links are formed by the joining of two hydroxylysine residues and one lysine residue. The cross-links are formed between residues near the amino terminus of one collagen molecule and the carboxyl terminus of another.

There is evidence that in the presence of hyperglycemia (such as in diabetes), some proteins, such as collagen, undergo nonenzymatic glycation (12–15). This process modifies the structure of collagen and has a direct effect on the mechanical properties of collagen, resulting in increased mechanical stiffness and decreased flexibility

of these collagen-containing tissues (16–18). Increased collagen cross-linking due to a buildup of advanced glycation endproducts (AGEs) is also believed to be a major contributor to many complications of diabetes (18,19). AGE content has been shown to be four times higher in the collagen of diabetic versus nondiabetic patients (20). Besides being more rigid, highly crosslinked tissues are more resistant to enzymatic digestion by collagenase (18,21).

The strength of collagen fiber is similar to that of skin, which suggests that collagen fibers are the dominant load-bearing material at high strains. However, the extension of collagen at failure is found to be only 10% that of skin. Studies of the geometry of collagen fibers show that the apparently randomly coiled collagen fibers do not carry any part of the applied stress during the initial elastic deformation of skin. As fibers become oriented and straightened out in the stress direction, they start to carry stress, and the high stiffness of the collagen prevents any further large strain.

Elastin. Elastin accounts for 4% of the dry weight of dermal tissue. Elastin polypeptide molecules are cross-linked together to form rubberlike, elastic fibers. Each elastin molecule uncoils into a more extended conformation when the fiber is stretched and will recoil spontaneously as soon as the stretching force is relaxed. Elastin fibers are highly extensible, and their extension is reversible even at high strains. They exhibit linear elasticity with low stiffness up to about 200% elongation followed by a short region where the stiffness increases rapidly until failure. The loading and unloading paths of elastin fibers do not show significant hysteresis. Elastin fibers are characterized as low-modulus elastic material. Analyzing skin disks from cadavers mechanically and histologically, Dick (22) concluded that the loss of elastin fibers in older persons resulted in a loss of skin resistance to deformation at low stress. King and Lawton (23) investigated the behavior of elastin-rich tissues in terms of elastomer theory and found good agreement with experimental data. When other structural components such as collagen and ground substance are present, however, the elastomer theory is no longer applicable. Daly (24) found that the elastic recovery of skin is completely lost when elastin is removed. Thus, he concluded that the elastic behavior of skin during the initial low strain region is due to the small amount of elastin in dermis.

Ground Substance. Ground substance is the intercellular, non-fibril material in connective tissue. It is composed of tissue (extracellular) fluid, amorphous component proteoglycans, and GAGs. Ground substance accounts for 20% of the dry weight of dermal tissue.

Ground substance contributes to the time-dependent properties of skin. Minns et al. (25) performed stress-strain and relaxation studies on human tendon, aorta, and bovine ligamentum nuchae after removing the ground substance with an enzyme or chelating agents. They noted a decrease in stress level, stiffness, stress relaxation, hysteresis, and other time-dependent effects in all three tissues.

Much is known about the structure of collagen, elastin, and proteoglycans at the molecular level. However, less is known about the higher level of structure. For example, how the collagen fibers and elastin fibers are connected to each other in the network of skin and how this might be affected by disease, such as diabetes, are not known.

Skin Mechanics

Most engineering materials are elastic material, which can be described, for small strains, by Hooke's law of linear elasticity: Stress σ is linearly proportional to strain ϵ . Elastic materials show time-independent material behavior, that is, they deform instantly when external loading is applied and return back to their original state immediately when the applied loads are removed.

Unlike engineering materials, the responses of most biological tissues to mechanical loading are complex. Biological tissues have self-adapting and self-repairing characteristics. That is, they can alter their mechanical properties to adapt to changing mechanical demands and can repair themselves. The mechanical properties of biological tissues tend to change with age and some connective tissue diseases. Most biological tissues are composite materials with nonhomogeneous and anisotropic properties, and almost all biological tissues are viscoelastic in nature.

Viscoelasticity. The response of viscoelastic materials not only depends on the strain level applied but also on the time and rate at which the external loading are applied. Skin is such a composite material, made up of collagen fibers, elastin fibers, keratin, and ground substance. Collagen fibers and elastin fibers explain the solid behavior of skin; ground substance contributes to the fluid behavior of skin. The mechanical properties of skin are determined not only by the individual component properties, but also by the geometry configuration and interaction of these components.

As a viscoelastic material, skin has the characteristic of creep, stress relaxation, hysteresis, and precondition.

- Creep: When skin is suddenly loaded with a constant tension, its lengthening velocity decreases against time until equilibrium.
- Stress relaxation: When skin is suddenly extended and maintained at its new length, the stress gradually decreases over time.
- Under cyclic loading, the stress-strain curve shows two distinct paths corresponding to the loading and unloading trajectories. This phenomenon is called hysteresis. With repeated loading cycles, the load-deformation curves shift to the right in a load-elongation diagram and the hysteretic effects decrease. By repeated cycling, eventually a steady state is reached at which no further internal changes in tissue structure will occur unless the cycling routine is changed. At this point, tissue is defined as preconditioned.

Nonlinear Elasticity. The elasticity of skin is strongly nonlinear (Fig. 2). In the initial low-strain region, elongation of skin occurs without appreciable force (a). In the

Figure 2. Typical stress-strain curve of skin under incremental loading (4).

mid-strain region, the curve increases in a roughly exponential manner (b) until, at the high-strain region, it becomes almost a straight line (c) immediately before rupture occurs. The accepted explanation of the curve is that the initial deformation (Fig. 2a) is due to deformation of the delicate elastin network; the second part of the curve (b) is due to a gradual straightening of the randomly oriented collagen fibers; the third part of the curve (c) is because most collagen fibers are elongated in the direction of the stress. If the initial part of this curve is magnified, a straight-line approximation will allow the calculation of elastic properties such as Young's modulus. From a functional part of view, the first parts of the curve are more important because they correspond to the physiological range in which the skin normally functions.

Anisotropy. Like most composite materials, skin is anisotropic. This mechanical behavior of human skin can be demonstrated by stretching skin in different directions or by a biaxial loading test (26). Results from tests such as these show directional variance related to lines of tension or cleavage (known as Langer's lines) within the skin that are characteristic for each part of the body. They are named after Austro-Hungarian anatomist Karl Langer (1819–1887), the first to systematically investigate the configuration of the tension on cuts in the human body. Microscopic examination of sections of skin along and across Langer's lines shows a preferential orientation of the collagen fibers of skin. The orientation seems to be at an angle slightly less than 45° from the direction of the lines. Ridge and Wright (27) performed a series of experiments with an extensometer in which they stretched pieces of skin with and against the normal skin tension lines. They could show a clear difference in the directional mechanical properties in the skin, which corresponded to Langer's lines.

Measurement of Skin Mechanical Properties

Information about the mechanical properties of skin falls under three broad categories: strength values (e.g., breaking strain), time-dependent values (e.g., creep, relaxation),

and non-time-dependent values (e.g., elasticity). The measurement of mechanical properties of skin can be performed either *in vitro* or *in vivo*. Results from *in vitro* tests are estimates of properties that are assumed to have an important influence on function *in vivo* and can provide information about the basic mechanical properties of strength, elasticity, or density inherent in the architecture of skin. However, *in vitro* studies are limited in that the characteristics of isolated skin are modified. Dissected skin samples no longer have the same physiological properties as *in vivo* skin, such as those of internal tension, hydration, and vascularization. *In vivo* tests may provide information on the function and the kinetics of change in mechanical properties.

In Vitro Studies. In testing the strength characteristics of biological material, Yamada (28) suggested that the material should be in a mechanically stabilized state in which constant values are obtained. Such a state can be achieved by putting the biological material in a physiological saline solution and storing it in a refrigerator overnight or longer. Yamada noted that the duration of the mechanically stabilized state for skin is 3 days.

There have been many investigations of the mechanical properties of both animal and human skin. Most have used uniaxial test procedures. Many of these early experiments were flawed due to unsophisticated equipment and poor control of such variables as temperature and humidity. Ridge and Wright (1964) developed a skin extensometer, which stretched 1 cm × 0.4 cm strips of skin at a constant rate of 0.2 in. per min. They characterized the resulting stress-strain curves with the equation:

$$e = c + kL^b$$

where e is extension; L is load; and c , b , and k are constants. The authors felt that constant b reflected a specific property of the collagen fibers and constant k represented the condition of the fiber network, which was related to the length and area of the fibers.

Daly (3) further refined uniaxial testing. He first appreciated that for consistent results the specimens must be tested at a constant temperature, humidity, and pH and with a constant strain rate. In addition to measuring stress-strain curves and Poisson's ratio, he performed extensive experiments documenting stress relaxation and creep in human cadaver skin.

An accurate biomechanical description of skin requires constitutive equations that characterize soft tissues in three dimensions. For practical analysis, skin can be considered an incompressible solid material. It is possible to determine three-dimensional mechanical properties from two-dimensional tests for an incompressible solid. Lanir and Fung (29) developed a two-dimensional experimental system for biaxial testing. Each specimen of skin is hooked along its edges by many small staples. Each hook connects by means of a small thread to a force-distributing platform, where tension can be individually adjusted. The investigators used this device to measure the biomechanics of rabbit skin. In their study, the deformed skin always returned to its predeformed state so long as no surface dimension had been allowed to decrease below its initial

unstressed value. This study is obviously different from uniaxial tests, in which the skin essentially always diminishes in lateral directions and usually does not return to its prestress state. Biaxial tests showed that:

1. The stress-strain relationship was extremely nonlinear.
2. Hysteresis was present at all strain levels.
3. Stress-strain relationships were minimally dependent on the strain rate.
4. The relaxation curve did not terminate at the origin and returned to it only after a long period of relaxation.

Reihsner et al. (9) studied the two-dimensional biomechanical behavior of human skin samples from different anatomical sites. Using the *in vivo* geometry of the specimen as reference, a set of incremental strains was applied to the skin. After stress relaxation was completed, the final values of stresses were recorded and related to the incremental strains. Six independent elastic constants were determined. The average deviation of the orientation of maximum principal stress from the direction of the Langer cleavage lines was in the range of angles of -10° to $+10^\circ$. The effect of a directional dependency was most pronounced in skin samples from patella and abdomen. Across a range of ages, Reihsner et al. observed no uniform trend in the principal stresses except that the oldest subject showed the highest principal stresses. The strain necessary to restore the *in vivo* configuration decreased with age in both principal axes of strain. Reihsner et al. suggested that the regional differences in anisotropic behavior could be explained by the different interdigitation between the epidermis and the dermis, the polydispersity of fiber diameter distribution, and the differences in fiber bundle orientation.

Daly (4) conducted tensile tests on specimens oriented at right angles to each other and found that anisotropy is related only to the magnitude of the initial large extension region and the initial low stiffness and the final high stiffness is not orientation dependent. He concluded that the geometry of elastin is not entirely random, as the elastin network determines the initial configuration of the collagen.

In Vivo Studies. *In vivo* tests can be classified as static or dynamic. In static tests, a single modulating stimulus is applied and some resulting change is measured. In dynamic tests, a cyclical stimulus is applied and the initial adapting and final steady-state reactions are monitored. Dynamic tests can provide more information than static tests. However, there is a potentially unlimited combination of frequencies, magnitude, and attachment area. The effects of these parameters on the skin may not be fully understood and may result in difficulties in interpretation of data.

Several techniques have been used to study the mechanical properties of human skin *in vivo*:

1. Tonometric measurements that evaluate the ability of the skin to withstand vertical forces of extension (8).

2. Traction, which applies a linear displacement in the horizontal plane of the skin.
3. Indentation.
4. Torsion, which applies a torque to the skin. The response of skin to shear force can be measured with this device. A device using this technique, the "dermal torque meter," has been commercialized.
5. Suction, which involves placing a suction cup or cylinder on the skin surface and applying a negative pressure to raise a dome of skin. The pressure and the height of the dome are used to calculate elasticity parameters. Two devices based on suction, the Cutometer SEM 474 (Courage and Khazaka, Cologne, Germany) and the Dermaflex A (Cortex Technology, Copenhagen, Denmark), have been commercialized.
6. Elastic wave propagation systems involve measurements of shear wave velocities and the rate at which they are dissipated during their passage in the skin. One study using this technique suggests a probable reduction in skin water content with age (10).
7. Mechanical impedance method. Skin is made to vibrate by a probe over a rectangular frequency spectrum of 20 to 500 Hz after applying a standard preload. One device using this method (DPE, Cotas Computer Technology, Denmark) has been commercialized.

When studying the mechanical properties of skin *in vivo* by such methods, consideration should be given to the contribution of different tissue layers (i.e., dermis and subcutaneous fat). Diridollou et al. (11) reported a device called the "echorheometer," comprising a suction system with an ultrasound scanner. Using this device, the behavior of the dermis and subcutaneous fat under suction was investigated. They observed that there is a certain amount of infiltration of fluid into the tissue under suction. Upon returning to atmospheric pressure, excessive fluid remained in the tissue, which might explain the hysteresis of skin. The authors found that resistance of skin to the applied vertical stress is essentially due to the dermis rather than the subcutaneous fat. The relative contribution of each is not easily evaluated. With high suction pressures applied to large surface areas or low suction pressures to smaller surface areas, the effects on skin cannot be isolated from those of the subcutaneous fat.

Biomechanics of Diabetic Skin Ulceration

The mechanics of skin breakdown under the foot incorporate several aspects described in this article: biaxial skin properties and applied stresses, differing stiffness values within each skin layer, effects of subcutaneous fat, collagen cross-linking and nonlinear, and viscoelastic properties of connective tissue. Although it is recognized that neuropathy and ischemia are primary predisposing factors in the formation of diabetic foot ulcers, an initiating factor, such as physical or mechanical stress, is required for an ulcer to develop (30). For patients with neuropathy, this

mechanical stress need not be excessive, only repetitive, for ulcers to develop.

Brand (31) conducted a series of experiments on rat footpads in which lightly anesthetized rats had one foot placed in a machine that applied repeated intermittent stress to the footpad to simulate a human walking 7 miles. The footpads became swollen after 2 to 3 days, blistered by 1 week, and ulcerated and necrotic after 10 days. In neuropathic animals, the number of cycles that could be tolerated was reduced. Histologic studies on the rats showed inflammation of the footpads after a few days, with small foci of necrosis in areas with large numbers of inflammatory cells. Brand postulated that a similar mechanism occurs in the formation of neuropathic foot ulcers, with a sterile inflammatory autolysis occurring in the subcutaneous tissue due to the repetitive moderate stresses imposed by walking.

The stresses that the foot experiences during walking are vastly different from those encountered by any other skin surface. At the foot-ground interface, a complex combination of shear and pressure exists (32) that could explain why some patients get foot ulcers and others do not. Mathematical modeling of (1) the effects of stresses at the skin/fat interface and (2) the influence of more cross-linked collagen (33) showed that small increases in shear stresses and/or increased skin stiffness had a profound effect on the stresses at the interface between dermis and underlying soft tissue (Fig. 3).

The effects of increased dermal interface stresses have also been assessed in an experimental study (1). In total, 21 diabetic (68.0 ± 2.4 years) and 17 nondiabetic (74.6 ± 3.8 years) amputated foot specimens were tested. The procedure involved peeling strips of skin off the plantar surface of each foot specimen. Each strip was approximately 8 mm wide (in the antero-posterior direction) and 20 mm long (in the medio-lateral direction). While tension was applied via a Materials Testing System (MTS), force and displacement of the loading head were recorded at a sampling rate of 60 Hz. Data across all 38 specimens are shown in Fig. 4.

Within the nondiabetic group, analysis of variance showed that the required forces for removing skin at different sites were significantly different ($p < 0.001$), with the skin-fat interface being significantly stronger

Figure 3. Through finite element modeling of the hindfoot, the predicted effect of diabetes-induced skin stiffening is to increase the stresses at the skin-fat interface by 100% (33).

Figure 4. Combined diabetic and control data showing the forces required to remove skin strips off the plantar surface of amputated foot specimens. These forces are significantly higher ($p < 0.05$) in the forefoot and hindfoot regions compared with the midfoot area (1).

in both the metatarsal head and heel regions than in the midfoot area. These regions also withstand the largest weight-bearing loads during normal locomotion. Neuropathic diabetic patients (who typically have higher plantar pressures) also showed higher strengths at the skin-fat interface than age-matched nondiabetic subjects (1). Every strip (e.g., first strip on medial side, or third strip on lateral side, etc.) for the diabetic group required larger forces to pull it off the underlying soft tissue ($p < 0.05$). Across all skin strips, diabetic specimens required a 20% greater removal force.

SUMMARY

Skin has multiple essential functions ranging from protection against injury or invasion by microorganisms, to a barrier to water loss, to maintaining normal body temperature. It consists primarily of two principal layers—epidermis and dermis—and various sublayers. From a mechanical point of view, these layers have stiffness values that can differ by three orders of magnitude! The area of skin that withstands the greatest daily history of loading—that under the foot—has an interface between the dermis and the epidermis characterized by rete ridges. The precise mechanical function of these ridges is not yet clear. What is known is that this interface is profoundly affected by the magnitudes of shear and pressure loading that plantar soft tissue is required to withstand. Areas that have higher loading (e.g., heel or metatarsal head region) have a dermis that is more tightly bonded to the subcutaneous soft tissue than other regions. In this respect, skin seems to follow the “form follows function” law (or “Wolff’s Law”) that is usually used to describe bone’s adaptation to applied loading. When these loads become extreme (e.g., greater than 1 MPa applied pressure), even the short weight-bearing intervals during gait are sufficient to lead to skin breakdown. The precise site for the initiation of failure (e.g., which layer of skin fails first) has yet to be determined. As skin breakdown under the foot is a clinical problem with significant risks for the patient, it is likely that research into this problem will continue until skin failure mechanisms are better understood. These may then serve as the basis for better prevention or treatment strategies.

SLEEP LABORATORY

RICHARD K. BOGAN
SHAWN D. YOUNGSTEDT
University of South Carolina
Columbia, South Carolina

INTRODUCTION

Sleep is a fundamental, homeostatic process necessary for human existence and quality of life. Sleep disorders account for impairment of alertness (1); cognitive function (2), especially short-term memory and divided-attention tasks (3); mood (4); work productivity (5); and driving ability (and hence, an increase in automobile accidents). Obstructive sleep apnea has been clearly linked to cardiovascular disease.

There are > 80 sleep disorders, which generally increase in prevalence with age. Indeed, > 50% of adults over age 60 years suffer from some sleep-related complaint (6), including daytime fatigue, difficulty initiating or maintaining sleep, snoring, obstructive apnea, insomnia, restless legs syndrome, narcolepsy, or circadian rhythm disorders. Most disorders have attendant morbidity issues. For example, patients with sleep apnea have an increased risk of cardiovascular disease, stroke, and diabetes. Patients with protracted insomnia have

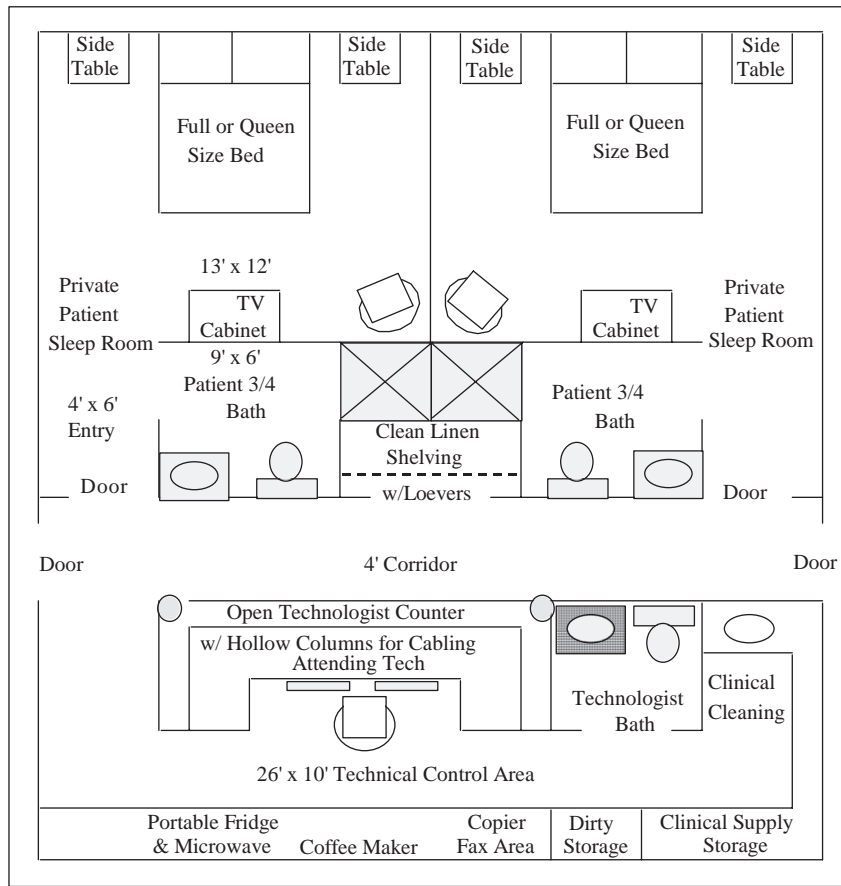

Figure 1. Sample sleep lab layout (26 ft × 32 ft 832 ft² for a two-bed sleep lab).

an increased risk of depression, anxiety, and substance abuse. Many sleep disturbances are secondary to other medical problems, such as nocturia, pain associated with arthritis, and cardiopulmonary disorders.

POLYSOMNOGRAPHIC RECORDING

The traditional evaluation of normal sleep and sleep disorders incorporates the gold standard, nocturnal polysomnography, performed in a sleep clinic or laboratory (Fig. 1). Growth of laboratories has occurred in the last 30 years to 2515 estimated labs, generally located in hospitals. Most current laboratories require a night tech, a scoring tech, a clinician, or a scientist to acquire and process sleep data. Some laboratories are freestanding or exist in private clinics. Contract service entities also provide outsourcing of sleep diagnostics.

The sleep laboratory classically consists of diagnostic bedrooms, accompanied by a central technical area for collection of data, observation of patients, and data processing. Ancillary areas include a business office, exam rooms, a lounge area, a break area, and file storage, much like a clinical practice. Sleep diagnostics for the sleep bedroom are focused primarily on a monitoring EEG to determine sleep states, with expanded measurements to allow quantitative assessment of EEG (see Table 1). The sleep laboratory environment attempts to achieve a bedroom environment,

with the patient interface allowing minimally invasive techniques.

Electroencephalography

The EEG is the fundamental measurement of polysomnography and consists of application of electrodes according to the International 10–20 electrode placement system (7) (Fig. 2). The skin interface is established through cleansing and removal of dead skin layers, with electrode application, typically using an electrode cup with a conductive medium. There are many derivations of electrode placement, but for sleep, typical placements are at occipital lobe sites (O1 or

Table 1. Sleep Laboratory Measures (Possible)

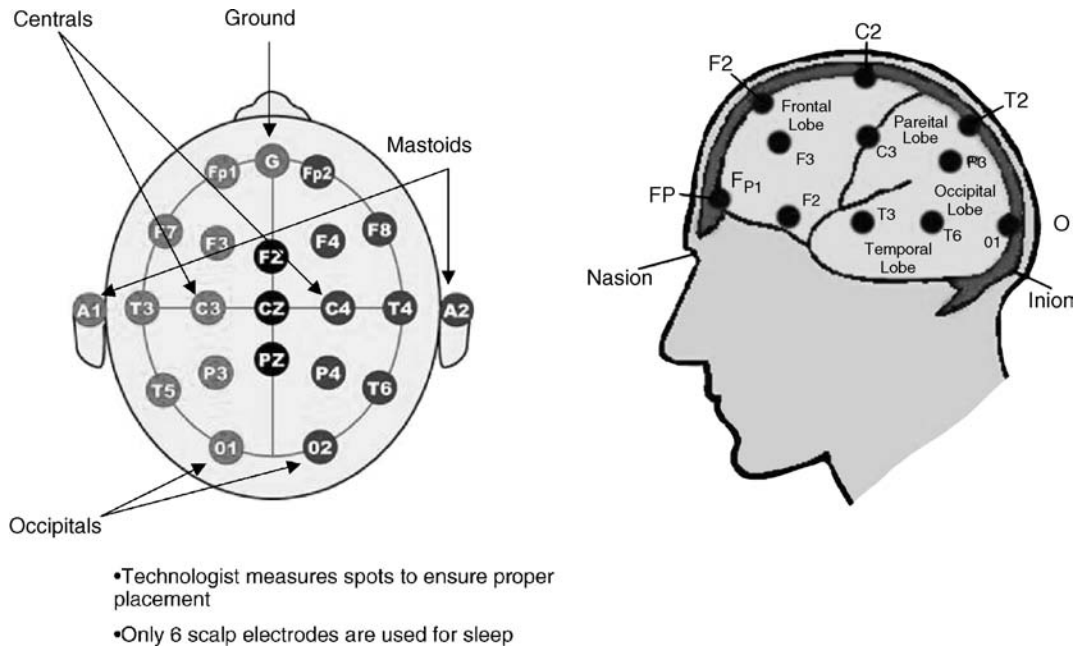

Figure 2. Electrode placement.

O2) with contralateral placement of a reference electrode on the mastoid process or earlobe. This gives the standard O1/A2 or O2/A1 electrode placement. Many labs also incorporate central electrode placement (usually C3/A2 or C4/A1). Occasionally, frontal electrodes are placed. The contralateral reference of electrodes typically allows a high amplitude of EEG signal, enabling adequate measurement of frequency and amplitude information. Normal sleep scoring rules have been based on central electrode placement. Occipital electrodes enhance alpha frequency (8–12 Hz) measurements and frontal electrodes enhance delta frequency (2–4 Hz) measurements.

Full montage EEG electrode placement is sometimes done to enhance the capture of nocturnal seizure activity. This replicates bipolar studies done for seizure monitoring and is especially useful for nocturnal movement disorder evaluation.

Electroculography

The electrooculogram (EOG) is a measurement of eye activity. Phasic bursts of rapid eye movement occur during rapid eye movement sleep (REM sleep). The EOG is important for recognition of REM sleep, as well as for detecting the transition from wakefulness to Stage 1 sleep, which is characterized by slow, rolling eye movements.

The EOG recordings are possible due to a small electro-potential difference from the cornea to the retina. The electrodes are positioned at the right outer canthus (ROC) and the left outer canthus (LOC), eferenced to auricular electrodes. Thus, ROC/A1 and LOC/A2 will register as out-of-phase pen deflections. This facilitates artifact recognition, as well as EEG activity recorded in the eye electrodes. EOG placements incorporate a somewhat superior placement of the electrode on one eye and inferior on the other eye, which allows recognition of vertical eye movements.

Electromyography

Three electromyographic (EMG) electrodes placed in the mentalis–submental area allow detection of EMG activity. During sleep, there is a gradual decline in EMG activity, and the dramatic reduction of muscle tone during REM, makes the EMG an important confirmation of REM sleep. Again, adequate removal of oils and dead skin cells with a conductive electrode placement enhances signal processing.

Electrodes or strain gauge sensors are also commonly placed on the tibialis muscles (Fig. 3). The EMG and movement signals from the lower extremities, and sometimes the arms, allow measures of isolated movements, as well as periodic limb movements that may be seen in restless legs syndrome, periodic limb movements of sleep, REM behavior disorder, seizures, parasomnias, and other disorders.

Figure 3. Electrodes applied to legs.

Figure 4. Technologist monitors through the night.

Other Measures and Filtering of Signals

Other biological measures have been incorporated into the polysomnographic measurements. These include body position, body movement, transient arousals, respiratory abnormalities, heart rate, oxygen saturation, esophageal pH, and esophageal pressure.

Video monitoring, as well as audio monitoring, are desirable features and occur in most laboratories. Video recordings with infrared or low light allow correlations of behavioral states with the physiologic measures.

The multiple channels of biological data are gathered in a bundle of electrical wires (the ponytail) at the back of the scalp. The electrical signals require signal processing, amplification, filtering, monitoring, and subsequent collation. The impact of signal output, sampling rates, filtering, and video recording are all factors in the design and in the monitoring of the patient (Fig. 4), as well as scoring information that is processed according to peer-reviewed criteria and event definitions.

The essential measurements in a sleep laboratory involve sleep staging (described below) and this requires calibration, with close attention to signal amplitude and filtering. Frequency measurements ranging from 2–50 Hz are common for measurement of EEG signals. The EMG signals have much higher frequency and sample filtering usually up to 75 Hz, with a notch filter at 60 Hz used to reduce alternating current noise. Signals <10 Hz are usually filtered for an EMG signal.

SCORING AND INTERPRETING PSG

Sleep Staging

Standard sleep stage scoring is guided by Rechtschaffen and Kale's scoring rules (8). The standard EEG recording is negative-up with amplitude measured from peak to valley of the waveform. Delta rhythm is 2–4 Hz; theta is 4–8 Hz; alpha rhythm is 8–12 Hz; beta rhythm is 13–30 Hz; and gamma is >30 Hz. Sleep is scored in 30 s epochs, with a chart speed equivalent to 10 mm·s⁻¹. The EEG, EOG, and EMG signals are necessary for sleep state assessment and are used to study clinical and research physiology, as well

as pathologic processes. The epoch is scored based on the majority population of EEG/EOG/EMG activity during the 30 s epoch.

Sleep is thus staged as non-REM sleep Stages 1, 2, 3, and 4 and REM sleep. The data are collated in both graphic, as well as tabulated, form to present information from lights-out to sleep onset, as well as quantifying total sleep time, time in bed, sleep efficiency (sleep time divided by time in bed), wake after sleep onset, and sleep stage distribution. A sleep histogram of the night of sleep summarizes the stage distribution pictorially.

Special rules are established for movement, arousals, and periodic limb movements in sleep, as well as consideration for specific disease processes. For example, narcolepsy may be associated with excessive motor activity during sleep, with an elevated EMG amplitude, particularly during phasic rapid eye movement sleep. Obstructive sleep apnea patients may have <15 s of sleep during a 30 s epoch due to arousals from obstructive events, forcing the scoring of the epoch as awake. Special rules to allow for these variances are in place.

Sleep-Disordered Breathing

Abnormal breathing during sleep is one of the most common disorders and accounts for as much as 70% of patients presenting to a sleep laboratory. Some laboratories specialize in sleep-disordered breathing alone. Snoring with increase in upper airway resistance due to functional relaxation of dilator muscles in the pharynx is a common disorder, ranging from 20% to 40% of the adult population and 13% of children. Anatomic changes, particularly tonsillar hypertrophy, add to the increase in upper airway resistance. This increase in the work of breathing may cause unstable breathing, with episodes of apnea or hypopnea, with associated changes in oxygenation, autonomic tone, and sleep state.

Obstructive apnea is defined as 10 s of cessation of airflow, despite a continued effort to breathe, in the adult population. Hypopnea is defined as a discernable reduction in flow or effort that produces a 4% desaturation. Central apnea is cessation of flow associated with cessation of effort for at least 10 s in the adult population. In the pediatric population, the duration for defining apneas is shorter. In some laboratories, hypopneas are also defined as a discernable reduction in flow or effort, which terminates in a 3% desaturation or an arousal. Mass loading of the diaphragm due to obesity and intrinsic central nervous system regulation of breathing are other variables to be considered clinically, as well as in research.

Current laboratories monitor flow, effort, and oxygen saturation as surrogate measures of minute ventilation and gas exchange. The intent is to assess the effort to breathe, the results of the output of ventilation, and, ideally, gas exchange, especially O₂ content or oxygen saturation. These measurements along with clinical correlation provide risk assessment and guide treatment plans.

Methods to detect airflow include pneumotachography, nasal airway pressure, thermistors, and thermocouples, as well as expired CO₂. Nasal airway pressures resemble the signals from a pneumotachograph, and therefore give a

Figure 5. Sleep setup with respiratory belts.

qualitative measure of increase in upper airway resistance. The pressure gradient intranasally compared to ambient atmospheric pressure is used to calculate the flow. Effort signals may be generated by flexible bands around the chest and the abdomen to detect movement. This is the most common technique (Fig. 5). Strain gauges, impedance pneumography, inductance plethysmography, and intercostal muscle electromyography have been used. Snoring sensors include microphones and piezoelectric assessment of vibration.

Oxygen content is most commonly measured by pulse oximetry. Decrease in oxygen saturation during sleep is most commonly due to changes in ventilation. Oxygen desaturation is an important criterion for scoring respiratory events, and thus critical for diagnostic studies. Intrinsic lung disease or cardiac disease may produce ventilation-perfusion mismatch and may also produce decreases in O_2 saturation. In a stable state, however, most decreases in oxygen saturation reflect changes in minute ventilation.

Pulse oximetry uses a two wavelength light transmitter, using spectrophotoelectrical techniques based on oxyhemoglobin absorption. Pulsatile tissues are necessary for pulse oximetry, and therefore these are usually applied to the finger, earlobe, or nasal sites. Reduction in pulsation, skin pigment, and dyshemoglobinemias may interfere with signal processing. The sampling rate, filtering, and proprietary algorithms for signal processing may affect the resolution of the signal.

Transcutaneous oxygen and carbon dioxide are other techniques available, but they are not commonly used, except in neonates. Transcutaneous CO_2 may be useful to assess chronic hypoventilation, but the resolution time for these measures limits their use in routine polysomnography.

Esophageal pressure measurements using an esophageal balloon provide a highly accurate measure of intrapleural pressure and, therefore, work of breathing. Some sleep centers use esophageal pressure measurements; however, this is not routine, as the invasive technique disturbs sleep. However, esophageal pressure measurements enhance the ability to measure upper airway resistance syndrome and central alveolar hypoventilation.

Cardiac data primarily consists of heart rate and rhythm. Limited EKG electrodes, equivalent to lead II (right arm–left arm) or precordial leads (V5 or V6) are used, depending on the electrical axis and lab protocol. Clinical studies focus on high, mean, and low heart rates, as well as semiquantitative data on arrhythmias as to frequency and type. These are correlated with respiratory events or sleep state.

In patients with obstructive sleep apnea, efficacy of treatment is measured by applying positive airway pressure (PAP) or bilevel positive airway pressure (BiPAP). Flow signals are generated from the hardware device, allowing quantitative measures of flow and upper airway resistance based on waveform characteristics. Sleep state, body position, oxygen saturation, electrocardiogram, flow, and effort data are recorded to assure proper titration. The goal is to reduce the respiratory disturbance index, ideally < 5 , and to minimize oxygen desaturations.

Daytime Sleepiness

Objective assessment of daytime sleepiness is another important laboratory diagnostic measure. The multiple sleep latency test involves a series of nap opportunities at 2 h intervals during the day. The standardized technique and normative data facilitate objective measures of excessive daytime sleepiness. This test is primarily used in the diagnosis of narcolepsy. The maintenance of wakefulness test is similar to the multiple sleep latency test, but requires the individual to attempt to remain awake during 20 or 40 min nap opportunities in a dark room.

Treatment Guidelines. Practice-based guidelines by the American Academy of Sleep Medicine and medical specialty societies have established guidelines for diagnosing and treating sleep disorders. These can be accessed on their website (www.aasmnet.org).

ADDITIONAL AMBULATORY MEASURES

Alternative or ancillary devices have been developed, primarily in the area of sleep-disordered breathing and brain state (sleep–wake estimate). Screening devices have been developed for obstructive sleep apnea primarily. Portable outpatient systems for unsupervised polysomnography are available. The unattended study is considered a level II evaluation. Level III is portable sleep apnea testing, monitoring airflow, effort, electrocardiogram, and oxygen saturation. Level IV is arterial oxygen saturation measurement alone.

Actigraphy incorporates an accelerometer used to measure wrist movement. Complex algorithms have been developed to estimate sleep/wake state, periodic limb movements, and circadian rhythm abnormalities. Actigraphy is particularly useful for long-term monitoring of patients in their homes, and for detection of daytime napping, which is usually not possible for EEG, as it is restricted to the night.

DIGITAL PGS AND FUTURE TRENDS

The EEG, EOG, and EMG signals were traditionally recorded in a sleep laboratory with limited channels on

analog systems, with pen deflections recorded on paper. Digital recording systems are more often used now, replicating a chart-paper speed of $10 \text{ mm} \cdot \text{s}^{-1}$. Digitized signals with current hardware and software systems allow enhanced collation of data, increased numbers of channels, enhanced filtering, and the potential for automated analysis. Archiving, data compression, and feature extraction are also possible.

Digitized signals of the ECG with high sampling rates, preferably at 200 Hz or higher, provide an opportunity for high resolution analysis. High resolution analysis might provide clearer insights into autonomic tone and vascular resistance and, the influence of sleep states, pathological conditions, and transient arousals. Further development of quantitative measures of ventilatory response, changes in gas exchange, as well as central nervous system and cardiovascular changes, could be helpful for diagnosing and treating sleep-disordered breathing.

Software processing collates data, presenting information in a tabular, as well as in a graphic, format. Clinicians and scientists review raw data, as well as human-supervised or scored changes. These changes can produce an audit trail referenced to the raw data. The fields of data can populate an electronic medical record, as well as a database, including demographics, comorbidities, medications, and fields of data from the polysomnogram, as well as the final diagnosis, treatment, and outcome measures.

Conceivably, advanced EEG analysis might reduce interscorer variability, thus better defining state and process. Enhanced resolution of EEG with improved consistency might allow better feature extraction, such as transient arousals and continuity measures that may improve research and clinical care. This could significantly improve the efficiency, cost and safety in drug development.

Opportunities for the future in sleep diagnostics are numerous. The duration of a polysomnogram, as well as long-term EEG monitoring, create challenges in the quality of the signal. Improvement of electrode-skin interface and conductivity are desirable. Application of wireless technologies to minimize the ponytail bundle of wires would be extremely useful. Audiovisual monitoring quality, advanced respiratory analysis, high resolution cardiac assessment, technical acquisition, collation, and data management are all current challenges.

INTRODUCTION

Human beings spend approximately one-third of their lives asleep. Prior to the advent of physiological records, technology, and digital computers, our understanding of this ubiquitous phenomenon was based on observations of people or animals sleeping. Yet, this observational approach placed severe limitations on our understanding of the functions of sleep and the neurological processes that underlie this apparently quiescent period. It was because of several major scientific developments, all of which occurred during the twentieth century, that the concept of sleep as an active process (rather than a passive one) became appreciated, making the advent of modern sleep medicine possible.

Sleep was generally regarded as a passive process, “. . . the intermediate state between wakefulness and death. . .” (1). In 1939, University of Chicago physiologist Nathaniel Kleitman published a monograph “Sleep and Wakefulness” based on observations of human subjects who were sleep deprived. He determined that sleep may be viewed as a “let down of waking activity” and that “there may be different kinds of wakefulness” (2). In the 1950s, Kleitman and his students, Aserinsky and Dement, went on to describe rapid eye movement sleep (REM) in humans and the relationship between REM and dreaming (3,4). To follow up on the earlier work of, Dement and Kleitman (5) undertook a particularly ambitious project, considering the available technology. They recorded the electroencephalogram (EEG) and electrooculogram (EOG) continuously from 33 subjects for a total of 126 nights. Recordings were all done on paper and manually scored. This work revealed that sleep had an architecture and that the EEG showed cyclical variation throughout the night. REM periods occupied ~20–25% of sleep. Dement and Kleitman characterized sleep stages as they are known today and determined that sleep consisted of two distinct states (REM and non-REM), neither of which could be considered as a time of brain inactivity.

Importantly, the foundation for this work was the recording of the human EEG in 1928 by Berger who showed that there were differences in the rhythm (or EEG frequency) when subjects were awake or asleep. Berger’s work allowed, for the first time, the EEG to be monitored continuously during sleep without disturbing the individual. Hobson (6) suggested that Berger’s work was the turning point of sleep research. Much of what is known about the EEG characteristics of the different stages of sleep was described in the 1930s. Further, it was determined that sleep was an active process that involves the synchronization of a number of neurological systems.

Perhaps one of the most important events in the history of sleep medicine was the discovery of sleep apnea by two separate groups in France and Germany in 1965. Narcolepsy and complaints of insomnia by patients further spurred the development of sleep centers that monitored patients’ physiology as they slept. According to Dement (7), the “consolidation and formalization of the practice of sleep disorders medicine was largely completed” (p. 13) at the end of the 1970s. This labor intensive all night monitoring of patients was done without the benefit of digital computers, which did not become generally available for over a decade.

The purpose of this article is to discuss the use of computers in sleep disorders medicine and how this technology has enhanced the diagnostic and scientific capabilities of the sleep laboratory. The focus of the remainder of this article is on the computer analysis of the data obtained during polysomnography.

INTEGRATION OF COMPUTERS INTO POLYSOMNOGRAPHY

Over the years, and in particular with the development of the digital desktop computer, tools for studying sleep have

advanced rapidly. Polysomnography (PSG), a term coined in 1974 by J Holland at Stanford University, allows for the assessment of sleep by simultaneously measuring multiple physiologic parameters. These parameters generally include EEG, EOG, electromyogram (EMG), electrocardiogram (ECG), respiration (both effort and air flow or pressure), blood oxygenation, and body–limb movement (8).

The results of an 8 h PSG can consist of >1000 pages (depending on the paper speed, or epoch length (e.g., 10, 15, 30 s) of data from multiple recording channels, making manual and visual interpretation a difficult and overwhelming task (9). Typically, each page (e.g., 30 s) of the recording was examined and sleep stage was determined based on the Rechtschaffen and Kales scoring system (10). Depending on the reason for the study, respiratory events such as nasal–oral air flow and respiratory effort, as well as blood oxygen saturation, were frequently recorded. Paper speeds were used so that each page of recording represented a 15–30 s epoch over the full night. So, for example, for a 7 h study and a paper speed set at 30 s epochs, there would be 840 pages of data to review. Scoring was done during the day after the study was completed and, as noted, each page was examined not only for sleep stage, but for changes in other measures including respiration, oxygen saturation, and limb movements. These events, along with stages, were manually tabulated and summarized. For clinical studies, each record was reviewed by the polysomnographer or sleep specialist and a report was composed that summarized the major diagnostic aspects of the study. For research purposes, variables of interest were entered into a data base for later analysis.

The development of digital computers (in particular the PC), their general availability, and the evolution of software for these systems specifically designed for the collection, storage, and manipulation of sleep data have played a significant role in the growth of the field of sleep medicine, and insights into sleep, in general. The vast amount of data collected from a full night sleep study can now be rapidly consolidated, allowing for comprehensive visualization of the measures obtained. Summary statistics pertaining to the sleep data recorded during the night are also obtained and easily accessed with the commercial computer data acquisition and analysis systems available for sleep studies. For example, once data are collected in an all-night study, the study can be examined over a variety of epoch window sizes from 10 s up to the thousands of seconds required to represent the entire study as one epoch. The ability to change the epoch window width allows for evaluation of different waveforms (e.g., EEG, respiration) using an optimal time scale. Further examples of sleep analysis software capabilities are presented below. By using such sleep systems, many laboratories that focus on the diagnosis of sleep disorders are now able to study as many as 6–10 patients in a single night.

COMPUTER ANALYSIS OF POLYSOMNOGRAPHIC DATA

Stages of Sleep

Sleep can be dichotomized into REM sleep and nonrapid eye movement (NREM) sleep (11). The NREM sleep can be

Figure 1. Illustration of Stage 1 sleep in Patient C. Epoch width and recording channels are the same as those in Fig. 1. Note the slowed eye movements (arrow).

further divided into four stages, according to rules established by Rechtschaffen and Kales (R&K) (10). The following outlines these stages and summarizes the major criteria that characterize them. *Stage 1 Sleep, illustrated in Fig. 1*, consists of a relatively low voltage EEG, with activity prominently from 2 to 7 cycles per second (Hz). Waves at this frequency are referred to as theta waves (12). Rapid eye movements are not present and eye movements are generally slow and rolling. This stage typically occurs during the transition from wakefulness (seen in Fig. 2) to the other sleep stages, and is relatively short. *Stage 2 Sleep, illustrated in Fig. 3*, is marked by K complexes and sleep spindles on a background of relatively low voltage EEG. The K complexes are negative, sharp, high voltage waves that are usually followed by a positive component. The complex duration, according to the R&K rules, should not exceed 0.5 s. The K complexes can occur spontaneously or in response to sudden stimuli and they are highest in amplitude over the vertex scalp regions (10,11). Sleep spindles are defined as “bursts of waves having a frequency of 12 to 15 [Hz]” (11, p. 16). In addition to the K complexes and sleep spindles, Stage 2 sleep lacks waves of high amplitude and slow activity seen in later stages (10). *Stage 3 Sleep, illustrated in Fig. 4*, is defined by delta waves, or slow waves of 2 Hz or less and amplitudes $>75 \mu\text{V}$ (11,12). The EEG activity in Stage 3 should account for 20–50% of the time interval (epoch) studied (10). Sleep spindles may or may not be present. *Stage 4 Sleep, illustrated in Fig. 5*, is defined when $>50\%$ of the epoch consists of high amplitude waves that are 2 Hz or slower.

Stage REM, illustrated in Fig. 6, typically occurs after the first 70–100 min of sleep. Rapid eye movements characterize this stage of sleep. The EEG during REM sleep is similar to a waking or Stage 1 EEG, with low amplitude mixed frequency waves. If eye movements and EEG activity were the only available data by which to characterize this sleep stage, one would suspect that the person was likely awake. It is because of the similarity to wakefulness that REM sleep has often been called paradoxical sleep. Other significant features of REM are as follows: saw tooth waves that may or may not be present in conjunction with bursts of REM activity, the lack of sleep spindles, and mental–submental EMG that is almost always lowest during REM than that seen for other stages of sleep. After REM sleep, there is generally a cycling through Stages 2, 3, and back to 4. These cycles continue throughout the night (11).

Computer Identification of Sleep Stages

Manual scoring of the various sleep stages is a tedious and time-consuming task, with interrater reliability between 67 and 91% (13). As such, both research and clinical laboratories have explored the use of computers to objectively classify these stages. Initial attempts at automating sleep analysis concentrated on programming computers to identify sleep stages according to the R&K rules. However, newer methods have focused on pattern recognition of distinct sleep stages (13,14).

One method, the polysomnogram assay (PSGA), was developed by Bartolo et al. (9), and condenses the large

Figure 2. Example of a 30 s epoch of wakefulness from patient C being evaluated for a sleep disorder. The labels on the left indicate the measures at each channel of recording. The first two channels are EEG from the left central and left occipital scalp sites. LOC and ROC = left and right eye movements followed by chin EMG, nasal/oral air flow, thorax and abdominal respiratory effort, oxygen saturation, electrocardiogram, average pulse, left and right leg movement. Labels on the right indicate the patient's body position, average oxygen saturation (not shown), average pulse rate, level of continuous positive or bilevel air pressure (CPAP/BIPAP), if administered.

Figure 3. Illustration of Stage 2 sleep in patient C. Epoch width and recording channels are the same as those in Fig. 2. Note the K complexes (arrow Channel 1) and sleep spindles (arrow Channel 2).

Figure 4. Illustration of Stage 3 sleep in patient C. Epoch width and recording channels are the same as those in Fig. 2. Note the high amplitude slow EEG waves and the sleep spindles in EEG channels 1 and 2 (arrow).

Figure 5. Illustration of Stage 4 sleep in patient C. Epoch width and recording channels are the same as in Fig. 2. Note the high amplitude slow EEG waves in EEG channels 1 and 2 (arrow). This slow activity occupies >50% of the epoch.

Figure 6. Illustration of Stage REM sleep in patient G. Epoch window and recording channels are the same as in Fig. 2. Note the low voltage EEG in EEG channels 1 and 2, the rapid eye movements in eye channels 3 and 4 (arrow), and the low amplitude chin EMG in channel 5.

amount of PSG data into a more comprehensible format while retaining events of diagnostic significance. The program allows gross distinction among sleep stages without manually scored data. However, because features associated with each sleep stage vary among individuals, the investigators noted that “it is unlikely that adequate sleep staging in the traditional sense can be accomplished by the PSGA or any other method except by visual analysis of the PSG itself” (p. 119). Nonetheless, the PSGA is able to present consistent patterns related to different sleep states, and with refinement may be useful for sleep staging. Two examples of how the data are consolidated are seen from the descriptions of leg and eye movements. Leg jerks appear as “abrupt peaks” (p. 121) in the EMG window assigned to leg movements. The EMG variables are represented by signal intensity or power. According to these investigators, periodic leg movements are more visible in the PSGA than in the PSG record. Additionally, the PSGA replaces the PSG EOG signals by markers that indicate the presence and intensity of eye movements. Thus, the PSGA transforms the data into events or markers appropriate for each type of measurement and displays these measures in a highly condensed format, allowing for up to 15 min of PSG data to be displayed on a single page. This method reduces the output from nearly 1000 pages to ~30. The purpose for the development of the PSGA was to “reduce the considerable human effort involved in scoring and evaluating PSG studies” (p. 124). This approach exemplifies how computers can assist in analyzing sleep, maximiz-

ing the amount of time polysomnographers can have for diagnosis and understanding unusual aspects of the sleep study that computers can only identify.

Agarwal and Gotman (13,15) described a computer assisted sleep staging method, which searches for clusters of wave patterns that have been identified and programmed as prototypes of waves or sleep stages. In this method, the PSG is first divided into multiple segments, containing at least 3 s of data. Second, prespecified features, such as sleep spindles and eye movements, are extracted by the computer from the PSG. Also, each epoch is examined for the different types of waves, including alpha and slow waves (delta, theta). After the data have been segmented and extracted, they are then “clustered” into groups with similar properties. These clusters can then be classified as particular sleep stages according to R&K or any other system preferred by the user. It appears that the approach taken by Agarwal and Gotman (13,14) relies on a self-organizational scheme that is based on relative differences in activity within a subject rather than fixed rules. So, for example, according to these investigators, stage REM sleep may be lost if hard thresholds for detection of atonia are used. This is the first study that has applied “self-organization[al] techniques to generate a hypnogram for an all night PSG in the context of R&K classification” (p. 1419). Agreement between automated staging and manual scoring according to R&K standards was 80.6% for 12 sleep records. This process uses the computer to initially analyze the data and identify various sleep

stages before it is inspected manually by a polysomnographer. Since this method is not fully computer automated, but is computer assisted, the investigators referred to this approach as "computer-assisted sleep staging (CASS)."

Because sleep stages are not distinct entities, computer errors are made. Empirical studies confirm that, despite our best effort to demarcate sleep stages for computer detection, errors occur, especially for the less clearly defined stages (13). For example, Agarwal and Gotman (13) reported that many errors occur when attempting to define Stage 1 sleep, perhaps the most ambiguous, which was often misclassified as either wakefulness or Stage 2 sleep. For computers to identify components of sleep, these components must be clearly defined. At present, the best defined features of sleep are the various stages according to the R&K rules. Some of these rules are specific enough for an algorithm to be programmed so that a computer can identify it on a polysomnogram. For example, Stage 3 sleep is defined by delta waves with amplitudes $>75 \mu\text{V}$, present between 20 and 50% of the time. Other definitions are less precise, such as the definition of Stage 2 sleep, which is marked by sleep spindles, K-complexes, and waves that lack the amplitude and slower activity seen in sleep Stages 3 and 4. Stage 2 sleep is more difficult to quantify and, therefore, less amenable to detection by computers.

Computer Analysis of Sleep Microstructure

From a more academic, less clinical, perspective, computers have been used to assist with analysis of the microstructure of sleep, such as parsing out the various components of specific waves (e.g., sleep spindles, K complexes) and exploring their relationships to various sleep problems. Although the presence of sleep spindles in Stage 2 sleep is well known, the different types of spindles and their subsequent spatial distribution are less well studied. With the aid of computers, two types of spindles have been identified: 12 spindles per second located primarily in the frontal region and 14 spindles per second located primarily in the centroparietal region (14). Our understanding of K complexes has also been improved with the aid of computers. Specifically, a classification of K complexes has been recommended, that includes K0 complexes (without sleep spindles), K1 complexes (spindles preceding the K complexes), K2 complexes (spindles occurring simultaneously with the K complexes), and K3 complexes (spindles following the K complexes (14)).

Computers have also been used to assess new components within the stages of sleep (e.g., slow wave sleep and REM sleep). Initially, slow wave sleep was defined as sleep marked by delta waves, occurring during stages 3 and 4. Delta waves were believed to be uniform, with no variable components. However, with the aid of computers, two types of these waves have been identified with scalp topographical differences. Sinusoidal $1\text{--}2 \text{ s}^{-1}$ delta waves tend to be located frontally, and have been compared to K complexes that are not precipitated by sensory stimuli. Polymorphic $<1 \text{ s}^{-1}$ delta waves, on the other hand, are located parietotemporally. The role of these components is presently unclear. Our understanding of the microelements of REM sleep is also being explored. For instance, although saw-

tooth waves have been linked to REM sleep, their function is poorly understood (14). Only since the advent of computers have such microelements of the various stages of sleep been able to be identified, and is it only possible to study these components with computers in order to understand their functions and their possible contribution to sleep disorders.

A PROTOTYPICAL COMMERCIAL SLEEP ACQUISITION, ANALYSIS, AND MANAGEMENT SYSTEM

Although, computers do not eliminate errors in scoring sleep stages or various waves, they do substantially increase our ability to measure more aspects of sleep and to organize and reduce the data so that they are more readily interpretable. Digital polysomnography has become an important means of sleep analysis today. An important advantage is probably that the tracings can be zoomed in and out. While the EEG is best displayed on a high resolution monitor with 10–15 s per page (s/p) and 20–30 s/p is sufficient for sleep staging, respiratory-related signals and body movements can best be recognized at 2–10 min/p. The correlations between slight respiratory changes and EEG arousals are sometimes best observed with a 2 min page. Thus events that often remain undetected by the conventional paper method can be visualized. Consequently, the paper method is not an optimal method or a good alternative for a "gold standard". The possibility of adjusting the gain off-line is also valuable. However, the low dynamic range provided by many manufacturers set unnecessary limits. Eight-bit A/D conversion is still used in many systems, which gives a resolution of only 256 points. The introduction of 24 bit resolution in modern equipment has allowed for same amplifiers and gains to be used for practically all signals.

Computers also can provide summary statistics from data obtained over the entire night of recording. One frequently used commercial computerized sleep system allows up to 64 channels of recording. Computer algorithms are available that will detect significant changes in EMG, EEG, respiration, and heart rate. These programs are dependent on people to set criteria based on specific standards of what constitutes an event, such as an arousal, an obstructive apnea, hypopnea, a bradycardia, and a tachycardia.

In order to provide the reader with an appreciation of the state of the art in sleep study computer technology, one of the systems used by many sleep laboratories, including our own will be described next. The software runs on most PCs and is designed to collect, store, analyze, summarize, and manage the large amount of physiological data obtained during an all night sleep study. This system, with its appropriate amplifiers, digitizes the electrical voltages obtained from the various sensing devices, such as electrodes applied to the scalp, face, and chest. After these data are collected and saved, the software provides a number of analytic tools and modules that allow the polysomnography technician/polysomnographer to reduce and quantify the data. As described by the manufacture (Sandman Sleep Diagnostic Systems), the software consists of four main

components: (1) *Data Collection*, for recording and saving the signals obtained from the patient. (2) *Analysis*, for scoring and analyzing the data saved from in the patient file. Computer assisted scoring modules are part of this component. (3) *Data Management*, used for file manipulation such as copying, backing up, and deleting patient data. (4) *Configuration*, provides the user with the ability to manipulate some of the features of the software, change the storage media, and so on.

Figures 2–6 illustrating the stages of sleep are examples of the data obtained in our laboratory with this system. These figures represent epochs or time periods of the actual, data collected during an all night polysomnogram. Figure 7 presents sleep data from a patient with obstructive sleep apnea. Apnea is characterized by a cessation of airflow for 10 s or longer. Obstructive sleep apnea in contrast with central sleep apnea is caused by an actual obstruction of the airway and is characterized by a cessation of air flow, arousal, and increased effort to breathe (Fig. 7). Hypopnea is also an obstructive event, but the obstruction is not complete. It is generally defined by a reduction, without complete cessation, in airflow or effort (16). There are several criteria that laboratories have used to define an event as hypopnea. For example, with respect to air flow, both a 50% and 30% decrease from baseline air flow have been used. The EEG arousals and amount of oxygen desaturation have also played a role in the definitions of obstructive respiratory events. These criteria, used to define respiratory events, are all entered into the sleep scoring program so that the computer using the appropriate definition can select these events automatically. In

addition, a polysomnographic technician reviews the entire sleep study and manually stages and confirms the relevant events. Once stages and events are reliably identified, a number of calculations are made via computer algorithms that summarize the information obtained over the sleep study. Figure 8 is an illustration of how data obtained over an entire night of sleep are summarized.

Software programs can now provide a report format that consolidates the information from the entire 6–8 h study once criteria are specified for relevant events by a sleep technician or polysomnographer. Such information can include measures of sleep efficiency, percentage of time in various sleep stages, the number of respiratory disturbances, the number of arousals, and other aspects of sleep, in order to accurately diagnose sleep disturbances. Figures 9 and 10 present a numerical summary and graphs of the data obtained for a patient being evaluated for sleep apnea. The system allows each laboratory to customize their own summaries and graphs with those variables they wish to send to the clinician along with the diagnostic interpretation. Note in Fig. 9 the patient’s respiratory disturbance index (RDI) during REM sleep is 19.6 h^{-1} . Thus, this patient, during their total time in REM sleep, had an average of 19.6 respiratory events in one hour of REM.

As indicated, all of these processes are semi-automated and under the watchful eyes of trained polysomnography technicians and sleep specialists. The degree of automation is dependent on the reliability of the measure. As would be expected, sleep staging is less automated than the detection of awakenings or arousals. The most automated

Figure 7. Illustration of obstructive sleep apnea in patient M. Epoch window is 120 s. Recording channels are the same as in Fig. 1–6. Arrow indicates EEG arousal following the event.

Figure 8. Illustration of computer summary of nocturnal polysomnogram for patient M. Note the oxygen desaturations (SaO_2) associated with respiratory events (Respiratory Module). Periodic limb movements (PLM Module) were not present.

processes are those that involve specific calculations derived from the data collected during the sleep study. For example, the calculation of the overall RDI is the total number of respiratory events that occurred over the entire sleep study divided by the number of hours of sleep.

A tool available on the system, more for research than clinical evaluation, is the fast fourier transform (FFT). FFT is a mathematical analysis of a wave form that derives a frequency spectrum over time. The software displays a signal as a function of amplitude on the y axis versus time on the x axis. The module will perform this transformation on data of interest and write the results to a specified file. Frequency spectral analysis is also available for data reduction of EEG activity. For example, sleep spindles and EEG activity, such as alpha, beta, delta, and theta, can be summarized by plotting the signal amplitude on the y axis versus the frequency of the signal on the x axis. However, the utilization of fixed frequency bands can give misleading results. The bands can be too wide, too narrow, or displaced. Alpha activity of drowsiness and sleep is often on the border between alpha and theta (17) and the frequency of the sigma spindles can have a frequency in both the alpha and the beta range (18). Ideally bands should not be preselected. Rather, bands should be adjusted according to the signal. Martens et al. (19) applied matched filtering based on information obtained by FFT for this purpose. Another attempt to solve the problem is to study very narrow frequency bands and their relationships (20).

The accuracy of frequency analysis is also dependent on sampling rate. Often frequency is understood as an equivalent to the inverse of the baseline-crossing interval of a

wave. However, in spectral analysis it is defined by the frequency content of the signal. With FFT the Nyquist theorem states that the sampling rate has to be at least twice the frequency of the fastest sine waves. However, EEG rhythms are often not sine waves and thus include frequency components that are both faster and slower than the frequencies calculated on the basis of their baseline-crossing intervals. Thus, in order to preserve the form of the waves, higher sampling rates have to be used. Also, the accuracy of baseline-crossing is dependent on the sampling rate. Thus, if the maximum frequency of a sigma spindle is 16 Hz, then a sampling rate of 1024 Hz is required in order to obtain an accuracy of at least 0.25 Hz.

LIMITATIONS OF THE USE OF COMPUTERS TO ANALYZE SLEEP

Despite the overwhelming contribution of computers in analyzing and furthering our understanding of sleep, limitations exist. Such limitations are expected when computers are relied on to explain a complicated, biological process. In fact, both intra- and interindividual variability contribute to the challenge of quantifying components of sleep, such as sleep stages or waveforms. The separation of wakefulness and stage REM is, in some systems, very dependent on the quality of the EMG recording. Because separation of REM and wakefulness is often difficult due to the considerable variation in the EMG activity level obtained for each stage, human supervision and adjustment of detection levels are necessary in practice.

Figure 9. Illustration of a sleep study summary. The values are calculated by specific computer algorithms and represent, in this case, data obtained over ~7 h of recording. This summary accompanies the diagnostic interpretation of the study that is forwarded to the patient's clinician.

Computer analysis is also often dependent on measurement of the wakefulness alpha activity, which causes problems with low alpha subjects. In this case, it is an advantage to rely on theta activity and non-EEG waveforms (21,22). Also, the distinction between REM and NREM sleep is difficult in patients with poor sigma spindles or if the spindles are of a frequency outside the usual range (18). Toussaint et al. (23) discussed the first-night effect in sleep studies, noted by lower sleep efficiency, increased wakefulness, and longer REM periods in patients. Computer algorithms have been difficult to derive that can take into account the first-night effect in individuals because it is relative to the person's normal sleep rather than referring to objective, specific changes in sleep across all individuals.

Interindividual differences in sleep measures have also been demonstrated. For example, variability in polysomnograms has been associated with both gender (24-26) and

age (27,28). For example, Stage 4 sleep presents differently in a young child than it does in an adult (28). Older adults have lower amplitude delta waves than children. Although this is a broader issue regarding the definition of Stage 4 sleep across the age range, it is also illustrative of the difficulties in standardizing automated computerized sleep staging systems. A computer must be programmed to specifically identify such sleep variability for fully automated scoring to be accurate. Furthermore, studies also show marked variability between various patient populations, with different polysomnograms seen for patients with schizophrenia (29,30), autism (31), and attention deficit/hyperactivity disorder (32). Thus, one issue with computer automated sleep scoring is how automated can or should the process be? Computers can only accomplish what they are programmed to do (27), and errors will occur due to artifacts or unexpected events (15). This issue was highlighted in a study by Cirignotla et al. (33) in which they

Figure 10. Illustration of graphs representing the numerical data presented in Fig. 9. These graphs are automatically plotted by the computer. The specific format is designed by the laboratory. Note that this patient, for example, has a significant positional component to their sleep apnea. As indicated in Fig. 9, the Supine RDI is 13.7 h^{-1} compared to a nonsupine RDI of 0.0 h^{-1} .

investigated the MESAM 4, a computerized, ambulatory cardiorespiratory monitor that can help diagnosis sleep apnea. However, the investigators found that this computerized system significantly underestimated the oxygen desaturation index in patients with complicated obstructive sleep apnea, or patients who suffered from sleep apnea along with another respiratory syndrome (e.g., chronic obstructive pulmonary disease). In other words, the MESAM 4 was unable to identify patients that did not fit the programmed definition of sleep apnea. This study highlights the current limitations of computers and the need for humans to be intimately involved in setting criteria for event identification and evaluating the reliability of the computerized measures obtained.

CONCLUSIONS

Advances in technology have contributed to major insights into the mechanisms and processes of sleep. However, computer programs can be written to recognize only what we understand and can clearly define (14). At present, reliable completely automated sleep scoring systems are not available. The EEG variables present particular difficulties for automated sleep staging systems. However, the ability of computers to store large amounts of data, to organize and consolidate these data, and to perform summary statistics has allowed the polysomnogram to become a significant clinical and research tool. It provides clinicians and scientists with increased power for the

evaluation and understanding of sleep pathology, as well as the basic mechanisms underlying sleep itself.

SPINAL CORD STIMULATION

TERRENCE L. TRENTMAN
KENT P. WEINMEISTER
Mayo Clinic Scottsdale
Scottsdale, Arizona

INTRODUCTION

Spinal cord stimulation (previously known as dorsal column stimulation) is a minimally invasive technique used primarily to treat chronic, refractory neuropathic pain. It is

based upon Melzack and Wall's gate control theory (1), and was first introduced by Shealy in 1967 (2). Neuropathic (nerve injury) pain has many etiologies, including trauma, stroke, diabetes, infection [e.g., human immunodeficiency virus (HIV), or shingles], and cancer. Unfortunately, nerve injury pain can be extremely difficult to manage. Many types of therapy have been used for neuropathic pain including medications such as antiinflammatories, opiates, and antiepilepsy drugs. Physical therapy and psychologically based approaches have also been tried with variable success. Spinal cord stimulation (SCS), transcutaneous electrical nerve stimulation (TENS), and peripheral nerve stimulation (PNS) are all forms of neuromodulation that are used for nerve injury pain.

Spinal cord stimulation is typically reserved for patients with refractory neuropathic pain, whereas deep brain stimulation is currently used for patients with movement and some pain disorders. In SCS, a lead is percutaneously inserted into the epidural space, and an electric field is applied in the vicinity of the spinal cord. The electric field depolarizes neural elements or in some way modifies the function of the nervous system. The goal is for the patient to experience a pleasant paresthesia, often described as "tingling", in the area of their pain. After an initial successful trial, a permanent stimulator can be implanted that the patient controls with a hand-held device.

This article reviews the equipment used in spinal cord stimulation, patient selection, and the possible mechanisms of this therapy. The process of inserting a stimulator will be described with possible complications, and the effectiveness of this therapy will be analyzed. Finally, possible future uses of SCS will be discussed.

EQUIPMENT

Medtronic, Inc. (Minneapolis, MN), Advanced Neuromodulation Systems, Inc. (Allen, TX) and Advanced Bionics (Valencia, CA) are the primary manufacturers of spinal cord stimulators. There are two types of implantable leads available: the paddle (surgical) lead and the tubular percutaneous lead (see Fig. 1). The percutaneous lead can

Figure 1. Various percutaneous and paddle leads. (Used courtesy of ANS, Inc.)

Figure 2. Current distribution between electrodes on SCS leads.

have four or eight contact points (electrodes), whereas the surgical leads are available with two, four, or eight electrodes. Each electrode can be programmed to function as an anode or cathode for the electrical current used in stimulation (see Fig. 2). The paddle lead is shielded on one side, such that stimulation is produced only on the side with the electrodes (see Fig. 3). This finding has the advantage of directing the entire electrical field toward the spinal cord, as opposed to the percutaneous lead that produces an electrical field circumferentially around the lead, including away from the spinal cord. Hence, the paddle lead can produce SCS at lower amperage, prolonging battery life. The surgical lead also has the potential advantage of greater stability (less likely to move postimplantation) as it is sutured to surrounding tissue (3). However, the paddle lead requires a minilaminotomy, whereas the percutaneous lead is placed less traumatically via a 15 gauge touhy needle.

The percutaneous lead is made of inert polyurethane with an outside diameter of ~ 1.3 mm. On its distal end, it has four or eight electrodes made of platinum iridium. These are spaced 4, 6, or 12 mm apart. The electrodes are 3–6 mm long. The plate lead has a two- or four-midline circular or eight parallel rectangular electrodes. There are several options to provide current to the electrodes. An implantable pulse generator (IPG) can be placed subcutaneously (usually in the low abdomen), similar to a

Figure 3. Examples of surgical (paddle) leads. (Used courtesy of Medtronic, Inc.)

pacemaker generator. Recently, a rechargeable IPG has become available. Depending on use, the Pt will percutaneously recharge the IPG every few days to weeks. Finally, a radio frequency (rf) receiver can be placed subcutaneously and powered by an external rf transmitter coil that is held over the device (see Fig. 4). In either case, a cable is tunneled subcutaneously from the power source to the lead in the spine.

Figure 4. Implantable rf receivers. (Used courtesy of ANS, Inc.)

Figure 5. Implantable IPG with hand-held controller. (Used courtesy of Medtronic, Inc.)

The IPG provides pulses of electrical current that are rectangular and biphasic. Programmable features include pulse width, amplitude, and rate. Rates generally used are 30–80 Hz, amplitude is 0–12 V, and pulse width is 200–450 μ s. Battery life varies depending on rate, amplitude, and time the device is used. Unless the patient uses the stimulator constantly with high rate and amplitude, the battery should last at least several years. One obvious advantage of an rf receiver system is that there is no need to periodically replace the battery. The energy source of the IPG is a hermetically sealed silver vanadium oxide cell. The power source and electronics are sealed in an oval shaped titanium shield (see Fig. 5).

PATIENT SELECTION

As noted earlier, spinal cord stimulators are used primarily for neuropathic pain. Although there are many types of neuropathic pain, chronic unilateral lower extremity neuropathic pain seems to respond best to this type of therapy. A typical patient may have the failed back surgery syndrome with residual leg pain, or the patient may have some type of neural compressive lesion that is not operable and refractory to medical management. Spinal cord stimulation may also be indicated for chronic arachnoiditis, complex regional pain syndrome, peripheral neuropathy of the lower limb, and phantom limb syndrome. Patients with idiopathic pain, mechanical low back pain, or other forms of nociceptive pain have a lower success rate when compared to those with neuropathic conditions. Clinical experience and studies have shown that SCS is most efficacious when the entire painful area is covered with paresthesia. The more diffuse the patient's pain, the more difficult it will be to cover with SCS.

Selection for SCS often includes psychological screening. Patients with untreated depression, anxiety, or drug abuse issues are not good candidates. Obviously, the patient needs to be able to understand how to use the stimulator. A trial of stimulation is probably the best predictor of long term success (4). Although the value of

psychological testing in predicting success with SCS is controversial, there is no question that patients with chronic pain are best managed with a multidisciplinary approach. This may include physical therapy, psychological and spiritual support, medications, and surgical procedures as indicated.

MECHANISMS

Both animal and human research studies have provided a partial understanding of the mechanisms of SCS (5). Melzack and Wall's gate control theory (1) suggested that stimulation of large cutaneous A- β fibers would inhibit nociceptive input from the smaller A- δ and C fibers. Since SCS has been shown to be more effective for neuropathic pain than nociceptive pain, the mechanism must include more than simple inhibition of nociceptive input. Endorphins or other endogenous opiates do not seem to be involved. In patients with ischemic lower extremity pain or refractory angina, the mechanism of SCS appears to be an increased local blood flow (i.e., microcirculation). This may be due to both inhibition of the sympathetic nervous system and activation of vaso-active chemicals (6).

Animal studies have supported the contention that A- β fiber stimulation is one of the mechanisms of SCS. Animal models of neuropathic pain can be created by lesioning the sciatic nerve, which creates tactile allodynia in the animal, a phenomenon mediated by A- β fibers. Spinal cord stimulation has been seen to suppress this sign. Another effect of SCS is on wide-dynamic range neurons. Wide-dynamic range (WDR) neurons are second order neurons in the dorsal horn of the spinal cord. They receive input from a variety of sensory neurons. In the face of continuous stimulation from injured neurons, the WDR neurons will "wind-up," that is, fire at lower depolarization thresholds. Spinal cord stimulation may decrease this WDR response while simultaneously decreasing the central excitatory neurotransmitters glutamate and aspartate. γ -Aminobutyric acid (GABA), a central inhibitory neurotransmitter, is simultaneously released; therefore, SCS may have beneficial effects on both excitatory and inhibitory pain mechanisms (7).

Recent computer modeling of SCS has led to a greater theoretical and empirical understanding of the interaction of current with spinal structures (8). These models demonstrate how the depth of cerebral spinal fluid and the distance of the electrodes from both the dorsal columns and dorsal roots can affect the patient's paresthesia perception.

IMPLANTATION TECHNIQUE

Before a spinal cord stimulator is implanted, the patient needs to be informed of potential risks. These include infection, bleeding, nerve damage, allergic reaction, and failure of the stimulator to adequately cover or reduce the patient's pain. The patient may experience swelling around the site of the generator and a seroma may develop requiring drainage. If the lead or the generator becomes infected, it may have to be removed. Lead displacement, fracture, or movement can occur such that an initially adequate pat-

tern of stimulation becomes inadequate. Lead and battery revision may become necessary at some point. After placement of a SCS, the patient is instructed not to drive an automobile with the device turned on. Furthermore, they should not undergo a magnetic resonance imaging (MRI) scan or any type of diathermy.

Once consent has been obtained, a trial of SCS is performed. This consists of placing a trial lead in the epidural space, and if adequate coverage of the patient's area of pain can be achieved, allowing the patient to use the stimulator on an outpatient basis for 5–7 days. In 1993, Barolat et al. published a database of 106 patients in whom they had placed spinal cord stimulator leads (9). The electrodes were placed between the C1 and L1 spinal levels for chronic pain management, and the areas the patients felt stimulation were mapped. These maps provide a guideline as to which body areas will be stimulated by implanted electrodes. Barolat also noted that certain body areas were difficult to cover with paresthesia, including the low back, neck, and perineum. Clinical experience has shown that patients with bilateral extremity pain or pain in both the low back and legs may require bilateral lead placement to obtain adequate coverage. The placement of more than one lead in the epidural space allows not only wider paresthesia coverage, but also the use of complex stimulation programs that can be tailored to meet the patient's needs (see Fig. 6). With bilateral eight electrode leads, the possible stimulation combinations (anodes and cathodes) reach the thousands.

To insert the lead, the patient is placed in the prone position and sedated. The operative area is sterilely prepped and draped, and the skin is anesthetized with local anesthetic. When treating lower extremity pain, the puncture site is usually at the L1–2 level. The epidural space is entered with a Touhy needle, through which a lead is advanced in a cephalad direction. Using fluoroscopy, the lead is observed to move up the spinal canal until it reaches approximately the T9–T10 level. The lead can be manipulated to direct it slightly to the side corresponding to the patient's pain. For upper extremity pain, the skin is usually punctured at T1–T2, and the tip of the lead is placed at the C3–C4 level. The presence of scar tissue or other anatomic barriers can make lead placement difficult and occasionally impossible.

Figure 6. Dual leads allow wider paresthesia coverage. (Used courtesy of ANS, Inc.)

Figure 7. SCS covers painful area with pleasant paresthesias. (Used courtesy of Medtronic, Inc.)

Once the lead is felt to be in proper position, it is attached via a cable to the trial generator. This is an external programmer that allows various combinations of electrodes to be stimulated in an effort to cover the patient's pain with pleasant paresthesia, usually described as "tingling" (see Fig. 7). If the amplitude is set too high, the patient may experience discomfort or muscle stimulation. The patient must be awake enough at this point to answer questions and describe where they feel the stimulation. It is not unusual to need to adjust the position of the lead(s) several times before adequate coverage is obtained.

Once adequate coverage is obtained, the trial lead is secured with tape and/or suture. After recovery from anesthesia, the patient is given instructions as how to operate the stimulator. The patient is allowed to turn the device on or off, and can adjust the amplitude and rate to comfort. Reprogramming the pulse width and lead combinations is generally reserved for the pain specialist. The patient is told not to drive a car with the stimulator turned on, and excess twisting or raising the arms above the head is discouraged. As noted above, the patient will return to the clinic for removal of the trial lead in 5–7 days; however, the patient is encouraged to call sooner should anything change with the function of the device.

During the follow-up visit, several decisions are made. The patient is asked if the stimulator continued to cover their painful area, and if so, did it reduce the discomfort. Ideally, the patient obtained at least a 50% reduction in their pain during the trial. If the patient has received significant pain relief and they want to proceed with permanent implantation, the type of lead (surgical vs. percu-

Figure 8. Paddle lead surgically inserted into the epidural space. (Used courtesy of Medtronic, Inc.)

taneous) is selected. Placement of the surgical lead requires a minilaminotomy, which includes removal of part of the inferior portion of the lamina and a portion of the *ligamentum flavum*, followed by insertion of the paddle lead into the exposed epidural space (see Fig. 8). Villavicencio et al. followed 27 patients who underwent placement of SCS leads (3). Patients who had electrodes placed via a laminectomy had significantly better long-term effectiveness than the patients with percutaneous leads. Nonetheless, permanent placement of percutaneous leads remains a viable and effective option that does not require a minilaminotomy. The placement of the permanent SCS lead requires that a generator (IPG) be inserted in a subcutaneous pocket, usually in the low abdomen or over the buttock. A cable is tunneled under the skin to the lead inserted in the spine. After permanent implantation, the spinal cord stimulator is controlled with a hand-held device.

OUTCOMES

A number of studies have looked at outcomes after SCS. Van Buyten et al. described 10 years of experience with SCS in 254 patients, 217 of whom had permanent stimulators placed (10). Before the study began, 10% of the patients had died and another 10% had undergone explantation. Reasons for explantation included ineffectivity (4.6%), infection, allergy, and recovery from pain. An independent review of the remaining patients who could be contacted and would participate in the study ($n = 123$) showed that 68% of them graded the treatment as excellent to good (excellent, very good, good, moderate, weak, no

improvement, worse). After excluding retirees and others not pursuing a career, 31% of the patients who had been working before their pain began had returned to work. The authors noted that their success rate is one of the highest reported.

Kay et al. published another retrospective study of SCS covering 13 years (11). Of 70 patients treated with SCS, there were 72 surgical revisions, including electrode (32), connecting cable (6), or generator revision (22). Battery depletion was the single most common indication for generator revision (16/22). Of the 72 revisions, 12 were for explantation. Of 48 patients who responded to a questionnaire, 60% rated their pain relief as substantial (>50%).

Bhadrakant et al. prospectively studied 29 patients over a 2-year period (12). The primary indication for SCS was failed back syndrome. Four of the 29 failed to obtain relief during the SCS trial. Of the 25 patients with permanent implants, SCS was beneficial in 50%. This result is similar to North et al. results for a large series ($n = 320$), where 52% of patients reported at least 50% pain relief (13).

Although these and other studies support the use of SCS for certain chronic pain syndromes, methodological problems preclude drawing final conclusions. Its retrospective nature, lack of controls, and heterogeneous patient populations flaw much of the research on SCS. More prospective studies, perhaps looking at SCS for individual pain syndromes, will be needed before this expensive technology becomes widely accepted.

FUTURE USES OF SCS

Greater understanding of both peripheral and central pain mechanisms combined with evolving technology have expanded the potential uses of SCS. Multiple-electrode configurations have allowed coverage of diffuse pain generators and made reprogramming simple when coverage is lost or new pain symptoms arise. Lumbosacral placement of SCS leads may allow treatment of refractory pelvic neuropathic conditions including sacral neuralgia, vulvodynia, or coccydynia. Urinary incontinence may also be treatable with this technique (14). Peripheral placement of SCS leads has been used for a number of conditions, including occipital neuralgia (i.e., spinally transformed migraine) and trigeminal neuralgia (15,16).

Other current and evolving uses for SCS include chronic regional pain syndromes (RSD and causalgia), postherpetic neuralgia, and postamputation pain. Patients with peripheral vascular disease suffering from rest and night pain seem to benefit from SCS; this indication is used more commonly in Europe than the United States. Spinal cord stimulation has also been shown to be effective in refractory angina (17). Other conditions treated with SCS include severe Raynauds phenomena, Buerger's disease, and diabetic neuropathy.

ABHIJEET JOSHI
Abbott Spine
Austin, Texas

INTRODUCTION

Spinal implants constitute the fastest growing segment of the orthopedic medical device industry. The area has until

the last 5 to 10 years been vastly under-studied for the proportion of patients who are afflicted with diseases and injuries to the spine. Consequently, new spine medical devices and medical device companies are emerging every day with new and better treatment strategies for prevalent spine disorders. This article will explore the physiological conditions and disease states that require treatment and then demonstrate some treatment strategies that are being used today. The devices in this text are not comprehensive (we would need a much larger space to do that) but do allow an understanding of the state-of-the-art in medical treatment of spinal disorders.

Human Spine

The human spine is a mechanical structure as it performs three fundamental biomechanical functions simultaneously (1). First, it transfers the weights (and resultant bending moments) of the head, trunk, and any weights being lifted to the pelvis. Second, it allows the sufficient physiological motion among the head, trunk, and pelvis. Third, and most important, it protects the delicate spinal cord from the potential damaging forces (and moments) resulting from the physiological motions and trauma (1).

Figure 1 show a schematic of the human spine, which is divided into three main regions: the upper region with 7 vertebrae (cervical spine), the middle region with 12 vertebrae (thoracic spine), and the lowermost with 5 vertebrae (lumbar spine). At the distal end of the spine, there is a basin-shaped structure, the pelvis, that supports the spinal column and is made of sacrum and coccyx with fused vertebrae. The human spine is not a straight structure, but it has specific curvature. The spine in the cervical and in the lumbar region is slightly convex anteriorly, whereas in the thoracic and sacral region, it is slightly convex posteriorly. The specific shape allows the increased flexibility while maintaining the overall spinal stability. It also facilitates increased shock-absorbing capacity along with adequate stiffness (1).

Each vertebra is made up of several parts. Figure 2 shows schematic of the vertebrae in a vertebral column. The body of the vertebra is the primary weight-bearing area. Between the vertebrae lie the intervertebral disks, which separate the adjacent vertebrae and act as cushions between them while allowing the movement of one vertebra relative to another. There is a large hole in the center part (spinal canal) that is covered by the lamina. The spinal cord runs through this spinal canal. There is a protruded bone in the central posterior region, called the spinous process. There are pairs of transverse processes that are orthogonal to the spinous process and provide attachment sites for the back muscles. Four facet joints are also associated with each vertebra. Four facet joints in two pairs (superior and inferior) interlock with adjacent vertebrae and provide the stability to the spine (1). An intervertebral disk is situated in between adjacent vertebrae. The disks are labeled with respect to the vertebrae levels, between which they are located. Thus, the T12/L1 disk is located between the twelfth thoracic and first lumbar vertebrae, whereas the L3/L4 disk is located between the third and fourth lumbar vertebrae.

Figure 1. Schematic of human spine (2).

The intervertebral disk is basically a composite structure made up of three different tissues; the central core is called the nucleus pulposus (Fig. 3), which is attached radially to the multilayered fibers of the annulus fibrosus and attached superiorly and inferiorly to cartilaginous end plates (1). The nucleus is predominantly water in a matrix of proteoglycan, collagen, and other matrix proteins. The water content of the nucleus is very high at birth (approximating 90%) and then decreases through the aging cycle down to 70% or less. The annulus surrounds the nucleus with successive layers of tissue with collagen fibers oriented in alternating directions. The annulus is under tension when the nucleus absorbs water and swells. The cartilaginous end plates have multiple perforations that allow exchange of water and nutrients into the disk (4–6).

Figure 2. Spinal vertebrae (3).

SPINAL DISORDERS

Various spinal disorders are observed in humans; some manifest in pediatric patients, whereas others affect middle-aged and older patients. The most common spinal disorders can be generally described by three different categories: developmental bone deformities (scoliosis and kyphosis), bone degeneration (vertebral compression fractures), and degenerative disk disease (herniation, rupture and spinal cord stenosis).

Developmental Bone Deformities

The spine is a complex biomechanical structure and performs complex functions. This puts spine under greater strains, and bone deformities may develop during the course of time while performing the demanding functions such as supporting the cranium and trunk, or absorb stresses generated during daily physiological activities. Most common spinal disorders under this category include scoliosis and kyphosis.

Scoliosis. Scoliosis is a lateral curvature of the spine. The symptoms of the scoliosis include uneven waist,

different height shoulders, raised/prominent hip, and leaning of body to one side (7). Some causes of scoliosis include congenital deformity, cerebral palsy, atrophy, and neuromuscular problems.

Scoliosis can either be structural or functional. Structural scoliosis is referred in case of adjacent vertebrae rotation upon each other. This is generally followed by deformation of rib cage. In case of functional scoliosis, there is no fixed vertebral rotation or fixed deformity in the thoracic region. The rate of curve progression is not constant; however, the lumbar curves progresses more rapidly than thoracic curves. The scoliosis is generally classified as adolescent idiopathic scoliosis (AIS), adult scoliosis (with or without degenerative changes), and *de novo* scoliosis (which develops secondary to degenerative changes of the lumbar spine, especially in older age) (7).

The most common tools used for diagnosis of scoliosis include plane radiograph, computed tomography (CT) scans, and magnetic resonance imaging (MRI). Treatment options depend on the various factors, including the age, curvature angle, progress rate, location, flexibility, and spinal maturity. Conservative management (no treatment) is commonly incorporated when the curvature is mild (less than 20°).

Orthopedic braces are recommended in case of curvature angle of 25–40°, to prevent further spinal deformity, especially in children. The bracing, however, merely prevents the worsening of the existing curvature and does not restore normal alignment (8). Many types of braces are commercially available in the market. The brace, depending on the type and application, may extend from neck to pelvis (Milwaukee Brace) with plastic pelvic girdle, neck ring, and pressure pads (Fig. 4) (9), or it may just cover below the breast to the initial pelvic region only (Boston Brace). The use of braces has been generally effective in case of children, to prevent the further worsening of the scoliosis, but there is still a lack of consensus about the indications for the brace, type, and wearing time over the body.

Surgical options are used only in case of severe scoliosis (curvature angle greater than 45°) or for the curves that do not respond to nonsurgical treatments. The goals of the

Figure 3. Schematic of an intervertebral disk (1).

Figure 4. Milwaukee Brace (9).

surgical treatment are to prevent the progression of the curve and correct the deformity using instrumentation (7). The most common method to treat severe scoliosis is spinal fusion (anterior or posterior) and bone grafting/substitute. Bone graft can either be autologous iliac crest, from rib or allograft. In general, the facetectomy is followed by placement of bone graft and fixation. Various instrumentation options are available to surgeons for fixation. Basically, fixation is achieved by use of single/dual rods, posteriorly or anteriorly, along with screws and wires to the fixation point(s). The structures of the vertebral body, such as pedicles, sublaminar region, facets, and processes, may serve as fixation points for fusion (7). Anterior structural support is generally provided by mesh cages or ring allografts. Single thoracic curves are generally treated posteriorly using posterior instrumentation (hooks) and fusion.

Kyphosis. When viewed from the side, the normal spinal column is not completely straight. There are several gentle curves due to the shape and alignment of the vertebrae. Kyphosis is an exaggerated curvature of the spine or a rounded, "hunched" back. Most causes (metabolic, neuromuscular conditions, osteogenesis, spina bifida, among others) of the kyphosis are due to shortening of the anterior column, a weakening or lengthening of the posterior column, or both (7). The symptoms of kyphosis include difference in shoulder heights, forward bend of head compared with the rest of body, and tight hamstring (back thigh) muscles.

As in scoliosis, plane radiographs are also useful in diagnosing kyphosis. These help in defining the nature of sagittal deformities. Cobb (angle) measurements on these radiographs are performed to quantify the deformity in the sagittal and coronal plane. The angle is measured using the adjacent vertebral endplates (plane) as the basis of calculation. CT scans and MRI also find a place as useful diagnostic tools for better assessment of the spinal deformity.

The use of braces is recommended when the curve angle is between 40° and 60° on X ray. Surgical treatment is recommended when the curvature deformity is progressive, and the deformity may lead to neurological compromise. Again, spinal fusion (anterior or posterior) is referred for cases of severe deformity. In the case of young patients, posterior fusion might be considered, which would allow continuous anterior growth to partially correct the deformity (anterior release with posterior instrumentation).

Bone Degeneration

Compression fractures are generated in vertebrae when the bone tissue becomes weak due to degenerative changes. In most cases, the cause of the compression fracture is reduction in bone mineral density leading to weakening of bone (osteoporosis) (1,7). Osteoporosis causes both inorganic and organic phase bone loss. Loss of bone crystal weakens the bone to compressive loading, whereas loss of the organic matrix of bone makes the tissue more brittle, making the bony construct more susceptible to fracture. Other manifestations of osteoporosis include hyperkyphosis with chronic spinal pain and osteoporotic burst

fractures. However, the most common manifestation of the bone loss is a vertebral compression fracture (VCF).

To diagnose vertebral compression fractures, plane radiographs are used. To follow the progression of bone density loss throughout the osteoporotic disease process, dual photon absorptiometry (DPA) (which measures axial skeletal bone mass density) and dual energy X-ray absorptiometry (DEXA) (which measures baseline bone density with precision) are used. Quantitative CT can also be used in diagnosis of compression fractures.

Surgical treatment available for reduction of compression fractures is vertebral body augmentation: either kyphoplasty or vertebroplasty (7). Vertebroplasty is a procedure performed to relieve the pain and strengthen the weak vertebrae. During the procedure, an image-guided (X-ray) bone needle may be passed through the patient's back to have precise control over its location. Bone cement (polymethylmethacrylate or PMMA) is pushed through the needle to stabilize the fractured location of the vertebra. After curing, the PMMA biomaterial serves to stabilize the vertebra and to minimize the pain associated with the fracture.

Kyphoplasty is another method of vertebral augmentation, which uses bipedicular approach and balloon tamps to create voids in the bone. The instrumentation (cannula) used in kyphoplasty differs that from used in vertebroplasty. The void created by balloon is filled with PMMA. Other materials, such as calcium phosphate, hydroxyapatite, polymeric hydrogels, and combinations thereof, are being investigated as an alternative solutions to PMMA.

Degenerative Disk Disease

Lower back pain is one of the most prevalent socioeconomic diseases and one of the most important health-care issues today. Over five million Americans suffer from lower back pain, making it the leading cause of lost work days next only to upper respiratory tract illness (10–14). On an average, 50–90% of the adult population suffers from lower back pain (15), and lifetime prevalence of lower back pain is 65–80% (16). It is estimated that 28% experience disabling lower back pain sometime during their lives, 14% experience episodes lasting at least 2 weeks, whereas 8% of the entire working population will be disabled in any given year (16). The total cost of the lower back disabilities is in the range of \$50 billion per year in the United States (17) and £12 billion per year in the United Kingdom alone (18). The causes of lower back pain often remain unclear and may vary from patient to patient. It is estimated that 75% of such cases are associated with lumbar degenerative disk disease (DDD).

Many conservative treatment options exist for lower back pain. These generally aim at reducing the pain arising out of nerve root impingement and inflammatory response because of the migrated nucleus. The most commonly used surgical treatments include discectomy and spinal fusion and are sought when conservative treatments fail.

Progression of Degenerative Disk Disease. As the human life progresses, significant changes occur in the tissues of the intervertebral disk. DDD can be simply defined as the

loss of normal disk architecture accompanied by progressive fibrosis. At birth, the water content of the annulus fibrosus is about 80% and that of nucleus pulposus is about 90%. Through the degenerative process, this water content decreases to as low as 70% for the nucleus (19). Microscopic changes such as fragmentation of fibers, mucinous degeneration of fibers leading to cyst formation, and focal aggregation of the collagen to form round aggregates of amorphous material are observed in early stage of degeneration (20). The salient features of the DDD can be denoted as the loss of gelatinous nucleus pulposus, gradual disappearance of the originally well-defined border between the nucleus and the annulus, coarsening of the annulus lamellae, progressive fibrosis, and later fissuring of the annulus fibrosus with the deposition of the aging pigment (21–24).

The load transfer mechanism is clearly altered in the case of a dry nucleus. As a result, the end plates are subjected to reduced pressure at center and more pressure around the periphery. The stress distribution in the annulus is also altered significantly. Essentially, the nucleus does not perform its function of load transfer and the load transfer occurs through end plate—annulus—end plate route (1). The annulus is subjected to abnormal stresses and is more prone to injuries, and cracks/fissures first develop into the annulus.

With continued degeneration, the central nucleus may migrate through the crack developed in the annulus toward the periphery. The migration of the nucleus material is referred to as “disk herniation” (17). Approximately 90% of the disk herniation would occur at the L4-L5 and L5-S1 levels. The migrated material may impinge on the nerve root. The contact of the migrated nucleus with the nerve root irradiates debilitating back pain. Also, the herniated material elicits an inflammatory response because of the avascular nature of the nucleus. It is difficult to distinguish between the effects of aging from that of degeneration on the biomechanical behavior of the lumbar disk. The biomechanical behavior of the disk is dependent on its state of degeneration, which in turn depends on the age.

In case of the normal disk, any load acting on the disk is transferred to the annulus by means of swelling pressure (intradiscal pressure) generated by the nucleus (1). The water binding capability of the nucleus is a function of chemical composition of the nucleus. However, with aging and/or degeneration, changes occur to the proteoglycans as proteases and MMPs attack the molecules. The result is a decrease in the proteoglycan/collagen ratio, which leads to the lower water binding capability of the nucleus (25,26).

The load transfer mechanism in case of such a dehydrated disk is significantly altered (Fig. 5). The nucleus cannot generate sufficient intradiscal pressure to maintain disk height and normal mechanical function (25,27,28). Although it is not well understood, the consequence of the structural and mechanical changes to the disk may be a cause of lower back pain.

Stenosis. The reduction in the disk volume leads to instability, resulting in the growth of bone, end plates, and ligaments to compensate for this volume loss (stenosis). Stenosis is narrowing of the spinal canal (29). It occurs as a

Figure 5. Degenerated disk (1).

result of aging and/or degenerative disk disease. The water content of the nucleus decreases, causing an abnormal load transfer mechanism within the disk. The disk height is reduced, and this dry/hardened disk may bulge into the spinal canal space. Additionally, the facet joints may become thick, thus narrowing the spinal canal further. Spinal stenosis in the lumbar spine may result in cauda equina syndrome and loss of bowel and bladder function. In general, the symptoms are not observed with stenosis. However, when present, the symptoms may include low back stiffness, leg weakness, numbness in the back/legs, and cramping.

Most common methods to diagnose and analyze the stenosis are plane X ray, MRI, and CT scan (7). These treatments, alone or in combination, provide valuable information about the patient's spine structure, location, and the extent of the disease. In particular, the following information can be revealed:

- Disk space narrowing
- Endplate osteophytes and sclerosis
- Facet enlargement and osteophytes formation
- Loss of lumbar lordosis

If conservative treatments such as medication, physical therapy, and spinal injections fail, a surgical approach may be recommended in the cases with persistent back pain

and/or progressive leg weakness. The indications for surgical treatment include radicular pain or neurogenic claudication with MRI or CT. In general, the goals of surgery are pain relief, increased mobility, and improvement in the patient's quality of life. Most common surgical treatments are laminectomy (in case of simple stenosis) and spinal fusion. Fusion is recommended when there is a stenosis in conjunction with

- Degenerative scoliosis or kyphosis
- Degenerative spondylolisthesis

The goal of the laminectomy or, lumbar decompression surgery, is to widen the spinal canal (30) to allow more space for spinal nerves. The treatment would ideally relieve the leg pain and, to a certain extent, back pain. When there is a vertebrae slippage relative to each other (spondylolisthesis), an abnormal motion would occur, which might require spinal fusion along with decompression.

Spondylolisthesis. Spondylolisthesis is defined as displacement or slippage of one vertebra on another (7). Osteoarthritis of the facet joints (degenerative arthritis that breaks the cartilage between the facet joints) can lead to instability of the vertebral segments. The L4-L5 motion segment has most flexion-extension movement and is more prone to such slippage, as a result of weakened facet joints.

The most common symptoms are pain irradiating in lower extremities and cauda equina compression along with incontinence of bowel or bladder. Like most other spinal disorders, surgical treatment is recommended only when the nonsurgical treatments such as activity modification and physical therapy show no significant improvement in the patient's quality of life. The goals of the surgical treatment are pain reduction, prevention of further slip, and stabilization of spine (7). Surgical treatments include spinal fusion (with or without decompression), slip reduction or instrumentation, and interbody fusion.

Recommended operative treatments of degenerative spondylolisthesis are decompressive laminectomy (removal of lamina and medial joints), decompression with postero-lateral fusion (complete laminectomy and partial facetectomy along with fusion of the transverse process), and decompression with instrumental fusion.

TREATMENT OPTIONS AND MEDICAL DEVICES

Most spinal medical devices involve permanently fusing vertebral bone to correct a deformity or to limit a motion segment to stabilize the joint segment and relieve pain. Spine medical devices have their origin in plates, screws, and rods made from stainless steel and titanium, and today, these components comprise the majority of the implantable devices today.

Implants for Developmental Spine Deformities

Implants for developmental bone deformities such as scoliosis and kyphosis, generally use metal rods, screws,

Figure 6. VEPTR for the treatment of pediatric scoliosis from Synthes Spine (41).

plates, and rib cages. For example, CD Horizon from Medtronic (Fig. 10) can be used for treatment of such deformities. Recently, the Food and Drug Administration (FDA) approved the Vertical Expandable Prosthetic Titanium Rib (VEPTR) from Synthes Spine (41,43), which is a surgically implanted device used to treat thoracic insufficiency syndrome (TIS) in pediatric patients. TIS is a congenital condition where severe deformities of the chest, spine, and ribs prevent normal breathing and lung growth and development.

The VEPTR device (Fig. 6) is a curved metal rod that is attached to ribs near the spine using hooks located at both ends of the device. The VEPTR device helps straighten the spine and separate ribs so that the lungs can grow and fill with enough air to breathe. The length of the device can be adjusted as the patient grows. It is hoped that the device will accomplish more normal growth pattern without spinal growth limitations, decreased chest, spine, and rib deformity and increased lung volume (43).

Implants for Degenerative Bone Disease

In case of kyphosis caused by osteoporosis (decrease in bone mass density with increased bone brittleness), minimally invasive methods such as vertebroplasty or (balloon kyphoplasty) are being used (7). Vertebroplasty involves the percutaneous injection of (PMMA) into a fractured vertebral body. Balloon kyphoplasty is another surgical approach to treat the kyphosis or deformity of the spine. In this procedure, an inflatable balloon is inserted between the vertebrae space to increase the disk height. Increase in disk height helps to reduce the deformity. The extra space created by balloon is filled with bone cement (PMMA), which when cured, binds the fracture. The hardened cement thus provides the strength to fractured/weak vertebrae and stability to the spine along with reducing the pain.

Implants for Degenerative Disk Disease

The treatment options for the patient would vary based on the age, pain history, and severity. When conservative treatments (such as rest, medications, physical therapy, etc.) fail, the patient is advised to undergo surgery. The goal of the surgery is to alleviate the pain. Most popular surgeries include lumbar microdiscectomy, lumbar laminectomy, microendoscopic surgery, and arthroscopic lumbar discectomy (30,31).

Lumbar microdiscectomy (or lumbar decompression) is a proven technique to reduce the back pain associated with herniated disks. In this treatment, a small portion of the

bone over the nerve root is removed to get relief from pain. A microscope is used to aid in visualizing the pinched nerve and subsequent microsurgical procedure to remove the excess portion of the herniated disk. Similarly, an open decompression (lumbar laminectomy) is another type of surgery that is performed to reduce the pain caused by neural impingement, which is particularly effective as a treatment for spinal stenosis. It is typically done with a posterior approach. The spine is approached by cutting the left and right back muscles off the lamina and removing the lamina itself. The facet joints are then trimmed to allow more space to nerve roots (30).

Even with these surgical treatments, pain may not be relieved for disks that are more severely degenerated. In these cases, fusion is required to restrict the motion of the segment and thus attempt to relieve pain. A discussion of fusion technologies and the associated implants follows. More recent advances in non-fusion technologies are aimed at preserving the motion segment while relieving pain. Such non-fusion technologies include total disk replacement, nucleus replacement, and annulus repair. Numerous new companies and new medical implant strategies are being explored currently and will hopefully prove to be clinically relevant pain relief and function restoring solutions to DDD.

Fusion Solutions. Spinal fusion is recommended when the discectomy approach may not be clinically relevant, and the goal is to relieve pain by stopping the motion of a spine segment. Spinal fusion instrumentation is essentially of three main types: pedicle screws, anterior interbody cages, and posterior lumbar cages. The bone generally fuses more effectively when its motion is minimized; hence, these devices are used to limit the motion of the fused segment. Similarly, the spinal fusion is based on the assumption that if the joint does not move, it will not create pain.

Pedicle screws (Fig. 7) are the means of providing anchor to the spine. They are used in combination with the short rod to grip the spine and are made from biocompatible metals such as medical-grade stainless steel or titanium. After a sufficient time, these screws can be removed by doing a surgery; however, most surgeons recommend keeping the screws unless it causes discomfort to patient.

Figure 7. Pedicle screws and instrumentation from Medtronic (32).

Figure 8. Jaguar Interbody Cage from Depuy Spine (33).

Anterior interbody cages (Fig. 8) have been recently approved by the FDA to use in the disk space. The cages are made from titanium and are porous, which allows the bone graft to grow. Cages are also made of novel composite materials (e.g., Jaguar from Depuy) such as carbon fiber-reinforced polymeric materials. The bone graft grows through the cage from one vertebra to another.

These cages are placed in front (anterior) of the lumbar spine and, hence, the name. The cages can be inserted using either mini-laparotomy or endoscopy, however, the former is preferred. In general, a 3 to 5 in. (7.6 to 12.7 cm) incision on the left side of the abdomen is made to approach the damaged disk.

Anterior lumbar interbody fusion (ALIF) surgery is often combined with posterior lumbar interbody fusion (PLIF) surgery to provide more rigid fixation. When the cages are placed from back of the spine, it is called posterior fusion. Coda (Fig. 9) is a titanium alloy device for PLIF with pedicle screws from Abbott Spine and features intraoperative adjustment for lordosis.

There is another form of the fusion surgery: transforaminal lumbar interbody fusion (TLIF), which is considered as an extended form of PLIF. In TLIF, an entire facet joint is removed to get a better access to disk space as compared with PLIF. This facilitates better visualization and more removal of the disk material and placement of larger bone graft/implant. The success rate of the cages almost entirely depends on the vertebrae condition. The surgery is not recommended in the case of osteoporosis because the vertebral body would not sustain the cage, leading to eventual failure of the end plates. In that sense, the pedicle screws are better than anterior cages as a

Figure 9. Coda PLIF device with pedicle screws from Abbott Spine (34).

Figure 10. CD Horizon Legacy from Medtronic (32).

fixation device. The anterior/posterior fusion is performed in the case of severe spinal instability or in revision surgery. The advantage of the anterior/posterior fusion is that it provides more surface area for the bone fusion to occur.

The gold standard in the case of fusion is considered to be postero-lateral gutter fusion surgery (30). A bone graft is placed in the postero-lateral portion of the spine. The transverse process of the vertebral body serves as an attachment site to the bone graft, which eventually grows to complete the fusion at the site.

The recent trend is to offer the spinal systems that can be used for multiple spinal treatments. For example, the CD Horizon Legacy Spinal System (Fig. 10) can be used as a posterior, noncervical, nonpedicle screw fixation system for treatment of DDD, spinal stenosis, spondylolisthesis, spinal deformities like scoliosis, and kyphosis. When used as a pedicle screw fixation system of the noncervical posterior spine, it may be indicated for degenerative spondylosthesis, kyphosis, and scoliosis.

Novel concepts for spine care (e.g., Dynesys from Zimmer Spine and Wallis from Abbott Spine) are recently introduced in the market. Dynesys (Fig. 11) is a posterior

Figure 11. Dynesys from Zimmer Spine (35).

Figure 12. Wallis from Abbott Spine (34).

dynamics stabilization system, which is designed to bring the lumbar vertebrae back into more anatomical position while stabilizing the affected segments. The system used flexible materials threaded through pedicle screws, achieving dynamics stabilization.

The Wallis device (Fig. 12) from Abbott Spine is also another non-fusion spinal stabilization device that is under clinical trials in United States. The system is designed to treat the pain caused by initial stage DDD and aims to stabilize the lumbar spine without fusion, with a minimally invasive procedure.

The bone grafts used for the fusion can be either taken from patient's iliac crest (autograft) or from a human cadaver (allograft), such as Puros (Fig. 13) from Zimmer Spine (34). Autografts have the obvious advantage of compatibility with the patient's body. It helps in osteoconduction (bone growth) by means of providing calcium scaffold along with osteoblasts (bone growing cells) and morphogenic proteins (bone growing proteins). The allografts, in comparison, do not have osteoblasts and morphogenic proteins and merely provide the calcium scaffold for the fusion to occur. However, autografts lead to higher and longer postoperative pain as the bone graft is taken from the patient's own body.

Recently, synthetic bone grafts are introduced (e.g., Infuse), which represents an rhBMP-2 (recombinant human bone morphogenetic protein- 2) formulation combined with a bovine-derived absorbable collagen sponge (ACS) carrier. The INFUSE Bone Graft/LT-CAGE Lumbar Tapered Fusion Device, from Stryker Spine (36) (Fig. 14) is indicated for spinal fusion procedures in skeletally mature patients with DDD at one level from L4-S1, who may also have up to grade I spondylolisthesis at the involved level.

Figure 13. Puros allograft from Zimmer Spine (35).

Figure 14. Infuse synthetic bone graft from Stryker Spine (36).

Bone stimulators offer another approach that potentially aid in spinal fusion. These externally applied devices emit low electrical current (30). This is aimed at facilitating stimulation of bone growth and increasing the chance of achieving spinal fusion. These are used in the case of patients who have a potentially very slow rate of obtaining solid fusion or in the case of the revision surgery.

The fusion and discectomy relieve pain but do not restore the normal spinal motion (37,38). The motivation behind exploration of the new and better solutions for the treatment of lower back pain is the failure of current treatments (conservative and surgical) in terms of restoring the motion and normal disk biomechanics. This is further aggravated by the complications that may occur after the surgical treatments, such as discectomy and/or spinal fusion.

Non-Fusion Solutions. Total disk replacement, where an entire diseased disk is removed and replaced by a synthetic implant, and nucleus pulposus arthroplasty, where only the nucleus of the disk is replaced either by a synthetic implant or recreated using tissue engineering approach, are the emerging approaches as alternatives to current surgical procedures for the treatment of the lower back pain (39). Annulus repair techniques, where defects in the annulus are either modified or repaired, also finds a place in emerging techniques and can be potentially used either alone or in combination with nucleus pulposus arthroplasty procedures, depending on the degenerative state of the intervertebral disk.

Total Disk Replacement. Total disk replacement targets later stages of disk degeneration (Galante grade IV), where the annulus is severely degenerated and is beyond repair (40). The diseased disk is entirely removed and replaced by a medical device that provides motion to the joint segment. Disk replacement may serve to eliminate the back pain and restore the physiological motion. A similar approach for total knee and hip replacement is highly successful. Total disk prostheses may be better options to spinal fusion and/or discectomy as it allows the physiological motion between the adjacent vertebrae. Another advantage would be that the effectiveness of the surgery will not be dependent on

Figure 15. Charite from Depuy Spine (33) and ProDisc from Synthes Spine (41).

the integrity of the annulus or degeneration state. To simulate the natural structure and function of the spinal unit, total disk prostheses also provide adequate fixation to the vertebrae.

There are a variety of total disk replacement design strategies, but two of the concepts that are furthest along are the Charite and the ProDisc, which are each based on metallic end plates that are porous coated and allow fixation to the superior and inferior end plates as well as an ultra-high molecular end plate polyethylene core, which provides a low friction articulation of the adjacent vertebrae. The use of artificial disks (Fig. 15) as a replacement to the damaged disk is currently in various phases of development and clinical trials. The Charite received FDA approval in 2004, and ProDisc, Maverick, and Flexicore are under clinical evaluation at the time of this writing (30).

Nucleus Replacement. The nucleus pulposus is a major component of the intervertebral disk and is actively involved in the disk function and load transfer mechanism. It is also involved with the pathologic changes of the disk. Researchers began to consider replacement of the nucleus alone because this tissue seems to degenerate before the annulus fibrosus. If this tissue alone can be replaced, preserving the annulus fibrosus, this may prolong the life of the disk and postpone or prevent the need for a more aggressive procedure such as fusion or total disk replacement. Nucleus replacement, as in case of total disk replacement, aims for restoration of the normal disk mechanics and functions, in contrast with the current surgical procedures of the discectomy and the spinal fusion.

There are several nucleus implants in the various phases of development and clinical trials. Some are already implanted in humans in Europe (e.g., RayMedica PDN, Disc Dynamic's DASCOR), whereas most other nucleus implants are undergoing bench-top testing and/or investigational device exemption (IDE) submissions. The Raymedica prosthetic nucleus device (Fig. 16) has the longest history of all nucleus implants on the market. The clinical results of the PDN have been promising for pain relief and disk height restoration (41), but they are troubled by expulsion of the device from the annulus. Alternative implant designs and surgical procedures have limited this complication, but it remains a major challenge for these types of devices.

To perform surgical intervention on the intervertebral disk (e.g., in the case of nucleus replacement), outer

Figure 16. Single prosthetic nucleus device by Raymedica (42).

annulus fibrosus needs to be compromised. If the artificial incision in the annulus is not repaired, there is very high risk of nucleus implant expulsion, even under mild physiological loading. The main idea is to seal the annulus incision and/or prevent the expulsion of the nucleus implant from the created window. A barrier can be placed in between the nucleus and the annulus to prevent expulsion. These technologies are currently being explored in early clinical trials and in preclinical evaluations.

CONCLUSIONS

This is perhaps the most exciting time in the development of medical devices for spinal applications. Never before have so many academic researchers, clinicians, and corporations so aggressively pursued solutions to spinal conditions that have a potential to be solved with medical devices. Along with this tremendous interest is the interest in better understanding of the anatomical structure, biochemistry, and function of the spinal structures. As more information becomes available, further refinements in treatments through medical devices will be improved offering more tools to the surgeon and a better chance of relieving pain while preserving the function of the spine.

APPENDIX 2. TERMINOLOGY

Allograft The transplant of an organ or tissue from one person to another.

Autograft The transplant of an organ or tissue from one body site to another body site of the same person.

Compression Fracture Collapse of the bone of the vertebral body, mostly due to osteoporosis and trauma.

Disk Degeneration The loss of normal disk architecture accompanied by progressive fibrosis. This is seen as loss of hydration of the disk material and loss of disk height. This complex process alters the normal biomechanics of the spine and may cause back pain.

Disk Herniation Migration of the central nucleus pulposus of the disk toward disk periphery through cracks or fissures in outer annulus.

Discectomy A procedure in which an excess portion of the disk impinging on the nerve root is cut off.

Kyphosis An exaggerated curvature of the back bones (vertebrae) in the upper back area or a rounded, "hunched" back.

Kyphoplasty A procedure that combines the vertebroplasty technique with balloon catheter technology to treat the osteoporotic vertebral compression fractures.

Laminectomy A procedure in which the lamina (roof) of the vertebra is trimmed to create more space for the spinal nerves.

Nucleus Implant An artificial material, which can be used as a replacement to the degenerated nucleus of the intervertebral disk to relieve back pain and preserve the normal motion.

Osteoporosis A disease in which bones become fragile and brittle, making it prone to break easily.

Scoliosis A curvature of the spine.

Spinal Fusion A procedure in which an intervertebral disk between the adjacent vertebrae is replaced by bone graft. The procedure is performed to relieve the back pain and stabilize the spinal segment by fusing the vertebrae together, with or without spinal instrumentation.

Spondylolisthesis Slippage of one vertebra on another.

Stenosis Narrowing of the spinal canal.

Total Disk Prosthesis An artificial device, which can be used as a feasible replacement of the degenerated disk to relieve back pain and preserve the motion.

Vertebroplasty A procedure that stabilizes the collapsed vertebra with the injection of the medical-grade bone cement into the spine.

STATISTICAL METHODS

ARNAUD DELORME
University of San Diego,
La Jolla, California

INTRODUCTION

Statistics can be called that body of analytical and computational methods by which characteristics of a population are inferred through observations made in a representative sample from that population. Since scientists rarely observe entire populations, sampling and statistical inference are essential. Although, the objective of statistical methods is to make the process of scientific research as efficient and as productive as possible, many scientists and engineers have inadequate training in experimental design and in the proper selection of statistical analyses for experimentally acquired data. Gill (1) states: "...statistical analysis too often has meant the manipulation of ambiguous data by means of dubious methods to solve a problem that has not been defined." The purpose of this article is to provide readers with definitions and examples of widely used concepts in statistics. This article first discusses some general principles for the planning of experiments and data visualization. Then, since it is expected that most readers are not studying this article

to learn statistics, but to find practical methods for analyzing data, a strong emphasis has been put on choice of an appropriate standard statistical model and statistical inference methods (parametric, nonparametric, resampling methods) for different types of data. Then, methods for processing multivariate data are briefly reviewed. The section following it deals with clinical trials. Finally, the last section discusses computer software and guides the reader through a collection of bibliographic references adapted to different levels of expertise and topics.

DATA SAMPLE AND EXPERIMENTAL DESIGN

Any experimental or observational investigation is motivated by a general problem that can be tackled by answering specific questions. Associated with the general problem will be a population. For example, the population can be all human beings. The problem may be to estimate the probability by age bracket for someone to develop lung cancer. Another population may be the full range of responses of a medical device to measure heart pressure and the problem may be to model the noise behavior of this apparatus.

Often, experiments aim at comparing two subpopulations and determining if there is a (significant) difference between them. For example, the frequency occurrence of lung cancer of smokers compared may be compared to nonsmokers or the signal/noise ratio generated by two brands of medical devices may be compared and determined which brand outperforms the other with respect to this measure.

How can representative samples be chosen from such populations? Guided by the list of specific questions, samples will be drawn from specified subpopulations. For example, the study plan might specify that 1000 presently cancer-free persons will be drawn from the greater Los Angeles area. These 1000 persons would be composed of random samples of specified sizes of smokers and nonsmokers of varying ages and occupations. Thus, the description of the sampling plan will imply to some extent the nature of the target subpopulation, in this case smoking individuals.

Choosing a random sample may not be easy and there are two types of errors associated with choosing representative samples: sampling errors and nonsampling errors. Sampling errors are those errors due to chance variations resulting from sampling a population. For example, in a population of 100,000 individuals, suppose that 100 have a certain genetic trait and in a (random) sample of 10,000, 8 have the trait. The experimenter will estimate that 8/10,000 of the population or 80/100,000 individuals have the trait, and in doing so will have underestimated the actual percentage. Imagine conducting this experiment (i.e., drawing a random sample of 10,000 and examining for the trait) repeatedly. The observed number of sampled individuals having the trait will fluctuate. This phenomenon is called the sampling error. Indeed, if sampling is truly random, the observed number having the trait in each repetition will fluctuate randomly ~10. Furthermore, the limits within which most fluctuations will occur are estimable using standard statistical methods.

Consequently, the experimenter not only acknowledges the presence of sampling errors, but he can estimate their effect.

In contrast, variation associated with improper sampling is called nonsampling error. For example, the entire target population may not be accessible to the experimenter for the purpose of choosing a sample. The results of the analysis will be biased if the accessible and nonaccessible portions of the population are different with respect to the characteristic(s) being investigated. Increasing sample size within the accessible portion will not solve the problem. The sample, although random within the accessible portion, will not be representative of the target population. The experimenter is often not aware of the presence of nonsampling errors (e.g., in the above context, the experimenter may not be aware that the trait occurs with higher frequency in a particular ethnic group that is less accessible to sampling than other groups within the population). Furthermore, even when a source of nonsampling error is identified, there may not be a practical way of assessing its effect. The only recourse when a source of nonsampling error is identified is to document its nature as thoroughly as possible. Clinical trials involving survival studies are often associated with specific nonsampling errors (see the section dealing with clinical trials below).

DESCRIPTIVE STATISTICS

Descriptive statistics are tabular, graphical, and numerical methods by which essential features of a sample can be described. Although these same methods can be used to describe entire populations, they are more often applied to samples in order to capture population characteristics by inference.

The two main types of data samples will be differentiated: qualitative data samples and quantitative data samples. Qualitative data arises when the characteristic being observed is not measurable. A typical case is the “success” or “failure” of a particular test. For example, to test the effect of a drug in a clinical trial setting, the experimenter may define two possible outcomes for each patient: either the drug was effective in treating the patient, or the drug was not effective. In the case of two possible outcomes, any sample of size n can be represented as a sequence of n nominal outcome x_1, x_2, \dots, x_n that can assume either the value success or failure.

By contrast, quantitative data arise when the characteristics being observed can be described by numbers. Discrete quantitative data is countable, whereas continuous data may assume any value, apart from any precision constraint imposed by the measuring instrument. Discrete quantitative data may be obtained by counting the number of each possible outcome from a qualitative data sample. Examples of discrete data may be the number of subjects sensitive to the effect of a drug (number of success and number of failure). Examples of continuous data are weight, height, pressure, and survival time. Thus, any quantitative data sample of size n may be represented as a sequence of n numbers x_1, x_2, \dots, x_n and sample statistics are functions of these numbers.

Table 1. Result of a Hearing Aid Device Satisfaction Survey in 1000 Patients Showing the Frequency Distribution of Each Response

Satisfaction rank	Number of Responses
0	38
1	144
2	342
3	287
4	164
5	25
Total	1000

Discrete data may be preprocessed using frequency tables and represented using histograms. This is best illustrated by an example. For discrete data, consider a survey in which 1000 patients fill in a questionnaire for assessing the quality of a hearing aid device. Each patient has to rank product satisfaction from 0 to 5, each rank being associated with a detailed description of hearing quality. Table 1 represents the frequency of each response type. A graphical equivalent is the frequency histogram illustrated in Fig. 1. In the histogram, the heights of the bars are the frequencies of each response type. The histogram is a powerful visual aid to obtain a general picture of the data distribution. In Fig. 1, notice a majority of answers corresponding to response type 2 and a 10-fold frequency drop for response types 0 and 5 compared to response type 2.

For continuous data, consider the data sample in Table 2, which represents amounts of infant serum calcium in $\text{mg}\cdot 100\text{ mL}^{-1}$ for a random sample of 75 week old infants whose mothers received vitamin D supplements during pregnancy. Little information is conveyed by the list of numbers. To depict the central tendency and variability of the data, Table 3 groups the data into six classes, each of width $0.03\text{ mg}\cdot 100\text{ mL}^{-1}$. The “frequency” column in Table 3 gives the number of sample values occurring in each class. The picture given by the frequency distribution in Table 3 is a clearer representation of central

Figure 1. Frequency histogram for the hearing aid device satisfaction survey of Table 1.

Table 2. Serum Calcium (mg·100 mL⁻¹) in a Random Sample of 75 Week Old Infants Whose Mother Received Vitamin D Supplement During Pregnancy

9.37	9.34	9.38	9.32	9.33	9.28	9.34
9.29	9.36	9.30	9.31	9.33	9.34	9.35
9.35	9.36	9.30	9.32	9.33	9.35	9.36
9.32	9.37	9.34	9.38	9.36	9.37	9.36
9.36	9.33	9.34	9.37	9.44	9.32	9.36
9.38	9.39	9.34	9.32	9.30	9.30	9.36
9.29	9.41	9.27	9.36	9.41	9.37	9.31
9.31	9.33	9.35	9.34	9.35	9.34	9.38
9.40	9.35	9.37	9.35	9.32	9.36	9.35
9.35	9.36	9.39	9.31	9.31	9.30	
9.31	9.36	9.34	9.31	9.32	9.34	

tendency and variability of the data than that presented by Table 2. In Table 3, data are grouped in six classes of equal size and it is possible to see the centering of the data about the 9.325–9.355 class and its variability: The measurements vary from 9.27 to 9.44 with ~95% of them between 9.29 and 9.41. The advantage of grouped frequency distributions is that grouping smoothes the data so that essential features are more discernible. Figure 2 represents the corresponding histogram. The sides of the bars of the histogram are drawn at the class boundaries and their heights are the frequencies or the relative frequencies (frequency/sample size). In the histogram, the distribution of the data centered about the point 9.34 is clearly seen. Although grouping smoothes the data, too much grouping (that is choosing too few classes) will tend to mask rather than enhance the sample’s essential features.

There are many numerical indicators for summarizing and describing data. The most common ones indicate central tendency, variability, and proportional representation (the sample mean, variance, and percentiles, respectively). We assume that any characteristic of interest in a population, and hence in a sample, can be represented by a number. This is obvious for measurements and counts, but even qualitative characteristics (described by discrete variables) can be numerically represented. For example, if a population is dichotomized into those individuals who are carriers of a particular disease and those who are not, a 1 can be assigned to each carrier and a 0 to each noncarrier. The sample can then be represented by a sequence of zeroes and ones.

The most common measure of central tendency is the sample mean:

$$M = (x_1 + x_2 + \dots + x_n)/n \quad \text{also noted } \bar{X} \quad (1)$$

Table 3. Frequency distribution of infant serum calcium data

Serum Calcium mg·100 mL ⁻¹	Frequency
9.265–9.295	4
9.295–9.325	18
9.325–9.355	24
9.355–9.385	22
9.385–9.415	6
9.415–9.445	1
Total	75

where x_1, x_2, \dots, x_n is the collection of numbers from a sample of size n . The sample mean can be roughly visualized as the abscissa of the horizontal center of gravity of the frequency histogram. For the serum calcium data of Table 2, $M = 9.34$, which happens to be the midpoint of the highest bar of the histogram (Fig. 2). This histogram is roughly symmetric about a vertical line drawn through M , but this is not necessarily true of all histograms. Histograms of counts and survival times data are often skewed to the right (long-tailed with concentrated mass at the lower values). Consequently, the idea of M as a center of gravity is important to bear in mind when using it to indicate central tendency. For example, the median (described later in this section) may be a more appropriate index of centrality depending on the type of data and the kind of information one wishes to convey.

The sample variance, defined by

$$s^2 = \frac{1}{n - 1} [(x_1 - M)^2 + (x_2 - M)^2 + \dots + (x_n - M)^2] \\ = \sum_{i=1}^n \frac{(x_i - M)^2}{n - 1} \quad (2)$$

is a measure of variability or dispersion of the data. As such, it can be motivated as follows: $x_i - M$ is the deviation of the i th data sample from the sample mean, that is, from the “center” of the data; we are interested in the amount of

Figure 2. Frequency histogram of infant serum calcium data of Tables 2 and 3. The curve on the top of the histogram is another representation of probability density for continuous data.

deviation, not its direction, so the sign is disregarded by calculating the squared deviation $(x_i - M)^2$; finally, the squared deviations are averaged by summing them and dividing by the sample size $n - 1$. (Division by $n - 1$ ensures that the sample variance is an unbiased estimate of the population variance.) Note that an equivalent and often more practical formula for computing the variance may be obtained by developing Eq. 2:

$$s^2 = \frac{\sum x_i^2 - nM^2}{n - 1} \tag{3}$$

A measure of variability in the original units is then obtained by taking the square root of the sample variance. Specifically, the sample standard deviation, denoted s , is the square root of the sample variance.

For the serum calcium data of Table 2, $s^2 = 0.0010$ and $s = 0.03 \text{ mg}\cdot 100 \text{ mL}^{-1}$. The reader might wonder how the number 0.03 gives an indication of variability. Note that for the serum calcium data $M \pm s = 9.34 \pm 0.03$ contains 73% of the data, $M \pm 2s = 9.34 \pm 0.06$ contains 95% and $M \pm 3s = 9.34 \pm 0.09$ contains 99%. It can be shown that the interval $M \pm 3s$ will include at least 89% of any set of data (irrespective of the data distribution).

An alternative measure of central tendency is the median value of a data sample. The median is essentially the sample value at the middle of the list of sorted sample values. We say essentially because a particular sample may have no such value. In an odd-numbered sample, the median is the middle value; in an even-numbered sample, where there is no middle value, it is conventional to take the average of the two middle values. For the serum calcium data of Table 3, the median is equal to 9.34.

By extension to the median, the sample p percentile (say, e.g., 25th percentile) is the sample value at or below which $p\%$ (25%) of the sample values lie. If there is no value at a specific percentile, the average between the upper and lower closest existing round percentile is used. Knowledge of a few sample percentiles can provide important information about the population.

For skewed frequency distributions, the median may be more informative for assessing a population center than the mean. Similarly, an alternative to the standard deviation is the interquartile range: it is defined as the seventy-fifth minus the twenty-fifth percentiles and is a variability index not as influenced by outliers as the standard deviation.

There are many other descriptive and numerical methods (see, e.g., Ref. (2)). It should be emphasized that the purpose of these methods is usually not to study the data sample itself, but rather to infer a picture of the population from which the sample is taken. In the next section, standard population distributions and their associated statistics are described.

PROBABILITY, RANDOM VARIABLES, AND PROBABILITY DISTRIBUTIONS

The foundation of all statistical methodology is probability theory, which progresses from elementary to the most advanced mathematics. Much of the misunderstanding

and abuse of statistics comes from the lack of understanding of its probabilistic foundation. When assumptions of the underlying probabilistic (mathematical) model are grossly violated, derived inferential methods will lead to misleading and irrational conclusions. Here, only enough probability theory to provide a framework for this article is discussed.

In the rest of this article, experiments that have more than one possible outcome, the actual outcome being determined by some chance mechanism will be studied. The set of possible outcomes of an experiment is called its sample space; subsets of the sample space are called events, and an event is said to occur if the actual outcome of the experiment is a member of that event. A simple example follows.

The experiment will be the toss of a pair of fair coins, arbitrarily labeled coin number 1 and coin number 2. The outcome (1,0) means that coin No. 1 shows a head and coin No. 2 shows a tail. Then, the sample space by the collection of all possible outcomes can be specified:

$$S = \{(0,0)(0,1)(1,0)(1,1)\} \tag{4}$$

There are four ordered pairs so there are four possible outcomes in this coin-tossing experiment. Consider the event A “toss one head and one tail”, which can be represented by $A = \{(1,0)(0,1)\}$. If the actual outcome is (0,1) then the event A has occurred.

In the example above, the probability for event A to occur is obviously 50%. However, in most experiments it is not possible to intuitively estimate probabilities, so the next step in setting up a probabilistic framework for an experiment is to assign, through some mathematical model, a probability to each event in the sample space.

Definition of Probability

A probability measure is a rule, say P , which associates with each event contained in a sample space S a number such that the following properties are satisfied:

1. For any event, A , $P(A) \geq 0$.
2. $P(S) = 1$ (since S contains all the outcomes, S always occurs).
3. $P(\text{not } A) + P(A) = 1$.
4. If A and B are mutually exclusive events (that cannot occur simultaneously) and independent events (that are not linked in any way), then

$$P(A \text{ or } B) = P(A) + P(B) \quad \text{and} \quad P(A \text{ and } B) = 0$$

Many elementary probability theorems (rules) follow directly from these definitions.

Probability and Relative Frequency

The axiomatic definition above and its derived theorems dictate the properties that probability must satisfy, but they do not indicate how to assign probabilities to events. The major classical and cultural interpretation of probabilities is the relative frequency interpretation. Consider an experiment that is (at least conceptually) infinitely

repeatable. Let A be any event and let n_A be the number of times the event A occurs in n repetitions of the experiment; then the relative frequency of occurrence of A in the n repetitions is n_A/n . For example, if mass production of a medical device reliably yields 7 malfunctioning devices out of 100, the relative frequency of occurrence of a defective device is 7/100.

The probability of A is defined by $P(A) = \lim n_A/n$ as $n \rightarrow \infty$, where this limit is assumed to exist. The number $P(A)$ can never be known, but if the experiment can in fact be repeated a large number of times, it can be estimated by the relative frequency of occurrence of A .

The relative frequency interpretation is an objective interpretation because the probability of an event is assumed to be independent of judgment by the observer. In the subjective interpretation of probability, a probability is assigned to an event according to the assigner's strength of belief that the event will occur, on a scale of 0–1. The assigner could be an expert in a specific field, for example, a cardiologist that provides the probability for a sample of electrocardiograms to be pathological.

Probability Distribution Definition and Probability Mass Function

It has been assumed that all data can be numerically represented. Thus, the outcome of an experiment in which one item will be randomly drawn from a population will be a number, but this number cannot be known in advance. Let the potential outcome of the experiment be denoted by X , which is called a random variable in statistics. When the item is drawn, X will be realized or observed. Although the numerical values that X will take cannot be known in advance, the random mechanism that governs the outcome can perhaps be described by a probability model. Using the model, the probability that the random variable X will take a value within a set or range of numbers can be calculated.

One such popular mathematical model is the probability distribution of a discrete random variable X . It can be best described as a mathematical equation or table that gives, for each value x that X can assume, the probability associated with this value $P(X = x)$. For example, if X represents the outcome of the tossing of a coin, there are two possible outcomes, tail and head. If it is a fair coin $P(X = tail) = 0.5$ and $P(X = head) = 0.5$. In statistics, the function $P(X = x)$ is called the probability mass function of X .

It follows from the relative frequency interpretation of probability that, for a discrete random variable or for the frequency distribution of a continuous variable, relative frequency histograms estimate the probability mass functions of this variable. For example, in Table 3, if the random variable X indicates the serum calcium measure, then

$$\hat{P}(X \text{ is in the first bin}) = \hat{P}(9.265 \leq X < 9.295) = 4/75$$

the $\hat{}$ symbol on P indicating estimated probability values, since actual probabilities describe the population itself and cannot be calculated from data samples. Similarly the probability that X is in the second bin,

the third bin, ... can be estimated and the collection of these probabilities constitute an estimated probability mass function.

Probability Density Function for Continuous Variables

The probability mass function above best describes discrete events, but what probabilities can be assigned to continuous variables? Since a continuous variable X can assume any value on a continuum, the probability that X assumes a particular value is 0 (except in very particular cases that will not be discussed here). Consequently, associated with a continuous random variable X , is a function f_X , called its probability density function that can be used to compute probability. The probability that a continuous random variable X assumes a value between values x_1 and x_2 is the area under the graph of f_X over the interval x_1 and x_2 ; mathematically

$$P(x_1 \leq X \leq x_2) = \int_{x_1}^{x_2} f_X(x) dx \tag{5}$$

For example, for the infant serum data of Table 2 (see also Table 3), it can be estimated that the probability that an infant whose mother received a vitamin D supplement during pregnancy has between 9.35 and 9.38 mg·100 mL⁻¹ calcium is 22/75 or 0.293, which is the relative frequency of the 9.355–9.385 class in the sample. For continuous data, a smooth curve passing through the midpoint of a histogram bars' upper limit should resemble the probability density function of the underlying population.

There are many mathematical models of probability distribution. Three of the most commonly used probability distribution models described below are the binomial distribution and the Poisson distribution for discrete variables, and the normal distribution for continuous variables.

The Binomial Distribution

The scenario leading to the binomial distribution is an experiment that consists of n independent, repeated trials, each of which can end in only one of two ways arbitrarily labeled success or failure. The probability that any trial ends in a success is p (and hence $q = 1 - p$ for a "failure"). Let the random variable X denote the total number of successes in the n trials, and x denote a number in $\{0; \dots; n\}$. Under these assumptions:

$$P(X = x) = \binom{n}{x} p^x q^{n-x} \quad x = 0, 1, \dots, n \tag{6}$$

with

$$\binom{n}{x} = \frac{n!}{x!(n-x)!} \tag{7}$$

where $n! = 1 * 2 * 3 * \dots * n$ is n factorial.

For example, suppose the proportion of carriers of an infectious disease in a large population is 10% ($p = 0.1$) and that the number of carriers follows a binomial distribution. If 20 individuals are sampled ($n = 20$) and X is the number of carriers (successes) in the sample, then the probability

that there will be exactly one carrier in the sample is

$$P(X = 1) = \binom{20}{1} (0.10)^1 (0.90)^{20-1} = 0.27$$

More complex probabilities may be calculated with the help of probability rules and definitions. For instance the probability that there will be at least two carriers in the sample is

$$\begin{aligned} P(X \geq 2) &= 1 - P(X < 2) \\ &\quad \text{(see third probability definition)} \\ &= 1 - P(X = 0 \text{ or } X = 1) \\ &= 1 - (P(X = 0) + P(X = 1)) \\ &\quad \text{(see fourth probability definition)} \\ &= 1 - \binom{20}{0} (0.10)^0 (0.90)^{20} - \binom{20}{1} (0.10)^1 (0.90)^{19} \\ &= 1 - 0.12 - 0.27 = 0.61 \end{aligned}$$

Historically, single trials of a binomial distribution are called Bernoulli variates after the Swiss mathematician James Bernoulli who discovered it at the end of the seventeenth century.

The Poisson Distribution

The Poisson distribution is often used to represent the number of successive independent events of a specified type (e.g., cases of flu) with low probability of occurrence (<10%) in some specified interval of time or space. The Poisson distribution is also often used to represent the number of occurrence of events of a specified type where there is no natural upper limit, for example, the number of radioactive particles emitted by a sample over a set time period. Specifically, X is a Poisson random variable if it obeys the following formula:

$$P(X = x) = e^{-\lambda} \lambda^x / x! \quad x = 0, 1, 2, \dots \quad (8)$$

where $e = 2.178 \dots$ is the natural logarithmic base and λ is a given constant. For example, suppose the number of a particular type of bacteria in a standard area (e.g., 1 cm²) can be described by a Poisson distribution with parameter $\lambda = 5$. Then, the probability that there are no more than 3 bacteria in the standard area is given by

$$\begin{aligned} P(X \leq 3) &= P(X = 0) + P(X = 1) + P(X = 2) + P(X = 3) \\ &= e^{-5} 5^0 / 0! + e^{-5} 5^1 / 1! + e^{-5} 5^2 / 2! + e^{-5} 5^3 / 3! \\ &= 0.265 \end{aligned}$$

Note that the Poisson and the binomial distributions are closely related. In the case of a rare event ($p < 10\%$), the binomial distribution (described by probability p and n events) is well approximated by the Poisson distribution with the constant $\lambda = np$. The Poisson distribution was named after the French mathematician Siméon-Denis Poisson, who discovered it in the early part of the nineteenth century.

The Normal Distribution

The binomial and Poisson distributions describe discrete events, but there are also many distributions describing

continuous variables. The most important one is the normal distribution (also called Laplace–Gauss distribution as it was discovered by the French astronomer Pierre–Simon Laplace and the German mathematician Karl Friedrich Gauss in the early nineteenth century). Normal distributions arise as a result of many small random fluctuations about some general average (e.g., repeated recordings of a constant body temperature using a noisy electronic thermometer). A random variable X is said to be a normal or Gaussian random variable with mean parameter μ and standard deviation parameter σ if its probability density function is

$$f_X(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-(x-\mu)^2/2\sigma^2} \quad -\infty < x < \infty \quad (9)$$

The normal probability density function graphed in Fig. 3, is bell shaped with tails rather rapidly receding to zero height. Because f_X represents probability density, the total area bounded by the curve is 1 (see Eq. 9). The area between two values of variable X (x_1 and x_2 where $x_1 < x_2$) represents the probability that X lies between x_1 and x_2 , (Eq. 5).

As shown in Fig. 3, if X is normal (μ, σ), it can be calculated that $P(\mu - 3\sigma \leq X \leq \mu + 3\sigma) = 0.997$, which, according to the relative frequency interpretation of probability, states that $\sim 99.7\%$ of a large sample from a “normally distributed population” will be contained in the interval mean plus or minus three standard deviations ($\mu \pm 3\sigma$).

Note that there is a relation between the normal and the binomial distribution. Using the same notation as in Eq. 6, if n , the number of samples, is large enough then the variable z defined as

$$z = \frac{x - np}{\sqrt{npq}} \quad (10)$$

is approximately normally distributed with mean 0 and standard deviation 1. In a coin throwing experiment, throwing the coin a large number of times and counting

Figure 3. The normal probability density function showing symmetry about a vertical line through μ , and the role of σ as a variability parameter. Vertical bars indicates $\pm\sigma, \pm 2\sigma, \pm 3\sigma$.

the number of heads x , then building a histogram for the value z , the histogram will be close to a normal distribution (as shown in Fig. 3). Similarly, there is a relation between the Poisson and the normal distribution, the variable z defined as $z = (x - \lambda) / \sqrt{\lambda}$ is normally distributed for large values of λ .

Many statistical inferential methods described in the next section assume that the data is approximately normally distributed. Much abuse occurs, however, when these methods are applied blindly with no verification of the normality assumption. Incidentally, methods that incorporate assumptions of normality often can be applied to non-normal situations because under certain conditions, the normal distribution can approximate other distributions, such as the binomial and the Poisson distributions. Sometimes, the data can also be preprocessed to fit the normal distribution. For example, a histogram might indicate nonnormality, while a histogram of the logarithms of the data would fit the normal distribution, indicating that normal-based models can be applied to the log-transformed data. These transformations are discussed in most experimental design textbooks.

The importance of the normal distribution in statistics is also due to the central limit theorem in statistics that states that the distribution of any linear mixture of two or more independent random variables is more normal (has a shape closer to the normal distribution) than the distribution of the random variables themselves. This property is used by some algorithms processing multivariate data (as described in a later section).

There are many other continuous probability distributions besides the normal distribution. For example, the most commonly used distribution in survival analysis is the Weibull distribution. The von Mises distribution allows parametric statistical tests for periodic data (i.e., seasonal).

Characteristics of Probability Distributions

Just as there are numerical indexes for sample description, for example, sample means, variances, and percentiles, there are numerical characteristics of probability distributions. The expectation or mean (not sample mean) of a random variable X is

$$\begin{aligned}
 E(X) &\equiv \sum_x xP(X = x) && X \text{ discrete} \\
 &\equiv \int_{-\infty}^{\infty} x f_X(x) dx && X \text{ continuous}
 \end{aligned}
 \tag{11}$$

The expectation E is a measure of central tendency for a population (i.e., the center of gravity of the probability distribution about the y axis). The variance of X is defined in terms of expectation by

$$\text{Var}(X) \equiv E\{[X - E(X)]^2\}
 \tag{12}$$

In words, $\text{Var}(X)$ is the expected squared deviation of X from $E(X)$, and in this sense is a measure of variability or dispersion for a population. The standard deviation of X is the square root of its variance. Table 4 indicates mean and variance for the binomial, the Poisson, and the normal distribution.

Numerical descriptors of populations are often the very things we want to know about populations. They should not

Table 4. Mean and Variance for Standard Distributions (see text for details)

	Binomial	Poisson	Normal
Mean	$\mu = Np$	$\mu = \lambda$	μ
Variance	$\sigma^2 = Npq$	$\sigma^2 = \lambda$	σ^2

be confused with their sample counterparts; the sample numerical descriptors are the basis for drawing inferences regarding their population counterparts, which are of primary interest.

Statistical Inference

A statistical hypothesis is a statement about the probability distribution of populations using one or more data samples. Typical questions are Is this single data sample consistent with this theoretical distribution of values?, Are these two data samples originating from the same population?, Are these n data samples originating from the same population?. Associated with each of these questions, in statistics, two hypotheses are usually formulated.

Hypothesis H_0 : All data samples originate from the same population (or the single data sample is consistent with a given theoretical distribution).

Hypothesis H_1 : Some data samples do not originate from the same population (or the single data sample is not consistent with the given theoretical distribution).

The test is called significant if hypothesis H_0 is rejected with respect to a user-defined confidence interval (e.g., 5% of chance of wrongly rejecting H_0). It is important to remember that inference tests can never disprove hypothesis H_0 . Instead, based on the significance threshold and on the inference test chosen, it can be said that the data support rejecting H_0 . The test is called nonsignificant if the hypothesis H_0 and reject hypothesis H_1 is accepted. Accepting H_0 means that we failed to find any significant difference with respect to our user-defined confidence interval. Because the error in accepting H_0 is usually large (see error types below), in general we should avoid drawing any conclusion about the experiment when accepting H_0 .

Degree of Freedom. Elementary tests usually depend on the data sample size as well as the number of parameters (e.g., mean or variance) that have to be estimated from the sample, to run the test. Specifically, the number of degrees of freedom of a statistics is defined as the number of independent observations minus the number of population parameters, which must be estimated from sample observations. Details will be provided for each test.

p -Values. Once hypotheses H_0 and H_1 have been defined, that a test has been chosen to address these hypotheses (see below), and that parameters for this test have been calculated, one must choose a level of significance. The term $p < 0.05$ is the arbitrary value that is generally accepted to be significant. This means that there must be $< 5\%$ possibility of falsely detecting a significant difference. Now describe how the p value relates to the different types of errors associated with elementary tests.

Type I and Type II Errors. If a hypothesis H_0 is rejected when it should be accepted, it can be said that a type I error has been made. If a hypothesis H_0 is accepted when it should be rejected, it can be said that a type II error has been made. In either case, a wrong decision or judgment has occurred. This is not a simple matter because decreasing one error type usually leads to increasing the other error type. One way of getting around this problem is just to set your significance level at 0.05 (and not at 0.01 or 0.001). In this way, you are balancing between type I and type II errors in your decision making process. One way to decrease both error types is to increase the size of the sample. However, two ways of analyzing the same size dataset (i.e., two types of inference test) might have different efficiency, so that the more efficient might give better performance on both error types. As an example of type I and type II errors, let us imagine that there is a significant difference between the average of blood pressure measured from a population of patients and the general population at $p = 0.05$. Then there will be a 5% chance that our statement is false (type I error). This means that if we repeat the test 100 times, when in fact no real effects are present, we will draw a wrong conclusion ~5% of the time that we observe a significant difference. In contrast, if we state that there is no such difference between population of patients at $p = 0.05$, there is not a 5% chance of being wrong, but usually more (type II error). This is why, in general, when accepting hypothesis H_0 , no conclusions should be drawn about the results of an experiment. The exact calculation of type II error usually depends on the size of the actual effect in the population, hence it is usually described by curves as a function of effect magnitude.

Correction for Multiple Comparisons. When multiple tests are performed, the probability that one of them is significant by chance becomes larger. As for type I error, if 100 tests are performed with significance threshold of $p = 0.05$, when in fact no real effects are present, then on average about five of them will indicate significance, but will be false positives. This is the case, for example, when processing biophysical images, such as magnetic, resonance imaging data: a collection of values is acquired for each coordinate on a three-dimensional (3D) grid and a statistical test must be performed on this data. The same problem may arise when processing time series data. The standard conservative approach developed by Bonferroni (3) consists of dividing the p -value threshold by the number of comparisons performed. For example, for 100 tests performed at $p = 0.05$, the corrected p value is $0.05/100 = 0.0005$. This is a conservative approach and a less stringent method has been developed by Holm (4): first choose a significance level $p = \alpha$ (e.g., $p = 0.05$). Then compute the exact p -value for each test, which is usually possible using modern computerized approaches. Rank the collection of p -values from smallest to largest. The smallest p -value is tested against α/N , where N is the number of tests. If the smallest p -value is not $< \alpha/N$, stop the procedure. However, if it is $< \alpha/N$, proceed to test the second smallest p -value against $\alpha/(N - 1)$, and so on. A variant of the Holm's procedure consist of testing the first p -value against α/N , the second one against $2\alpha/N$, the third one against $3\alpha/N$, and so on. Technical details and theory about multiple comparisons may be found in (5).

Paired/Unpaired Samples. Table 5 distinguishes between paired versus unpaired data samples. For

Table 5. Which Statistical Inference Test to Use for Which Type of Data

Goal	Dataset		
	Binomial or Discrete	Continuous measurement (from a normal distribution)	Continuous measurement, Rank, or Score (from non-normal distribution)
Example of data sample	List of patients recovering or not after a treatment	Readings of heart pressure from several patients	Ranking of several treatment efficiency by one expert
Describe one data sample	Proportions	Mean, SD	Median
Compare one data sample to a hypothetical distribution	χ^2 or Binomial test	One-sample t test	Sign test or Wilcoxon test
Compare two paired samples	Sign test	Paired t test	Sign test or Wilcoxon test
Compare two unpaired samples	χ^2 Fisher's exact test	Unpaired t test	Mann-Whitney test
Compare three or more unmatched samples	χ^2 test	One-way ANOVA ^a	Kruskal-Wallis test
Compare three or more matched samples	Cochrane Q test	Repeated-measures ANOVA ^b	Friedman test
Quantify association between two paired samples	Contingency coefficients	Pearson correlation	Spearman correlation

^aAll statistical tests in this table are described in the text and often instantiated using a numerical example.

^bAnalysis of Variance = ANOVA

unpaired data samples, there is no direct correspondence between values. This may be the case when a specific measure (e.g., blood pressure) is taken from two distinct populations of patients (e.g., patients suffering from heart failure and control patients). The two data samples corresponding to the two groups of patients are said to be unpaired because there is no relationship between them. In contrast, for paired samples, each value in one sample corresponds to a value in the other sample. In the previous example, it could be the case if each patient tested had a twin volunteering to be a control patient. This would also be the case if two assessments were performed on the same patients (e.g., measure of blood pressure before and after taking a drug). Note that paired groups must necessarily be of the same size. Matched/unmatched data samples are an extension of paired/unpaired data samples when there are more than two samples.

Sampling With or Without Replacement. Sampling with replacement means that each item is put back in the data sample after being sampled (so it may be sampled more than once and appear twice or more in a data sample). Sampling with replacement satisfies the requirement that the trials are independent, but when the sample size is small relative to the size of the population, sampling with or without replacement makes little difference. In elementary statistics, a representative sample is synonymous with the concept of a random sample. When sampling from a population of finite size, a sample of n items is a random sample if it is chosen in such a way that any other sample of size n would be equally likely to be chosen. Sampled items can be chosen with or without replacement. Although impractical in many situations, sampling with replacement leads to easier mathematical analysis. When the population is large relative to the sample size, the analytical methods developed for sampling with replacement yield good approximations. A random sample can be chosen by assigning a number to each member of the population, and then choosing at random n numbers (with or without replacement). This can be done by the so-called Monte Carlo method (consisting of random draws) that uses computer-generated (pseudo)-random numbers.

Table 5 indicates which statistical test should be used depending on data type and question type. Most types of questions have already been described when hypotheses H_0 and H_1 were defined. The last row of Table 5, which is concerned with the relationship between data samples (or more specifically the relationship between variables underlying two paired data samples) was not covered. The corresponding question may be formulated as ‘Is there any relationship between the two variables (e.g., two paired measurements)?’ The H_0 hypothesis is that there is no relationship between the two variables.

Columns of Table 5 contain elementary tests for different types of variables. Elementary tests cover confidence interval estimation and parametric hypothesis testing for situations involving normally distributed samples, including two-sample situations where the purpose is to compare two populations with respect to their means or variances. Other types of elementary confidence intervals are for proportions and difference of proportions, usually based

on the binomial distribution or based on the normal approximation to the binomial distribution. Confidence interval estimation for parameters of nonnormal distributions are much more difficult and closed form formulas often do not exist. In these cases, experimenters must use nonparametric statistical tests that only take into account rank ordering of data samples. They may also use resampling statistical tests, which estimates confidence intervals using many computer-generated random resamplings. For practicality, in Table 5, hypothesis testing was divided into three main categories: hypothesis testing on discrete variables, parametric statistical testing on continuous variables, and nonparametric statistical testing on continuous variables. In a separate section, resampling methods will be dealt with, since it may be applied to any type of data. The list of tests is not exhaustive but instead seeks to provide, within the limited scope of this short article, a range of methods to perform statistical inference on different types of data.

Which type of test to use is often one of the most delicate choices an experimenter has to make. For continuous data, for example, one could use at least three tests: a parametric, a nonparametric, or a resampling inference test. Different tests make different assumptions: parametric test, such as the t -test, make the hypothesis that the data is normally distributed. Nonparametric tests make fewer assumptions about the population distribution but require more data samples. Resampling tests make the assumption that the data samples are an accurate representation of the population. There is no ideal test (although some applied statisticians would argue that resampling methods are indeed superior to other methods), and the test to choose often depends on the type of data being processed or common usage in one specific field of research.

Testing Hypothesis on Discrete Variables

For discrete variables, data is most often represented by proportions of different outcomes. As shown in the first column of Table 5, specific tests have been designed to deal and compare proportions between data samples. Some of these tests (as indicated below) can only deal with binomial data samples (success or failure).

Goodness of Fit to Distribution for One Data Sample. A goodness of fit test may be used to compare one data sample to a hypothetical value or distribution. In a goodness-of-fit test the hypotheses are concerned with the distribution itself. For example, a drug has been repeatedly tested on adults and has shown minor side effects in 2.5% of the cases in which it was administered. To validate this drug for treating children, it is given to a sample of 300 children. The goal of this study is to determine if children showed more or less side effects than adults. The hypothesis H_0 is that the distribution of sample data values for children is generally the same as the hypothetical distribution for adults. The hypothesis H_1 is that the distribution of sample data values for children generally differs from the hypothetical distribution for adults. Table 6 indicates that 13 out of 300 children showed an abnormal reaction to the drug. The

Table 6. Measured and Expected Frequencies of Side Effect for 300 Children Treated With a Test Drug

	Children	Expected value
Side effect	13	7.5
No side effects	287	292.5
Total	300	300

second column in Table 6 indicates the expected values from the theoretical distribution (2.5% of cases for 300 subjects is 7.5 individuals; it is not so important that the expected value is not a whole number since this distribution is only theoretical).

The χ^2 value is then simply calculated by comparing the expected frequencies e_1 (7.5 individuals showing side effects) and e_2 (292.5 individuals showing no side effects) to the observed frequencies O_1 (13) and O_2 (287) using the formula:

$$\chi^2 = \frac{(O_1 - e_1)^2}{e_1} + \frac{(O_2 - e_2)^2}{e_2}$$

or more generally

$$\chi^2 = \sum_i \frac{(O_i - e_i)^2}{e_i} \tag{13}$$

where O_i is the frequency observation in row i and e_i is the corresponding expected frequency. The degrees of freedom is equal to $(n - 1)$, where n is the number of rows in the table. Once the χ^2 value and the degrees of freedom have been calculated, the critical value for χ^2_{crit} can be looked up in Table 7 for a given level of significance. If $\chi^2 > \chi^2_{crit}$, we reject hypothesis H_0 in favor of hypothesis H_1 and conclude that the data support the hypothesis that there is a difference between the sample data and the theoretical distribution at the 5% level of significance.

In the example shown in Table 6,

$$\chi^2 = \frac{(13 - 7.5)^2}{7.5} + \frac{(287 - 292.5)^2}{292.5} = 4.13$$

with 1 degree of freedom (2 rows minus 1). For a test at the 5% level of significance ($p = 0.05$) with 1 degree of freedom, χ^2_{crit} in the χ^2 table (Table 7) is equal to 3.84. Since $4.13 > 3.84$, the hypothesis that the proportion of children having side effects in the same as that of adults is rejected. Comparing actual and expected frequencies in Table 6, we conclude that children have higher occurrences of side effects than adults for this drug.

Note that the construction of the χ^2 table is relatively simple. One can simply assume that a known population (whose expected distribution is known) is sampled several times and that the χ^2 value is computed for each of these samples. The histogram of these observed χ^2 values, when in fact no real effects are present, is an approximation to the χ^2 distribution for the null hypothesis (Fig. 4). The tails of this distribution may be used to set thresholds for significance testing (if an observed χ^2 value ends up in the tail of the distribution, then it is likely that it does not originate from the known population). For example, the χ^2

Table 7. χ^2 Distribution of Critical Values^a

	$p = 0.05$	$p = 0.01$	$p = 0.001$

100	124.34	135.81	149.48

^aTo use this table, choose a p value (column) and read the value for your calculated degrees of freedom (df). If your calculated χ^2 value is larger than the one you read in the table, the test you performed is significant (see text for details).

value for a data sample is significantly different from the χ^2 standard distribution at $p = 0.05$ if it lies in the lower or upper tails each containing only 2.5% of the values of the standard χ^2 distribution.

Binomial Test for Binomial Variables. For data samples that are assumed to be obeying the binomial distribution, it is possible to compute exact p values as explained in a previous section. For example, a coin is tossed 10 times to determine if it returns fair results or not. It returns 9 heads. The hypothesis H_0 is that the coin is fair and that the probability of obtaining a head is 0.5. The H_1 hypothesis is that the coin is biased toward head. Using the binomial distribution, the probability of obtaining an equal or more extreme number of heads than the one measured needs to be computed. The probability of obtaining 9 heads

Figure 4. Standard distributions (χ^2 , t , and F). Tails of these distributions are used to determine significance thresholds (see text).

or more is

$$P(X \geq 9) = P(X = 9) + P(X = 10) = \binom{10}{9} 0.5^9 (1 - 0.5)^{10-9} + \binom{10}{10} 0.5^{10} = 0.011$$

It appears that this result would appear by chance in only 1.1% of coin tossing trials if the coin is returning fair results. If $p < 0.05$ is considered to be the standard threshold for significance, it can be concluded that the coin does return more heads than a fair coin at the 5% level of significance. Note that this was a one-sided test, assuming that there was prior knowledge that the coin will be biased toward heads (based, e.g., on the aspect of the coin): for a two-sided test that would assess if the coin is fair in returning both faces and heads, it would be necessary to add the probability of obtaining both 9 to 10 heads and 9 to 10 faces.

Sign Test to Compare Paired Samples. This test is best illustrated by an example. To determine if drug *A* is more effective than a drug *B* for pain control, 10 patients are tested with these two drugs (with an interval of 7 days to prevent carry over effects) and asked if the drug was effective in controlling their pain. Hypothetical results are shown in Table 8, with + signs indicating a positive effect of the drug and - signs indicating no effect of the drug. The last row indicates the sign of the difference between the first two rows: a + sign indicates that drug *A* is performing better than drug *B* and a - sign indicates that drug *B* is performing better than drug *A*. When the outcome is the same, the cell is left empty. If the two drugs are equally effective, and if the sample is large enough, then there should be approximately equal numbers of + and - signs in the last row. The expected number of + signs (6 out of 7 nonempty cells) using binomial probability (note that for a large number of values, the approximation of the binomial distribution by the normal distribution may be used). We need to compute the probability of obtaining an

equally or more extreme number of + or - than the one obtained, hence to compute $P(0, 1, 2, 5, 6, 7)$:

$$P(+ = 0, 1, 2, 5, 6, 7) = \binom{7}{0} 0.5^0 (1 - 0.5)^{7-0} + \binom{7}{1} 0.5^1 (1 - 0.5)^{7-1} + \dots = 0.45$$

Although it seems that drug *A* is a better pain killer than drug *B*, the p value did not reach significance ($p > 0.05$). In other words, H_0 , the hypothesis that the two drugs are performing equally well cannot be rejected. This type of test applied to binomial variables is also sometimes called the Mc Nemar's test.

χ^2 Test to Compare Two or More Unpaired Samples. The χ^2 test allows the comparison of proportions observed in several groups under two or more conditions. Suppose that we wish to determine which of four prosthetic devices perform better for improving muscular response. Each of the four devices is implanted in four random samples of 100 patients each. For each patient, a clinician then estimates if there has been no improvement or partial to full restoration. Data is cross-classified as shown in Table 9. The test described here is usually called the χ^2 test of independence because it aims at finding if results from different groups can or cannot originate from the same population.

Here, the objective is to determine whether improvement is independent of the type of device. If it is the case, then the proportion of responses with no improvement and partial to full restoration should be similar for all four types of devices. The χ^2 test allows the comparison of the actual proportion of responses to each type of device to the idealized proportions, where all types of devices perform equally well. These proportions (also called expected frequencies) are calculated by pooling the responses for all types of devices. For instance, in Table 9, irrespective of the device type, there are 120 patients showing no restoration and 280 patients showing some degree of restoration, so the expected frequency for no restoration is 30% and the expected frequency for partial to full restoration is 70%.

Table 8. Success (+) or Failure (-) of Drug A and B for Reducing Pain in 10 Patients

Patient	1	2	3	4	5	6	7	8	9	10
Drug A	+	+	+	-	+	+	+	+	+	+
Drug B	+	-	-	+	+	-	-	+	-	-
Sign		+	+	-		+	+		+	+

Table 9. Results of Improvement in Muscular Response Following Implantation of an Electronic Device Available in Four Types

	Type of Device				Total
	1	2	3	4	
No improvement	35(30) ^a	40(30)	35(30)	10(30)	120
Partial-to-full restoration	65(70)	60(70)	65(70)	90(70)	280
Total	100	100	100	100	400

^aNumbers are observed frequencies and number in parentheses are expected frequencies.

As for the simpler example earlier in this section comparing a sample data distribution to a theoretical distribution, the χ^2 is simply calculated by comparing the expected frequencies, denoted by $e_{i,j}$ for device i (where i ranges from 1 to 4) and outcome j (where $j = 1$ indicates no restoration and $j = 2$ indicates partial to full restoration), to the observed frequencies $O_{i,j}$ using the formula:

$$\chi^2 = \sum_{i,j} (O_{i,j} - e_{i,j})^2 / e_{i,j} \tag{14}$$

The degrees of freedom is equal to $(r - 1)(c - 1)$, where r and c are the number of rows and columns in the table. Once the χ^2 value and the degrees of freedom have been calculated, the critical value for χ^2_{crit} can be looked up in Table 7 for a given level of significance. If $\chi^2 > \chi^2_{crit}$, then there is a significant difference between the groups being compared.

For the example shown in Table 9,

$$\chi^2 = \frac{(35 - 30)^2}{30} + \frac{(65 - 70)^2}{70} + \frac{(40 - 30)^2}{30} + \dots = 26.2$$

The degrees of freedom is $(4 - 1)(2 - 1) = 3$. In this example, for a test at the 5% level of significance ($p = 0.05$) and three degrees of freedom, Table 7 indicates that $\chi^2_{crit} = 7.82$. Since $26.2 > 7.82$, the hypothesis that all four devices are equally effective is rejected. It can be seen that device type 4 is most effective. In fact, further analysis supports the conclusion that differences between the other device types can be explained by sampling variation, and that there is a statistically significant difference between the first three device types taken together and the fourth device type. The additional analysis is sensible because the first three types are different vintages of essentially the same design, whereas the type four device is an experimental version of a fundamentally different design.

The χ^2 test may be used on a table of any size and not necessarily on binomial variables. For the example shown in Table 9, three possible outcomes could be imagined: no improvement, partial restoration, and full restoration. This would have added a row to Table 9 but the χ^2 formula (Eq. 14) would still apply.

Quantify Relationship between Variables. Classification in a table often reflects characteristics of individuals or objects, so they are often referred to as attributes. A measure of the degree of relationship, association, or dependence of two attributes (and the associated variables in the population) is called the coefficient of correlation. It

is given by

$$r = \sqrt{\frac{\chi^2}{N(\min(\text{No. rows}, \text{No. columns}) - 1)}} \tag{15}$$

where χ^2 represents the value computed from the χ^2 table; N is the total number of observations, and $\min(\text{No. rows}, \text{No. columns})$ represents the smaller number between the number of rows (No. row) and the number of columns (No. columns). r can only take values between 0 and 1. The closer r is to 1, the greater the association between the two (or more) columns of the table. To determine if a value of r is significant or not, χ^2 tests previously described in this section may be used.

Parametrical Hypothesis Testing on Continuous Variables

A parametric statistical hypothesis assumes that the data sample originates from a population that fits a specific model (most often the normal model). This is usually the case when recording a measure that fluctuates around a fixed mean because of environmental noise. Before running any statistical tests, one must verify that the data distribution is consistent with the normal distribution. First, plot the histogram to check that the distribution's overall shape is similar to that of the normal distribution. You may then perform a goodness of fit test with the normal distribution. In a goodness-of-fit test, the hypotheses are concerned not with the parameters, but with the distribution itself. For example, H_0 : X has a normal distribution; H_1 : X does not have a normal distribution. This may be done using the χ^2 goodness of fit test (mentioned in the previous section) applied to the data histogram frequencies compared to expected values calculated from the normal distribution (by integrating Eq. 9 using Eq. 5). Other goodness-of-fit tests are the Kolmogorov–Smirnov, Cramer–Von Mises, and Anderson–Darling. There are also tests when H_0 involves some specific distribution, for example, the Shapiro–Wilk test for normality. Most computer packages incorporate such tests.

One-Sample t-Test to Compare One Data Sample to a Hypothetical Distribution. This test is used to determine if a data sample belongs to a population with mean μ and standard deviation σ (the hypothesis H_0 is that it does belong to this population). This test applies to continuous or noncontinuous data that have a distribution that is not significantly different from normal. First, check that the standard deviation of the data sample is similar to the

^aTo use this table, find your degrees of freedom in the *df* column (or a lower one if yours is not present in the table). Then, look up the probability in the top row ($p = 0.05$ is a test of significance at 5%). If your calculated *t* value is larger than the one you read in the table, the test you performed is significant (see text for details).

population’s standard deviation σ (within a twofold range). For a data sample containing N values that has a mean M and standard deviation SD , the variable t is defined as

$$t = \frac{M - \mu}{SD} \sqrt{N} \tag{16}$$

The degrees of freedom associated with t is equal to $df = N - 1$. After calculating t and df , set up a threshold for significance (i.e., $p < 0.05$) and look up t_{crit} critical value in Table 10. In the t -test table, you may choose either one- or two-tailed t -test critical values. One-tailed t -tests are used when there is some prior knowledge to predict the direction of the difference. Most commonly, two-tailed t -tests are used when there is no such knowledge. If the calculated t value is $> t_{crit}$, there is a statistically significant difference between the data sample and the hypothetical distribution (the null hypothesis H_0 is rejected).

As for the χ^2 table, building the t -test table is straightforward. One may assume that, for a given degree of freedom, a known population (with a normal distribution) is sampled several times and that the t value is computed for each of these samples (M should on average be the same as μ since it is the theoretical population which is being sampled). The histogram of these observed t values, obtained when in fact no real effects are present, is an approximation to the t distribution (Fig. 4, middle panel). The tails of this distribution allow for threshold setting for significance (as for the χ^2 , if an observed value ends up in the tail of the distribution, then it is likely that it does not belong to this distribution). Note that for an infinite number of degrees of freedom, the t distribution is equal to the normal distribution.

For example, in the past, a machine has been producing washers having a thickness of 0.06 in. (0.15 cm) on average.

To test if the machine is still working properly, 10 washers of size (0.065; 0.062; 0.060; 0.059; 0.061; 0.064; 0.067; 0.064; 0.061; 0.062) are produced. The sample mean is 0.0625 and the sample standard deviation is 0.0025. The t value is equal to

$$t = \frac{0.0625 - 0.06}{0.0025} \sqrt{10} = 3.16$$

A two-tailed t -test is used since there is no *a priori* knowledge about the sampled distribution. At the 5% significance level, $t_{\text{crit}5\%}$ is equal to 1.83. Since $t > 1.83$, it can be concluded that there is a significant difference between the expected washer thickness and the observed one (reject hypothesis H_0 , which assumes that the sample distribution has a mean of 0.06 in., 0.15 cm). However, at 0.5% significance level, $t_{\text{crit}1\%}$ is equal to 3.25. Since $t < 3.25$, it cannot be concluded that such a difference exists at this level of significance (hypothesis H_0 cannot be rejected).

Paired t-Test to Compare Paired Data Samples. This test applies to two paired samples of continuous or noncontinuous data that have a distribution nonsignificantly different from normal and similar standard deviations (with less than twofold difference). First calculate the difference between each pair and average them (D_{av}) (note that differences in values also have to be normally distributed). Then calculate the value of t using

$$t = \frac{D_{\text{av}}}{SD} \sqrt{N} \tag{17}$$

where SD is the standard deviation of the difference between each pair. Since the accuracy of a statistic is influenced by the population size, the degrees of freedom (df) or the number of independent parameters used in the calculation of the test statistic must then be calculated. The degrees of freedom is equal to the degrees of freedom used in calculation the sample SD , that is, the number of pairs minus 1: $df = N - 1$.

Finally, as for the one sample t -test, set up a threshold for significance, look up t_{crit} critical value in Table 10, and compare it to the calculated value. If the calculated t value is $> t_{\text{crit}}$, there is a statistically significant difference between the two groups (the null hypothesis H_0 is rejected).

For example, to test if a newly designed electronic blood pressure (BP) device returns similar (hypothesis H_0) or different (hypothesis H_1) readings compared to an old manual blood pressure device, readings on 10 patients are performed and presented in Table 11 (only systolic pressure in Hgmm is reported in the table).

First, ensure that the two standard deviations are similar (14.1 for the electronic BP device and 13.5 for the manual BP device). To calculate the t value, compute the

difference between each pair, check that their distribution is normal, and then average them, $D_{\text{av}} = ((121 - 115) + (130 - 131) + \dots) / 10 = 2.8$. The standard deviation of the difference is $SD = 2.57$, and the degrees of freedom is 9 (10 readings minus 1). Thus the t value is equal to

$$t = \frac{2.8}{2.57} \sqrt{10} = 3.44$$

At the 5% level of significance, for 9 degrees of freedom, $t_{\text{crit}5\%}$ is equal to 2.26. Since $t > 2.26$, it can be concluded that the two devices return different averages (reject hypothesis H_0). The newly devised electronic BP device probably has to be recalibrated to better match the readings of the manual one.

Unpaired t-Test to Compare Unpaired Data Samples. An unpaired t -test aims to compare two unpaired data samples and applies to continuous or noncontinuous data that have a distribution not significantly different from normal. Sample sizes should be similar (with less than twofold difference) for the two groups and, if $n < 30$, variances should also be similar (with less than twofold difference). If the t -test is used in other circumstances, the results will have no meaning.

The most common way of calculating the t -statistics for unpaired data samples is to use the pooled variance estimate (it is also possible to use unpooled variance estimates, but this is less common and will not be presented here). First, calculate the unbiased pooled variance estimate:

$$V = \frac{V_A(N_A - 1) + V_B(N_B - 1)}{N_A + N_B - 2} \tag{18}$$

Then estimate the standard error of the difference of the means:

$$SE = \sqrt{V(1/N_A + 1/N_B)} \tag{19}$$

Then the t statistics is the difference of the means divided by its estimated standard error:

$$t = \frac{M_A - M_B}{SE} \tag{20}$$

where M_A , and M_B are the means of groups A and B, respectively, and where V_A and V_B are the variances of groups A and B, respectively. For this test, the number of degrees of freedom is equal to the total number of points minus 2, because two means are estimated.

$$df = (N_A + N_B) - 2$$

Finally, set up a threshold for significance ($p < 0.05$, e.g.), and look up the critical value t_{crit} in Table 10 (see the section above on one sample t -test for the difference between one- and two-tailed t -tests). If the calculated t

Table 11. Systolic Blood Pressure in Hgmm Measured in 10 Patients Using Either a New Electronic Device or an Old Manual Device

Patient	1	2	3	4	5	6	7	8	9	10
Electronic BP device	121	130	129	113	145	132	110	116	125	155
Manual BP device	115	131	127	111	140	131	111	111	121	150

Table 12. Heart Rate in Beats per Second of Control and Test Patients Suffering from Heart Failure

HF patients	78	81	88	76	93	112	83	96		
Control patients	80	71	68	80	95	67	85	69	85	77

value is $> t_{crit}$, there is a statistically significant difference between the two groups (the null hypothesis H_0 is rejected).

For example, to test if patients diagnosed with heart failure have similar (hypothesis H_0) or higher (hypothesis H_1) heart rates than control patients, 15 readings are performed at rest for these two groups of patients A and B of matched age, sex, and ethnicity. Heart rate is reported in beating per minutes in Table 12.

After testing for normality (see for how to test for normality at the beginning of this section), it is ensured that standard deviations for the two data samples are similar ($SD_A = 11.5$ and $SD_B = 9.1$). To calculate the t -value, it is necessary to compute the mean heart rate for each group. For patients suffering from heart failure, $M_A = 88.4$, and for control patients, $M_B = 77.7$ (variances are $V_A = 140.3$ and $V_B = 82.9$). Thus the pooled variance estimate is $V = 108$, the standard error of the mean is 4.93 and the t value is equal to

$$t = \frac{88.4 - 77.7}{4.93} = 2.17$$

At 5% significance level for 16 degrees of freedom (10 heart failure patients plus 8 control patients minus 2), $t_{crit1\%}$ is equal to 2.12. Since $t > 2.12$, the data support the fact that patients with heart failure have higher heart rate than controls (hypothesis H_0 cannot be rejected).

One-Way ANOVA for Unmatched Samples. One-way ANOVA is used to test the hypothesis that two or more samples are drawn from the same distribution of values and have the same mean and variance. Unpaired student t -test is a particular case of one-way ANOVA applied to two data samples. As for t -test, ANOVA test applies to continuous or noncontinuous data that have a distribution that is not significantly different from normal. Sample sizes should be similar (with less than twofold difference) for all sample groups and, if $n < 30$, variances should also be similar (less than twofold difference). If the test is used in other circumstances, the test outcome will lead to erroneous conclusions. The basis of ANOVA is the F (Fisher) variable, which combines the unbiased variance between sample groups ($V_{interGroup}$) and the variance within sample groups ($V_{withinGroup}$).

$$F = \frac{V_{interGroup}}{V_{withinGroup}} \tag{21}$$

For several data samples A, B, C, \dots of the same size, intergroup variance is defined as

$$V_{interGroup} = \frac{N_A(M_A)^2 + N_B(M_B)^2 + N_C(M_C)^2 + \dots - N_T(M_G)^2}{N_G - 1} \tag{22}$$

where $M_A, M_B,$ and M_C are the means of sample A, B, C, \dots and N_A, N_B, N_C, \dots are the number of values in samples A, B, C, \dots M_G is the average of all values from all sample groups and N_G is the number of samples. The within sample group variance is defined as

$$V_{withinGroup} = \frac{(N_A - 1)(SD_A)^2 + (N_B - 1)(SD_B)^2 + (N_C - 1)(SD_C)^2 + \dots}{N_T - N_G} \tag{23}$$

where SD_A, SD_B, SD_C, \dots are the standard deviations of group A, B, C, \dots and N_T represents the total number of observations (for all data sample pooled together). Degrees of freedom for the numerator of F and the denominator of F are defined as

$$df_{numerator} = N_G - 1$$

$$df_{denominator} = N_T - N_G$$

Note that each variance in Eqs. 22 and 23 is divided by the appropriate degrees of freedom to give unbiased estimate of population variance (assuming the null hypothesis H_0 is true). As for other inference tests, the computed F value is tested against critical F values (Table 13) obtained from the tail of null-hypothesis F distribution (Fig. 4, right panel).

For example, a clinician planning to purchase equipment for electroencephalography compares the signal to noise ratio for three sets of electroencephalographic equipment. For each system that has been made available to him, he records 10 new patients performing standard psychophysical tasks and measures the signal to background noise ratio of the encephalographic equipment (Table 14).

After testing for normality, we must ensure that standard deviations are similar (i.e., no twofold differences). Standard deviation for Brand A is equal to $SD_A = 1.11$; Brand B: $SD_B = 0.75$; Brand C: $SD_C = 0.94$. After calculating $V_{intergroup} = 0.44$ and $V_{withinGroup} = 0.89$, F may be calculated using Eq. 21

$$F = \frac{0.44}{0.89} = 0.49$$

The degrees of freedom for the numerator is $df_{numerator} = N_G - 1 = 2$. The degrees of freedom for the denominator is $df_{denominator} = 30 - 3 = 27$. Reading $F_{crit} = 2.95$ in Table 13, we may conclude that there is no significant difference (since $F < 2.95$) in terms of signal/noise ratio between the three sets of EEG equipments (accept hypothesis H_0).

One-Way ANOVA for Matched Samples. One-way ANOVA may also be used to compare paired sample groups. In fact, since for matched samples, one may

^aTo use this table, read the value at the intersection of the numerator's degrees of freedom (df_1) and the denominator's degrees of freedom (df_2). If your calculated F value is larger than the one you read in the table, the test you performed is significant (see text for details).

analyses either the rows or the columns of a table, the formula given here may be used both for rows or columns, and are usually associated with two-way ANOVA. The formula for the F (Fisher) variable is now equal to

$$F = \frac{V_{\text{interGroup}}}{V_{\text{error}}} \tag{24}$$

The variance due to error or chance is defined as

$$V_{\text{error}} = \frac{\sum_{j,k} (x_{jk} - M_j - M_k - M)^2}{(N_R - 1)(N_C - 1)} \tag{25}$$

where x_{jk} are all the elements in the array, M_j are the row means, M_k are the column means, M is the global array mean, N_C is the number of columns, and N_R the number of rows. The degrees of freedom for the numerator and

denominator are now defined as

$$df_{\text{numerator}} = N_R - 1 = N_G - 1$$

$$df_{\text{denominator}} = (N_R - 1)(N_C - 1)$$

Using the same example as shown in Table 14, and now assuming that the data samples are paired (EEG systems were tested with the same patients), the intersubject variance $V_{\text{error}} = 1.04$ can be computed, and

$$F = \frac{0.44}{1.04} = 0.42$$

The degrees of freedom for the numerator is $df_{\text{numerator}} = N_G - 1 = 2$. The degrees of freedom for the denominator is $df_{\text{denominator}} = (N_R - 1)(N_C - 1) = (3 - 1)(10 - 1) = 18$. For a test at 5%; significance, reading

Table 14. Signal/Noise Ratio for 10 Patients and for Three Brands of EEG Systems

Brand A	1.87	3.88	2.68	1.19	0.93	0.38	2.69	1.8	0.39	1.62
Brand B	2.48	1.71	3.05	1.58	1.7	3	0.47	2.11	2.18	2.22
Brand C	2.29	1.49	2.52	1.26	3.71	2.14	2.33	2.79	2.61	0.29

Table 15. Example of Table for a Two-Factor Experiment

	Protocol 1			Protocol 2			Protocol 3		
Brand A	6	8	8	1	0	2	1	4	4
	10	8	2	2	0	1	4	2	2
	10	6	2	1	3	3	3	5	0
Brand B	2	2	10	4	9	8	3	3	6
	6	10	10	5	5	9	5	4	2
	6	2	6	3	7	7	3	5	6
Brand C	6	0	4	5	3	2	6	6	8
	6	4	4	1	1	1	6	0	10
	4	8	8	3	3	2	4	8	6

$F_{crit} = 3.55$ in Table 13, it can be concluded that there is no significant difference (since $F < 3.55$) in terms of signal to noise ratio between the three sets of EEG equipments.

Note that one could argue that instead of using ANOVA analysis, t -tests could be performed between each pair of samples. Although this is possible, the ANOVA test is more sensitive than a series of paired t -tests because it processes all data samples simultaneously.

Two-Way ANOVA for Two-Factor Experiments. This type of test is being used for experiments with two factors or two attributes. In the example above, to test the reliability of the EEG equipment, the clinician might want to perform three experimental protocols and measure the signal to noise ratio in each of these protocols. The two factors are now the three sets of EEG equipment and the three protocols as shown in Table 15.

In each of the cells of Table 15, the clinician recorded nine values. In the case of only one value per cell, the analysis would be similar to the one-way ANOVA (row and column data may be analyzed separately using one-way ANOVAs for matched samples). However, if several values are recorded for each cell (several subjects, e.g.), one must use the repeated measures two-way ANOVA test. This test is especially interesting because it is possible to test for interaction between variables. Hypothesis H_0 would be that there is no significant relationship between brands and type of protocol and Hypothesis H_1 would be that there is indeed such a relationship. Running a repeated measures two-way ANOVA test under any software will return 3 p -values: the first value is for significant differences between rows; the second value is for significant differences between columns; the last p -value is for the interaction between columns and rows. In the case of Table 15, the p -value for the columns (protocol) is 0.0004 indicating a significant difference between protocols. As observed in Table 15, the values for the first protocol are indeed higher than the values for other protocols. The p -value for the different rows (device brand) is not significant ($p = 0.22$). The p -value for the interaction between brand and protocol is 0.0006. In fact, it appears that the device of brand *B* returns higher values for protocol 2 than other brands, and that the device of brand *C* returns higher values for protocol 3 than other brands.

Experimental design and ANOVA in its many variations is perhaps the most important statistical methodology for experimenters, and the literature is immense. Extreme care should be taken when choosing an ANOVA

test. For example, there are different ways to treat multi-factor ANOVAs analytically when the number of observations is unequal among the treatment combinations (called unbalanced designs). A nontechnical discussion is the classic Planning of Experiments by Cox (6). Other general introductions are Refs. (1,7–12).

Regression and Correlation. Regressions and correlations aim at determining relationship between variables. We may wish to determine if there is a significant correlation between independent and dependent variables, the independent variable being set by the experimenter, and the dependent variable being measured. For example, to test the reliability of a device, an experimenter may change the temperature of the room where the device is being tested (independent variable), and see if this change affects measures returned by the tested device (dependent variable). Regression and correlation can also be used to estimate the relationship between two (or more) dependent variables.

The first step in determining the relation between two variables is to plot values of one variable versus values of the other variable. This is usually called a scatterplot (Fig. 5). From the scatterplot it is often possible to visualize a smooth curve that approximates the data. If it is a straight line, then the least-squares regression method may be used. Otherwise, other curve fitting procedures may be used. It is sometimes useful to plot scatterplots of transformed variables (e.g., log transformation of values in first variable versus values of the second variable).

The method of least-squares computes the best linear regression between two variables. Specifically, for two variables X and Y , the data consist of n pairs $(x_1, y_1), \dots, (x_n, y_n)$. For all values of X and Y , we wish to find the parameter a and b such that

$$Y = aX + b \tag{26}$$

Assuming the jittering of points along the straight line is normally distributed, parameters a and b may be obtained using the formula

$$a = \frac{N \sum x_i y_i - (\sum x_i)(\sum y_i)}{N \sum x_i^2 - (\sum x_i)^2} \tag{27}$$

$$b = \frac{1}{N} \left(\sum y_i - a \sum x_i \right) \tag{28}$$

Figure 5. A typical scatterplot with the least-square line drawn through the data points. The r^2 value as well as the best fit equation is indicated on the diagram. The t -value is equal to 9.24 and indicate a significant relationship between X and Y (at $p = 0.05$, for 22 degrees of freedom, $t_{crit} = 2.07$).

To draw the linear regression line, y_i^{est} values may be calculated using Eq. 44 for all values of X . A sample-based measure of the strength of the linear association between the X and Y variables is the sample correlation coefficient (also known as the Pearson correlation coefficient) defined by

$$r = \pm \sqrt{\frac{\text{explained-variation}}{\text{total-variation}}} = \pm \sqrt{\frac{\sum (y_i^{est} - M_Y)^2}{\sum (y_i - M_Y)^2}} \quad (29)$$

r may also be expressed using the original variables X and Y .

$$r = \frac{\text{cov}(X, Y)}{SD_X \cdot SD_Y} = \frac{\frac{1}{n} \sum_{i=1}^n (x_i - M_X)(y_i - M_Y)}{\sqrt{\frac{1}{n} \sum_{i=1}^n (x_i - M_X)^2} \sqrt{\frac{1}{n} \sum_{i=1}^n (y_i - M_Y)^2}} \quad (30)$$

where M_X and M_Y (SD_X and SD_Y) are the mean (the standard deviation) for X and Y , respectively, and $\text{cov}(X, Y)$ is the covariance between X and Y (the numerator on the right of Eq. 30 is equal to $\text{cov}(X, Y)$) and the denominator is equal to $SD_X \cdot SD_Y$). Necessarily $-1 \leq r \leq 1$. Positive (respectively negative) values of r indicate that large values (respectively small values) of X are associated with large values (respectively, small values) of Y . Values of r near 0 indicate little or no linear association. Interpretation must be done with care because there are many reasons for the presence or absence of a correlation. Also, comparing r values may be misleading as a value of $r = 0.6$ does not mean that the linear relationship is twice as strong as $r = 0.3$. On the other hand, r^2 , called the sample coefficient of determination, represents the proportion of the total variation in the sample values of Y that can be “explained” by a linear relationship as in Eq. 26. Thus $r^2 = (0.3)^2 = 0.09$ versus $r^2 = (0.6)^2 = 0.36$ indicates a 9%

versus 36% accountability for total variability by the proposed linear relationship.

To test if the linear correlation between the two variables is significant, different tests may be used. The null hypothesis H_0 states that there is no relationship between the two variables. A t -test (with degrees of freedom equal to $N - 2$) may be used if the expected population correlation coefficient between variable X and Y is 0 and if we expect the correlation coefficient to be normally distributed when random samples of X and Y are drawn. The variable t is defined as

$$t = \frac{r\sqrt{N - 2}}{\sqrt{1 - r^2}} \quad (31)$$

More details for determining if correlation coefficients are significant or to compare between correlation coefficients may be found in Spiegel and Stepens (2).

As shown in Fig. 5, most regression computer packages will output scatterplots, and correlation coefficients. Residuals plots (not shown here) indicate if the distribution of distance between estimated and actual values of Y . A histogram of these residuals should be normally distributed (computing the parameter a , b , and the coefficient of correlation r requires that these residuals are normally distributed with mean 0 and a constant standard deviation irrespective of the X values).

A comprehensive presentation of regression methods for linear and nonlinear regression is given in Refs. 2, 7, 13.

Nonparametric Testing

Elementary tests mentioned in the previous section require that the distribution of values in the population be normally distributed. In practice, this assumption may not hold so statisticians have devised tests that are less dependent of population distribution. Nonparametric or distribution-free statistical methods generally are not concerned with inferences about parameters of distributions and assume little or no knowledge about the distributions of the underlying populations. Their primary advantage is that they are subjected to less restrictive assumptions than their parametric counterparts. Moreover, the data need not be quantitative (data values may indicate ranks on an ordinal scale). However, a disadvantage of nonparametric methods is that they may not utilize all the information in a sample, consequently requiring a larger sample than the parametric version to attain the same Type II error (see error types).

The χ^2 goodness-of-fit tests previously mentioned is an example of a nonparametric test. Other nonparametric tests make various hypotheses for medians (or means of a symmetric distribution) and differences in location and/or variability of two populations. There are also tests for randomness, independence, and association among random variables. Relatively elementary texts that give a fairly broad and complete coverage of nonparametric methods are Refs. 14 and 15.

Compare Sample Distribution to a Hypothetical Distribution. As for binomial and discrete data, a χ^2 goodness-of-fit test may be performed. For continuous data, a χ^2

Table 16. Heart Rate Variability for 10 Patients While Their Pacemaker Is Switched On or Off, and Calculation of Signed Rank for Wilcoxon Test

Patient	1	2	3	4	5	6	7	8	9	10	Sum
Pacemaker off	0.15	0.32	0.25	1.1	0.82	0.83	0.94	0.42	0.48	0.21	
Pacemaker on	0.12	0.19	0.28	0.56	0.37	0.52	0.24	0.73	0.81	0.13	
difference	0.03	0.13	-0.03	0.54	0.45	0.31	0.70	-0.51	-0.43	0.08	
abs difference	0.03	0.13	0.03	0.54	0.45	0.31	0.70	0.51	0.43	0.08	
Rank of abs difference	1.5	4	1.5	9	7	5	10	8	6	3	
Signed rank	1.5	4	-1.5	9	7	5	10	-9	-6	3	23

goodness-of-fit test may be used on the frequency distribution (histogram) of the data compared to a hypothetical distribution.

Sign Test and Wilcoxon Test for Paired Samples. As for binomial and discrete data, a sign test allows the comparison of paired samples (see the beginning of the section for a definition of paired and unpaired samples). A sign test simply involves pair-wise comparisons of measures between the two sample data sets (see sign test for binomial and discrete data). A variation of this test is called the Wilcoxon test, which takes into account the signed rank of the difference between each pair (instead of using all the signs). This is best illustrated using an example. To test if a pacemaker device has any effect on heart rate variability (defined as the standard deviation of heart beat intervals in seconds), 10 patients' heart rate variability are measured while the pacemaker was either switched on or off (Table 16).

The Wilcoxon test begins by taking the difference in heart rate variability between the two conditions for each patient (forth row of Table 16). If a difference is equal to 0 it is eliminated from further consideration, since it provides no useful information. The second step consists of taking the absolutes of the differences, which is accomplished simply by removing all the positive and negative signs (fifth row of Table 16), then ranking these absolute differences from lowest to highest, with tied ranks included where appropriate. Tied rank means that if two values are equal they are first-ordered randomly and then assigned their average rank (see the first and third columns of the sixth row in Table 16). Finally, reattach to each rank the positive or negative sign that was removed from the difference in the transition from row four to row five, and sum up these values. In our case, $W=23$ and the number of values used in this sum is 10 (degrees of freedom).

If two sets of sample values from the same distribution (which verify hypothesis H_0 that the two samples belong to the same distribution) were to drawn repeatedly and W values were calculated, it would be realized that the distribution (histogram) of W values is close to normal.

In fact,

$$z = \frac{W}{SD_W} \tag{32}$$

may be defined, where z is normally distributed with mean 0 and variance 1, and SD_W is the standard deviation of W , which can be shown to be equal to

$$SD_W = \sqrt{\frac{N(N+1)(2N+1)}{6}} \tag{33}$$

For $N=10$ values, $SD_W=19.6$, so $z=23/19.6=1.17$. As mentioned earlier, the t -distribution is equal to the normal distribution for infinite degrees of freedom. Looking in the last row of the t -table (Table 10), for a significant threshold at $p=0.05$ (two-tailed), $z_{crit}=1.64$ is obtained. Since $z < 1.64$, hypothesis H_0 cannot be rejected. Although it seems that heart rate variability is higher when the pacemaker is switched on, the difference did not reach significance.

Mann-Whiney U Test for Unpaired Samples. The Mann-Whitney U test is similar to the Wilcoxon test. Once more, this test will be illustrated using an example. To compare sensitivity of two hearing aids, the minimum sound a patient can hear using each brand is measured (in dB) and reported in Table 17, where 10 different patients tested each prosthetic device (unpaired samples).

To perform a Mann-Whitney test, first combine all values in an array and assign a rank from 1 to 20 to all these values, assigning tied ranks where appropriate (see Wilcoxon test). The rank for each value is indicated in Table 18.

Then, sum up the ranks for each brand, where $R_A=80$ is the sum for brand A and $R_B=130$ is the sum for brand B. A significant difference between the two rank sums implies a significant difference between the two samples. Calculate the U statistic to test the difference between the ranks:

$$U = N_A N_B + \frac{N_A(N_A+1)}{2} - R_A \tag{34}$$

Note that the formula above is symmetrical with respect to A and B. In the hearing aid example, $N_A=10$ and

Table 17. Patient Maximal Sensitivity (in dB) for Two Brands of Hearing Aids

Brand A	0.1	-1	4.1	2.4	-2.3	3.8	0.9	1.4	0.4	1.2
Brand B	2.7	3.1	5.2	2.1	4.7	1.5	-1.2	3.7	2.8	3.1

Table 18. Rank of Measures for Table 17

Brand A	4	3	18	11	1	17	6	8	5	7
Brand B	12	14.5	20	10	19	9	2	16	13	14.5

$N_B = 10$, so

$$U = 10 * 10 + \frac{10(10 + 1)}{2} - 80 = 75$$

There is no table for U values. Instead, as for the Wilcoxon test, the table for z values is used because of a property of the U distribution. When calculating the U value repeatedly on samples known not to be statistically different (e.g., two data samples drawn from the responses of the same device), then it can be shown that the repeated U values (U_1, U_2, U_3, \dots) have a Gaussian distribution with mean M_U and standard deviation SD_U defined as

$$M_U = \frac{N_A N_B}{2} \tag{35}$$

$$SD_U = \sqrt{\frac{N_A N_B (N_A + N_B + 1)}{12}} \tag{36}$$

This means that the U distribution can be normalized and that

$$z = \frac{U - M_U}{SD_U} \tag{37}$$

is normally distributed with mean 0 and variance 1.

In the example above, $M_U = 10 * 10 / 2 = 50$ and $SD_U = 13.2$, so $z = 3.78$. Looking up the last row of the t -table (Table 10) for a significance level of 5%, we read $z_{crit} = 1.64$. Since $z > 1.64$, hypothesis H_0 can be rejected and it can be concluded that one hearing aid performs better than the other one. Looking at the mean or median for each brand, or for this simple example simply at Table 17, brand A clearly allows patients to hear sounds of smaller amplitudes than brand B. Note that the calculations above are usually not necessary since most statistical software will return the value of U along with its significance level.

Kruskal–Wallis Test for Unmatched Samples. The Kruskal–Wallis H test is a generalization of the Mann–Whitney U test to more than two samples (e.g., three brands A, B, and C of sample sizes N_A, N_B, N_C, \dots with the total number of samples equal to N). As for the Mann–Whitney test, values from all distributions are sorted and once the sum of the rank for each sample is calculated R_A, R_B, R_C, \dots the value of H is given by

$$H = \frac{12}{N(N + 1)} \left(\frac{R_A}{N_A} + \frac{R_B}{N_B} + \frac{R_C}{N_C} + \dots \right) - 3(N + 1) \tag{38}$$

It can be shown that, after collecting repeated measures of H from several samples from the same population (verifying the hypothesis H_0 that they originate from the same population), the histogram of H values is very close to a χ^2 distribution with degrees of freedom equal to the number of groups minus one (so the χ^2 table may be used for H). Thus,

to use the Kruskal–Wallis test, first calculate H , then compute the degrees of freedom (number of groups minus one), and look up the χ^2 critical value in Table 7. If the calculated H value is larger than the critical value, reject hypothesis H_0 .

Friedman Test for Matched Samples. Suppose it is wished to determine if three spectroscopy machines A, B, and C returns the same hematocrit density (density of blood cells in a blood sample). We test the three machines using 20 blood samples (the same blood sample is used for all machines). Since preliminary analysis shows that the readings are not normally distributed, nonparametric test will have to be used. To do so, for each blood sample, rank the machines (from 1 to 3) and compute the total rank for each machine T_A, T_B , and T_C . The parameter T_{all} being the sum of all the ranks, the squares deviate SS is equal to

$$SS = \frac{(T_A)^2 + (T_B)^2 + (T_C)^2}{N_G} - \frac{(T_{all})^2}{N_G N} \tag{39}$$

where N_G is the number of groups and N is the number of samples in each group. As for the Kruskal–Wallis test, we may use the χ^2 distribution with degrees of freedom equal to $df = N_G - 1$. In the Friedman test, simply refer to this value as χ^2

$$\chi^2 = \frac{SS}{N_G(N_G + 1)/12} \tag{40}$$

If the calculated χ^2 value is larger than the critical value for the specified degrees of freedom, reject hypothesis H_0 .

The Spearman’s Rank Correlation Test. Rank methods may also be used to determine the correlation between two variables. Instead of using exact variable values, their ranks may be used. For two sample A and B of the same size, corresponding to two variables X and Y (e.g., lifespans and prices of a family of devices), rank each sample value from 1 to N separately for A and B. Then calculate the difference D_1, D_2, D_3, \dots between the sorted rank for A and B and compute

$$r_S = 1 - \frac{6((D_1)^2 + (D_2)^2 + (D_3)^2 + \dots)}{N(N^2 - 1)} \tag{41}$$

If r_S is close to 0, there is no correlation between the two variables, whereas if it is close to 1 or -1 , there is a strong correlation between the two variables. To test if r_S is significantly different from 0, the same t -test as for the Pearson correlation coefficient may be used (replacing r by r_S and using the same degrees of freedom $df = N - 2$).

Resampling Methods

Resampling methods help provide confidence intervals for parameters in situations where these are difficult or impossible to derive analytically. Resampling methods also help

perform statistical inference without assuming a known probability distribution for the data. The bootstrap method consists of drawing random subsamples and the randomization method consists of shuffling data samples.

Bootstrap Method. The bootstrap method is the most recently developed method to estimate errors and other statistics. It is not primarily aimed at performing inference although it may be used to do so, since it provides confidence intervals for the measure of interest. The term “bootstrap” derives from the phrase “to pull oneself up by one’s bootstrap” (Adventures of Baron Munchausen, by Rudolph Erich Raspe). Suppose we have a data sample and an estimator (e.g., mean). The basic idea involves sampling with replacement to produce random samples of size N from the original data sample (of size larger than N). Each of these samples is known as a bootstrap sample and provides an estimate of the parameter of interest. Repeating the sampling a large number of times provides information on the variability of the estimator and help define confidence limits. There are N to the power of N , N^N , possible samples, called the ideal bootstrap samples. It is important to emphasize that subsamples are drawn with replacement: for example, for an empirical distribution composed of 2 values (5 and 8), the bootstrap samples are (5,8), (5,5), (8,8), and (8,5) (note that there are $2^2 = 4$ of them). Getting all ideal bootstrap samples becomes unrealistic as N becomes larger, so the Monte Carlo approach (which consists of random draws) is used. The sampling is said to be balanced if each sample value is drawn the same number of times. For each bootstrap sample, let us suppose that the mean is calculated. The standard deviation of the bootstrap distribution for the mean correspond to the standard error (Eq. 19) and may be used in parametrical t -test to compute the t value (Eq. 20), and perform inference testing (assuming normality of the distribution of course). However, this mixture of bootstrap and parametric t -test is relatively unconventional, and it is better to estimate the bootstrap distribution of t -values as explained below.

To perform a statistical inference test using bootstrap, first state a null hypothesis H_0 . Null hypotheses for resampling tests are usually vague because there may be many reasons (based on the shape of the distribution) why two samples may differ (whereas when performing a parametric t -test, the nonnull hypothesis states clearly that the means are nonequal). Moreover, bootstrap statistics use the implicit assumption that data samples are representative of the underlying population and in fact do as if the data samples were the population itself. Therefore it is not possible to draw direct conclusions about the underlying population either.

In the case of the heart rate study of Table 12, for example, where comparing a measure (i.e., heart rate) for patients suffering from heart failure (sample A) and control subjects (sample B), the null hypothesis would be “patient suffering from heart failure have abnormal heart rate”. One way to test this hypothesis is to perform a bootstrap t -test. Two bootstrap samples are first drawn from the pooled distribution of A and B: sample A' and B' of the same size as A and B, respectively. The t -value is then

Figure 6. Bootstrap t -distribution for Table 12 (top) and randomized t -distribution for Table 12 (bottom). Since the actual t -value obtained from the original samples in Table 12 ($t = 2.17$) belong to the rightmost 2.5% value in both the bootstrap and the randomized distribution (the 2.5% limit being indicated by a vertical line), it may be considered significant at 5%.

computed using the two bootstrap samples as in Eq. 16. The operation is repeated m times to obtain the distribution of t -values for the null hypothesis. Note that, even if a t -value, is computed it is not assumed normality for the data samples since the distribution of t -values for the null hypothesis is estimated using bootstrap samples. The actual t -value is calculated for the original data samples A and B and tested against the bootstrap t -distribution. If it lies in the lower 2.5% or upper 2.5% tails, then the bootstrap test may be considered to be significant at the 5% level of significance. In Fig. 6 (top), 10,000 bootstrap t -values were accumulated for the two samples in Table 12. Since the original t -value for Table 12 is equal to 2.17 (see the t -test section) and since it lies in the upper 2.5% of the bootstrap t -value distribution, it may be concluded that the data support the hypothesis that heart rate is affected in patients suffering from heart failure at the 5% significance level.

There are other ways to test for significance using bootstrap, such as the bootstrap-percentile method, or the bootstrap-bca method (see Ref. 16 for a comprehensive reference). In general, it should be remembered that bootstrap methods are designed primarily for estimating characteristics of data samples, not for performing inference tests. Resampling methods specializing in statistical inference are called randomization methods and are describe below.

Randomization Methods. For the purpose of performing paired or unpaired comparisons, randomization methods consist of random permutations of data. Randomization methods are also often called permutation methods or surrogate methods. Specifying the null H_0 hypothesis is

the same as for the bootstrap and involves a vague formulation about the result of the experiment, such as “patient suffering from heart failure have abnormal heart rate” or “the drug treatment does not have an effect on blood pressure”.

Randomizing the data is straightforward. Using the same example as for the bootstrap distribution with two unpaired samples A and B of sizes N_A and N_B , a randomization method consists of pooling the data of A and B together (into C), then randomly drawing from C (without replacement) two groups A' and B' that have the same size as A and B, respectively (17). Then, compute the estimator (e.g., t -value) for each randomized pair of samples. Repeat this procedure a large number of times to obtain the distribution of the estimator (e.g., t -value) for the null hypothesis. Significance is assessed as for the bootstrap t -test. For example, in Fig. 6 (bottom), 10,000 randomized t -values have been accumulated for the two samples in Table 12. Note that irregularities in the distribution are due to the fact that we are randomizing a relatively small number of values. As for the bootstrap, since the original t -value ($t = 2.17$) lies in the upper 2.5% of the randomized t -values, it may be concluded that the data support the hypothesis that heart rate is affected in patients suffering from heart failure at the 5% significance level. It is reassuring to notice that the upper 5% significance threshold t -value for the bootstrap ($t_{crit} = 2.13$), the randomized ($t_{crit} = 2.11$), and the normal distribution ($t_{crit} = 2.12$) are all similar.

For paired comparisons, the principle is slightly different since we are now randomizing not the sample values but the pairs. For example, for the data of Table 11, one-half of the pairs are selected randomly then shuffled (the value for the first device is now attributed to the second device and vice versa) and the paired t -test value is recalculated (Eq. 17). This procedure is repeated many times. To assess significance, as in the previous paragraph, the original t -value computed using the nonrandomized samples is compared against the distribution of randomized t -value.

This procedure may be generalized to compare an arbitrary number of samples. For example, to compare several unpaired sample, data sample values may be randomized among groups and one-way ANOVA values may be calculated repeatedly. The ANOVA value for the nonrandomized groups is then compared against this ANOVA randomized distribution. Web Ref. 18 provides a clear introduction to resampling methods.

MULTIVARIATE METHODS

Previously the probability distributions involving one variable were discussed, but in many situations there are two or perhaps many interdependent variables, for example, height, weight, daily caloric intake, genetic strain. Data samples involving several variables are called multivariate. Many multivariate analytical methods involve inference for the parameters (means, variances, and correlation coefficients) based on multivariate normal distribution. One such method is known as discriminant analysis and is concerned with the problem of distinguishing between two or more populations on the basis of observations of a multivariate nature. Principal components analysis, cluster, and factor analysis seek to determine relatively few out of possibly many variables that will serve to explain the variability or the interrelationships in the variables. Principal component analysis (PCA) would specifically make each successive component account for as much as possible of the remaining variability uncorrelated with previously determined components. In Fig. 7, data points from two variables are represented. Coordinates of data points on the abscissa axis correspond to values of the first variable and coordinates on the ordinate axis correspond to values of the second variable. The PCA is able to find a first principal axis (labeled one) that accounts for most of the variance of the data. The second principal axis (labeled two) has to be perpendicular to the first principal axis and accounts for the remaining of the variance.

Recent progresses in signal processing and information theory have seen the development of blind source

Figure 7. Illustration of PCA and ICA algorithms. The PCA finds axis with maximum variance. By contrast in ICA, the projection of data point on ICA axis is maximally independent.

separation methods, which attempt to find a coordinate frame onto which the data projections have minimal overlap. For example, if two sources of sounds (e.g., a conversation and a CD player) are recorded simultaneously in the same room on two microphones, the sound signal from the two sources are mixed on both microphones. Coordinates of data points in Fig. 7 could represent the signal recorded from the two microphones. Separating the two sound sources from the microphone signal is called blind source separation. Independent component analysis (ICA) is a family of linear blind source separation methods. The core mathematical concept of ICA is to minimize the mutual information among the data projections. PCA components are orthogonal as shown in Fig. 7, which is usually not a realistic assumption for biophysical data. To find biologically plausible sources, PCA must be followed by an axis rotation procedure, and ICA can be viewed as a powerful rotation method. The ICA seeks to find axes for which the projection of data is maximally nonnormal (i.e., contains the maximum amount of information). It uses the property of the central limit theorem in statistics, stating that any linear mixture of two or more source activities is more normal than the original source activities, so, by finding axes that maximize nonnormality, source separation may be achieved. As can be seen in Fig. 7, ICA is free to adapt to the actual projection patterns of source generators, if their activity time courses are (near) independent of one another. Performing ICA decompositions is most appropriate when sources are linearly mixed in the recorded signal, without differential time delays.

The ICA is being applied to various biomedical signal processing problems that include performing speech and noise separation (19), decomposing functional resonance imaging data (20), and separating brain area activities and artifacts mixed in electroencephalography scalp sensors (21).

Texts that give broad coverage of multivariate analysis are (22–24).

CLINICAL TRIALS

A clinical trial is not a method *per se*, but is a term applied to any form of planned experiments that involves human patients. The purpose of a clinical trial is to evaluate and verify the efficacy and safety of a new treatment or sets of treatments for a given medical condition. Although most of the analytical methods employed for clinical trials are the same as in other contexts, there is a special effort to avoid bias, which leads to some unique designs. Another distinguishing characteristic of clinical trials is the constraint imposed by studying living patients and the often difficult ethical considerations that must be addressed.

Double Blind. The usual method to avoid bias in experimental designs is the random allocation of experimental subjects to treatments, but this will generally not suffice in clinical trials. A major potential source of bias is when subjects or evaluators in a trial know which treatment (e.g., placebo or active) is being received. In double-blind trials, neither the subject nor the evaluators are

aware of which treatment is being received. Sometimes ethical or practical considerations make double-blinding infeasible, and sometimes partial blinding, for example, independent blinded evaluators only, may be sufficient to reduce bias in treatment comparison.

Within Patient Studies versus Across Patient Studies. Most clinical trials are conducted as parallel studies in which two or more treatments are evaluated concurrently in separate groups of patients. As many researchers remain reluctant to assign patients randomly to new or standard treatments, current patients on the new treatment may be compared with data external to the study containing patients who had received standard treatments. Such an approach invites severe bias, since there is no assurance that treatment and control groups do not differ with respect to some factors other than the treatment itself. In crossover studies, each patient receives in succession two or more treatments. When feasible, such within-patient studies require smaller sample sizes than between-patient studies to achieve the same level of significance.

Lifetime Variables. Some clinical studies are conducted as life data analysis and survival studies, and require specific statistical tools. In such studies, a variable represents the time to the occurrence of some event of interest, and is called a lifetime variable. In the engineering context, a life test consists of monitoring the operation of a sample of devices and to observe causes of and times to failure for all or some of the devices. In the clinical context, a survival study may involve observing cause of death (and time from entry to the study until death occurs) for some potentially fatal or, in the case of animal studies, induced disease. Alternatively, the event of interest may be time to relapse or time to remission for some diseases or conditions. The purpose of life tests or survival studies is to estimate or to compare lifetime or survival between different treatment groups.

Statistical Test for Lifetime Variables. Since a lifetime variable must be positive (number of remissions, e.g.), the normal distribution is not usually a suitable model. The normal-based methods of multiple regression and analysis of variance cannot be used in the usual manner and in general requisite mathematical and computational methods are much less tractable than normal-based methods. Consequently, a nonparametric, partially parametric, or nonnormal distributional analytic approach is taken. Data is usually visualized using Kaplan–Meier survival curves where censored patients (patients that have left the study) are explicitly indicated on the curve. Comparing between unpaired groups usually involve a log-rank test or a Mantel–Haenszel test. Conditional proportional hazards regression may be used to compare between two or more paired groups. Finally, Cox proportional hazard regression may be used to compare between more than two unpaired groups and perform regression analysis.

Censoring. As mentioned above, a further complicating factor for survival studies is censoring. Under censoring,

exact lifetimes are known only for a portion of the experimental units, the remainder known only to exceed certain censoring times. Censoring is usually a practical necessity and must be preplanned. For example, a life test on a random sample of 100 devices that has median time-to-failure of 2500 h will likely take over a year to complete if the tests were to continue until all devices fail. Instead, the test might be terminated at some predetermined time (e.g., 1000 h), or immediately upon achieving some predetermined number of failures (e.g., 30). These are called Type I and Type II censoring, respectively, and are the simplest to deal with. A distinguishing characteristic of survival studies involving human patients is that censoring times are often random. For example, suppose patients with a certain cancer are undergoing different chemotherapy treatments. Patients may enter the study in a random manner and patients may survive the termination time of the study or may die due to causes unrelated to the cancer. There are probability models that incorporate these data and lead to appropriate statistical inferential techniques. For example, some techniques assess the effectiveness of different treatments by comparing estimated mean survival times with the effect of unrelated causes of death removed. Other methods used for dealing with censoring will not be discussed. It is sufficient to say that the special problems of statistical inference in the presence of censoring necessitate the use of large sample approximations and computer-aided numerical solutions. Some of these methods incorporate strong assumptions that users should be aware of.

Extensive treatment of methods for censoring and the analysis of survival data is given in Refs. 25–27. Nontechnical discussions of clinical trials and the special statistical treatments they require are given by Pocock (28) and Shapiro (29).

STATISTICAL COMPUTING AND SOFTWARE

Standardized computer programs aiming at performing a variety of statistical analyses were developed through the 1960s at several universities and became widely available in the 1970s. There is now a large number of them and the one to use will depend on the users' expertise in statistics and field of research. For infrequent usage on small data samples and testing of simple hypothesis (χ^2 , t -test, ANOVA), MS Excel, which is usually already installed on many computer desktops, may be sufficient. Note the availability of extra statistical functions when one selects the Analysis Toolpack add-in (installed but inactive by default). However, MS Excel is not a statistical software *per se*, so to go beyond exploratory analysis stages it is better to rely on professional statistical software.

The best known and most comprehensive of these, now all under privately managed companies, are the Statistical Package for the Social Sciences (www.spss.com), the Statistical Analysis System (www.sas.com), and JMP (www.jmp.com). As its name suggests, SPSS, was developed primarily for use by social scientists and is relatively easy to learn by individuals with limited statistical and computer backgrounds. The SPSS graphical interface is

organized as tabular spreadsheets similar to MS Excel. The programs comprising SPSS, their output format, and the examples in the manuals retain a social science flavor. The SAS has evolved into a widely utilized and extremely flexible package that is generally regarded to be more statistically sophisticated and complete than SPSS. JMP, also developed by the SAS institute, is a user-friendly graphical interface that sequentially guides the user through all stages of the experimental design and data analysis.

Apart from the graphical packages mentioned above, most other statistical softwares rely on command line calls, where users call functions from a prompt (note that most of these softwares also include menus). The free R software (www.r-project.org) offers powerful functions contributed by leading statisticians in the world. Because it is an open source project, it is used by many scientists and its extensive libraries are probably the place to look for rare statistical procedures. The Biomedical Programs (BMDP) (www.statsol.ie) contains a large variety of elementary and advanced statistical procedures. The programs are widely applicable, but some are particularly appropriate in biomedical contexts, such as repeated measures ANOVA designs (see ANOVA). The S-plus software is also very popular (www.insightful.com) and very similar to R. It is based on the S language developed at AT-T. Finally, a widely used package in academia, as well as in industry is a package called MINITAB (www.minitab.com), which is one of the most user-friendly command line software.

There are many smaller, less comprehensive statistical analyses packages available for computers. These range from packages that perform elementary, mostly descriptive analyses, to some that are rather sophisticated. For bootstrap and surrogate statistics, SAS software is preferred among graphical software, although it is possible to program bootstrap and surrogate data routines in SPSS. The R software contains the majority of such user-contributed routines and S-Plus also contains a few of them. Finally, MATLAB (www.mathworks.com), an interpreted language widely used in engineering, also has a large number of user-contributed bootstrap and surrogate statistics routines available.

Caution against the ignorant use of computerized statistical analyses cannot be overemphasized. In planning studies, the methods of analysis and the constraint they impose on experimental designs should be taken into consideration in advance. If not, much work and data collection efforts could be wasted. Worse still, misleading and even meaningless results are often given undeserved weight merely because they represent the voluminous output of computer programs. How often do we hear that “a computer analysis shows...”, but such programs can be totally inappropriate. For example, the mathematical methods underlying repeated-measures ANOVA incorporate restrictive assumptions on the normality of the data and the experimental design for appropriate randomization of events. Although these considerations are often ignored, researchers should systematically assess the degree to which test-related assumptions are satisfied. These facts notwithstanding, computer-aided data

management and analysis can be of great benefit if used properly and wisely.

REFERENCES USED

This list is not meant to be comprehensive. For the naïve reader, a basic introduction to statistics with a plethora of exercises is given in the Schaum's outline series on statistics (2). For the nonnaïve reader in statistics, a more technical yet still accessible reference is Ref. 30. Other texts dealing with general statistical methods, particularly regression and analysis of variance are Refs. 31 and 32. Comprehensive web references are Refs. 18, 33, and 34.

Statistical books have also been written for specific research topics. For example, see Ref. 35 for a beginner's reference in designing biology experiments and Refs. 6, 8–10 for more detailed references. As already mentioned, see Refs. 28, 29, 36, and 37 for clinical trials. Finally, a recent development in statistics is statistical process control that deals with optimizing production and quality in the industry (38).

INTRODUCTION

Stereotactic surgery evolved from the need of neuroscientists and neurosurgeons to approach areas deep in the brain with minimal disruption of its structure. In (~1000 AD, the Incas already had some idea of which regions of the brain could be operated on without causing detectable functional deficits (1). They concentrated their trepanations in the right frontal area knowing that lesions in this region of the brain would be safe (2). The scientific literature, however, registers the first minimally invasive attempt to approach the noneloquent areas of the brain in the late 1800s. Zernov, a Russian anatomist, described the first device used to localize the sensory-motor areas of the brain (3,4) This device allowed the surgeon to use noneloquent areas as approaches to targets in the depth of the brain. He designed a frame that was attached to the patient's head and supported a hemisphere with a drawing of the brain gyri. This drawing guided the surgeon where to perform the craniotomy avoiding eloquent areas (4). This device was crude, however, and needed to be replaced by a precision instrument capable of being applied to patients' individual anatomy and not on a generic drawing.

Cartesian coordinates, developed by Renee Descartes (5), were called upon to guide the neurosurgeons in their endeavor. Initially developed for use in laboratory animals, the first stereotactic frame based on Cartesian spatial localization was designed by an electrophysiologist and a neurosurgeon. The Cartesian system provides precise localization of a point in space by the distance that the point is located from each of the three planes. Clarke and Horsley applied a stereotactic frame in animals to guide electrodes into the depth of the cerebellum to study neuronal function (6,7) (Fig. 1). This apparatus inspired the Canadian bioengineer Aubrey Mussen to develop the first true stereotactic device for humans (8,9). This device was never applied to a patient, since Mussen could not convince any neurosurgeon in Canada to use it. It is believed to have been created 1918, as it was found several years later wrapped in a newspaper of that year. It is currently in exhibit at the Montreal Neurological Institute (10).

All early localization of brain structures was based on cranial landmarks. Unfortunately, these bony reference points frequently failed to guide the surgeon to the precise area of the brain to be approached. Only when angiography (11) and ventriculography (12,13) became available, stereotactic surgery based on intracranial reference points

Figure 1. A. Horsley–Clark stereotactic device: Horsley, a neurosurgeon and Clark, a physiologist, developed the first stereotactic apparatus. It was used in experimental studies in animals.

became reliable. It took another 17 years for the first human stereotactic surgery based on Cartesian coordinates to be performed. Spiegel and Wycis performed the first stereotactic surgery in 1947, in Philadelphia (14). It was a thalamotomy to treat psychiatric disease (15).

Functional neurosurgery, mainly movement disorders, was the major field for stereotactic surgery at the beginning. During the 1930s and 1940s, multiple central nervous system procedures involving the motor cortex to the cervical spine were used in an attempt to relieve parkinsonian symptoms. Despite tremor improvement, none of the procedures resulted in rigidity and akinesia amelioration, and usually resulted in paralysis of the affected limb. In 1940, Meyers published his patients series in whom either tremor and rigidity were improved (16–18). Meyers performed a craniotomy to section the pallidofugal fibers as they emerged the medial Globus Pallidus. In 1947, Spiegel and Wycis developed the stereotactic apparatus, therefore avoiding a craniotomy. It was with Irving Cooper, in 1952, that the surgical treatment of Parkinson's Disease gained popularity by the inadvertent lesion of the anterior choroid artery during a pyramidotomy (19). Cooper et al. provoked a pallido-thalamic infarction due to the lesion and observed an effective relief of the parkinsonian tremor. Thereafter, more precise targets were defined (16–24) for the treatment of Parkinson's disease (PD), essential tremor, dystonia and others. Initial results were encouraging, but recurrence and morbidity, specially in bilateral procedures, were not irrelevant. After the introduction of levodopa therapy in 1968, the indication of surgical procedures declined. Nevertheless, levodopa therapy proved not to be as effective after a medium period between 5 and 10 years (22,25). Over this period of time, tolerance to levodopa occurs and a dose increase is necessary to maintain the prior therapeutic effects. The extra amount of medication leads to a complication known as dyskinesia. The patient

presents involuntary movements that may be mild or severely disabling during the peak period of the dose. Since medication was highly effective only for a period of time, attention was directed once more toward surgical treatment. In the 1980s, stereotactic procedures for movement disorders again became routine (26,27).

The applications of the stereotactic techniques have grown since that time (28–30). New devices were developed to facilitate surgery and increase precision. Frames are still widely used in clinical practice; however, guidance techniques independent of skull fixation are improving and may completely replace the use of the stereotactic frame (31–35). This article discusses the evolution of the stereotactic instrumentation during the last century and describes the directions of the stereotactic technique at the beginning of the millennium.

PRINCIPLES OF STEREOTACTIC SURGERY

The stereotactic frame establishes the stereotactic space. It is described mathematically as a cube with X , Y , and Z coordinates corresponding to lateral, anteroposterior (AP) and vertical measurements, respectively. When the head is placed inside the stereotactic device, precise coordinates can be assigned to any location within the brain. Initially, orthogonal approaches were used, which were adequate because only orthogonal images were available, as represented by plain X rays. The AP projection offered the X and Z values and the lateral projection offered the Y , but also Z values (10).

The early stereotactic devices allowed only orthogonal approaches to the brain in relation to the applied stereotactic frame. This is a straightforward method in which the probe is perpendicular to a square base fixed in the skull. Other mathematical approaches were used over the years: the burr hole mounted system (Ward and McKinney), the interlocking arcs system (Brown–Robbers–Wells, BRW), the phantom-based system (Riechert–Munding), and the arc centered system (Leksell). In the burr hole mounted system, the depth of the probe is dependent on the angle of the burr hole mounted apparatus. A minor variance of angulation can lead to a major error in the deep as well as anteroposterior and lateral position of the probe. Therefore, this system is not used nowadays. The interlocking arcs system requires the adjustment of individual arcs to define the trajectory making calculations very complex. Despite that, the first computer-based computed tomography (CT) stereotactic was performed with the interlocking arcs (BRW) system. The arc centered system, the most currently used nowadays, was developed by Lars Leksell in 1949 (36). The trajectory of the probe is perpendicular to the arc (vertical axis) and the quadrant (horizontal axis). A spatial spherical shape is defined by the arc-quadrant. When the probe reaches maximum depth, it will always be in the center or at a focal point of that sphere, independent of the entry point. The arc centered became the instrument of choice since the end of the twenty century (37).

Historically, neurosurgeons have been dependent on neuroimaging to perform their craft. Before that, neuro-

surgery was dependent on symptomatic clues to approach the brain. Only *postmortem* correlation studies served as references for the surgeon to operate in the living brain. Ventriculography was the first great step in the development of stereotactic surgery (12,13). It provided the indispensable brain landmarks for the neurosurgeon to start electrophysiological brain mapping. Functional and anatomic atlases of the brain were developed to guide the stereotactic operations. To date, atlases developed during the 1950s and 1960s are still used in stereotactic surgery (38). Initially, the foramen of Monroe and the pineal gland were the landmarks used for internal guidance of the stereotactic surgeon. These landmarks were well seen on air ventriculography, which was the first contrast material medium used in neurosurgery to delineate the internal structures in a plain X-ray film. Soon after, the positive iodine contrast became available for neurosurgery. The positive contrast injected into the ventricular system provided exquisite delineation of the anatomy of the third ventricle. The anterior commissure (AC) and posterior commissure (PC) could be promptly defined. They became the landmarks of choice for stereotactic surgeons. The main atlases of the brain were developed based on these two landmarks (38,39) (Fig. 2).

The Cartesian planes were largely based on the initial intercommissure plane. This imaginary plane hinged on the AC and PC line being parallel to the skull base. Two other planes perpendicular to this plan and to each other composed the necessary three planes to determine the Cartesian system. The coronal plane passes through the midcommissural point and is perpendicular to the midsagittal plan. The mathematical challenge during stereotactic surgery consists of transforming the numbers generated

Figure 2. Sagittal T1 weighted magnetic resonance imaging (MRI) scan showing the AC, which is defined at the anterior wall of the third ventricle. The PC is placed at the posterior wall of the third ventricle, directly above the beginning of the Aqueduct. The AC–PC line is of the utmost importance in functional neurosurgery. The coordinates established in the major stereotactic atlases were defined using this line as reference.

in the internal Cartesian system of the brain to one of the stereotactic devices. This simple mathematical transformation was done in the operating room by stereotactic surgeons, now this is automatically generated by computer software.

The indirect visualization of the brain by shadows of the ventricular system obtained with plain X rays of the skull was sufficient for functional localization of sites in the brain. These indirect visualizations and calculations allowed stereotactic surgeons to accumulate a wealth of knowledge of the brain's electrophysiology. Standardized atlases allowed a degree of stereotactic accuracy during functional procedures. Pathological anatomy secondary to space occupying lesions did not require the use of standardized atlases. This knowledge was limited to directing surgeons in the treatment of brain tumors and other morphologic diseases of the brain. Visualization of brain lesions while inside of the stereotactic frame was necessary for reaching these lesions for biopsy and possible therapy. This soon became possible with the angiography since indirect targeting based on deformation of the vascular anatomy made the localization reliable. However, due to the vascular nature of the lesions visualized, biopsy would be too risky. Stereotactic biopsy only flourished with the advent of CT and direct soft tissue visualization. During the angiography period, arteriovenous malformations (AVMs) were treated with radiation and tumors were treated with implants of isotopes guided by stereotactic surgery.

STEREOTAXIS BASED ON CT

Targeting based on tomographic images resulted in a remarkable increase of the use of stereotactic techniques in many centers. It also expanded its applicability to different fields. Focused radiotherapy became possible because CT allowed reliable targeting when compared to early angiography and pneumoencephalography–ventriculography generated targets.

The *X* and *Y* coordinates were acquired from one axial CT slice. Determining the *Z* coordinate by CT was a challenge. The initial idea was to correlate the vertical displacement of the CT table from a reference point to the target slice. This parameter was not reliable and a new form of calculating vertical displacement was elaborated. The fiducial markers were made possible by obtaining an accurate three-dimensional (3D) target (37). The fiducials (Fig. 3) are placed perpendicular to the image acquisition plane, either axial, sagittal, and coronal. The fiduciary system is composed of vertical outer bars and a diagonal internal one. According to the slice obtained, the distance between the diagonal line to the vertical one is going to be specific and the precise 3D localization of a point inside the stereotactic space was easily obtained. This same arrangement is applied for MRI image guidance.

STEREOTAXIS BASED ON MRI

Magnetic resonance imaging became a major diagnostic tool for many reasons: multiplanar capability, high spatial

Figure 3. The CRW CT scan localizer (Radionics, Burlington, MA): The fiduciary system is composed of vertical outer bars and a diagonal internal one. Fiducial markers allow a precise 3D targeting.

resolution, excellent soft tissue contrast, absence of ionizing radiation, and bony artifact on adjacent soft tissue (40). These characteristics made MRI attractive for framed procedures and also enabled the use of MRI in frameless guided procedures (Fig. 4).

However, there are some disadvantages. The MRI is more prone to geometric distortion than CT. The maximum localization error reported in the literature ranges from 1 to 5 mm (33,40). The variation in the maximum error may be accounted for partly by the use of different stereotactic systems and different reference imaging modalities to which MRI is compared. Actually, the geometrical accuracy of MRI is not significantly different from the accuracy of conventional stereotactic frames (41,42). The spatial accuracy of MRI depends on the linearity and calibration of magnetic field gradients and on magnetic susceptibility artifacts that manifest as spatial distortions. Meticulous

Figure 4. View of the UCLA interventional MRI (Sonata, Siemens, Erlangen, Germany) operating room.

quality control should decrease errors into magnetic field linearity and calibration. High bandwidth signal acquisition reduces spatial distortion due to susceptibility effects. Several researchers have proposed practical correction algorithms to further improve the spatial accuracy of MRI (40,43,44).

Functional and biopsy cases may be planned based only on the MRI scan since there are other means to confirm final target localization. However, targeting based only on the MRI is not accurate enough when performing radiosurgery (SRS) or stereotactic radiotherapy (SRT) (45). In SRS–SRT cases, only the fusion of the CT and MRI offers the reliability required for the delivery of focused radiation to the target selected.

Several stereotactic systems with frames designed for MRI localization are commercially available: the BRW and CRW (Radionics, Burlington, MA), Leksell (Elekta Instruments Inc, Atlanta, GA), Laitinen (Sandstrom Trade & Technology Inc, Ontario, Canada), and others (10).

STEREOTACTIC FRAME-BASED PROCEDURES

Functional Stereotaxis

Functional procedures are performed under MRI guidance at UCLA. Under local anesthesia and sedation, MRI-compatible stereotactic frame (Leksell, Elekta Instruments Inc, Atlanta, GA) is attached to the patient's head. The

stereotactic frame is aligned to the MRI coil. The T1 weighted images 3 mm in thickness are obtained in the axial, coronal, and sagittal planes. The anterior and posterior commissures are identified to define the AC–PC line. The coordinates are obtained from the Shaltenbrandt and Wahren atlas. The *X*, *Y*, and *Z* coordinates can be reproduced in the axial, sagittal, and coronal MRI views by computer manipulations. The same target can be pinpointed on each of these images. The target determination is therefore better than the thickness of the imaging acquisition. Distortions of the MRI scan are not taken into account since the final position of the electrode is checked with microelectrode recording (MER) and macroelectrophysiology.

The patient is taken to the operating room either for lesion or deep brain electrode implant. The localizing microelectrode is introduced through a burr hole placed in the frontal region. Mapping with MER is obtained and the trajectory is adjusted if necessary. Parameters of electrical stimulation are manipulated aiming to improve symptoms until the point side effects are detectable. The final location of the definitive electrode or lesion site is therefore established (Table 1). The patient undergoes an intraoperative MRI to rule out bleeding and ascertain proper position of the target. Fusion of preoperative with intraoperative imaging is used to compare the accuracy of the surgery (10). This same approach is being used for cell transplantation, growth factors injection, and gene therapy (Table 2).

Table 1. Functional Stereotactic Procedures

Procedure	Indication
<i>Behavior</i>	
Amygdalotomy	Violence, aggressiveness
Anterior capsulotomy	Obsessive compulsive disorder (OCD)
Cingulotomy	Anxiety, depression, OCD
Posteriormedial Hypothalamotomy	Aggressiveness
Subcaudate tractotomy	Anxiety with depression
<i>Pain</i>	
Cingulotomy	Chronic pain emotionally charged
Dorsomedian thalamotomy	Chronic pain emotionally charged
Pulvinotomy	Intractable pain
Mesencephalotomy	Intractable pain
Periaqueductal stimulation	Intractable pain
Periventricular stimulation	Intractable pain
Cortical stimulation	Intractable pain
<i>Movement Disorders</i>	
Ventrolateral thalamotomy	Parkinson's disease, tremor, dystonia
Pallidotomy	Parkinson's disease
Campotomy (Forel's fields)	Parkinson's disease, athetosis, myoclonus
Zona incerta	Parkinson's disease, tremor, torticollis
Dentatotomy	Spasticity
Striatum fetal tissue transplant	Parkinson's disease
<i>Epilepsy</i>	
Amygdalofornicotomy/anterior Commissurotomy	Temporal lobe seizures
Pallidoamygdalotomy or Centromedian lesion	Salaam seizures
Deep electrode	Seizure focus determination

Table 2

Morphologic	Functional
<i>Diagnostic</i>	<i>Diagnostic</i>
Stereotactic biopsy	Deep electrode for seizure focus determination
<i>Therapeutic</i>	<i>Therapeutic</i>
Radiosurgery	DBS ¹ for pain control, movement and behavior disorders
Frameless neuronavigation	Ablative lesion for pain, movement and behavioral disorders
Hyperthermia	Tissue transplantation for movement disorders
Stereotactic craniotomy	Gene therapy delivery
Brachytherapy	Injection of active chemicals (growth factor)

^a Deep brain stimulator = DBS.

Stereotactic Biopsy

The determination of the biopsy target follows the same targeting procedure described above, however, electrophysiology is not used for confirmation. Instead, the histology obtained with a frozen section confirms the adequacy of the target.

Once the patient has the burr hole placed, the needle biopsy is introduced through the driver attached to the frame arc. The planning is established based on the three plan views: axial, coronal, and sagittal. Samples of tissue are collected and frozen pathology is performed. After obtaining histological diagnosis, the operative wound is closed and the patient is submitted to a postoperative MRI. Usually an air bubble is observed at the site of the biopsy, confirming the target (28). Pre- and postoperative images are fused. Minimally invasive approaches to vital structures, such as brainstem, became possible only after the development of high definition imaging methods (Fig. 5).

Radiosurgery

Radiosurgery is likely the most frequent reason for stereotactic frame application nowadays. Under local anesthesia, a CRW (Radionics, Burlington, MA) or SRS frame (BrainLab, Heimstetten, Germany) is attached to the patient's head. The patient is submitted to a CT scan and the CT-framed image is fused to the preoperative MRI. The planning starts by the drawing of the lesion, that is, in reality, the target determination. After conclusion of the planning, the patient is attached to a Novalis (BrainLab, Heimstetten, Germany) couch. Focused radiation is delivered with high precision achieved with frame-based spatial localization. At the end of the treatment, the frame is removed. In SRT cases, since the placement of a frame for 26–30 times in a patient is impracticable, a facial mask is manufactured. The frame and the fiducials are applied to the mask. The patient undergoes CT, which is fused with the MRI previously obtained. The reproducibility of accuracy with the facial mask, on a daily basis, has already been demonstrated to be ~2 mm (Solberg, personal communication). New radiosurgery devices, as Novalis and Cyberknife, allow the use of this frameless technique for radiosurgery of extracranial targets.

Stereotactic Craniotomy

This technique was popularized in the 1980s (46). Precise placement of the craniotomy based on computerized pre-surgical planning, guided retractors, and the use of microscopy were the major advancements in this area. Kelly et al. developed a very elaborate stereotactic system with integration of several imaging techniques. The purpose of this system, named COMPASS, was to guide the craniotomy and removal of deep-seated tumors under image and microscope guidance. Inspired by this idea, other similar equipments were developed. However, all these techniques lack the flexibility that neurosurgery requires. The frame frequently interferes with the craniotomy site and the limits defined for the boundaries of the lesion are not the same once the dura-mater is opened. Nowadays, neuronavigation has replaced stereotactic craniotomy.

Frameless Stereotactic Technique

The advent of image-guided neurosurgery and frameless stereotactic localization, also known as Neuronavigation, has advanced a new concept of stereotaxis (47–49). The development of multiple systems that utilize unique imaging and guidance technologies has established neuronavigation as a commonly used tool in many areas of neurosurgery, such as microsurgery for tumors (19,50–54), vascular lesions (51,52,55,56), biopsies (51,52,58–61) and epilepsy surgery (51,62,63). Moreover, modern neuronavigation techniques have begun to replace traditional image-guided tools, such as fluoroscopy and X rays (64–68). The success of neuronavigation hinges on the practical nature of this technique. It completely replaced the frame-based

Figure 5. (A) Preoperative MRI scan showing a lesion in the brainstem, anterior to the fourth ventricle (B, C, and D). The pre- and postoperative images were fused. The site of the biopsy (arrow) and the planned trajectory of the needle (dotted arrow) can be noticed.

stereotactic craniotomy approach, which was not well accepted by the general neurosurgeon.

New approaches to lesions situated in critical areas have been developed. For example, frameless guided biopsy of lesions inside the cavernous sinus through the *foramen ovale* is now possible (28). Not long ago, procedures like this would require a craniotomy to be performed. This demonstrates how neurosurgery has become sophisticated to the point of reaching multiple brain areas through natural pathways that could not be accessed before due to lack of precise guidance.

Neuronavigation has set the stage for the application of multiple and complementary imaging techniques to aid the surgical approach. For example, the fusion of magnetoencephalography (MEG), positron emission tomography (PET), and functional MRI (fMRI) has been reported in the literature (31,69,70). Additionally, new MRI modalities, such as diffusion tensor imaging (DTI), also fused to other functional images, have made possible the recognition of important white matter structures, further increasing the safety of surgery in the depth of the brain. The orientation of the eloquent tracts in the white matter can be mapped using the fact that only diffusion anisotropy along the principal direction of the magnetic field gradient is visible (31,70).

The frameless neuronavigation system is composed of four elements: (1) registration of the image to the real anatomy of the patient, (2) interactive localization device (ILD), (3) computer interface, (4) integration of virtual and real-time data (71). Fiducial markers are the most reliable method of registration. There are two types of fiducials: mobile and rigid. Soft tissue fixation (mobile fiducials) are less accurate. Rigid fiducial markers require a minor surgical procedure for placement. On the other hand, the improvement in precision is worthy. A physical pointer can be used to identify points or surfaces to be registered with ILD.

Two types of ILD can be used: linked or nonlinked. These terms refer to the presence of an unbroken physical connection between the patient and the device. An example of the linked type is the robotic arm, while one example of unlinked is triangulation, which can be sound or infrared (IR) light based. Although of historical importance, the localizing articulating arm has been replaced by the triangulation techniques, especially by the IR reflecting devices (28,52,72–74). Most recently, radio frequency (rf) emitters and receivers were an option to replace IR triangulation devices to eliminate line of sight problems in the operating room. Localization techniques using a magnetic field created to encompass the surgical area continue in development. Its advantage is localization independent of direct linear relation of the light source and probe. It allows the utilization of curvilinear probes or even catheters.

A new issue with the real-time data acquisition is the consistency of the brain. Current registration techniques assume the brain to be a solid and nondeforming structure. However, the brain is more dynamic and moves according to its environment. Preoperative image guidance, which assumes solid brain consistency, is not necessarily accurate at all times. Brain moves after dura opening due to release of cerebral spinal fluid (CSF). The magnitude of brain shift

is variable depending on age, brain atrophy, and positioning for the procedure (50,75). This dynamic brain shifts can be overcome by real-time imaging during surgery.

Interventional MRI

New open designs of MR scanners with in-room image monitors allow MRI-guided interventional procedures. (Fig. 4) The first step toward practical interventional MRI of the brain is the development of instruments that function satisfactorily and safely in the strong magnetic field of clinical MRI scanners. Some concerns derive from this assertive.

Traditionally, surgical instruments are made of stainless steel material. Susceptibility artifacts usually develop at the extremities of the instrument. At the moment, considerable effort has been converged to test different biomaterials in the MRI magnetic field. The goal is to define the most suitable material: minimal artifact and high resistance. Less artifact is produced by ceramics, zirconium seems to produce the smallest artifact among the ceramics (76). On the other hand, ceramics present lower retention force and lower flexibility when compared to metallic materials. Susceptibility artifacts are also dependent on the pulse sequence applied. Spin echo sequences are less sensitive to time-independent local magnetic field variations while gradient spin-echo sequences are more susceptible to time-dependent and time-independent local field changes.

The strength of the magnetic field also interferes with the degree of distortion. It is possible to minimize significantly the amount of distortion using a short echo-time, thinner slices, small field of vision (FOV) and higher read-out gradients. Any material used in manufacturing the instruments will produce some amount of artifacts.

The actual location of the instrument, for example, an electrode inside the artifact, is another important issue. This becomes important to evaluate the final placement of the electrode according the planned target comparatively. It is known that artifacts develop parallel to the direction of the main magnetic field applied. The precise position of the electrode inside the distorted image was reported to be in the middle of the artifact (77).

Another concern is related to electromagnetic interference between the MRI scanner and interventional electronics. For example, the rf generator may emit electromagnetic radiation that interferes with image acquisition and generates artifacts. At UCLA, the use of MER in the MRI is routine, either the 0.2 (70) or the 1.5 T (Siemens, Erlangen, Germany), with special attention to work in the fringes of the strong magnetic field. Interferences can be safely avoided in so far as attention is centered in the strategic location of the devices inside the MRI room.

To approximate real-time imaging, either image acquisition or image reconstruction has to be of very high speed. Currently, millimetric resolution in the 0.2 T and submillimetric in the 1.5 T can be achieved with the parameters reported at Table 3.

Interventional MRI scanners offer the possibility of image acquisition in advance for planning the procedure, intraoperatively for compensation of brain shift that occurs

Table 3. Imaging Acquisition Parameters^a

Magnetic Field Strength	Low Field, 0.2 T		High Field, 1.5 T		
Pulse sequences	T2W FL2D	3 DF	T1W MPRAGE	T2W TSE	FL 2D
Region	WB	WB	WB	BG	WB
TR, ms	1500	56	2050	2800	800

FOV, mm	230	280	280	280	280
Matrix	224 × 256	256 × 256	256 × 256	256 × 256	168 × 256
Voxel Size, mm	1.0 × 0.9 × 6.0	1.1 × 1.1 × 3.0	1.1 × 1.1 × 1.0	1.1 × 1.1 × 2.0	1.5 × 1.1 × 7.0
Scan Time, min:s	11:16	7:42	17:31	2:47	4:28

^aT1W = T1 weighed. TSE = turbo spin echo. T2W = T2 weighed. WB = whole brain. FL 2D = flair 2D. BG: basal ganglia. 3 DF = 3D flash. FOV = field of view. MPRAGE = magnetization prepared rapid acquisition gradient echo.

after dura opening (50,78) and postoperatively for early detection of complications and confirmation of target localization. The reliability of intraoperative image acquisition is superior to the method based only on the preoperative data setting for targeting.

APPLICATIONS

Stereotactic surgery is widely applied for morphological and functional procedures in the brain. Functional and morphologic stereotaxis can be subdivided into diagnostic and therapeutic procedures. A brief summary of these applications is presented in Tables 1 and 2.

FUTURE DIRECTIONS

Advances in imaging techniques are characterized by faster acquisition sequences, more precise definition of eloquent structures, and minimization of artifacts. It is feasible to predict a more sophisticated integration among imaging, virtual reality computer, and robotics in a near future. Possibly new surgical tools as thermal ablation, cryoablation, and chemoablation will become routine, not only for the brain, but for the whole body. The MRI would also be able to provide sensitive monitoring of temperature changes and tissue injury with high temporal resolution. This would be an advantage once minimal injury inside or surrounding an eloquent area may lead to a major deficit (79), obviating the need of large surgical access to remove tumors.

The increasing amount of publications (57,80–86) discussing preliminary results using interventional MRI technique, exploring types of biomaterials (76,87–92), and new sequences of image acquisition (31,70) clearly show that interventional MRI is in its early stages of development. Whether frameless procedures under intraoperative MRI guidance will replace frame stereotaxis in the future is still an open question. Studies already claim that the same accuracy obtained with framed technique is achieved (33,40,41,87).

Frameless stereotactic concepts of registration of images to patients' anatomy will continue to be the basis of surgical guidance, even with real-time imaging. Technological advances as interventional MRI carry issues like high costs. Nevertheless, due to its minimally invasive nature compared with other open surgical approaches,

image guidance married to interventional MRI may emerge as a means of actually lowering the overall cost of medical care.

STERILIZATION. See CONTRACEPTIVE DEVICES.

STERILIZATION OF BIOLOGIC SCAFFOLD MATERIALS

DONALD O. FREYTES
STEPHEN F. BADYLAK
University of Pittsburgh
Pittsburgh, Pennsylvania

INTRODUCTION

Biologic materials such as collagen, tissue grafts, and extracellular matrix (ECM) derived scaffolds are used for tissue and organ repair and are typically regulated as devices by the U.S. Food and Drug Administration (FDA). As such, these materials must be properly processed and sterilized prior to clinical use. Sterilization of biologic materials involves unique considerations (e.g., the

shrink temperature of collagen, changes in the quaternary ultrastructure of the matrix materials, potential inactivation of any bioactive components, and effects upon surface chemistry and architecture). The purpose of this article is to discuss currently used methods of sterilization for biomaterials with emphasis upon biologic materials, the mechanism by which these sterilization methods destroy or neutralize microbes of interest, and the potential effects of the sterilization methods upon the structure and function of the naturally occurring biologic materials and their inherent bioactive constituents.

STERILIZATION METHODS

The FDA recognizes several effective methods of sterilization for medical devices. These methods include dry heat, moist heat (autoclave), ethylene oxide, ionizing radiation, and liquid chemical sterilants. Each of these methods involves a different mechanism of action for killing microbes, and therefore, the physical and chemical effects of these methods upon naturally occurring molecules will differ. A glossary of relevant terms for this article and the topic of sterilization is provided at the end of the article. A list of current international standards for each of the four sterilization methods described herein can be found in Table 1.

Sterilization Versus Disinfection

There is a clear distinction between the terms sterilization and disinfection. The FDA (1997) defines disinfection as the destruction of pathogenic and other types of microorganisms by thermal or chemical means (1). Sterilization is defined as a process intended to remove or destroy all viable forms of microbial life, including bacterial spores, in order to achieve an acceptable level of sterilization (1). Stated differently, sterilization implies the inactivation and removal of all forms of life. The term terminal sterilization refers to the last sterilization step performed prior to use or commercial distribution of a device.

Bioburden and Sterility Assurance Level

Before sterilizing a device, a certain amount of microbial debris remains (including bacterial wall remnants: pyrogens and endotoxins) on and within each device as a

Table 1. Summary of Sterilization Standards^a

Sterilization Method	Standard(s) ^b
Heat Sterilization	ISO 20857
Steam Sterilization	ISO 11134, ISO/DIS 17665-1, ISO/DIS 17665-2
Ethylene Oxide	ISO/DIS 11135-1, ISO/DIS 11135-2, ISO 10993-7 (Residuals)
Radiation	ISO/DIS 11137-1, ISO/DIS 11137-2, ISO/DIS 11137-3
Others	ISO 10993 (1-18), ASTM E1766-95, F2347-03, F2103-1, F2064-00

^aSee <http://www.iso.org>; <http://www.astm.org>.

^bISO – International Organization for Standardization; ASTM – American Society for Testing and Materials; DIS – Draft International Standard.

result of production and presterilization processing steps. This microbial debris is referred to as the *bioburden*. The bioburden that exists prior to sterilization is directly proportional to the difficulty of sterilization of a medical device. It is almost impossible to remove all organisms from some materials, and therefore acceptable levels of bioburden have been identified for which devices can be considered as sterile. These acceptable levels are referred to as the sterility assurance level (SAL), which represents the number of microorganisms that would be tolerable, or conversely, the probability that the device is nonsterile (e.g., 10^{-3} means there is a 1 in 10^{-3} chance that an organism survived the sterilization process). The specific SAL for each device will depend on the intended clinical application for the device and the standards established by regulatory agencies. The FDA recommends that implantable devices have a SAL of 10^{-6} while devices contacting intact skin may have a SAL of 10^{-3} (1,2).

Validation of Sterilization Methods

Validation studies of the chosen sterilization method must be performed to ensure proper reduction of endotoxins and pyrogens and appropriate SAL levels, while minimizing exposure to the sterilant. During these validation studies, the microorganisms are quantified by conventional techniques (1,3) following the sterilization process. Various parameters of the sterilization procedure are evaluated (e.g., time, heat, gas concentration), and then the devices are tested for sterility. A classic example of this procedure is the determination of the time needed to sterilize a device by dry heat at a fixed temperature. Briefly, devices are placed at the chosen temperature and samples are periodically removed at different time intervals (e.g., every 5 or 10 min) depending on the overall duration of the test. The number of surviving organisms is quantified at each collection time, the logarithm of the surviving organisms computed, and the values plotted against exposure time. From this curve, the exposure time to achieve the target SAL can be extrapolated as shown in Fig. 1. The same concept can be applied to gas and chemical exposure times.

Figure 1. Example of data obtained from a fractional sterilization run to determine the time required to achieve the desired SAL at a fixed temperature. *Note:* The data may not have a linear form and will depend on the microbial load and the type of microbes present.

The determination of the presence of pyrogens and endotoxins levels in a device is another aspect of the validation process. Pyrogens are fever inducing agents most commonly associated with Gram-negative bacteria, but can be produced by most microorganisms. Endotoxins are lipopolysaccharides from the cell wall of Gram-negative bacteria capable of inducing certain inflammatory responses. The most common test used to determine the levels of bacterial endotoxins is the limulus amoebocyte lysate (LAL) test (1,3). Pyrogen and endotoxin removal can be achieved via the use of acids, alkaline hydrolysis, hydrogen peroxide, dry heat destruction, and filtration (4).

HEAT STERILIZATION

Heat sterilization can be either applied in a dry or a moist form. Dry heat sterilization is a commonly used method for the sterilization of metallic instruments, powders, and petroleum products (5). Moist heat sterilization is commonly used for surgical instruments and equipment used for cell culture. Moist heat sterilization has also been used for bone grafts to destroy human immunodeficiency (HIV) and hepatitis viruses (6). Except for the sterilization of bone grafts, dry or moist heat is rarely used for biologic materials. Each form of heat sterilization will be discussed separately.

Dry Heat Sterilization

Mechanism of Action. Dry heat sterilization makes use of heated air to inactivate and/or destroy microorganisms. The mechanism of microbial death involves denaturation and coagulation of nucleic acids and proteins. A reduction in the water content of bacterial spores is also considered to be a mechanism by which dry heat sterilization is effective. Although oxidation is possible, it is less widely accepted as a mechanism by which dry heat sterilization exerts its effects (5).

The application of dry heat sterilization utilizes a dry oven-like environment. The air inside the chamber is heated and allowed to equilibrate to a constant temperature (from 120 to 170 °C depending on the duration). The duration of the procedure is a factor of the applied temperature and is determined during the validation process as described earlier. The time and temperature may also vary depending on the nature of the material being sterilized. Table 2 provides guidelines for the sterilization of medical devices using dry heat.

Table 2. Temperatures and Suggested Sterilization Time for a Typical Medical Device^a

Temperature	Sterilization Time
170 °C (338 °F)	60 min (1 h)
160 °C (320 °F)	120 min (2 h)
150 °C (302 °F)	150 min (2.5 h)
140 °C (284 °F)	180 min (3 h)
121 °C (250 °F)	Overnight

^aTimes suggested by Perkins (5).

Advantages And Disadvantages. The major advantages of dry heat sterilization are low cost and the compatibility with anhydrous oils, powders, and materials not affected by high temperatures. By definition, the moisture content of dry heat sterilization is low. Disadvantages of dry heat sterilization include a relatively long sterilization time and the use of elevated temperatures. Heat diffusion will depend on the ability of the dry heat to diffuse throughout the chamber and the type of material–device being sterilized. The killing rate may be slow due to delayed heat conduction of some materials in which the amount of heat delivered to the microorganisms is limited. Dry heat sterilization cannot be used for most liquids, heat labile substances (i.e., proteins), and heat sensitive materials (1,5).

Physical Effect upon Materials. High temperature can alter bulk properties of polymers and composites and can melt polymers and materials that have a melting temperature below or near the temperature being used for sterilization. The melting temperature of most linear polymers is below the temperatures commonly used in dry heat sterilization (7). Even when the melting temperature is above the temperatures employed, oxidation may still occur in polymers (e.g., nylon) (7). However, polytetrafluoroethylene (PTFE) and silicon rubbers may be effectively sterilized using dry heat (7). High temperatures can adversely affect structural proteins (e.g., collagen and elastin) and modify the mechanical properties of biologic materials (8–10). The high temperature used for dry heat sterilization may also denature bioactive molecules (e.g., growth factors and bioactive peptides present in tissue grafts and naturally occurring biomaterials).

Moist Heat Sterilization (Autoclave)

Mechanism of Action. The mechanism by which moist heat sterilization kills microbes is similar to the mechanism described for dry heat sterilization. Protein and nucleic acid coagulation and denaturation occur quickly once a critical temperature is reached. For the same reasons that protein and nucleic acid destruction inhibit the ability of bacteria to replicate or continue metabolic processes, this method is generally unacceptable for biologic materials that are composed of naturally occurring proteins (5). The high temperatures used with moist heat sterilization are effective for the inactivation of viruses and bacterial spores.

Moist heat (steam) sterilization or autoclaving is conducted under pressurized conditions with saturated steam usually at 121–125 °C. The process typically lasts from 15 to 30 min to ensure that all surfaces are exposed to the moist heat.

Advantages And Disadvantages. The advantages of moist heat sterilization are its efficacy, the relatively low temperature requirements (compared to dry heat sterilization), speed, process simplicity, and the lack of toxic residues when compared to methods such as ethylene oxide (ETO) sterilization (discussed in the next section). Since moist heat sterilization is performed in a pressurized

environment, it can also be used to sterilize liquids. The disadvantages of moist heat sterilization include the presence of water, the use of elevated temperatures, and the possible deposition of impurities present in the steam. Moist heat sterilization is obviously not suitable for heat labile materials or synthetic and natural polymers that are readily degraded by hydrolysis.

Physical Effect upon Materials. Moist heat sterilization can change bulk properties of polymers by hydrolysis and the hydrolytic byproducts may result in the formation of contaminants. For example, exposure of methyl diisocyanate based polyurethanes to prolonged steam sterilization results in the formation of methylene dianiline (due to hydrolysis), which leads to decreased lung function when used in lung perfusion devices (11). Polymers that are prone to hydrolytic degradation include poly(vinyl chlorides) (PVC), polyacetals, polyethylenes, and polyamides (7). For example, the mechanical properties of PVC can be adversely affected by repeated steam sterilization due to rearrangement of macromolecular chains (12). A separate example of the potential harmful effects of moist heat sterilization is the formation of oligomer crystals on the surface of Dacron grafts as a result of steam sterilization that can cause hemolysis when this material is used as a vascular graft (13). With respect to biologic materials, steam sterilization can have adverse effects upon the mechanical properties of tissue grafts as in the case of bone allografts (14). For obvious reasons, the denaturing effects of steam sterilization upon protein structures caused by the elevated temperatures makes this method generally unsuitable for most biologic materials.

In summary, both dry and moist heat forms of sterilization, although effective for nonbiologic materials, are typically unsuitable for the sterilization of biologic materials, due to adverse effects upon the structure and function of protein and non-protein constituents.

ETHYLENE OXIDE STERILIZATION

Ethylene oxide sterilization is a commonly used method for the sterilization of heat-sensitive materials, medical equipment, and biologic materials including those composed of ECM, such as TissueMend (fetal bovine skin from TEI Biosciences), and OaSis (small intestinal submucosa/SIS extracellular matrix from Cook Biotech, Inc.). Sterilization via ETO has also been explored for demineralized bone, tendons, dura mater, and fascia lata (15).

Mechanism of Action. Ethylene oxide is an unstable ring structure capable of reacting via alkylation with functional groups found in nucleic acids and proteins (1,16,17). Examples of reactions between functional groups and ETO are listed in Fig. 2. Sterilization via ETO exposure begins with the placement of the target device into a pressurized sterilization chamber. The humidity within the chamber is controlled by the introduction of moisture (40–90% humidity) and the temperature is maintained between 40 and 50 °C. The ETO is then introduced into the chamber at concentrations ranging from 600 to 1200 mg·L⁻¹ for a sufficient time (typically 2–48 h) to achieve the desired SAL. Following sterilization, room air is used to flush the vessel for removal of residual ETO and its toxic byproducts. Longer flushing time minimizes the presence of toxic byproducts but increases the overall sterilization time.

Advantages and Disadvantages. The advantages of using ETO sterilization include the relatively low temperature requirements (compared to heat sterilization), and the high degree of penetration of the ETO gas into the target device. Temperature and moisture sensitive materials are more readily sterilized via ETO than by heat sterilization methods. Perhaps the greatest disadvantage of ETO sterilization is the toxicity and carcinogenicity of the residual byproducts: ETO, ETC, and ETG (see Fig. 3). For samples weighing >100 mg, acceptable levels of ETO, ETC, and

Figure 2. Examples of possible reaction between ETO and common functional groups in biological molecules (16,17). For a more complete explanation of the reactions please refer to (16,19).

Figure 3. Structure of ETO and its byproducts: Ethylene glycol (ETG) and ethylene chlorohydrin (ETC). The ETO is flammable and highly explosive and has been associated with potential mutagenic, teratogenic, or carcinogenic properties. Both ETG and ETC are toxic as well (18).

ETG are 2500, 2500, and 5000 ppm, respectively (1,17). In addition to the alkylation reaction referred to above, ETO may also react with functional groups on the surface of biomaterials and with constituent proteins causing changes in bioactivity and bulk properties of the device.

Physical Effect upon Materials. Materials coated with proteins (e.g., albumin and heparin) may lose the benefit of these coatings as a result of ETO interactions with these surface molecules (20). Protein cross-links, alkylation reactions, and other chemical changes that occur as a result of ETO interactions may also have adverse effects upon the bioactivity and the mechanical properties of biologic materials (e.g., allografts) (15,21–23).

In summary, ETO sterilization with proper aeration and/or removal of toxic by products may be safely used to sterilize biologic materials. However, changes in bioactivity and structural properties can still occur using this method of sterilization.

IONIZING RADIATION STERILIZATION

Sterilization via radiation is the most commonly used technique to sterilize biologic materials at the present time. Examples of such devices include RestoreTM (SIS-ECM used for orthopedic applications, DePuy Orthopedics), CuffPatchTM (carbodiimide crosslinked SIS-ECM, Arthro-tech), and PermacolTM (crosslinked porcine dermis, Tissue Science Laboratories). Ionizing radiation is the preferred method of sterilization for other biologic materials such as heart valves, skin, fascia, dura mater, bone, and tendon grafts (24). There are different types of irradiation, including gamma irradiation and electron beam irradiation, that are approved by the FDA and commonly used by medical device manufacturers. These methods will be discussed separately.

Gamma Irradiation

Mechanism of Action. Gamma radiation arises from the decay of cobalt (⁶⁰Co) or cesium isotopes (¹³⁷Cs). Gamma irradiation exists in the form of photons generated from the transition of an atomic nucleus from an excited state to a ground state. The resultant high energy particles induce ionization by transforming an uncharged atom to a charged atom with the subsequent release of an electron that in turn collides with other atoms. The resulting discharge of

secondary electrons creates oxidizing free radicals that damage proteins and deoxyribonucleic acid (DNA) molecules by dimerization of bases and altering the sugar phosphate backbone. These changes reduce microbe's capacity to replicate or continue necessary metabolic functions (25).

Gamma sterilization is conducted by placing the target device in front of a radiation source, usually cobalt (⁶⁰Co) or cesium (¹³⁷Cs), that is usually directed by a window in a lead shielded container (Fig. 4). The dose of gamma irradiation is adjusted by varying the distance between the source and the device or by varying the exposure time. The dose or radiation absorption is commonly expressed in terms of "radiation absorbed dose" (rad) or grays (Gy). The former represents the absorption of 10⁻⁵ joules (J) per gram (g) (J·g⁻¹) while the later represents the absorption of 1 J·kg⁻¹. Hence, 1 kGy = 0.1 Mrads. Typical sterilizing doses range between 6 and 25 kGy.

Figure 4. Schematic representation of a gamma source and how devices are typically sterilized. Dosage may be adjusted by calibrating the distance between the source and the device. Other forms may be employed depending on the facilities and the intended application.

Advantages And Disadvantages. The advantages of gamma irradiation include its compatibility with many materials, the minimal amount of toxic residues, and the low temperature requirements. Disadvantages of gamma irradiation include its cost, complexity (e.g., requires highly specialized facilities), and incompatibility with some polymers due to degradation (e.g., polymethylmethacrylamide and cellulose derivatives) or cross-linking (e.g., polyethylene and polystyrene) of the polymer (7). Gamma irradiation also may adversely affect proteins in a dosage dependent manner by the introduction of free radicals and has been associated with reduction in strength of grafts and collagenous biomaterials (26–30).

Physical Effect Upon Materials. Ionizing radiation affects the backbone of synthetic and natural polymers and may cause cross-linking, oxidation, or chain scission (7,24,25). These changes may affect degradation kinetics and material properties (e.g., tensile strength, elastic modulus, elongation, and the color of the material). In general, polymeric materials, including biologic polymers, can be safely sterilized via gamma irradiation. Safe levels of gamma irradiation include a range of 2.5 Mrads (collagen-based materials, ECM scaffolds, polypropylene, polytetrafluoroethylene) to 1000 Mrads (polystyrene and epoxy resins) (7). The lower doses of gamma irradiation (e.g., 2.5 Mrads) effectively sterilize biologic materials with minimal adverse effects to the physical properties of the material.

e-Beam Irradiation

Mechanism of Action. e-Beam irradiation involves the generation of a beam of electrons from a linear accelerator. The beam of electrons can be manipulated to achieve the desired dose by varying power and the exposure time. The sterilizing effect of e-beam irradiation on polymeric materials is similar to that described for gamma irradiation except for less penetrability of the beam into target materials. The main effect of e-beam irradiation comes from the ionizing electrons that result in the destruction of nucleic acids and proteins required for cellular processes. One primary difference between gamma radiation and e-beam is that the electron beam can be focused on the target

material and turned off when the sterilization process is completed.

Advantages And Disadvantages. The advantages of e-beam irradiation compared to gamma irradiation include the fast sterilization time, less safety concerns (i.e., the source can be turned off), greater power, and the source does not deplete as occurs with the source of gamma irradiation. The disadvantages of e-beam irradiation include its cost and less penetrability than gamma irradiation. As in the case with gamma irradiation, electron beam irradiation has also been associated with a decrease in strength of collagenous materials (27–30).

Physical Effect Upon Materials. The overall effect of e-beam irradiation is similar to those described for gamma irradiation. Free radicals are created following exposure to the electron beam and if oxygen is present, peroxy free radicals can be formed that increase the rate of chain scission (25). Polylactic-co-glycolic acid (PLGA) exposed to e-beam shows a decrease in the molecular weight (M_w) and thermal properties mainly due to chain scission and crosslinking (31,32). e-Beam has also been shown to reduce the degradation rate of PVC and polypropylene (PP) when compared to gamma sterilization, mainly due to faster free radical termination reactions (25).

The effects of e-beam irradiation upon naturally occurring, biologic scaffold materials is dose dependent. In the lower dose range (~ 2.5 Mrad), there are minimal changes upon the physical and biologic properties of the irradiated materials (24). However, changes in strength (33,34) and degradability (35) of collagenous materials and the creation of cross-links may still occur as a result of e-beam exposure (33,34).

Table 3 summarizes some of the naturally occurring biomaterials currently available and the method used to terminally sterilize the device. Table 4 summarizes the advantages, disadvantages, and the typical doses for the sterilization methods discussed.

ALTERNATIVE METHODS OF STERILIZATION

Alternative approved methods of sterilization that are recognized by the FDA include liquid chemical sterilants,

Table 4. Summary of the Most Commonly Used Sterilization Methods and Their Advantages, Disadvantages, and Typical Doses as Discussed in this Article

Sterilization Method	Advantages	Disadvantages	Typical Dose
Dry heat	Inexpensive; Ease of use	Thermal damage to proteins	Dry air at 120–170 °C (250–338 °F) for 1–18 h
Moist heat	Faster than dry heat and less heat requirement; Inactivates some viruses	Thermal damage to proteins	Saturated steam at 121–125 °C for 15–30 min (pressure may be adjusted)
Ethylene oxide	Lower temperatures than heat sterilization and less moisture	Toxic by-products; Potential reactions with functional groups	ETO is added at 600–1200 mg·L ⁻¹ for 2–48 h (40–90% humidity at 40–50 °C)
Ionizing radiation	Minimal thermal damage; Good penetration	Cost; Changes in material properties	6–24 kGy

high intensity light, ultraviolet light, vapor systems (combination of hydrogen peroxide and peracetic acid), exposure to chlorine dioxide, and filtration methods (510 k Sterility Review Guidance K90-1). In addition, low temperature gas plasma and machine-generated X rays can be used for sterilization purposes.

Chemicals are often used to reduce the bioburden, disinfect, and sterilize biologic materials. Table 5 lists a few of the most commonly used chemicals for the disinfection and/or sterilization of grafts and naturally occurring biomaterials. Glutaraldehyde is currently used to sterilize and remove the antigenicity of many porcine-derived products (e.g., heart valves and pericardium). Formaldehyde and a combination of formaldehyde and low temperature steam

is another form of sterilization used for medical devices. However, this method is seldom used for biologic materials due to its high toxicity.

Extracellular matrix based bioscaffolds (e.g., Restore, DePuy Orthopaedics) and OaSis[®] (Cook Biotech, Inc.)TM undergo presterilization disinfection with a peracetic acid and ethanol treatment followed by water and phosphate buffered saline washes to remove any chemical residues. Table 6 summarizes a typical disinfection method used for naturally occurring biomaterials prior to sterilization. Collagen-based products (e.g., Contigen, Bard, Inc.) rely on sterile processing techniques, acidic environments, chemical cross-linking (e.g., glutaraldehyde), and sterile filtration (e.g., via 0.22 μ filters) to achieve the desired sterility.

Table 5. Common Chemical Sterilants and Disinfectants Used for Biologic Materials

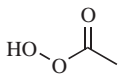

Chemical	Uses	References
 Glutaraldehyde	Used for sterilization and cross-linking of tissues (e.g., heart valves, pericardium, tendons, and collagen based biomaterials).	(1,36–39)
 Peracetic acid	Used to disinfect ECM derived bioscaffolds and disinfect and sterilize medical devices. It is usually combined with hydrogen peroxide and ethanol.	(1,36,40–47)
HO—OH Hydrogen peroxide	Used to sterilize grafts and medical devices. It is usually combined with steam sterilization or with other sterilants such as peracetic acid.	(1,23,48–52)
 Ethanol	Used to disinfect ECM derived bioscaffolds and grafts. It is usually combined with peracetic acid and it is also used to disinfect or sterilize instruments.	(1,36,39,45,53–55)

Table 6. Example of the Disinfection Process Used to Reduce the Bioburden of Naturally Occurring Biomaterials^a

Step	Solution	Time
Peracetic acid disinfection	0.1% (v/v) peracetic acid 4% (v/v) ethanol, and 95.9% (v/v) sterile water	2 h
Phosphate buffer saline wash	Sterile 1X PBS pH 7.4	30 min
Water wash	Sterile water	30 min

^aSee Ref. 56.

Figure 5. Reaction of glutaraldehyde polymers with amino groups and a pyridinium cross-link resulting from protein exposure to glutaraldehyde. (Redrawn from Ref. 1).

High levels of peracetic acid and combinations of peracetic acid (PAA), ethanol, isopropyl alcohol, hydrochloric acid, antibiotics, hydrogen peroxide, and detergents have been used for sterilization of demineralized bone grafts (48). A combination of steam sterilization and hydrogen peroxide may also be used for sterilizing allogeneic bone, but risks of denaturing collagen molecules still exists. Peracetic acid and hydrogen peroxide have been used for the disinfection and sterilization of acellular dermal matrices (24). The negative effects of these alternative sterilization methods upon biological materials include the molecular cross-linking that is caused by the chemical sterilant (see Fig. 5), collagen and protein denaturation, and the adverse effects of acids (e.g., the disruption of sulfhydryl and sulfur bonds by PAA) upon material properties at the concentrations needed for sterilization.

SUMMARY

There are several options for the sterilization of biologic materials and each option has its advantages and disadvantages. The majority of biologic materials classified as medical devices are sterilized by either gamma or e-beam

irradiation or by ethylene oxide. These methods tend to have dose-dependent effects upon the structure and function of biologic materials (e.g., strength of irradiated materials), but doses that effectively sterilize the material can be used with minimal effects upon the structure and function of currently marketed biologic devices.

GLOSSARY

- | | |
|----------------------------|---|
| Allograft | Organ or tissue graft obtained from the same species. |
| Bioburden | The microbiologic load or the number of contaminating organisms in the product before sterilization. |
| Disinfection | The destruction of pathogenic and nonpathogenic microorganisms by thermal or chemical means. The FDA (1997) definitions as given in Ref. 1. |
| Endotoxins | Toxic components of the outer membrane of Gram-negative bacteria that cause fever. |
| Extracellular matrix (ECM) | An insoluble network of polysaccharides and structural and non-structural proteins secreted by host cells and present in all tissues and organs. |
| Inactivation | Removal or inactivation of the activity of microorganisms by killing or inhibiting reproductive or enzymatic activity. The FDA (1997) definitions as given in Ref. 1. |
| Medical device | A device used for diagnosis, cure, treatment, or prevention of a disease or condition. A device that affects the structure and function of the body, does not achieve intended use through chemical reaction, and it is not metabolized. The FDA (1997) definitions as given in Ref. 1. |
| Pyrogens | Fever inducing agents (e.g., signals from inflammatory cells, chemicals, endotoxins, cell remnants from Gram-positive bacteria, and fungi). |
| Spore | The dormant state of an organism, typically a bacterium or fungus, which exhibits a lack of biosynthetic activity and reduced respiratory activity, and has resistance to heat, radiation, desiccation, and various chemical agents. The FDA (1997) definitions as given in Ref. 1. |

Sterility assurance level (SAL)	An indicator that no greater than the predetermined number of microorganisms exists in a product usually represented as the number of colony forming units per device.
Sterilization	A process intended to remove or destroy all viable forms of microbial life, including bacterial spores.
Xenograft	Organ or tissue graft obtained from a different species.

STRAIN GAGES

INTRODUCTION

Strain gages are devices that allow measurement of the change in the dimensions, displacement, or deformation of an object. These devices have been used extensively in a wide variety of engineering applications over the past century and, in recent decades, their use in biomedical applications, such as in the production of transducers for biomedical monitoring and research, has increased tremendously. These transducers measure a variety of parameters, including strain, displacement, pressure, acceleration, force, and temperature. The chief types of strain gages are mechanical, optical, acoustical, and electrical. There are several types of electrical gages including capacitance, inductance, semiconductor, and resistance strain gages. The electrical resistance strain gages are the most widely used types of gages in engineering and biomedical applications today and receive the most extensive treatment in this article. Before discussing the various types of strain gages in more detail, it is useful to have a working understating of what strain and stress are and their relationship to each other.

STRAIN AND STRESS

Strain is a dimensionless unit, which is defined as the ratio of the change in unit length over the original length,

$$\epsilon = \Delta L/L \quad (1)$$

where ϵ is strain, L is the original length of the object along an axis, and ΔL is the change in length along that axis. Measurements of strain are usually given in microstrain ($\mu\epsilon$) where $1.0 \mu\epsilon = 1 \times 10^{-6} \epsilon$. By convention, if an object is shortened in length, the strain is compressive and takes a negative value. If an object is lengthened, the strain is tensile and takes a positive value.

Although strain gages directly measure a change in electrical resistance that is proportional to a change in dimension, they can also be used to measure force or pressure if some of the properties of the test material are known. For many metals and other solids, a constant can be used to define a linear relationship between deformation or strain (ϵ) and stress (σ), where stress is defined

as force per unit area. This relationship, also known as Hooke's law, can be expressed as

$$\sigma = E\varepsilon \quad (2)$$

Where stress (σ) is directly proportional to strain (ε). The constant E is called the modulus of elasticity, the elastic modulus, or Young's modulus. Since strain is a dimensionless quantity and stress is defined in units of force per area, such as pascals (newtons per meter squared), E is also given in units of force per area.

Strain gages usually measure strain on a small portion of the surface area of a structure. A series of strain gages affixed to a structure allows determination of the way in which the structure is being deformed; the deformation can result from either axial, shearing, twisting, or bending loads. If a structure is loaded so that it is deformed in a predictable way, then strain gages can be affixed to the structure, calibrated, and used to measure the magnitude of the loading. An example of this kind of transducer would be a load cell, which can be used to measure force when load axially.

TYPES OF STRAIN GAGE

Depending on the material and the test situation, the parameters of strain measurement vary widely and require selection of a strain gage appropriate for the particular problem. Considerations in the selection of a gage include factors, such as knowledge of the required accuracy and stability of the gage, the maximum deformation of the material, the duration of the test, patterns and amount of loading of the gage, and the location and situation of gage installation. The following discussion describes some features and limitations of strain gages that are currently in use. Due to their widespread use, greater consideration is given to electrical resistance strain gages.

Mechanical Strain Gages

Mechanical strain gages have been in use longer than other types. However, due to their large size and relative inaccuracy, their use in engineering applications today is limited. These gages are most commonly used to measure strain in industrial applications where it is appropriate to summate strain over a range of several inches. Mechanical strain gages typically consist of a system of two points or knife-edges that can be securely attached to a structure. Then a series of compound levers within the gage magnify the displacement allowing a reading to be taken. The limited range of accuracy of these gages, with measurements restricted to magnifications of up to 2000 ($500 \mu\varepsilon$), contrast with the greater accuracy of electrical resistance strain gages (see below). Yet such gages are most useful where the size of the gage is not an issue and the ability to take a reading from a simple vernier or dial scale, without any associated electric instrumentation, is at a premium.

An additional type of mechanical strain gage, the electromechanical strain gage or extensometer, provides greater accuracy than other types of mechanical strain gages and is used in a variety of current industrial applications and in materials testing.

Optical Strain Gages

Optical techniques have been used in a variety of ways to measure strain. The simplest optical strain gages are similar to mechanical strain gages except that light rays are substituted for mechanical levers in magnifying the displacement. This change serves to decrease the size and inertia of the gage while making it appropriate for use at low frequencies in dynamic applications. The use of lasers as collimated light sources has led to the development of several optical strain gages, including those based on principles of diffraction. The diffraction strain gage, like some of the mechanical gages, has two blade-like edges that are bonded or welded to the test specimen. This gives the gage the advantage of automatic temperature compensation, if the blades are constructed of the same material as the test specimen, making the gage suitable for some use in extreme temperatures.

Another interesting optical gage is the interferometric strain gage. This gage measures strain by examining interference patterns caused by directing a light source, such as a helium-neon laser, at two V-grooves placed on the surface of a specimen. This method is most useful in test situations where it is preferable not to actually attach a strain gage to the test specimen, thus eliminating problems of bonding, inertia of the gage, and temperature compensation. A similar noncontacting device is the infrared (IR) extensometer, which is used in materials testing when deformations are large, such as with elastomeric and highly extensible materials, where strain gages or contracting extensometers cannot be readily attached. Resolutions of up to $5 \mu\text{m}$ can be obtained with these devices.

Electrical Strain Gages: Capacitance and Inductance Types

These two types of electrical strain gages are not as widely used as the semiconductor and resistance types, yet find uses in specialized applications and in the production of transducers. The capacitance strain gage uses a parallel plate capacitor where the positional relationship of the two plates varies with the capacitance. For example, increasing the distance between the two plates will effect such a change.

There are several types of inductance strain gages. One notable example is the linear variable differential transformer (LVDT). This device is useful for measuring displacements that range from several micrometers to several centimeters, thus making it useful in situations that require measurements of larger displacements than can be measured by electrical resistance strain gages. The device can also be modified with auxiliary mechanisms to measure velocity, acceleration, force, pressure, or flow rate. The LVDT consists of a freely moving iron core surrounded by a primary and two identical secondary coils. The device can be designed such that the voltage output is a linear function of the displacement of the core within the coils over a specific range.

Electrical Strain Gages: Semiconductor Type

Semiconductor strain gages are widely used gages, especially in the production of load cells, miniaturized

transducers, and other applications requiring measurement of very small strains. These gages provide a large signal output relative to strain, as indicated by their large gage factors (GF for a definition see below), which can be as high as 200. By contrast, GFs for electrical resistance strain gage are usually two or less. Unfortunately, semiconductor strain gages also suffer from an extreme sensitivity to temperature. In addition, the piezoresistive effect varies with strain giving these gages ranges of nonlinearity. Semiconductor gages are typically constructed from silicon or germanium. Because of the high receptivity of these materials, the gages consist of a small filament of a single crystal of the semiconductor material mounted on some type of carrier. The receptivity and strain-measuring properties of the crystal can be varied by altering the amount of impurities in the crystal. The fatigue life of semiconductor gages for cyclic strains is less than that of electrical resistance-type gages. These gages are then commonly employed in fields with low strains where frequent loading does not lead to gage failure.

Electrical Strain Gages: Resistance Type

The electrical resistance strain gages are the most widely used gages in engineering and biomedical fields (Fig. 1). The principles behind these gages were first discovered by Lord Kelvin in 1856 when he noted (1) that the resistance of a metal wire increases with increasing strain and decreases with decreasing strain and (2) that different materials have different sensitivities to strain.

Electrical resistance strain gages are also sensitive to temperature changes, but not to the extent of semiconductor gages. Most gages have a several hundred degree range under which they function best. However, within that range, temperatures must be monitored carefully in order to compensate for apparent strain caused by shifts in temperature. However, gages are available that have self-temperature compensation. In these gages, the

Figure 1. Four basic gage patterns (From eFunda Inc., with permission). Top left: single-element gage. This gage can be used to measure either maximum or minimum strains. Top right: T-style gage with two perpendicular elements. This gage can be used to measure maximum, minimum, and shear strains if the gage is aligned with the principle strains. Bottom left: rectangular rosette strain gage. This gage, as well as the delta rosette strain gage (bottom right), can be used to measure maximum, minimum, and shear strains and need not be aligned with the principal strains.

thermal expansion coefficient of the gage is matched to that of the test material.

Electrical resistance strain gages are available on a variety of backing materials ranging from various metal foils to polyamide and epoxy. The backing materials affect the performance of the gage and are varied to achieve the desired temperature range, extensibility, and fatigue characteristics for the gage. Many electrical resistance strain gages fail only when strain levels exceed 20,000 $\mu\epsilon$ (2%) and one million cycles, making them useful for many static and dynamic applications.

An important characteristic of an electrical resistance strain gage is the gage factor (GF). This factor can be defined as follows:

$$GF = (\Delta R/R)/\epsilon \quad (3)$$

$\Delta R/R$ is the change in resistance divided by the resistance, which is then divided by the strain (ϵ) in order to calculate GF. Thus, GF is a dimensionless constant for any given gage and a measure of sensitivity. Its value is affected by the pattern of the foil, the size of the gage, the geometry of the gage, and the temperature at which measurements are made. Commercially available gages come with calculated GFs throughout their temperature range as well as values for their resistance. A reworking of equation 3 can be used then to calculate ϵ if $\Delta R/R$ is measured. The parameter $\Delta R/R$ can be easily measured through the use of a Wheatstone bridge circuit or potentiometer, as discussed below. Typical, GFs of electrical resistance strain gages are ~ 2 , indicating the low sensitivity of these gages compared to semiconductor strain gages, which have high GFs. As a result, signals from electrical resistance strain gages require extensive conditioning to amplify the signal to a level acceptable to most recording devices.

A rosette strain gage is a combination of three electrical resistance strain gages configured adjacent to each other or stacked on top of one another on a single backing (Fig. 1). Rosettes can be used to calculate the direction and magnitude of the principal strains (minimum and maximum strain), and shear strain on a test material. They are available in two configurations: (1) a delta configuration with the principal axes of the three gages oriented at 60° apart and (2) a rectangular configuration with the principal axes of the three gages oriented at 45° apart. Another gage configuration, the T configuration (Fig. 1), consists of two gages at right angles to each other. This gage can also be used to calculate minimum strain, maximum strain, and shear strain if the directions of the minimum and maximum strains are already known and the elements of the gage are oriented along these axes on the test material.

A wide variety of insulation materials and bonding substances are available for use with electrical resistance strain gages. These include appropriate substances for constructing preparations for various conditions of temperature and moisture for static and dynamic applications.

Electrical Strain Gages: Elastic Resistance Type

Elastic resistance strain gages are specialized types of electrical resistance strain gages that are used in

cardiovascular and respiratory dimensional and plethysmographic (volume-measuring) determinations. The gages are made of a narrow silicone-rubber tubes, usually with an inside diameter of ~ 0.5 mm, and they range in length from 3 to 25 cm. The gages are filled with mercury or with an electrolyte or conductive paste and the ends are sealed with copper, silver, or platinum electrodes. When the gage is stretched, the diameter of the tube decreases and the length increases, increasing the resistance. These gages allow measurement of large-dimensional changes. They are accurate in the 10,000–100,000 $\mu\epsilon$ range. Strains as high as 300,000 $\mu\epsilon$ (30%) can be measured with distortion as small as 4%.

Wireless Strain Gage: Telemetry

Strain gages can be wireless, if coupled with telemetry transmitters and receivers. The elimination of the need for trailing wires from experimental objects makes possible data gathering from inconvenient or unsafe monitoring locations and it may reduce some of the noise of electrical interference (4,5).

SIGNAL PREPARATION AND AMPLIFICATION

Bridges

Two electric circuits, the potentiometer and the Wheatstone bridge, are commonly used to convert $\Delta R/R$ to a voltage that can be measured and used to determine ϵ . The Wheatstone bridge is the more widely used of the two types of circuits. There are some other variations; for further information, see the *Reading List*. A new circuit, the Anderson loop circuit, believed to outperform the Wheatstone bridge, shows much future promise.

Potentiometer. Figure 2 illustrates a potentiometer circuit (3). This circuit consists of a voltage source (E_i), two resistors (R_1 and R_2), and an output voltage (E_o). A strain gage can take the place of either or both of these resistors and standard circuit equations can be used to compute the changes in E_o and ΔE_o and thus $\Delta R/R$. These equations are not given here; for further information, see the *Reading List*.

A major limitation of the potentiometer circuit is that the output voltage E_o is usually quite large compared to

Figure 2. Diagram for a potentiometer circuit (3). Abbreviation: E_i -voltage source, R_1 and R_2 -resistors, E_o -output voltage.

Figure 3. Diagram for a Wheatstone bridge circuit (3). Abbreviation: R_3 and R_4 -resistors, others as in Fig. 2.

ΔE_o , making it difficult to obtain an accurate measurement of ΔE_o . This limits the usefulness of the circuit for static loading applications. However, a filter can be employed to block out E_o while allowing voltage pulses of ΔE_o to be measured. Such a filter enables the circuit to be useful in dynamic applications.

The Wheatstone Bridge. Figure 3 illustrates a Wheatstone bridge circuit (1). Note that the circuit contains four resistors. Strain gages can be used in the place of any combination of these resistors depending on the desired measurement. The advantage of this circuit over the potentiometer is that the bridge can be balanced so that the output voltage (E_o) is zero. The ratio of ΔE_o to the input voltage (E_i) can then be used to calculate the change in resistance in the strain gage ($\Delta R/R$) and the strain (ϵ). This feature makes the Wheatstone bridge circuit useful for the measurement of both static and dynamic strains. The circuit equations used to calculate strain differ depending on the configuration of gages in the Wheatstone bridge. For additional information on these equations, see the *Reading List*.

A limitation of the Wheatstone bridge circuit is that it is nonlinear when ΔR is $> 1\%$ (2). This is generally not a problem within the usual range of resistance changes of electrical resistance strain gages. However, large strains ($> 3000 \mu\epsilon$) measured with semiconductor gages may require the use of different circuitry (3). An additional advantage of the Wheatstone bridge is that it allows signals to be added or subtracted in multiple gage installations. In fact, sensitivity of a transducer can be quadrupled by using four active gages instead of one in the application. This can be accomplished, for example, by placing the two strain gages associated with the negative arms of the Wheatstone bridge on the compressive surface of the test specimen, and the two strain gages associated with the positive arms if the Wheatstone bridge on the tensile surface. Temperature compensation can also be achieved with Wheatstone bridges, through the use of a dummy gage, without sacrificing sensitivity.

The Anderson Loop Circuit. Figure 4 illustrates the topology of the Anderson loop circuit. This circuit consists

Figure 4. Diagram for a simple differential amplifier circuit for use with a Wheatstone Bridge (Modified from a drawing by O. Poroy (www.engineering.uiowa.edu/~bme080/lab/S05Lab7.pdf)). E_o is amplified by differential gain of sensors R_A and R_B compared to input resistance incurred by the source voltage (E_i).

of one or more sensors (strain gages) and typically one reference element (R_{ref}) connected in a series loop circuit. The same excitation current flows through each circuit element in the loop. The unique feature of this technology is the use of a subtractor function. In order to calculate strain from $\Delta R/R$, this function compares the voltage drop across various circuit elements in the loop, typically to determine the difference between each loop sensor voltage drop and the voltage drop across a reference element. Subtracting the voltage drop across two sensors yields a difference in $\Delta R/R$ between the two sensors.

Compared to the Wheatstone bridge, the Anderson loop circuit does not require four resistive elements. The loop provides a set of linear outputs that are twice that of the typical Wheatstone bridge for the same voltage across (and power dissipation in) each sensor. The loop topology overcomes some limitations normally encountered with the Wheatstone bridge, especially the detrimental effects of varying lead wire and connector resistances. These features open a vista for advanced transducer design. The impact of the Anderson loop circuit on the future of measurement and control is likely to be profound (6). This new technology was invented and developed in projects by NASA, who has placed it in the public domain. For more information, visit the Valid Measurements website, <http://www.v-m.us>.

Amplifiers

There are several good amplifiers and signal conditioners available commercially for use with strain gages (see *Further Reading* for some sources of information on specific amplifiers). An example for a simple differential amplifier circuit for use with a Wheatstone bridge is illustrated in Fig. 5, where the output voltage (E_o) is amplified by the including of sensors R_A and R_B . In general, the better amplifiers should have a variety of features including some of the following:

1. The ability to complete a variety of Wheatstone bridge circuits ranging up to a full bridge configuration with all resistors in the bridge replaced by strain gages. Dummy gages for a less than a full

Figure 5. Diagram for an Anderson loop circuit (From Karl F. Anderson/Valid Measurements Inc., with permission)

bridge configuration should be available for several of the standard resistances used in strain gages (including 120 and 350 Ω resistors).

2. A range of excitation voltages should be available for the Wheatstone bridge circuits.
3. The amplifier should be able to balance the Wheatstone bridge over a wide range of output voltages, although some computer-linked devices now automate balancing, making this task transparent to the user.
4. Variable gain to allow accurate readings of both large and small strains with a variety of gages.
5. Wide band operation, high input impedance, low noise level, and low temperature coefficient.
6. The ability to condition not only electrical resistance strain gages installed as part of Wheatstone bridge circuits but also potentiometer circuits, and the ability to condition and amplify output from piezoresistive (semiconductor) gages.
7. Additional features, such as digital readout and filters, depending on specific applications.

APPLICATIONS

Strain gages have enabled significant advances in many biological and biomedical fields. They have been used extensively in a wide variety of biomedical and clinical applications, chiefly to measure strain, stress, pressure, force, or displacement in or produced by living structures, or *in vitro* simulations. It is the aim of the following section to document several of these applications in order to give the reader a practical knowledge of the possibilities for using strain gages in basic biological and biomechanical research as well as in clinical sciences and medical diagnosis.

Biomechanical Research and Bone Health

An area of investigation with speculations that extend back into the nineteenth century and before is the study of the relationship between function and loading in bone. Of great mechanical interest are parameters of bone morphology and physiology, such as bone shape and size and the rate and amount of skeletal remodeling. In 1892, Wolff summarized much previous research in his Law of Bone Transformation that stated that every change in the function of a bone results in changes in trabecular orientation and in the external shape of the bone (7). Use of electrical resistance strain gages has led to much new research in this area.

Strain gages were first used in the 1940s to measure bone strain (8,9). Rosette configurations of electrical resistance strain gages have been most useful in these types of studies since they can provide information about changes in both the direction and magnitude of the strains on the skeleton.

A variety of experimental studies have used strain gages to assess how the craniofacial skeleton is loaded during normal oral and masticatory activities. Early studies used skulls with strain gages bonded to them to assess these loads, strain patterns and their links to bone morphology by simulation of muscular and occlusal forces (10). Later advances in strain gage technology and biological experimental techniques have enabled strains to be measured directly from bone *in vivo* in experimental animals (11–13; Fig. 6). For example, studies have used electrical resistance strain gages to assess how the craniofacial skeleton is deformed during normal oral and masticatory activities in primates (14,15). These studies cannot be repeated on humans because of their invasive nature. However, the animal studies have led to speculations and inferences about the biomechanics of mastication in humans, that can be explored through *in vitro* experiments using human cadaver specimens (9,16). Other interesting cranial studies have used strain gages to understand the behavior of open sutures and their effects on the function, growth, and adaptation of craniofacial skeleton (17,18). Moreover, patterns of craniofacial bone fracture have been related to bone loading and strain distribution determined with strain gage techniques (19–21).

Other studies have used strain gages in the postcranial skeleton to study loading patterns in long bones during locomotion (22). These techniques have also been applied to study skeletal loading during human locomotion (23) and to obtain better understanding of the function of prosthetic devices such as hip replacements (24). Other postcranial studies have used strain gages to measure tension in tendons or in tendons and bone simultaneously (25,26). In general, experimental studies have demonstrated a relationship between magnitudes and rates of loadings in bone and skeletal remodeling (22,27), although the precise nature of this relationship is the subject of considerable debate (27–29).

Coupled with techniques of measuring bone material properties and finite element analysis, the application of strain gages in studies of functional morphology contributes greatly in medical and biological fields (30–34). This research provides tremendous knowledge about bone

Figure 6. Experimental *In vitro* strain analysis in a skull of *Macaca fascicularis*. A couple of rectangular rosette strain gages were bonded to bone surface of craniofacial skeletons.

morphology, adaptation, and modeling and remodeling during aging, normal function, and under abnormal conditions, and provides rationales for bone health maintenance and bone reconstruction.

Dental and Craniofacial Research

In clinical dentistry and experimental craniofacial biology, measurements of occlusal forces have been used to give an overall assessment of functional capacities of the masticatory system (35–37). Such measurements are made with bite force transducers. These transducers have been used throughout much of the twentieth century and were originally mechanical devices. More recently, they have been constructed with electrical resistance strain gages or semiconductor gages. Figure 7 illustrates one such transducer constructed with electrical resistance strain gages (38). This transducer uses four strain gages in a full bridge configuration for an optimal voltage output. An individual would bite on the distal ends of the two bars to generate a change in resistance in the four gages. This change can then be measured and correlated with a specific biting force. Another feature of this transducer is that the gages are arranged in the circuit such that each upper and lower beam function as differential strain beams. In such beams, only the difference in strain between the two gages on the beam is measured. Thus force can be placed on the beam anywhere distal to the most distal gage and an identical reading will result. For a bite force transducer, this creates an advantage that the bite point does not have

Figure 7. Diagram for a bite force transducer (38). This is an example of a force transducer constructed with four electrical resistance strain gages in a full bridge configuration. Each beam of the device is a differential strain beam. (a) Distal end of the device (missing the handle) illustrating the dimensions. (b) Inner surface of the beams showing the arrangement of the strain gages. Units in millimeters.

to be precisely controlled in order to obtain comparable readings.

Strain gages are used to study teeth and the surrounding alveolar bone during normal masticatory function, and in the presence of orthodontic and functional appliances. For example, strain gages are used to monitor the behavior of a dental prosthetic device (39–41), and its impact on the bone strain environment and eventual bone structure and strength (42). Strain gages are also used in studies of dental materials. A transducer has been constructed with electrical resistance gages to measure dimensional changes in dental amalgam during setting (43). These studies using strain gages provide rationales for orthodontic and prosthodontic treatments.

Physiological Research and Clinical Applications

Strain gages were used to study blood pressure (44), intracranial pressure (45), and cerebrospinal fluid pressure (46). The plethysmograph, made of elastic resistance strain gages, has been used diagnostically for several decades. For example, the venometer uses plethysmography to detect deep vein thrombosis through monitoring changes in certain muscle dimensions while venous outflow is occluded by a cuff placed around body parts (47,48).

A number of transducers constructed with electrical resistance strain gages are available to study the contractile properties of muscle. For example, strain gages were used to design quantitative assessment of neuromuscular deficits (49). Strain gages have also been used for many years to study cardiac muscle physiology *in vitro*. The

Walton–Brodie strain gage arch has been used since the 1950s to measure forces exerted by the heart (50). For example, studies, have used the Walton–Brodie arch along with other strain gage transducers to examine the effect of halothane and enflurane on right ventricular performance (51), antiarrhythmic drugs on the heart rate (52), and biventricular mechanical alternans (53).

Elastic resistance or mercury strain gages have been used in cardiovascular and respiratory, and urological research. These studies have examined, for instance, changes in the volume of the larynx and movements of the rib cage and abdomen during respiration (54), the spontaneous contractions of trachea (55), and the change of bladder pressure with the use of catheters (56). Electrical resistance strain gages are also used to make transducers to study gut motility (57,58).

Strain gages were used in pharmacological studies to test physiological reactions to certain drugs (59), in psychophysiological research to examine how body physiology changes with emotion (60) and pain (61), and in sleep studies to evaluate sleep quality by recording eye movement during sleep (62,63) and to diagnose sleep related syndromes such as sleep apnea (64).

A unique application of electrical resistance strain gages was used to construct a transducer to evaluate erectile function in men by using strain gages to measure or monitor penile circumference and rigidity on various conditions (65,66). For example, a transducer called tonometer, measured force at which the penis buckles, giving a quantitative measurements of penile tumescence (67).

Sports Medicine

Strain gages have had been used in sports medicine, such as for performance evaluation, protection, and healing. For example, electric resistive strain gages have been used to construct instruments to measure hand strength (68), and to measure shoulder strength in football players, which is the most vulnerable body part in this sport (69). Strain gage transducers were used to document elongation of the human anterior cruciate ligament during various activities following a sprain. The transducer was temporarily placed in the ligament during arthroscopic surgery (70). Strain gages have also been used to evaluate sports equipments. For example, experiments were conducted to reveal how shoe gear can affect tibial strains in humans during dynamic loading, such as treadmill walking and free running while wearing various sport shoes (71).

Robotic Medicine

Within the concept of robotic surgery and telemedical care, medical practice is significantly enhanced with robotic systems incorporating tactile sensors made of essential strain gage elements. Examples include a tactile sensor system using a piezoelectric transducer to simulate the properties of the human hand for use as a surgical support instrument for conducting micro- or telesurgery (72), or a palpation probe to evaluate patterns of softness and elasticity of human skin (73).

INTRODUCTION

Definitions

In the most general terms, tactile stimulation is the deliberate elicitation of any of a range of sensations perceived through the sense of touch. The stimulation can be delivered by any means and to any part of the body where touch can be felt. Most commonly, tactile stimulation is applied to the skin, usually to the fingertips, abdomen, or forearms, but tactile stimulation is also used on the tongue as a possible communications tool and at the back of the throat during therapy in people with dysphagia. Clinically relevant tactile stimulation can be as simple as a caregiver stroking a baby to encourage healthy development or involve of thousands of sophisticated actuators in arrays working in concert to present a virtual tactile environment.

Tactile perception should be distinguished from kinesthetic and haptic perception. Tactile perceptions include temperature, skin curvature and stretch, vibration, slip, pressure and local contact force. Kinesthesia is the perception of the relative position and movement of our body parts (proprioception), as well as the sensation of muscular effort exerted while touching or manipulating objects. Although M. Dessoir (1892) originally defined haptic (*haptik* in German, modified from the Greek word *haptikos*) to mean “the study of touch and tactile sensations, especially as a means of communication” (Oxford English Dictionary), the term haptic is applied much more broadly now. Haptic perceptions combine tactile and kinesthetic perceptions to provide a sense of environmental or object properties such as shape (1). Many devices referred to as “tactile displays”, especially those intended for virtual reality or telepresence applications, actually combine tactile and kinesthetic feedback, but this article is concerned only with devices that deliver tactile stimulation. The focus will be on the mechanical (vibrotactile and shape displays) and electrical (electrotactile) stimulators that elicit sensations of vibration, pressure, and local contact force, because these types of stimulators are most often used in current tactile stimulation applications.

Applications

Telepresence and telerobotic technologies are emerging as important fields with great potential for use in biomedical applications such as the control of surgical robots. These applications require mechanisms for the feedback of information to the human operator from a set of remote sensors. This feedback has been visual and auditory in nature, but developing technologies are permitting the use of certain forms of haptic feedback such as force reflection to com-

municate information about a manipulated object’s compliance, viscosity, mass, size, and gross shape. Researchers have made less progress toward communicating tactile information such as surface texture, fine shape, roughness, slip, vibration or temperature. These later object properties could potentially be important in helping the user distinguish between morphologically similar objects or, in the case of surgical or medical imaging applications, to assess tissue type or of the degree and extent of tissue damage (2,3). Indeed, in cases where visual information is not available, tactile information may form a user’s only basis for decision making.

Other applications for tactile stimulation include sensory substitution or augmentation systems such as those for the blind or deaf. For example, using a computer poses a particular challenge for the visually impaired. Textual information can be read aloud by the computer, but as graphical computer interfaces become more and more ubiquitous, the blind user is placed at a greater disadvantage. One solution is to represent the graphical information through a tactile display. Further applications are discussed below in the section on stimulation techniques.

TACTILE PHYSIOLOGY

Understanding how tactile stimulation techniques function requires a basic understanding of the physiological mechanisms that mediate our sense of touch. When we touch an object, the distribution of contact forces deforms our skin. The temporal and spatial distribution of the deformation determines which mechanoreceptive nerve terminals are excited. Each mechanoreceptive nerve fiber terminates as one or more dendrites. The dendrites have stretch-gated ion channels that allow ions to flow and depolarize the dendrite when their membranes are stretched or deformed. If the depolarization is sufficient, nearby voltage gated channels initiate an action potential that travels up the nerve to the central nervous system. The particular way that the deformation of the skin leads to bending or stretching of the dendrites varies from one type of mechanoreceptor to another and is due to the structure of the sensory receptor at the end of the fiber. The firing frequencies of the mechanoreceptive nerve fibers are then decoded by the central nervous system to ultimately give rise to our sense of touch.

The skin is made up of three distinct layers: the epidermis, dermis, and subcutaneous fat. Made up of primarily keratinocytes, the epidermis is the outermost layer and serves as a protective interface with the outside world. The outermost portion of the epidermis is the *stratum corneum*, which is made up of dead, flat cells that shed and are replenished about every 2 weeks. The epidermis does not contain any blood vessels and is dependant on the deeper skin layers for its oxygen and nutrients. A very thin membrane, the basement membrane, attaches the

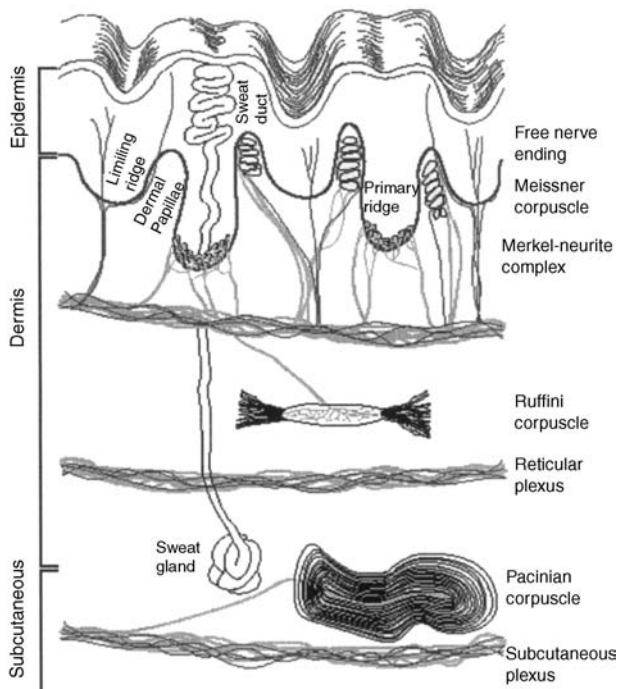

Figure 1. Mechanoreceptors in skin. Mechanoreceptive innervation of human hairless (glabrous) skin. (Diagram provided by Kenneth Johnson.)

epidermis firmly, though not rigidly, to the second layer, the dermis. The dermis contains blood vessels, nerves, hair roots, and sweat glands. Below the dermis lies a layer of fat, the subcutaneous fat, which serves as a cushion between the skin and the underlying muscle and bone. The depth of this layer differs from one person to another.

Four major types of mechanoreceptors are present in human glabrous skin (the hairless skin of the lips, soles, palms, and finger pads) that respond to touch or vibration: Pacinian corpuscles (PC or RAI), Meissner corpuscles (rapidly adapting or RAI), Merkel endings (slowly adapting or SA I), and Ruffini endings (slowly adapting or SA II) (Fig. 1). In hairy skin, the Meissner corpuscles are replaced by hair receptors with similar mechanoreceptive properties. Only a very basic overview of mechanoreceptor morphology. A recent review of the roles that mechanoreceptors play in perception can be found in Ref. 7.

Each type of mechanoreceptor is tuned so that its threshold for excitation is lowest for a particular range of vibration frequencies, although there is considerable overlap between receptor types. The receptors that respond best to higher frequency stimulation are referred to as rapidly adapting, while those that respond best to lower frequencies are called slowly adapting. A sudden but sustained skin indentation initially results in rapid firing of all the affected mechanoreceptors. The rapidly adapting ones soon cease firing (however, they may fire again at stimulus offset), whereas the slowly adapting mechanoreceptors continue firing (albeit at a lower rate) until contact is broken (Fig. 2).

The area in which stimulation leads to a response by a particular mechanoreceptive neuron is known as the

Figure 2. Response of RA and SA fibers. Responses of typical rapidly adapting (RA) and slowly adapting (SA) mechanoreceptors with large or small receptive fields to ramped and sustained indentation. The onset of the indentation stimulates rapid volleys of action potentials in both sets of mechanoreceptors, but the RAs adapt and cease firing after a few milliseconds. The SAs continue firing until indentation offset, which may trigger another burst from the RAs. (Figure redrawn from Ref. 124.)

receptive field of that neuron. The skin tissue acts as a low pass spatial filter so that the deeper a mechanoreceptor lies in the skin, the larger its receptive field. The receptive field also depends on how many receptors a mechanoreceptive neuron innervates and how widely they are dispersed. Mechanoreceptors with small receptive fields are more suitable for fine spatial discrimination than those with large receptive fields. Mechanoreceptors with small receptive fields are referred to as type I mechanoreceptors and those with large receptive fields are called type II.

The frequency tuning of a mechanoreceptive fiber (i.e., whether it is rapidly or slowly adapting) is due to its mechanical structure. For example, the Pacinian corpuscle receptor is shaped like an onion with multiple layers wrapped around the dendrite. When the skin is indented, the onion-shaped receptor is compressed. With sufficient pressure to deform the corpuscle, parts of the neural membrane are stretched and action potentials are stimulated. The Pacinian rapidly adapts to constant pressure because with maintained pressure, the gel-filled layers of the corpuscle begin to slide across each other in a way that relieves the stress on the dendrite and stops the generation of action potentials. A vibratory stimulus, on the other hand, repeatedly deforms the corpuscle, eliciting continued neuronal firing. The Pacinians are sensitive to a wide range of frequencies (50–1000 Hz), but are exquisitely sensitive to vibrations between 250 and 350 Hz, requiring only sub-micron surface displacements for excitation. The Pacinians lie deep in the dermis, so pressure anywhere over a fair amount of skin area can compress it enough to affect the dendrite, providing it with a large receptive field. Isolated stimulation of a particular Pacinian nerve fiber leads to a sensation of diffuse vibration. Even though their deep position renders them unsuitable for fine stimulus localization, the Pacinians aid in the perception of surface texture by detecting the vibrations elicited when the skin is brushed over a rough object (8). Pacinian corpuscles are also thought to play a role in tool use, specifically in our ability to attribute actions to the end of the tools we hold, by sensing the vibrations transmitted through the tool.

The ultrastructure of the Meissner corpuscle is more complicated than that of the Pacinian corpuscle, but Meissners are also rapidly adapting. The Meissners respond best to vibratory stimuli with frequencies between 30 and 70 Hz, but also respond to frequencies as low as 3 Hz. The Meissner corpuscles are located just below the dermal-epidermal boundary and have smaller receptive fields than Pacinians. Meissners are considered the primary mediators of the sensations of light touch and flutter while the Pacinians are considered the primary mediators of high frequency vibration and deep pressure.

The primary types of slowly adapting mechanoreceptors are the Merkel complexes and the Ruffini corpuscles. Merckels have a receptive field diameter of 3–4 mm, and a frequency range of 2–32 Hz (9). The Merkel sensory neurons have nonencapsulated nerve endings (neurites) that form a complex arrangement with disk-shaped Merkel cells in the basal layer of the epidermis. There is conflicting data about just how this structural arrangement accounts for the mechanoreceptive properties of the receptors, but there is general agreement that the Merkel-neurite complexes mediate the perception of steady skin indentation and their population response is thought to account for our perceptions of form and texture (7).

Ruffini corpuscles are relatively large spindle-shaped structures that are rooted in the connective tissue of the dermis. They have been studied less than other mechanoreceptors because we derive much of our understanding about mechanoreceptor physiology from studies performed on monkeys and Ruffini corpuscles have never been observed in neurophysiological studies of monkey hands. Additionally, it is not clear which perceptions should be attributed to them, because microstimulation of Ruffini fibers produces no sensation (10), and elicits no cortical somatosensory evoked potentials (11). There is some evidence, however, that Ruffini endings may participate in tactile sensations as SAI receptors (12). Currently, it is believed that Ruffinis mediate perceptions of directional skin stretch. Directional stretch sensitivity would allow them to participate in the perception of hand and finger position as well the perception of the direction of object motion or force (13,14).

In addition to the mechanoreceptors discussed above, the skin contains other sensory fibers that might be important for tactile stimulation that are outside the scope of this article, but deserve mention. The previously mentioned cutaneous and subcutaneous mechanoreceptors have large, fast, myelinated (A β) fibers, but there are also mechanically sensitive cutaneous free nerve endings with small, slower myelinated (A δ) fibers that respond to strong mechanical stimulation, especially by sharp objects. These mechanoreceptive *nociceptors* (receptors that respond to potentially damaging stimuli) mediate primarily pricking pain, but some also respond to thermal stimuli. Additionally, there are even smaller and slower, unmyelinated (C) fibers present that respond to noxious mechanical and/or thermal stimuli and are primarily responsible for sensations of burning pain. Although almost all sensory C fibers are traditionally considered to mediate pain, there is growing evidence that some mediate touch that is specifically pleasant and emotionally salient, such as from stroking by

another human (15,16). It is unknown what role C-fibers will play in tactile stimulation devices in the future.

TACTILE STIMULATION TECHNIQUES AND APPLICATIONS

The two main approaches used to artificially stimulate the tactile senses are based on exciting the receptors through mechanical perturbation of the skin or electrically exciting the mechanoreceptive nerve fibers that innervate the receptors. In both approaches, the goal is to manipulate the tactile information through variations in the four tactile primitives that code tactile information: intensity, frequency, spatial pattern, and temporal pattern (17). In addition to these classical primitives, there is evidence for a multidimensional electrotactile primitive that could be termed “color” or “quality”, of which frequency may be one dimension (18,19).

Efforts have also been reported to create tactile displays that illicit sensations of warmth or cold using thermal elements such as Peltier cells (20–22). Although interesting and potentially useful, these thermal displays are beyond the scope of this article.

Mechanical

Mechanical tactile stimulators predominately fall into one of two classes: vibrotactile or shape displays (Fig. 3). Vibrotactile displays use contactors that vibrate at a particular, usually fixed, frequency. Shape displays provide small-scale indentation, pressure, or shear profiles to the skin, often using an array of pins that can each be pressed into or withdrawn from the skin.

A useful vibrotactile display can be as simple as the early Tactaid (Audiological Engineering Corporation, Somerville, MA). The Tactaid is a single vibrator that is affixed to the chest, back of the neck, or wrist that transduces acoustic signals into vibration to convey certain speech information (the modern Tactaid VII uses an array of seven vibrators in a line). Single vibrators are also becoming common on force feedback devices such as joysticks and robotic manipulators. They are even becoming popular for home computer devices such as Logitech’s iFeel MouseMan computer mouse.

Relatively simple vibrotactile stimulators also offer clinical benefit for individuals with impaired tactile sensation. For example, Collins et al. (23) recently demonstrated that three small vibrating *tactors* (tactile stimulators), imbedded in gel-based shoe insoles, helped to maintain balance and improve postural sway during quiet standing in healthy young and elderly individuals, as well as patients with stroke, and patients with diabetic neuropathy (24,25). This application is particularly interesting because the stimuli were essentially random noise delivered at intensities *below* sensory threshold.

The subthreshold noise enhances the user’s ability to detect useful sensory signals from the sole of the foot through the principle of *stochastic resonance*. This principle, found to apply in many nonlinear physical and biological systems, describes systems in which the ability to detect a signal in the presence of noise is actually enhanced by adding a critical amount of noise. Collins contends that

Figure 3. Vibrotactile versus shape displays. Vibrotactile displays (a) use pins that vibrate around a common set point. Larger oscillations are used to produce sensations of higher intensity (top inset). Shape, or static, displays (b) present more naturalistic surface contours and use larger indentations to encode regions of higher intensity.

such noise-based devices could ameliorate age-related impairments in balance control. Similar devices using electrotactile stimulation are offered by Afferent, a company Collins helped found.

A small number of vibrotactile elements can also be useful in teleoperation applications. For example, a single vibrating element encoding manipulator force was found to improve the ease of use of a deep sea remote manipulator (26,27). Similarly, Debus et al. (28) used a cylindrical handle with four embedded vibrating elements to demonstrate that force feedback vibrations can significantly improve a teleoperated force control task by reducing the mean force errors by 35% compared to visual feedback alone.

Vibrotactile displays that utilize dense arrays of tactors can communicate more information than single oscillators. Tactile stimulators for use outside the laboratory were initially developed as sensory substitution aids for the sight and hearing impaired. One of the first tactile arrays used vibrating contacts on the users back to communicate visual information to blind users (29), an effect called "Tactile Television". Another example of an early vibrotactile array for sensory substitution was the Optacon (Optical to TActile CONverter), a portable reading device for the blind (30) that was originally developed in 1966 by John

Linvill and JC Bliss to assist Linvill's vision impaired daughter. The Optacon allowed the visually impaired to read printed material by feeling a tactile version of a visual image. A small hand-held camera scanned pictures or text in any document. The image was presented to the user via an array of vibrating metal rods that stimulated an index finger. The stimulator consisted of an array of 144 (24 rows \times 6 columns) of vibrating metal pins mounted on top of the controller. Each of the vibrating pins was driven by a piezoelectric bimorph reed actuator. The device was a technological success; many blind individuals reported that it provide increased autonomy. Debbie Stein, the First Vice President of the National Federation of the Blind of Illinois, and a long-time Optacon user stated (31) "The Optacon has given blind people a level of autonomy and flexibility unparalleled in history." As technically successful as the compact, lightweight, and highly portable Optacon was, it was not a financial success so Telesensory, Inc. discontinued manufacturing the Optacon in 1996, citing high cost and low demand.

From the time of the first vibrotactile displays, power consumption has been recognized as an important design factor. Higher power consumption requires larger and more expensive electronics, larger and heavier batteries, increased heat production, and less portability overall. Matching the display parameters (e.g., frequency, amplitude, tactor size, tactor density) to the mechanoreceptor characteristics (e.g., frequency response, sensitivity, receptive field) allows reduction of the power requirements, and many theoretical studies have pursued this goal (32–34). For example, the frequency at which the pins in a vibrotactile display oscillate is often selected to maximize the amplitude of the perceived signal (typically 200–300 Hz) while minimizing the power requirements of the display. The standard psychophysical term used to refer to the perceived amplitude of a vibratory stimulus is *Loudness*. For a given amount of actuator power, the loudness of a sinusoidal stimulus is maximized at \sim 250 Hz (35–37), the frequency Pacinian corpuscles are most sensitive to. Accordingly, several vibrotactile stimulators use sinusoidal vibrations at or near this frequency (200 Hz in the case of the Optacon). An average young, healthy user can feel 250 Hz vibrations $<1 \mu\text{m}$ in amplitude (38).

The use of rectangular pulses instead of sinusoidal waveforms can result in lower power requirement, especially if short pulses are used so that multiple pins can share the same driver stages. The electronics required to generate rectangular pulses can also be much simpler, potentially as simple as a single transistor operating as a switch (34), further reducing the size and cost of the display. A recent study that measured power consumption experimentally for electromechanical and piezoelectric vibrotactile actuators for sinusoidal and rectangular pulse waveforms (39) found that power consumption for the piezoelectric reed bimorph transducers was two orders of magnitude lower than for the electromechanical transducers. The piezoelectric transducers were more efficient despite their higher voltage requirements, because they required almost no current. Curiously, within the electromechanical transducers, the least power required to reach threshold was using short (0.7 ms low duty cycle)

rectangular pulses delivered at a rate of 25/s, but for the piezoelectric transducers the most efficient waveform was sinusoidal at 250 Hz. Clearly, the most efficient stimulus waveform depends on the type of actuators chosen for the display.

Shape displays tend to have low temporal resolution (unless constructed of piezoelectric actuators), but potentially very high spatial resolution. Static shape displays are perhaps the original example of tactile displays with the primary example being Braille. Blinded at the age of three, Louis Braille (1809–1852), invented the familiar tactile shape display reading system that bears his name. Individual letters, numbers, or common combinations of letters are represented by combinations of six or eight raised dots.

Ideally, a dynamic (changing) tactile shape display could be developed that would present patterns that would be indistinguishable to the user from direct contact with the original (or virtual) surface. The display must therefore deform the skin in the same way [or at least produce the same strain patterns at the receptor level (40–41)] that the represented surface would. The slow development of these dynamic fingertip tactile displays is due to the numerous unknown factors that characterize the sense of touch.

Designing an optimal dynamic tactile display requires precise knowledge of the biomechanics of the skin, which is both tough and deformable at the same time (42). When scanning a texture, we use contact forces ranging between 0.3 and 4.5 N and a scanning speed between 1 and 25 cm/s with an average of 2 cm/s (43). Theoretically, to have full control of the surface stresses, the ideal tactile display system needs an infinitely dense array of actuators, each with three degrees of freedom and infinite stiffness. Nearly ideal function would also require a display with actuators capable of delivering at least 50 N/cm² pressure, able to indent the skin at least 4 mm (with 10% resolution), an actuator density of 1/mm², and at least 50 Hz refresh bandwidth, requiring a power density of 10 W/cm² (44). In fact, it may even be advantageous to provide a refresh rate that matches the highest frequency response of the RA receptors, in the kilohertz. The optimal display would also be small enough for use with several fingers at once over a large range of positions and orientations. Due to compromises that have to be made between power, bandwidth, manufacturability, cost, size, actuator stiffness, ease of maintenance, and other factors, no tactile display currently comes close to satisfying these requirements.

One goal of some shape displays, such as those for telesurgery or telerobotics, is to communicate information about the compliance of the manipulated (or virtual) object. Human discriminability of softness (compliance) of objects depends on the object having a deformable surface (45–46). For deformable surfaces, the spatial pressure distribution within the contact region depends on object compliance, so that information from cutaneous mechanoreceptors is sufficient for the user to gauge subtle differences in compliance. When the surface is rigid, however, we require kinesthetic information for discrimination, and our ability to gauge softness is much poorer than that for objects with deformable surfaces. It is likely that the spatiotemporal

variation of pressure on the skin (or, equivalently the skin displacement and its derivatives) form the basis for the perception of softness of compressible objects. Consequently, a shape display that aims to communicate compliance information must itself be deformable (compliant) (45). This compliance might be achieved through either passive or active means.

Designers of shape displays have generally taken one of two approaches; (1) control the force the actuators exert on the skin (in the direction perpendicular to the skin), or (2) control the displacement (again, perpendicular) that the actuators impose on the skin. A smaller number have controlled the lateral stresses or strains applied to the skin. Almost all shape displays have been designed for the fingertips. Shape display designs have used solenoids (47), electrostatics (48–49), voice coil actuators (50), shape memory alloys (51–52), pneumatics (44,53), RC servomotors (54), MEMS (55), and even air jets (56). A good summary of the technologies and their relative merits can be found in Ref. (17), with an updated version currently available at http://www.cim.mcgill.ca/~jay/index_files/research_files/actuators.htm.

Electrotactile

The use of mechanical systems to communicate detailed tactile information is limited by the need for dense arrays of end effectors with sufficient mechanical compliance to overcome the stiffness of the skin and deeper tissues. Such stimulators require bulky actuators that are difficult to arrange in the dense arrays required for texture communication. For these reasons, researchers have turned to electrical stimulation of the tactile senses. Electrical stimulation that aims to produce a localized tactile perception is referred to as “electrotactile” or “electrocuteaneous” stimulation, whereas “transcutaneous” stimulation describes the more generalized stimulation of nerve bundles [e.g., transcutaneous electrical nerve stimulators (TENS)]. Electrotactile stimulation has the advantages that dense arrays of electrodes can be fabricated and that the stimulator itself can be remotely located so it does not limit the spacing or rigid presentation of the electrodes. Electrotactile stimulation displays also typically require much less power than vibrotactile devices.

In contrast to mechanical stimulators, which deform the receptor at the end of a mechanoreceptive nerve fiber, electrical stimulators depolarize the membrane of the mechanoreceptive nerve fibers directly by passing current through the skin from one electrode (or group of electrodes) to another. The current passing through the skin produces an electric field that extends some distance into the skin. This electric field creates currents within the nerve fibers that depolarize the neural membrane. If this depolarization is sufficient, the neuron fires an action potential that propagates to the central nervous system. In general, the smaller the stimulating electrodes and the closer they are spaced, the more superficial the electric field will be. For a given current, the strength of the electric field beneath an electrode varies inversely with the surface area of the electrode so stimulation will always occur at the smaller of the two electrodes. The usual practice is to use a large

remote electrode or a large surrounding electrode (or group of electrodes) as the current return and a smaller electrode as the stimulating electrode. The negatively charged electrode is referred to as the *cathode* and the positively charged one is the *anode*. Cathodic stimulation is therefore when the negatively charged electrode is the stimulating electrode, whereas anodic stimulation uses the positively charged electrode for stimulation. Cathodic stimulation is the most conventional and is best for exciting nerve fibers that are passing by the electrode, while anodic stimulation is best for exciting fibers that terminate in the vicinity of the electrode. The stimulating phase of the waveform is usually followed by a charge-recovery phase of opposite polarity and much lower amplitude. The reason for the charge-recovery phase is to avoid electrode corrosion and tissue damage by reversing as much as possible the chemical reactions that occur at the electrodes.

Electrocutaneous and transcutaneous electrical stimulation are used in a wide variety of applications including TENS units for pain control and sensory substitution systems such as speech aids (57,58) for the deaf and visual substitution systems (59,60) for the blind. Electrocutaneous stimulation also has been used to improve the utility of upper extremity (61–68) and lower extremity (69–71) prostheses for amputees. Subdermal electrocutaneous stimulation has been used to provide sensory feedback to users of an upper extremity neuroprosthesis (72). Electrocutaneous arrays on the forehead have been used to help people with advanced cases of Hansen's disease (leprosy) to perform detailed manual tasks with reduced chance of injury (73). An early electro tactile device that is still in widespread use is the Tickle Talker speech perception device for the severely hearing impaired (57). The Tickle Talker stimulates eight tactile sensory nerves as they pass between the second and third knuckles of the fingers with speech-encoding patterns and has been shown to provide benefits in supplementing lipreading or residual hearing for hearing-impaired adults and children (54). Visual information has been successfully presented to blind users through electro tactile arrays located on the abdomen (75,76), back, or tongue (81). The tongue is also the target region for a newly commercialized electro tactile device from Wicab, Inc. The 144-point electro tactile array sits on the roof of the mouth against the tongue surface and communicates patterns for a wide range of proposed sensory substitution applications such as providing crude visual information for the blind (78) or restoring postural stability in patients with vestibular deficits (79).

Although the trunk or tongue may be most appropriate for applications requiring independent use of the hands, the fingertips present a much more natural means to explore a virtual surface or environment. Indeed, active haptic exploration leads to better perception of two-dimensional (2D) shapes than does passive static touch (1). Additionally, both mechanical and electrostatic displays require fixed, flat displays, but electro tactile arrays can be mounted in the fingers of a glove, allowing the user to explore arbitrary tactile surfaces in a more natural manner. As with mechanical displays, arrays of tiny electrodes are needed to utilize the high spatial acuity of the fingertip.

The development of a fingertip, electro tactile interface with good spatial resolution will require techniques to selectively activate nerve fibers to produce well localized, precisely placed sensations. Such techniques will necessarily exploit the dynamical and geometrical characteristics of fingertip mechanoreceptive afferents while accounting for similar characteristics of the nociceptive afferents. One drawback of electro tactile stimulation, however, is that producing well-localized, painless sensations remains challenging (75,80–82). Previously successful attempts to use electrocutaneous stimulation as a communications tool have typically been limited to the use of a small number of large electrodes, a paradigm unsuitable for telepresence and most other fingertip applications. Another drawback of electro tactile stimulation for fingertip displays is that we know little about how surface electrical stimulation excites mechanoreceptors. In particular, there is still much to be learned about how to selectively activate one population of mechanoreceptors over another. Mechanical stimulation excites the mechanoreceptive sensors themselves, while electrical stimulation can potentially excite the mechanoreceptive neurons anywhere along their length. It is therefore very difficult to control both the quality and the location of the electrically induced perception.

There has been some progress toward better control of the perceived quality and location of stimuli presented through small electrodes. Poletto and Van Doren (83) performed a study a few years ago to investigate the effects of pulse width, electrode diameter, and stimulus polarity on mechanoreceptive and nociceptive thresholds, as well as their effects on the perceived location and quality of the induced sensations (83). Touch and pain thresholds were measured for every combination of six pulse widths (0.05, 0.126, 0.315, 0.792, 1.991, and 5 ms), four electrode diameters (1, 2, 4, and 8 mm), and two stimulus polarities (anodic and cathodic). After each threshold measurement, the subject reported the perceived location (local or distal to the electrode) of the induced touch and pain sensations, as well as a qualitative descriptor of the pain sensation. The perceived location results indicated that anodic stimulation through small electrodes can be used to reliably excite fibers terminating near the electrode without concurrent excitation of near-by axons of passage. On the other hand, traditional cathodic stimulation, particularly through large electrodes, is much more likely than anodic to excite axons of passage, resulting in a sensation distal to the electrode (Fig. 4). These results (along with other related trends evident in the threshold data) were echoed in the model simulations only when fiber morphologies similar to those observed microscopically were incorporated. A complete discussion of these experiments, as well as neurophysiological models that were created to explain them, can be found in (83). Similar modeling results and explanations for the experimental data have been found by Kajimoto et al. (84), who used a model of a different form.

Another challenge for electro tactile stimulation is that the difference between the pain thresholds and the sensation thresholds (this difference is known as "dynamic range") is smaller for electrical stimulation through small electrodes than for large. This could potentially limit the maximum intensity that can be presented through small

Figure 4. Qualitative results graphs. Electrotactile stimulation can produce sensations that are local or distal to the electrode. The graph shows the percentage of touch sensations that were felt local to (as opposed to distal to) the stimulating electrode, calculated as the percentage of all trials (summed across subject, session, pulse width and repetition, 271–288 total trials per bar) that the subject reported as “local”. Bar color indicates stimulus polarity: black, anodic; white, cathodic. Error bars indicate smallest and largest 95% confidence intervals. [Data taken from (83).]

electrodes and could limit the desirability of using electrotactile displays. One way to increase the dynamic range would be to inactivate the pain fibers by applying a long depolarizing prepulse (DPP) prior to the stimulus pulse (the DPP would only be introduced significantly above sensation threshold, to prevent the concurrent elevation of both thresholds). This approach has been shown to significantly increase the pain thresholds, thereby increasing the dynamic range (83).

Despite the difficulties associated with fingertip electrotactile displays using small electrodes, some groups have been successful using electrotactile stimulation to present simple patterns to the fingertips. Kaczmarek et al. (81) developed a 49-point fingertip-scanned electrotactile display that consists of 0.89 mm diameter, flat-topped stainless steel electrode “pins”, each surrounded by a 2.36 mm diameter air gap insulator arranged in a square 7×7 array

Figure 5. Fingertip electrotactile array. Electrotactile array with 576 electrodes (24×24) that can be scanned with multiple fingers. (Photo provided by Kurt Kaczmarek.)

(see Fig. 5 for a 24×24 array from the same group). They found that, using the highest comfortable current levels, subjects were able to correctly identify several simple geometric patterns $\sim 90\%$ of the time compared to near chance levels when stimulation was set to the lowest subthreshold current levels tested (81).

Other groups have also been working on electrotactile displays for selective stimulation of the various types of mechanoreceptors (56,84,86). Because the mechanoreceptors share the same neurophysiology (A δ nerve fibers), the only way to selectively stimulate them electrically is to take advantage of their differences in geometry and location. This is possible by focusing the current to flow deeply or superficially into the skin by changing the current source distribution at the skin surface. In this way, it is possible to manipulate the electric field applied to each type of mechanoreceptive fiber (83,84). Kajimoto et al. developed a tactile display capable of selectively eliciting sensations of pressure, high frequency vibration and low frequency vibration, which they refer to as “tactile primary colors”, analogous to the three primary colors for vision. This display was mounted on a computer mouse for tactile feedback in virtual reality (Fig. 6) and also on a surface with optical sensors underneath for conversion of light–dark patterns to tactile patterns (Fig. 7). The mouse-mounted application is innovative because it uses a force transducer beneath the fingertip array to allow the user to control the intensity of stimuli. This approach avoids the unpleasant sensation of sudden shocks that have discouraged the use of other electrotactile displays (87).

Electrotactile displays do not need to present pictographic information to be useful. In fact, even stimuli that are too weak to be felt can provide functional benefit. Low (subthreshold) levels of current (zero mean, white noise, 1 kHz bandwidth) delivered through large electrodes on the foot have been shown to enhance tactile sensitivity in the region between the electrodes in older adults (88). The effect is thought to result from the same principle of stochastic resonance as the vibrating insoles described above.

FUTURE DIRECTIONS

For most of its history, tactile stimulation has been developed and used primarily for sensory substitution or sensory augmentation systems for persons with sensory impairment. Many of these projects have been generally successful in restoring function and greater autonomy to their users, but target audiences have been small and large scale corporate investment has not been forthcoming. Although applications of tactile stimulation intended to help individuals with impairments are seen as important and will likely continue, it is also likely that applications with mass market appeal will drive the greater part of tactile stimulation technology development. Such applications are currently emerging in immersive virtual reality for entertainment and training purposes, teleoperation and telepresence for industry and medicine, and in personal communications.

There appear to be two separate trends in the technical progression of tactile displays. One trend is toward the development of fingertip tactile interfaces with greater sophistication and complexity for comfortably and portably communicating large amounts of data, such as surface texture. Such development will be important for applications where realistic surface perception is required, such as teleoperation, telesurgery, and immersive virtual reality.

The other trend is toward simpler, more intuitive and portable systems to interface with wearable computing or personal communication systems.

Sophisticated array designs for communicating realistic texture sensations will require greater collaboration between material scientists, engineers, physiologists, and psychophysicists. Optimizing the information transfer rates, increasing usability, and improving the naturalism of the displays will require improvements in all areas of display design. Both mechanical and electrical designs could benefit from greater reliability and ease of maintenance, as well as better power supply and control strategies. Mechanical displays require improved actuator technology for lower power consumption, more degrees of freedom, and greater actuator density. Ongoing efforts include adding lateral skin stretch to fingertip mechanical arrays as a means to reproduce novel sensations and provide improved power performance (89). Preliminary studies showed that subjects perceived small tangential displacements as intense as larger normal displacement (90). Novel dimensions such as slip and thermal stimulation could also be combined with mechanical or electrotactile displays (21).

Optimal display geometries beyond the common row and column design will also need to be addressed. Although at least three decades of work have provided us with a reasonable understanding of the physiology and psychophysics of single tactor (or, to a lesser extent, a single electrode) stimulation, mechanical display designs could be improved through better theoretical understanding of the mechanics of skin deformation and mechanoreceptor excitation. Recent modeling efforts provide a good start (91) and further studies in this area need to include the viscoelastic properties for dynamic simulation, the further refinement of relevant stimuli for each type of mechanoreceptor, as well as investigating the role of finger ridges in tactile neural coding.

Much work is also still needed to understand the physical, physiological, psychophysical, and cognitive interactions that exist between tactile stimuli presented at different sites. One example is the so-called rabbit effect, or sensory saltation, in which the perceived stimulus location falls between the locations of two stimulators (92–94). This effect can be elicited through mechanical (95,96) or electrical (97,98) stimulation and may be useful in increasing the effective density of stimulation sites. As well documented as saltation is for stimulators that lie on a common line, its application for arrays is not as straightforward as one might expect. When researchers using an array of nine electrodes arranged in a square on a subject's back attempted to use saltation to produce the sensation of a square being traced, the evoked sensation was actually that of a circle being traced (99). Clearly, when hundreds of stimulation sites are being used simultaneously, unanticipated interactions of this sort could be expected.

Substantial surround-masking effects have also been observed with two dimensional electrotactile arrays (100). Further research will be required to elucidate the impact of surround masking on fingertip array function. The precise application will most likely determine whether surround masking is beneficial (e.g., improving contrast and edge

detection, as in the retina) or detrimental (e.g., blurring the image or suppressing valuable tactile information).

Masking also occurs between two consecutive stimuli (101), and must be taken into account when predicting elicited percepts.

Continued improvements are also necessary in our understanding the way that the complex interactions between the various stimulus parameters influence stimulus perception. For example, the information transfer rate for a single stimulator can be improved through coherent modulation of stimulus frequency and amplitude, but when the frequency and amplitude are modulated independently, the information transfer rate of each channel is reduced due to cognitive processing interactions (103). Similar interactions may exist for all of the dimensions along which stimulus parameters can be modulated.

Many challenges still face designers of fingertip electro-tactile arrays. Physically, such an array must be held on the finger so that firm contact is maintained even during exploratory finger movements. Embedding the array in a custom-made glove should help solve this problem, but perspiration tends to accumulate between adjacent electrodes, providing a low impedance current pathway that circumvents the skin (103–106). Possibly, the material or chemical properties of the glove itself could be used to wick perspiration away or inhibit its secretion. Note that in an array where the electrodes positions are fixed relative to the fingertip, this problem is much less severe than when the finger is actively scanned over a flat array (108). Kajimoto et al. (108) suggested that for some applications, the electrodes could even be printed directly on the skin using conductive ink.

In addition to the physical problems, significant physiological and psychophysical problems of adaptation (habituation) and interaction must be addressed. It is well known that habituation, that is, a change in the perceived magnitude for constant stimulus amplitude, occurs over time with either mechanical (12,109–111) or electrical (68,112,113) stimulation of mechanoreceptors. Compensation for adaptation may be complicated when stimulating through an electro-tactile array since each electrode site will be stimulated at a different rate, and therefore the amount of habituation will vary across the array.

Recent evidence shows that a few hours of fingertip tactile stimulation results in cortical reorganization that improves spatial discrimination but impairs frequency discrimination performance (114). It is not yet known how long the impairment lasts and whether extensive long-term use of vibrotactile or electro-tactile stimulators could lead to learned functional sensory deficits.

The emerging field of wearable computing is giving rise to a new set of applications for tactile stimulation. Wearable computers for industrial and military maintenance applications have been reported for at least a decade and applications for the mass consumer market have been proposed, with several in current development. Tactile displays are considered viable alternatives to visual or auditory displays for wearable computers because they can be unobtrusive, socially discrete, and do not interfere with normal vision or sound. The goal of wearable tactile displays can be conceptually different than the sensory

substitution, virtual reality and teleoperation displays as discussed above. Most of the displays described above were concerned primarily with directly translating real or virtual visual, tactile, or audio information into tactile stimulation. The tactile information displays envisioned for wearable computers, on the other hand, present information that is not directly based on visual, tactile or audio information. Instead, they aim to communicate data on the state of the worn computer, the environment, or the person wearing it. A very simple example is the vibration of a cell phone in vibrate mode. The vibration is intended to alert the user to an incoming call, not to communicate the voice message itself. MacLean and Enriquez suggested that such tactile alerts will become more common and more complex, taking into account optimization along several perceptual dimensions to optimize information transfer (115). They coined the term “haptic icons” to refer to brief synthetic haptic or tactile signals to convey information such as event notification, identity, content or state.

According to Gemperle et al. (116), wearable tactile displays must be lightweight, silent, small, and physically discreet. They must also have low power requirements, be able to be felt through the clothing they are embedded in or worn on, and they must be held tightly enough to the body to maintain reliable contact. Initial designs would also benefit from being flexible enough to be used in multiple applications with little modification.

One wearable tactile display application currently being pursued by several independent groups is an aid for a personal navigation. Tactile navigation aids have been proposed for pilots (117), drivers (118), scuba divers (119), walkers or hikers (116), astronauts (120,121) and the blind (122). The basic principle is that vibrating tactors embedded in the user’s clothing signal either a particular direction (e.g., north, up, the direction to return the vehicle) or the distance to and direction of the next turn or position correction required to reach a destination.

Other applications of wearable tactile displays include providing silent and private alerts, socially subtle transmission of information, providing biofeedback of physiological states such as blood sugar or blood alcohol levels. Future work includes the development of standardized tactile display clothing elements (123), and requires continued research on where to define the spaces on the human body where solid and flexible forms can rest without interfering with fluid human movement. The widespread use of wearable tactile displays depends on consideration not only of function, but of comfort, mobility and social acceptance factors.

INTRODUCTION

Telemedicine and teleradiology have become increasingly important as our country's healthcare delivery system gradually changes from fee-for-service to managed, capitated care. During the past several years, we have seen the trend of primary care physicians joining health maintenance organizations (HMOs). These HMOs purchase smaller hospitals and form hospital groups under the umbrella of HMOs. Also, academic institutions form consortia to compete with other local hospitals and HMOs. This consolidation allows the elimination of duplication and the streamlining of healthcare services among hospitals. As a result, costs are reduced, but at the same time because of the downsizing, the number of experts available for service also decreases. Utilization of telemedicine and

Figure 1. A generic teleradiology setup. (a) Referring site, (b) expert center.

teleradiology is a method to alleviate the diminishing of experts, streamline the diagnosis process, and save health-care costs.

Teleradiology is a subset of telemedicine operation focusing in remote diagnosis of medical images. Teleradiology utilizes computer, display, and telecommunication technologies for radiologists to make remote diagnosis from radiological images generated at distant examination sites. The diagnostic report is sent to the examination site where a primary physician can provide proper treatments to the patient immediately. Figure 1 shows a generic teleradiology set-up illustrating that teleradiology is not a single medical device or an instrument, instead, it is a system integration of various imaging devices using communication technology and system software connecting multiple imaging centers and expert centers together (1-3). Dependent on the required turn around time in obtaining the diagnosis from the examination site, the expert center has three reading modes: teleradiology, teleconsultation, and telemanagement, which are shown in Fig. 2. These reading modes dictate the communication requirements of transmitting the images between the sites. Teleradiology operation can be very simple or extremely complicated. In the simple case, a radiology resident may send an image set from a CT (computed tomography) scanner using low quality teleradiology equipment and slow speed communication technology in the evening to the radiologist's home for a second opinion. This type of teleradiology operation does not require highly sophisticated equipment. A conventional telephone and simple desktop personal computer with modem connection and display software are sufficient to perform the teleradiology operation. This type of application originated in early 1970.

The complicated teleradiology operation can have different models starting from simple to complicated in ascending order as shown in Table 1. The complications occur when the current examination requires historical images for comparison, and when the radiologist needs information from the radiology information system (RIS) to

Figure 2. The expert center in teleradiology with three reading modes: telediagnosis, teleconsultation, and telemanagement. These three reading modes dictate the image communication requirements.

make a diagnosis. In addition, complications arise when the images and the corresponding diagnosis report are required to be archived to the patient data file. Teleradiology is relatively simple to operate when neither retrieval nor archive of previous information and images is required. However, when both archive and retrieval are required, the operation becomes extremely complicated.

TELERRADIOLOGY AND PACS

Picture Archiving and Communication System (PACS) is a hospital integrated imaging management system developed in the early 1990s (Fig. 3) (4). The infrastructure of PACS is shown in the upper three rows. Two types of servers in the bottom of the figure are for various PACS applications. When teleradiology service requires patient's historical images as well as related information, technologies used in both teleradiology and PACS become very similar. Table 2 shows technologies used in teleradiology and PACS, the major differences are in image capture, communication, and storage. Some current teleradiology operations still use a film digitizer as the primary method of converting a projection film image-to-digital format, although the trend is moving toward direct digital capture. In PACS, direct digital image capture using Digital Imaging Communication in Medicine (DICOM) standard format is mostly used. In networking, teleradiology uses slower speed wide area networks (WAN) compared with the higher speed local area network (LAN) used in PACS.

Table 1. Four Models of Teleradiology Operation According to Its Complexity

	Historical Images/RIS	Archive
Most simplistic	No	No
Simplistic	Yes	No
Complicated	No	Yes
Most complicated	Yes	Yes

Figure 3. A generic PACS components and data flow. The upper three rows are the infrastructure, the bottom row is PACS applications.

Table 2. Differences in Technology Used between Teleradiology and PACS

Function	Telerad	PACS
Image capture	Digitizer	DICOM
Display technology	Same	Same
Networking	WAN	LAN
Storage	Short	Long
Compression	Yes	May be

In teleradiology, image storage is mostly short term, whereas in PACS it is long term. Teleradiology relies heavily on image compression, whereas PACS may or may not.

PACS and teleradiology use medical images shown in Table 3 for radiologists to make diagnosis. In Table 3, the first and second columns give types and sizes of some common medical images. In clinical applications, one examination is composed of many images of different views and anatomical emphasis, since a single image is generally not sufficient for making the proper diagnosis. In general, a typical examination generates between 10 and 20 MB, although some current CT and MR imaging modalities can generate up to 3000 images per examination. The fourth column shows an average size of one typical exam-

ination in each of these image modalities. The high extreme is in digital mammography, which routinely requires 160 MB. To transmit 160 MB of images through WAN for teleradiology requires a very high bandwidth communication technology.

WHY DO WE NEED TELERADIOLOGY?

The managed care trend in healthcare delivery expedites the formation of teleradiology expert centers. However, even without the healthcare reform, teleradiology is still an extremely important component in radiology practice for the following reasons: First, teleradiology secures images for radiologists to read so that no images will be accidentally lost in transit. Second, teleradiology reduces the reporting cycle time after the image is generated. Third, since radiology is subdivided into many subspecialties, a general radiologist requires a specialist's second opinion on occasion. The availability of teleradiology will facilitate seeking a second opinion. Fourth, teleradiology increases radiologists' income since no images would accidentally be lost and subsequently not reported. The healthcare reform adds two more reasons. (1) It saves healthcare costs since an expert center can serve multiple sites reducing the number of radiologists required. (2) It improves the efficiency and effectiveness of healthcare because the report turn-around time would be reduced and there would be no loss of image (5).

TELERADIOLOGY COMPONENTS

A generic schematic of teleradiology depicted in Fig. 1 shows teleradiology components and their connections. Modalities generating images in teleradiology applications include CT, MR, CR, DR, US, NM, DSA—digital fluorography (DF), and film digitizer. Their respective image and examination file sizes Images are shown in Table 3. These acquisition devices are first generated from the examination site and then sent through communication networks to the expert center if they are already in digital format. Or, if these images are stored on films, then they need to be digitized by a film scanner at the examination site.

Table 3. Data Size of Some Common Medical Images and Examinations

Instrument	One Image, bits	No. of Images/Exam	One Examination
Nuclear medicine (NM)	128 × 128 × 12	30–60	1–2 MB
Magnetic resonance imaging (MRI)	256 × 256 × 12	60–3000	8 MB up
Ultrasound (US) ^a	512 × 512 × 8(24)	20–240	5–60 MB
Digital subt. Angiography (DSA)	512 × 512 × 8	15–40	4–10 MB
Digital microscopy	512 × 512 × 8	1	0.26 MB
Digital color microscopy	512 × 512 × 24	1	0.79 MB
Color light images	512 × 512 × 24	4–20	3–15 MB
Computed tomography (CT)	512 × 512 × 12	40–3000	20 MB up
Computed/digital radiog (CR/DR)	2048 × 2048 × 12	2	16 MB
Digitized X rays	2048 × 2048 × 12	2	16 MB
Digital mammography	4000 × 5000 × 12	4	160 MB

^aDoppler US with 24 bit color images.

Image Capture

In image capture, if the original image data are on film, then either a video frame grabber or a laser film digitizer is used to convert them to digital format. A video frame grabber produces low quality digital images, but is faster and cheaper. On the other hand, laser film digitizers produce very high quality digital data, but take longer and cost more compared to the video frame grabber. During the past several years, direct Digital Imaging and Communication in Medicine (DICOM) standard output images from CR, DR, CT, and MR have been used extensively in teleradiology.

Data Reformatting

After images are captured, it is advantageous to convert these images and related data to industry standards because multiple vendors' equipment can be used in the teleradiology chain. The two common standards used in medical imaging industry are the DICOM (6) for images and Health Level 7 (HL7) (7) for textual data. The DICOM standard includes both the image format as well as the communication protocols based on the standard TCP/IP. Health level 7 is the standard for textual data, it uses the TCP/IP communication protocols.

Image Storage

At the expert center, a local storage device is used before images are displayed. The capacity of this device can range from several hundred megabytes to many gigabytes. A long-term archive, such as a small DLT (digital linear tape) library, is used for teleradiology applications that require historical images and diagnostic reports, related patient information, and current images and diagnosis.

Display Workstation

For an inexpensive teleradiology system, a low cost 512-line single monitor can be used for displaying images. However, high resolution multimonitor display workstations are needed for the primary diagnosis.

Table 4 shows the specifications of a 2000- and a 1600-line workstation used for teleradiology primary readings. These state-of-the-art technology diagnostic workstations, use two monitors with over 2 GB of local storage, and can display images and reports from the local storage in 1–2 s. A 2000-line LCD monitor workstation costs from \$20,000 to 30,000, and a 1,600 line costs from \$15,000 to \$20,000. User-friendly image display software is necessary for easy and convenient use by the radiologist at the workstation.

Table 4. Specifications of High-End 2000 and 1600 Line Workstations for Teleradiology

Two LCD Monitors
1–2 week local storage for current + previous exams
1–2 s display of images and reports from local storage
HL7 and DICOM conformance
Simple image processing functions

Table 5. Transmission Rate of Current Wide Area Network Technology

DS-0	56 kbits/s
DS-1	56 to (24 × 56) kbits/s
DSL	144 kbits/s – 8 Mbits/s
DS-1 (T1)	1.5 Mbits/s
ISDN	56 kbits/s to 1.5 Mbits/s
DS-3 (T3)	28 DS-1 = 45 Mbits/s
ATM (OC-3)	155 Mbits/s and up
Internet-2	100 Mbits/s and up

Communication Networks

An important component in teleradiology is communication networks used for the transmission of images and related data from the acquisition site to the expert center for diagnosis. Since most teleradiology applications are not within the same hospital complex, but through inter-healthcare facilities in metropolitan areas or at longer distances, the communication technology involved requires wide area network (WAN) technology. Wide area network can be wireless or with cables. In wireless WAN, some technologies available are microwave transmission and communication satellites. Wireless WAN has not been used extensively in teleradiology due to its higher cost. Table 5 shows cable technology available in WAN from the low communication rate DS-0 with 56 kb/s, to DSL (Digital Subscriber Line, 144 kb/s to 8 Mb/s, depending on data traffic and the subscription), T-1 and T-3 lines starting from 1.5 Mb/s, to very high broadband communication DS-3 with 45 Mb/s (8). These WAN technologies are available through either a long distance or local telephone carrier, or both. The cost of using WAN is a function of transmission speed and the distance between sites. Thus, within a fixed distance, for a DS-0 line with low transmission rate, the cost is fairly low compared to DS-3, which is much faster, but very expensive. Most of the private lines, for example, T-1 and T-3, are point-to-point and the cost depends on the distance between connections. Table 6 gives an example showing the relative cost of the DSL and the T-1 between University of Southern California and St. John's Health Center ~ 15 miles apart in the Greater Los Angeles Metropolitan Area.

Table 6 demonstrates that the initial investment for the DSL is minimal since the WAN carrier pays for the DSL Modem for the network connection. The lowest

Table 6. WAN Cost Using DSL (144 kB/s–8 MB/s) and T-1 (1.5 MB/s) between USC and St. John's Health Center—20 miles

DSL		T-1	
Up front Investment	Minimal	Up Front Investment	\$ 5000
Modems (2)	None	T1 DSU/CSU ^a	
		WAN interface (2)	
		Router (2)	\$ 4000
Installation (2)	Minimal	T-1 Installation	\$ 1000
Monthly charge:	\$40	T-1 Monthly Charge:	\$600
(the lowest rate)			

^aDSU/CSU: Data service unit/ Channel service unit as of June, 2003.

monthly cost is ~\$40/month. On the other hand, for T-1 service, the up front investment is \$4000 for the two T-1 routers and \$1000 for installation. The monthly cost is \$600. The up-front investment for the T-1 is much higher than DSL, and for longer distances, its monthly charge is expensive. For example, the charge between Los Angeles and Washington, D.C. for a T-1 line could be as high as \$10,000/month. However, T-1 is a point-to-point private line, and it guarantees its 1.5 MB/s specification, and provides communication security. The disadvantages of DSL are (1) it is through shared networks, and hence has no security; (2) its performance depends on the load of the DSL carrier at that moment; and (3) it is not available everywhere. Using T-1 and DSL for teleradiology is very popular. Some larger IT (Information Technology) companies lease several T-1 lines from telephone carriers and sublease portions of them to smaller companies for teleradiology applications.

Another wide area network listed in Table 5, Internet 2 (I2) technology, is ideal for teleradiology application because of its speed of transmission and low cost of operation after the site is connected to the I2 backbone (9). The I2 network is a national infrastructure of high speed communication backbones [> 10 GB/s using gigabit switches and Asynchronous Mode Technology (ATM)] supported by the National Science Foundation (NSF), currently consisting of the vBNS (very high performance Backbone Network Service), the CalREN-2 (California Research and Education Network), and the Abilene. In the global level, vBNS, Abilene and CalREN-2, provide readily available high speed backbones and administrative infrastructure. In the local level, the users have to learn how to connect the hospital and clinic environments to these backbones. Table 7 shows the current performance of the I2 between some sites in the United States. The advantages of using Internet 2 for teleradiology are its high speed and low operational cost once the local site is connected to the backbones. The disadvantages are (1) the local site has to upgrade its conventional Internet infrastructure to be compatible with the high speed I2 performance, which is costly; (2) not enough experts know how to connect from the radiology department to the backbone; and (3) I2 is not yet open for commercial use.

Table 7. Current Internet 2 Performance between Sites in the United States

Test Sites	Response Time (32 Bytes)	Throughput*
CHLA/USC LAN (Childrens Hospital/ U Southern California)	<1 ms	9.8 MBytes/s
CHLA/USC-UCLA	4 ms	2.7 MBytes/s
CHLA/USC-Stanford U	23 ms	900 KBytes/s
CHLA/USC-UCSF	24 ms	700 KBytes/s
CHLA/USC-NLM (National Library of Medicine)	67 ms	320 KBytes/s
CHLA/USC -U Hawaii	76 ms	700 KBytes/s

*units used are MBytes/s and KBytes/s which are different from those used in Table 5.

User Friendliness

User friendliness includes both the connection procedure of the teleradiology equipment at both the examination site and the expert center, and the simplicity of using the display workstation at the expert center.

User friendliness means that the complete teleradiology operation should be as automatic as possible requiring only minimal user intervention. For the image workstation to be user friendly requires three criteria:

1. Automatic image and related data prefetch.
2. Automatic image sequencing and hanging protocol at the monitors.
3. Automatic look-up table, image rotation, and unwanted background removal from the image.

Image and related data prefetch means that all necessary historical images and related data required for comparison by the radiologist should be prefetched from the patient folder at the imaging sites and send to the expert center. When the radiologist is ready to review the case, these prefetched images and related data are already available at the expert center. Automatic image sequencing and hanging protocol at the display workstation means that all these images and related data are sequentially arranged so that at the touch of the mouse, properly arranged images and sequences are immediately displayed on the monitors. Prearranged data minimizes the time required for the searching and organizing of data by the radiologist at the expert center. This translates to an effective and efficient teleradiology operation. The third factor, automatic look-up table, rotation, and background removal, is necessary because images acquired at the distant site might not have the proper look-up table set up for optimal visual display, images might not be generated in the proper orientation, and might have some unwanted white background in the image due to radiographic collimation. All these parameters have an effect on the proper and efficient diagnosis of the images. Figure 4 shows an example of automatic splitting of a CT examination of both the chest and the abdomen into a chest and an abdomen sequence for automatic display using the concept of presentation of grouped procedures (PGP) in IHE (Integrating the Healthcare Enterprise) profile technology (10).

Image Compression

Teleradiology requires image compression because of the slow speed and high cost of using WAN. For lossless image compression, current technology can achieve between 3:1 and 2:1 compression ratios, whereas in lossy compression using cosine transform based MPEG and JPEG hardware or software, 20:1–10:1 compression ratios can be obtained with acceptable image quality. The latest advance in image compression technology is the wavelet transform (11 and JPEG 2000), which has the advantages over cosine transform for higher compression ratio and better image quality, however, hardware wavelet compression is not yet available. Some Web-based teleradiology systems use progressive wavelet image compression techniques. In this

Figure 4. Integrating the Healthcare Enterprise (IHE) Presentation of Grouped Procedures (PGP) Profile. Example shows a single CT acquisition procedure is used to acquire both chest and abdominal scans. The scheduled workflow profile provides information for the PGP to split the acquired images into two subsets, one for the chest and the other for the abdomen (10). Numerals represent the workflow steps in the IHE PGP.

techniques, image reconstruction from the compressed file is in a progressive manner in that a lower resolution image is first reconstructed almost instantaneously and displayed upon request. The user would have the psychological effect that the image is transmitted through the network in real-time. Higher quality images are continuously reconstructed to replace the previous ones until the original image is reconstructed and displayed.

Image Data Privacy, Authenticity, and Integrity

Image transmission in teleradiology is mostly through public networks, for this reason, trust in image data becomes an important issue. Trust in image data is characterized in terms of privacy, authenticity, and integrity of the data. Privacy refers to denial of access to information by unauthorized individuals. Authenticity refers to validating the source of the image. Integrity refers to the assurance that the image has not been modified accidentally or deliberately during the transmission. Privacy and authenticity are the responsibility of the public network provider based on firewall and password technologies, whereas integrity is the responsibility of the end user.

Imaging integrity is mostly done based on the concept of public and private keys digital signature encrypted with mathematical algorithms during the process of image generation. In general, the public and private keys digital signature concept consists of seven steps (12):

1. Private and Public Keys: Set up a method in assigning public and private keys between the examination site and the expert center.
2. Image preprocessing: To segment the object of interest in the image from the background (e.g., the head in a CT image is the object of interest), and extract patient information from the DICOM image header at the examination site while the image is being generated.
3. Image digest: To compute the image digest (digital signature) of the object of interest in the image based on its characteristics using mathematical algorithms.
4. Data encryption: To produce a digital envelope containing the encrypted image digest and the corresponding patient information from the image header.
5. Data embedding: To embed the digital envelope into the background of the image as a further security. The background is used because the embedding would not alter the image quality of the object of interest. In cases where the image has no background, such as a chest radiograph, a more involved lossless embedding technique can be used.
6. The image with the embedded digital envelope is sent to the expert site.

- The expert center receives Item 6, decrypts the image and the signature. It compares the two digital signatures. One comes with the image, the second is computed from the received image to validate the image integrity.

TELERADIOLOGY OPERATION MODELS

In this section, we discuss four teleradiology operation models that are common in current practice.

Off-Hour Reading

An off-hour reading model is to take care of the off-hour reviewing of the images including evenings, weekends, and holidays when most radiologists are not available at the examination sites. In this set up, image acquisition devices at different examination sites including hospitals and clinics are connected to an off-hour reading center with medium or low grade transmission speed (like the DSL) because the turn around time is not critical except for emergency cases. The connections are mostly direct digital with the DICOM standard. The reading center is equipped with network switches and various types of workstations compatible to the images generated by imaging devices at examination sites. The staffing includes technical personnel taking care of the communication networks and workstations, and radiologists who come in during the evening, weekend, and holiday shifts and perform on-line digital reading. They provide preliminary impression of the exam and transmit it to the examination site instantaneously after reading. The regular radiologists at the examination sites verify the readings and sign off the report the next day. This type of teleradiology set up is low technology but it serves its purpose of solving the shortage of radiologists during off hours.

ASP Model

Application Service Provider (ASP) model is a business venture taking care of the radiological image diagnosis for examination sites where on site radiology interpretations are not available. This model can be for supplying equipment only or for both equipment and radiologists. In the former, an ASP entity sets up a technical center housing network equipment and workstations. It also provides turnkey connectivity for the examination site where images would be transmitted to the center. The examination site can hire its own radiologists to perform reading at the center. In the latter, the center provides both technical support as well as radiologists for reading.

Web-Based Teleradiology

Web-based teleradiology is mostly used by hospital or larger clinics to distribute images to various parts of the hospitals or clinics, or outside of the hospital. A web server is designed where filtered images from PAC systems are either pushed from the PACS server to, or pulled by the Web server. Filtered images mean that the Web server has a predetermined directory to manage the image distribution based on certain criteria like what types of images to

where and to whom, and so on. The clients can view these filtered images from the client workstation through the web server. The clients can be referring physicians who just want to take a look at the images or for radiologists to make a remote diagnosis. Web-based teleradiology is very convenient and low cost to set up because most technologies are readily available, especially within the hospital intranet environment. The drawback is that since Web is a general technology, the viewing capability and conditions are not as good as that in a regular PACS workstation where the set up is geared for radiology diagnosis. In order to have full DCIOM image resolution for visualization and manipulation at the clients, modifications have to be made at the Web Server to receive full 12 bits/pixel data from the PACS server, and additional display software at the clients.

PACS and Teleradiology Combined

Teleradiology can function as a pure teleradiology operation shown in Fig. 5. In this operation, the teleradiology management center serves as the operation manager. It receives images from different imaging centers, 1, . . . , N , keeps a record, but not the images, routes images to different expert centers, 1, . . . , M according to need for reading. Reports comes back to the management center, it records the reading reports, forwards reports to the appropriate imaging centers. The management center is

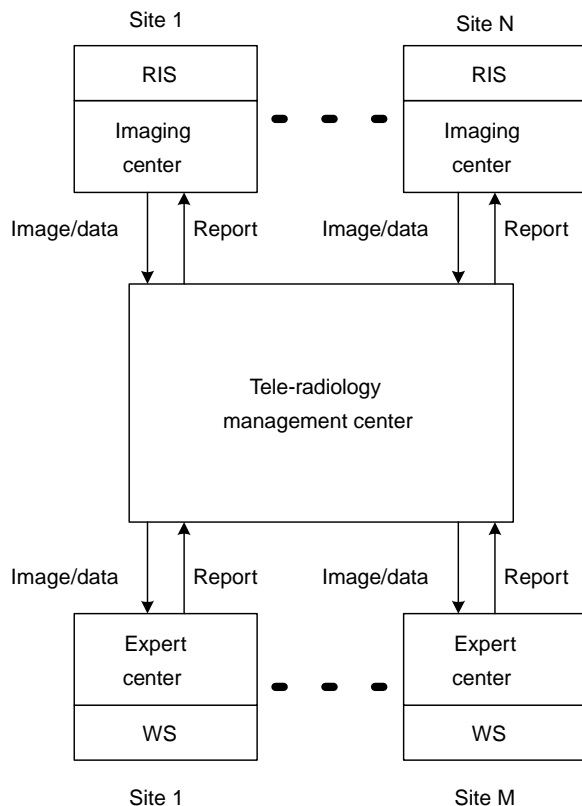

Figure 5. Pure teleradiology model. The management center monitors the operation to direct workflow between imaging centers and expert centers.

Figure 6. PACS and Radiology Combined Model: The PACS supports either the imaging centers, or PACS and Teleradiology support each other. See text for explanation of workflow steps in numerals.

also responsible for the billing and other administrative functions like image distribution and workload balancing. The networks used for connection between image centers, the management center, and expert centers can be mixed with various performances dependent on the requirements and costs.

Teleradiology can be combined together with PACS as a healthcare enterprise operation, as shown in Fig. 6. The two major components in the combined model are the PACS (see Fig. 3) shown inside the upper dotted rectangle, and the pure teleradiology (see Fig. 5) model shown in the lower dotted rectangle. The workflow of this combined model is as follows:

1. The image center can send images to the expert center for reading as in the pure teleradiology model (7).
2. Radiologists at PACS workstations can read exams from outside imaging centers as well (1).
3. After reading by in-house radiologists from its own workstations (2), reports are sent to the database gateway for its own in-house record (3), or to the expert center from where the report is also sent to the imaging center (4).
4. The PACS can also send exams directly to outside expert center for reading (5). The expert center then returns report to the PACS database gateway (6).

The combined Teleradiology and PACS model is mostly used in a large enterprise level healthcare center with satellite imaging centers, or in back-up radiology coverage between the hospital and imaging centers.

Enterprise Level PACS and Teleradiology Combined with Grid Computing

The PACS and teleradiology combined model described in the last section can be extended to the enterprise level using the grid computing infrastructure. The enterprise level PACS and teleradiology combined model is for very large-scale PAC systems and teleradiology applications. This large-scale model is becoming more and more popular in today's enterprise healthcare delivery system (13).

Grid computing is the integrated use of geographically distributed computers, networks, and storage systems to create a virtual computing system for solving large-scale, data-intensive problems in science, engineering, and commerce (14). A grid is a high performance hardware and software infrastructure providing scalable, dependable, and secure access to the distributed resources. Unlike distributed computing and cluster computing, the individual resources in grid computing maintain administrative autonomy and are allowed system heterogeneity; this aspect of grid computing guarantees scalability and vigor. Therefore, the grid's resources must adhere to agreed-upon standards to remain open and scalable. A popular standard grid computing toolkit is called Globus 3.0 (15). The grid computing provides the user with the following services: computational, data, application, and knowledge. For these reasons, grid computing infrastructure is the ideal technology for large-scale enterprise PACS and teleradiology combined model implementation.

Using the concept of grid infrastructure along with the DICOM standards and IHE workflow profiles, the PACS and teleradiology combined model shown in Fig. 6 can be extended to an enterprise level model conceptually shown in Fig. 7. Grid computing is still in its infancy for medical imaging application. The concept shown in Fig. 7 would require several years before it can materialize.

SOME IMPORTANT ISSUES IN TELERADIOLOGY

Relationship between Teleradiology Technologies and Operation

There are two sets of trade-off parameters in teleradiology. The first set relates to the operation consisting of image quality, reading turn-around time, and cost; and the second set relates to technologies used in the operation including image capture, workstation, compression, communication, and data security requirements. Table 8 shows the relationship between these two sets of parameters.

Image Data Security

In image data security, the patient confidentiality as well as image integrity are important. Since teleradiology uses a public communication method to transmit images that have no security, the question arises as to what type of protection one should provide to assure the patient's confidentiality, and the authentication of the sender. The second issue is the image integrity. After the image is created in digital form, can we assure that the image created has not been altered either intentionally or unintentionally during the transmission? To guarantee patient

Figure 7. Enterprise level large-scale PACS and teleradiology combined model using the grid computing technology. The center ellipse of the figure is the grid computing infrastructure consisting of the data and computation grid with the DICOM standard and IHE workflow profiles. The data grid handles the image data, and the computational grid takes care of the workflow and management (see Chapter Section 19.2.2.4, Ref (4) for the concept of grid computing and the functions of the data grid.) The top row above the dotted line is the enterprise PACS, which consists of several PAC systems 1, . . . , N rectangles under numerals. The bottom row under the dotted line is the pure teleradiology model described in Fig. 5. The connection between PACS and teleradiology in the enterprise is not a straight line of data communication, instead it goes through the grid computing infrastructure for resource allocation and management, as well as image data acquisition and distribution.

confidentiality and image authenticity, methods such as hardware and software firewalls used routinely in information technology can be set up. To protect image integrity, data encryption and digital signatures can be used. These techniques have been in the domain of defense research for many years, which can be modified for teleradiology application. If high security is imposed on image data, it will increase the cost of decryption and decrease the

easy access due to many layers of passwords. The trade-off between cost and performance, confidentiality, and reliability has become a major socioeconomic issue in teleradiology. Since altering a digital image is fairly easy in today’s computer technology, developing methods to protect the integrity of image data is essential in teleradiology applications.

Table 8. Relationship between Technologies and Teleradiology Operation

	Image Capture	WS	Compression	Communication	Image Integrity
Image quality	X	X	X		
Turn-around time	X	X	X	X	X
Cost	X	X	X	X	X

Medical–Legal Issues

There are four major medical–legal issues in teleradiology: privacy, licensure, credentialing, and malpractice liability. The ACR (American College of Radiology) Standard for Teleradiology adopted in 1994 defines guidelines for “qualifications of both physician and nonphysician personnel, equipment specifications, quality improvement, licensure, staff credentialing, and liability. Guidelines to these topics, although much is still uncertain, have been discussed extensively by others (16–19). It is important that these issues should be considered thoroughly before a teleradiology operation is set up.

TRENDS IN TELEMEDICINE AND TELERADIOLOGY

The concept of telemedicine and teleradiology originated in the 1970s, however, technology was not ready for real clinical applications for teleradiology until several years ago. As teleradiology is being integrated into daily clinical service, the associated socioeconomic issues discussed also surface. The trends in teleradiology are to balance the cost with the requirements of image quality, and turn-around time for the service. Costs are affected by technology used in image capture, workstation, image compression, communication, and image security. We see that teleradiology will become a necessity in medical practices of the twenty-first century, and will be an integral component of telemedicine as the not so distant method for healthcare delivery.

Teleradiology uses the Web and Internet technologies. Issues that must be resolved immediately are how to lower the communication cost and to bundle textual with image information effectively and efficiently to assure efficient operation, and image security. For the former, Internet 2 appears to be an excellent candidate, and for the latter, ePR (electronic Patient Record) will evolve as a potential winner. [4, Ch 21].

TEMPERATURE MONITORING

PETER FRASCO
Mayo Clinic Scottsdale
Scottsdale, Arizona

INTRODUCTION

The notion that illness and fever (elevation of body temperature above normal) are linked has been known since the time of Hippocrates and Galen. However, the concept of temperature as a quantifiable vital sign (like pulse rate and blood pressure) that could be measured and recorded is a relatively recent phenomena. Although the thermometer is as ancient as the microscope and older than the stethoscope, its use as an instrument for physical diagnosis in medicine is a relatively recent phenomenon (1).

The thermometer was invented in the fourteenth century, but its use in clinical medicine did not become commonplace until the early twentieth century (2). In 1625, Sanctorio Sanctorius described a device that was used to measure oral temperature. The practice of measuring body temperature with mercury in a glass thermometer began in the early eighteenth century with the work of the Hemann Boerhaave in the Hollan and his students in Vienna (1,2). One of his students, Anton DeHaen, noted changes in temperature with shivering or fever. He also described an increase in heart rate with increased body temperature (1). His contemporaries were unimpressed and the thermometer was largely neglected until the nineteenth century. In 1791, K.A. Wunderlich established the normal range of body temperature from 36.3 to 37.5 °C after recording nearly 1 million readings in 25,000 patients (1,2).

The most plausible explanations for the relative delay from the discovery that body temperature could be measured and monitored to the routine use to the technology relate to the complexity of the early instruments, which were nearly 12 in. (30 cm) long and required ~20 min to record a single measurement. In 1870, T.C. Allbut produced a thermometer that was portable (6 in. (15 cm) long) and reliable (2). It could record a temperature within 5 min. The Allbut thermometer was the forerunner for the mercury in glass thermometer in use presently.

In addition, the late nineteenth century was also an era of intense interest in the specific organ systems and the instruments with which to study them. During this time, the concept of disease shifted away from a holistic model toward a more organ-specific model. Illness was defined by the foci of alterations of function and structure. Overall body heat, as measured by the thermometer, which represented a general phenomena, did not fit easily into this local, organ specific disease concept.

This article will focus upon the technical aspects of temperature monitoring. This emphasis on basic science of the instrumentation of temperature monitoring will be balanced with a discussion of the clinically important topics of heat loss and heat conservation in the surgical patient.

DEFINITIONS

Heat

Heat is the form of energy that is transferred across a boundary of a system at a given temperature to another system at a lower temperature by virtue of the temperature difference between the two systems. This transfer of energy can occur through radiation, conduction, convection, and evaporation. The standard unit of heat (in the International System of Units, SI) is the calorie, which is the amount of energy needed to raise the temperature of 1 g of water by 1 °C. The British thermal unit (Btu), which is not frequently used in medicine, is defined as the amount of heat needed to raise the temperature of 1 lb of water by 1 °F (see discussion of temperature scales below). Heat is transferred from the substance at the higher temperature to the substance at the lower temperature.

Temperature

Temperature is defined as a measurement of the thermal state of a matter, which determines whether it will give heat to another substance, object or energy source, or receive heat from it (3,4). Temperature is a measure of the kinetic energy of the molecules or atoms of a substance. This energy is directly proportional to the velocity of the particles. Temperature will increase as heat energy is added and will decrease as heat energy is lost.

Body Temperature

Body temperature is best defined as the measure of the total kinetic energy within the body. This temperature represents the net thermal effect of total body heat produc-

tion and heat loss. Body temperature will vary in different parts of the body depending on perfusion, exposure, metabolic activity, local heat gain, or local heat loss. The physiologically important temperature is the “core temperature”, which represents the temperature of the body’s vital organs (brain, heart, lungs, gut). Any true change in body temperature (ΔT) represents an imbalance in the dynamic between production and loss and can be defined by the following formula (5):

$$\Delta T = \frac{\text{heat production} - \text{heat loss}}{\text{body mass} \times \text{specific heat}}$$

SCALES

Temperature scales are constructed by defining two points based upon a predictable and preferably linear change in the physical property of a given substance at a constant pressure, assigning temperature values to each and then defining the unit of increment between the fixed points. The relationship between temperature and the physical property can be defined as follows:

$$t(x) = ax + b$$

where t is the temperature of the substance. This temperature changes as the property x of the substance changes. The constants a and b depend on the substance used (e.g., mercury, ethanol, copper). The constants are also determined by specifying two points on the scale.

Kelvin

A reading of 1 K [named after William Thompson, a.k.a. Lord Kelvin (1824–1907)] is defined as $1/273.16(3.6609 \times 10^{-3})$ of the thermodynamic temperature of the triple point of pure water (3). The triple point of water is the point at which the solid, liquid, and gaseous phases of water are in equilibrium. Absolute zero, the absence of all heat, when the pressure of the ideal gas is zero, is a temperature of 0 K. The triple point of water in the Kelvin scale is 273 K. Kelvin is the SI unit of temperature.

Centigrade

The centigrade scale was first described by Carolus Linnaeus. The freezing point of water was set at 0 and the boiling point at 100.

Celsius

The celsius temperature scale was originally defined by Anders Celsius. He set the boiling point of water at 0 and the freezing point at 100. As such, the Celsius scale was the reverse of the Centigrade scale. In 1948, the centigrade scale was replaced with a newly defined Celsius scale that was based upon setting the triple point of water at 0.01 °C and the boiling point of water at 99.975 °C. The single degree increments in the Celsius scale are equal in magnitude to those in the Kelvin scale. To convert from celsius to kelvin the following formula can be used

$$K = ^\circ C + 273$$

Table 1. Characteristics of Common Thermometers

Type	Liquid Expansion	Resistance Coil	Thermistor	Thermocouple	Liquid Crystal	Infrared
Accuracy	±0.2 °C	±0.1 °C	±0.1 °C	±0.1 °C	±0.4 °C	±0.3 °C
Sites	Oral, Rectal	Skin	All sites	All sites	Skin	Oral Rectal Otic
Cost	Inexpensive	Expensive	Inexpensive	Moderate	Inexpensive	Very Expensive
Design	Expansion	Electrical	Electrical	Electrical	Chemical	Radiation

Fahrenheit

The fahrenheit [named after Gabriel Fahrenheit (1686–1736)] scale (°F), like the Kelvin scale, is also based upon the triple point and boiling point of water. The scale was originally calibrated with a mercury thermometer using a mixture of salt, ice and water as the zero point. The second point was obtained when the salt was eliminated from the ice and water. This was set at 30 °F. The boiling point of water is 212 °F on this scale. The freezing point of water was adjusted to 32 °F to allow the interval between the triple point and boiling point to be a more rational number (180).

To convert from Fahrenheit to Celsius the following formula can be used

$$^{\circ}\text{F} = (1.8 \times ^{\circ}\text{C}) + 32$$

TYPES OF THERMOMETERS

A thermometer measures temperature of a system in a quantitative way (Table 1).

NONELECTRICAL METHODS

Changes in Physical Dimensions (See Table 1)

Liquid Expansion Thermometers. The nonelectrical methods of thermometry are loosely based upon the second perfect gas law, Charles' or Guy Lussac's law, which states that at constant pressure the volume of a given mass of gas varies directly with the absolute temperature (4). As heat is added to a substance and temperature increases, the volume of liquids and gases increase. Mercury and ethanol are the most commonly used materials for the expansion based or liquid in glass thermometers.

Ethanol is an alternative to mercury in glass thermometers. Although cheaper than mercury, ethanol thermometers may be unsuitable for high temperatures since ethanol boils at 78.5 °C. Ethanol thermometers have a range from –75 to 120 °C. This is unimportant in the clinical setting of measuring and monitoring body temperature but may be important in other aspects of medicine. In addition, the scale of the ethanol-based thermometer may be less linear than that of the mercury thermometer (3,5).

The design of the liquid expansion thermometer has changed little in last century. The most sensitive location of the liquid in glass thermometer is the bulb, where the largest volume of liquid exists. However, the entire thermometer is temperature sensitive. These thermometers are manufactured with a constriction at the lower portion of the mercury column near the bulb. This prevents the

liquid from retracting into the bulb and allows the maximum temperature measured to be displayed until the thermometer is shaken.

Liquid expansion thermometers are impractical for continuous use due to the inherent rigidity of the device, the risk of breakage and the typically slow response (1–3 min) compared to the techniques listed below.

Bimetallic. The sensing element is comprised of two dissimilar metals bonded together in a coil, spiral, or disk. One end of the coil is attached to a lever, the other end is fixed to a point within the device. As temperature changes, the metals expand (with heat) or contract (with cold) by different amounts and the coil tightens or loosens, respectively, and moves a lever over a scale. These thermometers are not very accurate, but are relatively stable over time, require little maintenance, and are inexpensive. Bimetallic thermometer sensitivity to small changes in temperature can be increased by using a long strip wound into a tight coil. The most common clinical application for the bimetallic spring thermometer is use with thermostat devices, temperature alarm devices and operating room temperature monitoring.

The radius of curvature for a bimetallic thermometer is inversely proportional to the difference between the bonding temperature for the strip and the temperature being measured (3,5).

$$R = \frac{t\{3(1+m)^2 + (1+mn)[m^2 + (1/mn)]\}}{6(\alpha_2 - \alpha_1)(T - T_0)(1+m)^2}$$

where t = total thickness of the bimetallic strip; m = ratio of thicknesses (low/high expansion materials); n = ratio of Young moduli of elasticity (low/high expansion materials); α_1 = lower coefficient of thermal expansion (1/°C); α_2 = higher coefficient of thermal expansion (1/°C); T = temperature, °C; T_0 = initial bonding temperature, °C.

CHANGES IN ELECTRICAL PROPERTIES (SEE TABLE 1)

Resistance Thermometer

The conductivity of any metal depends on the movement of electrons through its crystal lattice. Resistance to this movement of electrons varies with temperature. Resistance temperature detectors (RTDs) utilize metallic conductors with positive coefficients of resistance or positive temperature coefficients (PTC). As temperature increases, resistance increases almost linearly. The metals that have nearly linear PTC include platinum, tungsten, nickel and nickel alloys. Each metal has a specific resistivity, ρ , which

varies directly with temperature (3,5–7).

$$\rho_T = \rho_0 [1 + \alpha(T - T_0)]$$

$$\text{Resistance}(\Omega) = \frac{(\rho)L}{A}$$

where L = metal wire length and A = cross-sectional area.

The RTD response relationship is nearly linear and is defined by the following equation (3–7):

$$R = R_0[1 - a(T - T_0) + b(T - T_0)^2]$$

Although the response is nearly linear throughout a wide range of temperature, it is linearity over the smaller temperature interval that is important in clinical medicine. In this scenario, resistance varies according to the following formula:

$$R_t = R_0 (1 + \alpha^*T)$$

Where a and b are calibration constants for resistor material and purity, T is measured temperature, and R_0 reference resistance measured at T_0 .

A simple RTD system is comprised of a metal resistor (e.g., platinum wire fashioned into a coil), a source of electrical potential and an ammeter calibrated to indicate temperature. Platinum is the preferred component due to its resistance to corrosion and large positive coefficient of resistance. Adding a Wheatstone bridge with an array of resistors increases the sensitivity of an RTD system.

The RTDs are the most accurate, most stable of the electrical methods for temperature measurement and are nearly linear over a relatively wide range of temperatures. They are, however, slow and expensive compared to thermocouples and thermistors (3,5). In addition, unlike thermocouples, an external current source is required to produce a voltage drop across the sensor. This source of current is a source of self-heating of the RTD if the current is not limited.

Thermistor

A thermistor (Fig. 1) is similar in principle to a resistance thermometer in that the ability to measure temperature depends on the changes in resistance of various metals in

response to temperature. There are some important differences. Unlike RTDs, which are made conductors with a positive coefficient to resistance, thermistors are made from semiconductor materials that have a large negative coefficient of resistance. Therefore, as temperature increases, the resistance within the thermistor decreases.

$$\text{Resistance}(\Omega) = A^{(B/\text{absolute temperature})}$$

The relationship between resistance and temperature is nonlinear. In addition, thermistors operate within a relatively high resistance range (1 kΩ–100 kΩ) compared to RTDs.

A digital readout thermistor-based thermometer is illustrated in Fig. 1.

Thermistors are made from heavy metal oxides (cobalt, iron, nickel, manganese, zinc). The metal is shaped into a bead that is sealed into a small measuring tip to which electrodes are attached. The tip can be sealed into a glass tube, cardiac catheter or stainless steel probe. Thermistors are accurate to $\pm 0.5^\circ\text{C}$ over a range of -80 to 150°C (3). Other advantages of thermistors include relatively small size, low production cost, reproducibility, very high sensitivity, and resolution and relative insensitivity to shock and vibration. Compared to RTDs, however, thermistors are less stable and are more susceptible to internal heating or self-heating. In addition, recalibration may be necessary because the resistance of the metal oxide increases over extended periods of time for unclear reasons. Calibration is defined by the following equation (3,8):

$$\text{Resistance} = R_0 e^{\beta(1/T - 1/T_0)}$$

where R_0 = reference resistance measured at T_0 ; T = measured temperature; β = material constant.

Thermocouple

When heat is applied to one end of a metallic conductor, electrons at this “hot” junction acquire increased thermal energy relative to those electrons at the unheated or “cold” junction. The electrons diffuse from the hot junction to the cold junction, and in doing so lose this thermal energy. Heat is conducted along the conductor and an

Figure 1. Digital thermistor thermometer ADC.

Figure 2. Seebeck principle.

accumulation of electrons at the cold end results in the production of an electric field between the ends of the metal (4). A small voltage is produced at the junction point (in an open circuit) of two dissimilar metals when heat is applied. The electromotive force or voltage across the terminals of an open circuit comprised of two dissimilar metals is proportional to the temperature difference of the two junction temperatures. Platinum, platinum–rhodium, nickel–chromium, and nickel–aluminum can be used as thermocouples. The thermocouple is enclosed in a metal or ceramic shield that protects the device from corrosion and other environmental factors. This voltage does not depend on the temperature along the metals between the junctions.

The thermocouple is based upon the Seebeck principle (Figs. 2 and 3). In 1821, T.J. Seebeck discovered that current is produced in a closed-circuit comprised of two dissimilar metallic conductors when heat is applied to one of the two junctions or if a temperature difference exists between the two junctions. Not every combination pair of metals is acceptable for thermocouple usage, since the direction and magnitude of the current produced is a function of the thermal properties of the metals that comprise the circuit and the temperature difference between the junctions.

In Fig. 2, dV is the voltage difference, K_c is the temperature of the cold junction, K_h is the temperature of the hot junction, S_{AB} is the factor of proportionality.

If the potential difference is to be measured, a second junction is required to produce a complete electrical circuit. This second junction will have its own thermoelectric electromotive force. The electromotive force generated is quantitatively and linearly related to the temperature difference between the two junctions. In order for the thermocouple to be used as a thermometer, this second

junction (reference junction, see Fig. 3) must be either maintained at a constant temperature or possess some form of mechanical compensation. The reference junction can be maintained at a constant temperature by immersion in an ice bath or kept at a precisely controlled, constant temperature. Mechanical compensation can be obtained by using a bimetallic spring attached to a coil suspension system. This suspension system functions as the galvanometer. The bimetallic spring is selected according to the range of the instrument. In solid-state instruments, an electrical zero can be used or a thermistor or RTD is used to monitor the reference or cold junction. The signal from the thermistor or the RTD is used to compensate for the cold junction temperature. Figure 3 illustrates a schematic of a thermistor and the relationship between temperature and voltage at the measuring junction.

Thermocouples are versatile, inexpensive, small, and durable. They are accurate within a wide temperature range and can be manufactured into a wide variety of physical forms. The low thermal capacity of thermocouples allows for a rapid response time for measurement. An added advantage over RTDs and thermistors is that thermocouples are self-powered. However, compared to the other contact sensors [thermistors, RTDs, and integrated circuit thermometers (ICs)], thermocouples are less sensitive and stable. Other disadvantages include necessity for compensation of the reference junction and, compared to RTDs, a relatively nonlinear voltage to temperature relationship.

Changes in Chemical Phase

Quartz Crystal Thermometry. Liquid crystals (LCs) have the optical properties of a single crystalline solid, but possess the mechanical properties of a liquid. Temperature changes can affect the color of certain liquid crystals. Crystals at specific temperatures, when exposed to light, will scatter some of the light that in turn produces iridescence. This property allows LCs to be used for temperature measurement. Liquid crystals are broadly categorized as either lyotropic or thermotropic. Lyotropic crystals are used in the production of soaps and detergents and react to the type of solvent with which they are mixed (9).

Figure 3. Thermocouple.

Thermotropic liquid crystals react to changes in temperature or pressure (9). Thermotropic crystals are further categorized as either isotropic or nematic (9). Isotropic crystals are random in their arrangement, while nematic crystals have a definite pattern or order. Nematic liquid crystals can be arranged in layers (smectic) or in spirals (cholesteric) (9). Temperature indicators can be constructed by embedding microencapsulated cholesteric liquid crystals into adhesive strips (3,8,9). These crystal devices can be applied to any accessible or visible location. These devices are more useful as trend devices during surgical procedures since they are only accurate to 0.5°C (3,8). Other disadvantages of LC thermometry include a lack of interfaces to other hemodynamic or respiratory monitors and inherent subjectivity, as colors may be interpreted differently by individual observers.

CHANGES IN EMITTED THERMAL RADIATION (SEE TABLE 1)

Infrared Thermometers

The electromagnetic spectrum is divided into a number of wavelength regions called bands. Light at frequencies less than red, which is at the low frequency edge of the visible portion of the spectrum, are called infrared (IR) and are not visible to the human eye. The IR band of the spectrum covers wavelengths between 0.7 and 1000 μm (4). All bodies with a temperature >0 K radiate energy in the IR band. This heat energy induces electron vibrations that cause electromagnetic emission. This energy travels like light (as an electromagnetic wave or photon) in all directions. The frequency of this emitted radiation is temperature dependent. The amplitude of the emission is dependent on the emissivity of the substance. Emissivity is the ratio of the energy radiated by an object at a given temperature to the energy radiated by a blackbody (perfect radiator) at the same temperature. Emissivity depends on the surface finish, color, aging, and oxidation state of the substance in question. For example, a highly polished metallic object would have a high reflectivity and a low emissivity.

Radiation striking a surface is reflected, absorbed and/or transmitted.

$$\rho(\text{reflectivity}) + \varepsilon(\text{emissivity}) + \tau(\text{transmissivity}) = 1$$

$$\varepsilon(\text{emissivity}) = \alpha(\text{absorbivity})$$

Infrared thermometers measure the amount of IR energy emitted from the object of interest. Contact with the surface or object of interest is not required. Infrared thermometers are composed of a lens (collection of energy emitted from an object), a sensor (thermal, photoelectric or photon detector), and a signal converter (converts thermal energy into an electrical signal). Infrared thermometers have very rapid response times (milliseconds), do not require contact with an object or surface (avoid contamination), are simple to use, and require little if any maintenance.

$$T_b = \frac{[\chi(N_T - N_{T0}) + T_0^4]}{4}$$

A basic IR thermometer is comprised of four parts: (1) a waveguide that collects and focuses the energy emitted by the target, (2) a pyroelectric sensor that converts the energy to an electrical signal, (3) a microprocessor that adjusts emissivity allowing thermometer calibration to match the emitting characteristics of the object being measured, and (4) a sensor temperature compensation circuit that ensuring that temperature variations within the thermometer are not transferred to the final output. which are fed through the amplifier, multiplexer (MUX), and analogue-to-digital converter (ADC) to the microprocessor for processing and display. The microprocessor that handles emissivity adjustment also performs temperature compensation and calculates the patient temperature.

CLINICAL APPLICATIONS

With the exception of monitoring temperature during anesthesia and surgery or during care in the intensive care unit, temperature is measured and recorded intermittently. During surgery, according to the guidelines established by the American Society of Anesthesiologists (www.asahq.org), the capability to monitor temperature must be readily available. In clinical situations where changes in body temperature are anticipated (long abdominal (10) or thoracic surgical procedures, pediatric) or intended (cardiopulmonary bypass (8,11), neurosurgical procedures), temperature must be monitored. In these situations, temperature is measured continuously with either internal (invasive) or external devices.

Sites

Accepted measurement sites of core temperature fall into four categories, with distinct advantages, disadvantages, and practical limitations: peripheral (skin); brain (tympanic, nasopharyngeal); visceral (bladder, esophageal, rectal); blood [Pulmonary artery catheter (PAC), esophageal].

There are distinct advantages and disadvantages for each site. These can be broadly categorized into ease of access, risk-benefit analysis, accuracy in measuring core temperature, and precision (5,8,12). For example, the pulmonary artery temperature clearly and accurately reflects core and cardiac temperature (except during the early transition periods during hypothermic cardiopulmonary bypass with extracorporeal circulation) (11), but requires access to the central circulation.

Skin

The skin is easily accessed for temperature measurement, but skin temperature can correlate poorly with core temperature. Disposable LCs or reusable metallic disks attached to thermistors or thermocouples can be used (see Fig. 4a). The LC devices are commonly applied to the forehead where fat distribution is minimal and where regional blood flow is adequate. The reusable probes can be placed in a number of locations including the back, chest or abdominal wall, axilla, or distal extremities. Measurement of skin temperature is also affected by moisture

(a)

(b)

(c)

Figure 4. (a) Liquid-crystal disk and contact-type (skin) thermistor. (b) Infrared otic (tympanic membrane) thermometer. (c) Contact-type thermistor for tympanic membrane temperature.

(sweat) and pressure applied to the probe. An increase in the amount of pressure on the probe will increase temperature measured. The unpredictable relationship between skin and core temperature during surgery and anesthesia makes the skin probe unreliable as an accurate marker for core temperature. Skin probes can be useful as a convenient and essentially risk-free trend monitor (as long as environmental temperature and skin perfusion are constant).

Oral Cavity

The mercury or ethanol in glass thermometers can be used in the oral cavity. As noted previously, the response time is slow relative to other techniques. Thermistors or thermocouples can be manufactured into probes that can be inserted into the oral cavity for rapid, intermittent temperature measurement. In addition, probes can be produced to allow continuous monitoring in the oral cavity. The oral cavity temperature can be up to 1.1 °C lower than simultaneous measurements from the pulmonary artery catheter (5,12).

Tympanic Membrane

The tympanic membrane is a useful and accessible site for IR thermometry. It is a relatively flat, uniformly textured structure that is (1) supplied by branches of the external carotid artery and (2) close to the internal carotid artery, which is the main supply of blood to the brain. As such, it is an acceptable location for core temperature measurement that accurately reflects hypothalamic temperature. The IR probe (see Fig. 4b) (with the aforementioned components) is configured into an otoscope-like device. This probe is covered with a disposable cone-shaped probe cover. The temperature is then displayed on a liquid crystal or light emitting diode display. They are, however, impractical for continuous measurements in medicine due to size, shape, and design of the current devices.

Contact type probes can be produced using thermocouples or thermistors. These probes can be used for continuous measurement of temperature during surgery and anesthesia. The probes are usually manufactured with a foam insulator so the tip of the probe is the only site of contact and measurement. Alternatively, a cotton or felt ball may be inserted to insulate and stabilize a wire probe (see Fig. 4c). There is little lag in the tympanic temperature during core cooling and warming studies, in contrast to most of the other available sites.

Nasopharynx

The nasopharyngeal probes are similar in construction (thermocouple or thermistor) to the tympanic membrane probes. The nasopharyngeal temperature is an adequate marker for brain temperature as long as the probe is placed posterior to the soft palate. The probe is quite uncomfortable in the awake patient. In addition, in the intubated patient, the probe is subject to airflow currents if leakage around the endotracheal tube occurs. These currents can adversely affect the accuracy of the probe in the nasopharynx.

Esophagus

Midesophageal temperature can be measured using a thermistor or thermocouple attached to a flexible probe. The probe can also be integrated with a stethoscope that can be used to monitor heart and breath sounds during anesthesia and surgery.

Position within the esophagus is important in predicting the accuracy of esophageal temperature as a marker of core temperature. Temperature can vary from 1 to 6 °C, depending on the position of the probe in the esophagus. For example, if the probe is inserted in a more distal location (eg, stomach), the temperature measured may be higher than the true core temperature due to warming caused by the normal metabolism in the liver, which is adjacent to the stomach. If the probe is positioned in more proximal position (adjacent to the trachea), accuracy relative to core temperature is affected by cooling secondary to ventilation with room temperature gases via the endotracheal tube. In addition, the probe may be cooled by infusion of cold fluids for irrigation into a chest incision for thoracic or cardiac procedures. The temperature will be affected by the cooling and warming phase of cardiopulmonary bypass with extracorporeal circulation. Optimal location of an esophageal temperature probe in an adult is between 35 and 45 cm from the nostrils.

Urinary Bladder

The bladder temperature correlates well with other measures of core temperature. Bladder temperature is recorded with specially modified urinary catheters. These catheters are commonly used to monitor urine output during surgical procedures or during treatment in the intensive care unit. A thermistor or thermocouple is attached to the patient end of the catheter.

Changes in bladder temperature during hypothermic cardiopulmonary bypass with extracorporeal circulation will occur later than changes in nasopharyngeal, tympanic membrane, and pulmonary artery temperature.

Rectum

The rectal mucosa was previously used as a site for core temperature measurement. It is now clear that the rectum is a relatively peripheral site. As such, it does not accurately reflect core temperature. In fact, at times, rectal temperature may exceed core temperature due to the heat produced by metabolism of the fecal bacterial flora. At other times, the presence of feces in the rectum may insulate the probe from contact with the rectal mucosa. In addition, the rectal veins receive blood from the lower extremities. This blood can have a cooling effect on the rectal temperature.

Rectal probes are seldom used for continuous temperature monitoring due to the inaccuracies listed above. In addition, awake patients may find them uncomfortable.

Intermittent rectal temperature measurements are often made in the pediatric population using mercury or ethanol in glass thermometers. In addition, a digital thermistor or thermocouple probe may be used in this location.

Intravascular

The most accurate location for measuring core temperature is the central circulation. The inferior vena cava and the superior vena cava drain into the right atrium, and this mixed-venous blood enters the right ventricle and exits via the pulmonary artery to the pulmonary circulation. The pulmonary artery temperature can be measured with a thermistor that is positioned at the tip of a pulmonary artery (or Swan-Ganz) catheter. This thermistor is actually intended for use in calculation of the cardiac output using the thermodilution technique, display of the temperature is a byproduct of this design.

The pulmonary artery catheter is inserted via an introducer or sheath that is placed into one of the large veins of the body (subclavian, internal jugular, or femoral) typically by percutaneous cannulation. While the temperature of mixed-venous blood accurately reflects true core temperature, there are variables that contribute to the accuracy of any given measure. The pulmonary artery temperature is affected by local heating or cooling during the rewarming phase or the hypothermic phase of cardiopulmonary bypass, the instillation of warm or cold irrigation fluids into the chest, and application of ice or slush to the pericardium. In the absence of these factors, the pulmonary artery temperature is an accurate monitor for core temperature.

Insertion of the pulmonary artery catheter involves significant risks including infection, hematoma, pneumothorax, and arrhythmia and is not appropriate for use solely as a temperature monitor. However, the cases in which pulmonary artery catheters tend to be used, including cardiac surgery, major vascular, and major abdominal surgery, tend also to be associated with the potential for profound changes in core temperature.

Temperature Regulation

The body's core temperature may change without any true change in the total heat content due to redistribution of heat to or from the periphery (7,13–15). This occurs most commonly during surgical procedures due to peripheral dilatation secondary to anesthesia.

The temperature control center is located in the anterior hypothalamus. The hypothalamic regulatory center receives afferent input from peripheral skin receptors and initiates appropriate responses, such as reduced heat loss through skin vasoconstriction, increased heat production through raised muscle tone, or shivering (7,13–15). Impairment of thermoregulatory control can occur due to a number of factors including (7,13–15): anesthetic drugs; hypoxemia; extremes of age; shock (Blood loss or hypovolemia); hypothyroidism; hypoglycemia; malnutrition; extreme exertion; central nervous system (CNS) dysfunction.

Heat production varies by age and gender. At rest, the average male produces 1 kcal·kg⁻¹ of heat per hour and the average female 0.93 kcal·kg⁻¹·h⁻¹ (16,17). Heat production occurs primarily by metabolic activity in the liver and skeletal muscles. Heat production in skeletal muscle increases with voluntary activity (movement and exercise) and shivering (see below). With exercise, heat production can increase to 3–9 kcal·kg⁻¹·h⁻¹ (16,17). This heat is transferred from the muscles to the blood supply of the muscular bed. This blood then

enters the liver raising core temperature. The specific heat of a human is $0.83 \text{ kcal}\cdot\text{kg}^{-1}\cdot\text{C}^{-1}$, with a 70 kg male having to gain 58.1 kcal to raise core temperature by 1°C (16,17). With basal heat production of only $1 \text{ kcal}\cdot\text{kg}^{-1}\cdot\text{h}^{-1}$, endogenous heat production, if normal, would still raise body temperature $1.2^\circ\text{C}\cdot\text{h}^{-1}$; assuming sufficient insulation to prevent any other heat loss from any other mechanisms.

The loss of body heat during anesthesia and surgery is the most significant contributing factor to the development of hypothermia. Heat loss occurs as a consequence of loss through multiple mechanisms, including (10,13,14): evaporative (15–30%); conductive (20–30%); convective (15–30%); radiant (30–50%).

Evaporation is the conversion of a liquid into a vapor at a temperature below its boiling point. Evaporation is always accompanied by a reduction in temperature. Molecules of water at the skin surface and mucosal surfaces in the airways and viscera with enough heat energy to overcome the cohesion of neighboring molecules will vaporize. The average energy of the remaining water molecules will decrease reducing the surface temperature. The intraoperative evaporative loss occurs via the skin, the surgical incision, and, most importantly, the lungs, secondary to controlled ventilation of cold, dry gases. Evaporative losses are dependent on the surface area of the exposed surface, minute ventilation, relative humidity, and airflow velocity. These losses can be reduced by increasing the humidity of respiratory gases. The anesthetic drugs, which produce peripheral and cerebral vasodilatation, certainly exaggerate the normal evaporative skin loss of heat and prevent peripheral vasoconstriction to conserve heat. However, sweating, which increases the amount of moisture available, increases evaporative losses. It is estimated that a general anesthetic reduces the shivering threshold to $<34.5^\circ\text{C}$, and muscle relaxants will completely abolish this protective response (13,14).

Conduction is the transfer of heat energy by random atomic or molecular motion between two objects. The transfer always occurs down the temperature gradient from the warmer surface to the colder substance. Conductive loss occurs from (1) placing the patient on the room temperature operating room table and (2) patient contact with the room temperature surgical instruments (18). Conduction is less important than radiation, evaporation, and convection clinically since the layer of air that surrounds a body insulates against heat loss unless air movement is present (see Convection below).

The administration of intravenous fluids, cold blood bank products, as well as surgical wound irrigation provides additional significant conductive heat losses (19). The thermal stress of infusing 1 L of unwarmed crystalloid is $\sim 17 \text{ kcal}$ and the stress from a liter of unwarmed bank blood is $\sim 30 \text{ kcal}$.

Calculation of the thermal stress from intravenous fluids or transfusions can be made with the formula:

$$\text{IV "Lost" kcal} = (T_c - T_f) \times V$$

Where T_c = body temperature, T_f = fluid temperature, and V = volume of fluid infused in liters. Hence, the administration of 3 L of room temperature (20°C) crystalloid to a patient represents a 61 kcal challenge whose core temperature is 37°C ($[37-20^\circ\text{C}] \times 3 \text{ L}$).

Convection is the transfer of heat secondary to air currents. Air adjacent to the skin is warmed by conduction. This warmed is less dense and rises. As air flows over the body, the current carries heat away from the body. Convective heat flux is defined by the following equation (4,5,20):

$$Q_{cv} = \gamma(T_s - T_g)$$

where γ is the proportionality constant ($\text{J}\cdot\text{g}^{-2}\cdot\text{K}^{-1}$), T_s is the surface temperature, and T_g is the air temperature.

Forced convective heat loss is caused by gas flow caused by external means (fan or pump). Free convective loss occurs due to the gas flow that occurs secondary to temperature differences (4,5,18,20).

Clinical convective losses occur secondary to the requirement of maintaining the air conditioner and/or the air handling system at the colder settings due to multiple layers of sterile clothing worn by the surgical staff. In addition, the rates of operating room air turnover may be significantly higher than in other ambient settings. This increase in air turnover serves to reduce the likelihood of infection, but increases convective losses. Convective losses can be reduced by trapping the layer of air between the skin and external environment with a barrier, such as a thermal blanket or forced air device (21).

Radiation heat loss occurs due to the transfer of heat in the form of electromagnetic energy. The magnitude of heat transfer is dependent on the surface area of the emitting object (4,13,18). It is not dependent on the presence of a material medium therefore no direct contact is required.

SUMMARY

Iatrogenic hypothermia predisposes the patient to profound physiological consequences, including delayed recovery from anesthesia, increased oxygen consumption, increased vascular resistance, cardiac instability and potential ischemia or infarction, coagulopathy, diminished patient satisfaction, and increased recovery room costs. In considering the need to provide the best patient outcomes, hypothermia induced complications can and should be prevented. Prevention of hypothermia requires monitoring of body temperature. The devices that can be used vary in accuracy, convenience and degree of invasiveness. Appropriate choices will influence patient outcome.

INTRODUCTION

The normal body temperature of human beings is considered to be constant $\sim 37^\circ\text{C}$. Heat energy is stored in the body

and it is essentially constant, as long as we are alive. Most of the heat produced in the organism comes from deep organs, mainly the liver, brain, and heart, as well as the skeletal muscles during exercise (1). A major part of this heat is dissipated at the skin surface by radiation, convection, evaporation, and respiration. However, as the environment temperature varies frequently, the body presents mechanisms to generate and loose heat, controlling and regulating the body temperature. It is done almost exclusively using feedback mechanisms that operate by means of regulatory centers located at the hypothalamus. Thus, if the environment temperature decreases, the body generates more heat and tries to keep it, while the heat generation is decreased and part of the body heat is dissipated when the environment temperature increases. Disease states introduces modifications in this equilibrium that can be indirectly evaluated by body temperature. That is the reason why it is one of the more important physiological parameter, measured virtually in all patients in every hospital bed, being used as a clinical index of disease, as well as an aid for diagnostic and prognostic purposes. Temperature can be measured at the human body in two basic ways: at skin surface and by systemic measurements. Although, in practice, systemic measurements are much more commonly used, both kinds provide valuable diagnostic information. Skin temperature is the result of the relationship between the heat supplied by blood surface circulation, the environmental temperature, and the air circulation around the area at which the measurement is being taken. Skin temperature data are usually obtained from sensors in contact with the skin's surface. However, the use of self-adhering foam patches to affix temperature sensors to the skin appears to procedure artificially higher mean temperatures (2). Systemic temperature is the temperature of the internal regions of the body. This parameter can be measured by temperature sensing devices placed at the mouth, in the rectum, or under the armpits. The oral temperature of a health person is $\sim 37^\circ\text{C}$. The rectal temperature is typically 0.5°C higher than the oral temperature, while the under-arm temperature is about 1°C lower than the oral one. Some clinical applications may need more specific measurements, as skull and core temperatures, for example. Skull temperature may be obtained by placing the thermal probe into the nasopharynx near the base of the skull, while core temperature may be obtained from a probe inserted into the esophagus. The basic characteristics of devices used in temperature measurements are ease of operation, cleaning and sterilization, and guarantee of patient safety. It is also important to mention the size and thermal mass of the probe, since these determine the disturbance imposed by the measurement and the speed of response.

The simplest phenomenon for temperature sensing is, perhaps, thermal expansion, which is the basis of the mercury-in-glass thermometer. In clinical routine measurements, however, electronic temperature recording and display are advantageous, since they permit the use of automatic continuous measurement of temperature and remote applications by connecting to computerized systems. Another convenient characteristic of these devices is their small size. There are numerous ways of measuring temperature electronically, most commonly by transducers

based on temperature dependence of electric resistance (RTDs and thermistors) and thermoelectric effects (thermocouples). Thermistors offer a high sensitivity and degree of interchangeability at lower cost than either RTDs or thermocouples. It makes them ideal for healthcare products that incorporate sensor probes that can be discarded after using and replaced with new probes of the same specification, without recalibration. In this section, the attention will be focused on thermal-sensitive resistors, their properties, and the basic instrumentation used in temperature measurements. Examples of commercial devices dedicated to temperature measurements are also discussed, as well as systems for clinical and research applications in several branches of medicine to measure flow, detect the presence of fluids, and evaluate the properties of tissue based on temperature measurements using thermistors.

THEORY

Thermistor (the contracted name of thermally sensitive resistor) is a general term used for both positive and negative temperature coefficient types of semiconducting thermal transducers. These devices are constructed of ceramic materials whose electrical conduction properties are temperature sensitive. At a fixed environmental temperature, a thermistor exhibits a specific ohmic value. However, if the environment temperature varies, this resistance changes. Thermistors are able to sense temperatures from -50 to 300 °C, which is a small range compared with metal wire sensors. A platinum wire, for example, can be used to measure temperature from -160 to 1000 °C. This range, however, is much greater than most of the medical temperature measurement tasks would require.

Thermistors usually have high negative temperature coefficients (NTC), resulting in a decrease of the thermistor resistance with increasing temperature. The negative temperature coefficient in nonmetallic materials (silver sulfide), was first observed by Michael Faraday in 1833, but it was not until 1940 that thermistors were developed that were able to produce reproducible results. The NTC thermistors are typically made of transition-metal oxides. The most usual oxides are those of manganese, nickel, cobalt, and iron (3,4). In the basic fabrication process, a mixture of two or more metal oxide powders are first combined with suitable binders, and are molded to a desired geometry. Then the products are dried and sintered at an elevated temperature. The units are finally coated with an epoxy layer for final protection and stabilization. Varying the types of oxides used, their relative proportions, the sintering atmosphere, and the sintering temperature, a wide range of resistivities and temperature coefficient characteristics can be obtained. More detailed descriptions of NTC manufacturing techniques can be obtained in Refs. 3–5. Since their first use in practical electronic thermometer in the early 1950s, thermistor technology has been enhanced continuously, resulting in improvements that probably situate this device as the most widely used temperature transducer for medical applications nowadays. These devices have been developed to be very sensitive to variations in temperature (~ -3 to -5 °C), present excellent

long-term stability ($\pm 0.2\%$ of nominal resistance value per year), and be small in size. Because of this small size, these sensors present a fast response to variations in fluid temperature. Thermistors are also relatively inexpensive.

Beyond the advantages of high sensitivity, interchangeability, and low cost cited previously, another major advantage offered by thermistors is that, unlike RTDs and thermocouples, thermistors are virtually unaffected by lead resistance, since they are high resistance devices. Specifically comparing them with thermocouples, we observe that thermistors can be used with less complex and expensive instruments. It happens because the thermal electromotive force (EMF) values produced by thermocouples are around a few microvolts per degree, requiring high gain and low noise amplification of the signal. Moreover, thermocouple demands additional circuits for compensation of cold junction temperature (4). There are many physical configurations in which thermistors are found, varying from very small bead thermistors, that are spherical and have diameters as small as 0.1 mm, to large flat disks having diameters of several centimeters. Some of these configurations are described in Fig. 1.

Thermistors with positive temperature coefficient (PTC) may also be constructed, by sintering barium and strontium titanate mixtures. These thermistors are often called switching thermistors because of their resistance–temperature characteristics. As temperature increases, the zero-power resistance of this device remains essentially constant until reaching the switching temperature or Currie point, where there is a sharp upward increase in the resistance. The switching temperature can be from -20 to $+125$ °C. The PTC thermistors are frequently used as thermostats to sense and regulate oven temperature (6) and for circuit protection.

THERMISTOR TERMINOLOGY

Dissipation constant (DC or δ) is the amount of power required to raise the temperature of the thermistor 1 °C above the surrounding temperature in steady-state conditions (6). It means that the resistance changes by an equivalent of 1 °C for each dissipation constant rating ($\text{mW} \cdot \text{°C}^{-1}$) for the selected device. It depends on the heat transfer from the thermistor to its surroundings (by conduction through the leads, free convection in the medium and radiation), the relative motion of the medium in which the thermistor is located, as well as the thermal conductivity. A typical value of the dissipation constant of a thermistor with a 0.24 cm outer diameter, coated with epoxy or phenolic layers, is $2 \text{ mW} \cdot \text{°C}^{-1}$ in still air (7). Its parameter increases with thermistor mass and in water is ~ 5 – 10 times the value measured in air.

Maximum operating temperature is the maximum body temperature at which the thermistor will operate for an extended period of time with acceptable stability of its characteristics. This temperature can be the result of internal or external heating, or both, and should not exceed the maximum value specified (6).

Self-heating is a process observed when a current flowing through a thermistor causes sufficient heating

Figure 1. Some thermistor configurations (from *Interfacing Sensors to the IBM PC*, by W. J. Tompkins and J. G. Webster, 1988 Reprinted by permission of Prentice-Hall).

by power dissipation to raise the thermistor's temperature above the ambient (6). As the effects of self-heating are not always negligible (or may even be intended), a distinction has to be made between the characteristics of an electrically loaded thermistor and those of an unloaded thermistor. The properties of an unloaded thermistor are also termed as zero-power characteristics. This effect depends on the thermal dissipation factor (δ) and the geometry of the thermistor itself. In general, the smaller the device, the smaller is the permissible current before self-heat.

Stability is the ability of a thermistor to retain specified characteristics after being subjected to designated environmental or electrical test conditions ($^{\circ}\text{C}\cdot\text{year}^{-1}$). This parameter is dependent on environmental conditions (e.g., humidity, excessive temperature, and thermal shock), which should be minimized to guarantee stability (7). Physical reasons for this may be thermal stress causing a change in concentration of lattice imperfections, oxygen exchange with the environment (with unprotected, nonglass-encapsulated thermistors), or diffusion in the contact areas of metalized surface contacts. To enhance long-term thermistors stability, they are usually subjected to an ageing process directly after manufacture (8). This results in chemically stable devices that are not significantly affected by aging, exhibiting typically $<0.02^{\circ}\text{C}\cdot\text{year}^{-1}$ of thermometric drift.

Zero-power resistance (R_0) is the direct current (dc) resistance value of a thermistor at a specified temperature, with negligible electrical power to avoid self-heating (6).

Temperature coefficient of resistance (α) is a useful measurement of the thermistor's sensitivity and is defined as the relative change in resistance referred to change in temperature at a specified temperature ($\% \cdot ^{\circ}\text{C}^{-1}$) under zero-power conditions (6,8).

$$\alpha = \frac{1}{R_T} \frac{dR}{dT} \quad (1)$$

Because the relationship between resistance and temperature is not linear, α is a function of temperature and it is usually specified over the temperature range where the temperature variation is expected. One of the most important characteristics of a thermistor is, without question, its extremely high temperature coefficient of resistance. A typical value is $-4.3\% \cdot ^{\circ}\text{C}^{-1}$ at 37°C .

Thermal time constant (TC or τ) describes the heat inertness of thermistors (5) and it is the time (s) required for a thermistor to change 63.2% of the total difference between its initial and final body temperature, when subjected to a step function change in temperature under zero-power conditions. This parameter is directly affected by the mass of the thermistor, the thermal properties of the medium surrounding the device, the thermal coupling to the environment, the motion of the medium, the conduction through the leads, and the radiation losses. An epoxy coated thermistor with a 0.24 cm outer diameter will typically have a time constant of 0.75 s in stirred oil and 10 s in still air (7).

Interchangeability tolerance: The rated thermistor parameters values are subject to manufacturing tolerances. They are determined by the composition and structure of the various metal oxides being used in the device production. The result will be a variation from unit to unit within a production lot, as well as from lot to lot. Interchangeability tolerance is the value of how far a specific family of devices may be from the nominal resistance versus temperature curve. For example, if a family of devices has an interchangeability tolerance of $\pm 1.0^{\circ}\text{C}$ over the range from 0 to 70°C , it means that, for this range, all devices of this family are within $\pm 1.0^{\circ}\text{C}$ of the resistance versus temperature curve. This feature results in accurate temperature measurements to $\pm 1.0^{\circ}\text{C}$, no matter the substitution of thermistors. Modern thermistor technology results in the production of devices with tight zero-power resistance tolerances. Over the medical temperature range, interchangeable tolerances to $\pm 0.1^{\circ}\text{C}$ are typical (9,10).

Maximum power rating is the maximum power (mW) that a thermistor will dissipate for an extended period of time with acceptable stability of its characteristics (11).

Standard reference temperature is the thermistor body temperature at which nominal zero-power resistance is specified and is usually 25 °C (11).

RESISTANCE-TEMPERATURE CHARACTERISTICS

Thermistors are one member of the family of resistive temperature sensors. Unlike the other members of this family, which presents linear relationship between resistance and temperature (platinum, nickel and cooper, e.g.), thermistors are very nonlinear. This can be seen in Fig. 2, where the characteristics of some typical NTC thermistors and a platinum RTD are compared, showing the higher sensitivity to temperature changes of the first ones (3). In thermistor literature, the most frequently used characteristic relationship between the thermistor resistance, and the ambient temperature is

$$R_T = R_0 \exp \left[\beta \left(\frac{1}{T} - \frac{1}{T_0} \right) \right] \quad (2)$$

where R_T is the thermistor resistance (Ω) at temperature T , R_0 is the thermistor resistance (Ω) at temperature T_0 , which is the standard reference temperature (K, $K = ^\circ\text{C} + 273.15$), and β is the material constant for thermistor (K). A typical thermistor resistance may vary from 5000 Ω at 0 °C, until 100 Ω at 150 °C, while the reference temperature T_0 is usually taken as 298 K (25 °C). Equation 2 can be rearranged to solve for β :

$$\beta = \frac{T T_0}{T - T_0} \ln \frac{R_0}{R_T} \quad (3)$$

Figure 2. Resistance-temperature relationship of thermistors (a,b,c) and RTD (d). Over the presented range, NTC thermistors offer higher sensitivity to temperature changes compared to RTD. (Reproduced from (3) with permission).

The constant β is usually between 2000 and 5000 K and increases slightly with temperature. Its value is determined by the material properties and it is usually calculated and specified by thermistor manufacturers using two temperatures over a given range. Applying the definition of the temperature coefficient of resistance (eq. 1) in equation 2 results in

$$\alpha = -\frac{\beta}{T^2} \quad (4)$$

It is important to point out that equations 2–4 are valid only over small temperature spans. The Steinhart–Hart equation is, however, more accurate over wider temperature ranges.

$$\frac{1}{T} = a + b(\ln R_T) + c(\ln R_T)^3 \quad (5)$$

where T is the temperature in K, a , b , and c are the coefficients derived from measurements. The Steinhart–Hart equation is an empirically developed polynomial that has been determined to be the best mathematical expression for resistance-temperature relationships of NTC thermistors and probes (12). Solving for resistance, when temperature is known, the form of the equation changes to

$$R_T = e \left[\left(-\frac{\chi}{2} + \left\{ \frac{\chi^2}{4} + \frac{\psi^3}{27} \right\}^{1/2} \right)^{1/3} + \left(-\frac{\chi}{2} - \left\{ \frac{\chi^2}{4} + \frac{\psi^3}{27} \right\}^{1/2} \right)^{1/3} \right] \quad (6)$$

where, $\chi = (a - 1/T)/c$ and $\psi = b/c$. The a , b , and c coefficients, can be solved measuring the thermistor resistance (R_1, R_2, R_3) at three different temperatures (T_1, T_2, T_3) and using simultaneously equation 5. The data calculated by equations 5 and 6 will be accurate to better than ± 0.01 °C, when $T_1 \leq -40$ °C, $T_3 \leq 150$ °C, $|T_1 - T_2| \leq 50$ °C and $|T_2 - T_3| \leq 50$ °C. Parameters T_1 , T_2 , and T_3 are evenly spaced and at least 10 °C apart.

VOLTAGE-CURRENT CHARACTERISTICS

If a constant electrical power is applied to the thermistor its temperature will first increase considerably, but this change will decline with time. After some time a steady state will be reached, where the power is dissipated by thermal conduction or convection. The voltage drop on the thermistor as a function of the flowing current under conditions of thermal equilibrium is

$$VI = \delta(T_T - T_A) \quad (7)$$

If the dissipation constant (δ) variations are negligible for a determined medium and established conditions, and the resistance-temperature characteristic is known, the static current-voltage characteristics can be obtained. Since $V = R_T I$, where R_T is the temperature dependent NTC resistance,

$$I = \sqrt{\frac{\delta(T_T - T_A)}{R_T}} \quad (8)$$

and

$$V = \sqrt{\delta(T_T - T_A) R_T} \quad (9)$$

Figure 3. Thermistor voltage versus current characteristics with the device in air and water on log-log coordinates (A), and characteristics on linear coordinates (B). Figure (A) is from *Interfacing Sensors to the IBM PC*, by W. J. Tompkins and J. G. Webster, 1988 (Reprinted by permission of Prentice-Hall) and Figure (B) is from *Ceramic Sensors: technology and applications*, T. G. Nenov and S. P. Yordanov, 1996, (courtesy of Technomic Inc, Pennsylvania, USA).

using the above equations the voltage–current curves can be plotted on log–log coordinates, where lines of constant resistance have a slope of $+1$ and lines of constant power have a slope of -1 (Fig. 3a) (6,13). For some applications, it is more convenient to plot the voltage–current characteristic on linear coordinates (Fig. 3b) (5,13).

The voltage–current characteristics of a NTC thermistor has three different sections: first, for small currents, the amount of power dissipated in the thermistor is negligible, and the voltage–current characteristic will describe a constant resistance that is equal to the zero-power resistance of the device at the specified ambient temperature (section A in Fig. 3a). In this condition, the temperature of the thermistor is that of the surroundings. This curve section is usually used when thermistors are employed as temperature sensors. As the current continues to be increased, in the second curve section, there is a rise in the thermistor temperature above that of the surrounding medium since this power cannot be completely removed from the thermistor and the effects of self-heating become evident, resulting in a decrease in its resistance (section B in Fig. 3a). In this condition, more current flows due to decreasing resistance (6). Subsequent incremental increases in current introduce a corresponding decrease in resistance. Hence, the slope of the voltage–current characteristic ($\Delta E/\Delta I$) decreases

with increasing current. This continues until a current value is reached (I_m), for which the slope becomes zero and the voltage reaches a maximum value (V_m) (Fig. 3b). As the current is increased above the value of I_m , the third curve section (section C in Fig. 3a) is entered. The slope of the characteristic curve continues to decrease and the thermistor exhibits a negative resistance characteristic (5). This last section of the operating area of NTC thermistors, when they are self-heated, is used in applications such as liquid level detection, air flow detection, and thermal conductivity measurement. However, care should be taken when designing a circuit for self-heated application, because the thermistor is vulnerable to destruction in this region by thermal runaway. This can be avoided by passing constant currents coherent with the thermistor dissipation characteristics. As the power dissipated is proportional to I^2R , when the current is constant, further increases in temperature causes decreased resistances and decreased power, protecting the device.

Anytime a thermistor is applied for temperature measurement, it is very important to avoid its self-heat. Since a thermistor resistance changes with the temperature, this self-generated heat will change this resistance value, producing an erroneous reading. For example, if the dissipation constant of the thermistor selected is $5 \text{ mW}\cdot\text{C}^{-1}$ and the power dissipated by the device is $20 \text{ mW}\cdot\text{C}^{-1}$, then a 4°C error is induced due to the effect of self-heating. This effect is more pronounced when dealing with a still fluid (i.e., neither flowing nor agitated), because there is less carry-off of the heat generated. This kind of problem does not arise with thermocouples, that are essentially zero-current devices. To maintain a higher degree of accuracy, the temperature error caused by self-heating should be an order of magnitude less than the required sensor accuracy. As an example, if the power dissipation constant of a thermistor is $\sim 2 \text{ mW}\cdot\text{C}^{-1}$ in still air, in order to keep the self-heat error $< 0.1^\circ\text{C}$ the power dissipation must be $< 0.2 \text{ mW}$. Very low current levels are required to obtain such a low power dissipation factor. This mode of operation is usually called zero-power sensing.

THERMAL CHARACTERISTICS

The power dissipated by a thermistor (P) is equal to the rate at which thermal energy (H) is supplied to the thermistor. This is the same as the rate at which energy is lost from the thermistor to its surroundings (H_L), plus the rate at which energy is absorbed (H_A) (13,14).

$$P = \frac{dH}{dt} = \frac{dH_L}{dt} + \frac{dH_A}{dt} \quad (10)$$

The rate at which thermal energy is lost from the thermistor is proportional to the temperature raise of the thermistor,

$$\frac{dH_L}{dt} = \delta(T_T - T_A) \quad (11)$$

The dissipation constant (δ) is typically measured under equilibrium conditions. It is not a true constant, since it varies slightly with temperature and with an increase in

temperature. The following relation can express the rate at which thermal energy is absorbed by the thermistor to produce a specific amount of rise in temperature:

$$\frac{dH_A}{dt} = sm \frac{dT_T}{dt} \quad (12)$$

where s is the specific heat and m is the mass of the thermistor. Thus, the heat-transfer equation for an NTC thermistor, at any instant after the application of power to the circuit, can be expressed as

$$P = RI^2 = \frac{dH}{dt} = \delta(T_A - T_T) + sm \frac{dT_T}{dt} \quad (13)$$

The thermal transient conditions at turn-on is given by the solution of equation 13, which is obtained considering P constant:

$$T_T - T_A = \frac{P}{\delta} \left[1 - \exp\left(-\frac{\delta}{sm}t\right) \right] \quad (14)$$

It means that when a significant amount of power is dissipated in a thermistor, its body temperature will rise above the ambient temperature as a function of time. In steady-state condition, when thermal equilibrium is achieved ($dT_T/dt = 0$ in equation 13, or when $t \gg ms/\delta$ in equation 14), the rate of heat loss is equal to the power supplied to the thermistor (remind equation 7, where $VI = \delta(T_T - T_A)$). When self-heating is negligible ($P \cong 0$), the heat-transfer equation 13 can be rewritten,

$$\frac{dT_T}{dt} = \frac{-\delta}{sm}(T_T - T_A) \quad (15)$$

which can be solved to

$$T_T = T_A + (T_I - T_A) \exp\left(\frac{-t}{\tau}\right) \quad (16)$$

where T_I is the initial body temperature and τ is the thermal time constant ($\tau = ms/\delta$), which depends on the same environmental factors as δ .

All of the preceded discussions of thermal properties of NTC thermistors have been based upon a single device structure with a single time constant. When these devices are encapsulated into sensor housings, the simple exponential response no longer describes adequately the system response. The mass of the housing and the thermal conductivity of the materials used in the sensor housing will normally increase the system dissipation constant, increasing the thermal response time. In this case, the thermal properties are somewhat difficult to predict by mathematical modeling, usually requiring experimental tests of the system to obtain data on the resulting response time and dissipation constant (13). In general, the thermal response time may be reduced keeping the thermal resistance between the actual temperature sensor and the tissue being measured as low as possible.

THERMISTOR LINEARIZATION

The inherent nonlinearity of the resistance versus temperature characteristics of thermistors is rather troublesome in many applications. Even if we are interested in

temperature measurements close to the body temperature, with variations of only a few degrees, the thermistor must be linearized. This can be accomplished basically in three ways: modifying the transducer circuitry, using analog circuits, or using digital techniques (15).

In the first option, the output of the transducer can be linearized over a limited temperature range with the addition of series or parallel resistors (6,16,17). It causes the voltage or the resistance of a simple fixed resistor thermistor to have zero error along a linear temperature scale at three equidistant points (Fig 4). The series resistance (R_s) required to make the conductance-temperature characteristic of a thermistor approximately linear may be calculated as follows (16,18):

$$R_s = R_{T_m} \left(\frac{\beta - 2T_M}{\beta + 2T_M} \right) \quad (17)$$

Where R_{T_m} is the resistance of the thermistor at the mid-scale temperature T_M . As can be observed in Fig. 4, this procedure reduces the sensitivity of the transducer. However, as the sensitivity of a thermistor is relatively high, the reduction is often a satisfactory tradeoff. The temperature coefficient of the series combination (α_s) is given by (6)

$$\alpha_s = \frac{-(\beta/T_M)^2}{(G_{T_M}/G_s) + 1} \quad (18)$$

Where G_{T_M} is the conductance of the thermistor at the mid-scale temperature and G_s is the conductance of the series resistance. An alternative method is to define the low, mid, and high end of the desired temperature range at three

Figure 4. Linearization of a thermistor using a parallel resistor. (Adapted from (17) with permission).

equidistant points, and calculate R_s by (19,20):

$$R_s = \frac{[R_{T_M}(R_{T_{LO}} + R_{T_{HI}}) - (2R_{T_{LO}}R_{T_{HI}})]}{[(R_{T_{LO}} + R_{T_{HI}}) - (2R_{T_M})]} \quad (19)$$

where R_{LO} , R_{T_M} , and R_{HI} are the thermistor resistance at the low, mid, and high end of the range, respectively. In this procedure, the addition of series resistor R_s forces the equivalent resistance of the fixed resistor thermistor to have zero error along a linear temperature scale in the three points chosen. The temperature range of the application determines the maximum error. For example, if the range is taken to be -50°C to 100°C , the errors are 0 at -50 , 25, and 100°C , and the errors elsewhere are distributed in an S-shaped. If the temperature range is reduced, the errors become smaller; being 2.0°C over a 60°C range, 0.05°C over a 30°C range, and 0.01°C over a 10°C range. Another way to linearize thermistors includes the use of a Wheatstone bridge. In most applications, the bridge consists of a linear thermistor voltage divider and a fixed resistor voltage divider, as described in Fig. 5a (21). This circuit is designed to produce 1 V at 25°C and 200 mV at 45°C , with an output voltage that is linear within $\pm 0.06^\circ\text{C}$ in this temperature range (Fig. 5b). Hoge (22) showed that circuits based on resistors (serial, parallel, or bridge) are equal in their ability to linearize thermistor

Figure 5. Use of a thermistor in a Wheatstone bridge for temperature measurements (A) and respective output voltage as a function of temperature (B) (courtesy of Alpha Sensors, 2121 Palomar Airport Rd., Carlsbad, CA 92009, USA).

characteristics. Thus, the choice of a linearizing circuit should be made on other grounds, such as simplicity or convenience.

Theoretically, an improved linearization over wider temperatures can be achieved using more complex circuits. For many applications, it can be a better option to linearize the transducer at some point of the analog process, as in cases where no digital processing is used. It is also true when limited processing capability and/or memory are available, and the analog processing can be done simply and at low cost. Analog circuitry using piecewise-linear approximations has been developed to be used with temperature transducers (23). However, these circuits are complex and costly, and are not usually used in practice. Voltage-to-frequency converters (24), logarithmic (25), and temperature to frequency (26) circuits, were proposed for this objective. In 1990 Slomovitz and Joskowicz (27) compared the quality of these active linearizing circuits. They concluded that the errors (2, 1, and 0.7K , respectively) were in the same order as those obtained in single resistor circuits. The authors attributed the origin of the errors to the fact that all of them were based on the simple exponential approximation. More recently, Kaliyugavardan et al. (28) proposed a method for linearization of thermistor response using series-parallel resistors based on a new four-constant curve fit method, which resulted in a temperature-to-frequency converter that provides accuracy better than 0.2K . The same researchers obtained even more accurate results by using the circuit described in Fig. 6, which works essentially as an astable multivibrator. Experimental results obtained using a standard thermistor in the range of $35\text{--}95^\circ\text{C}$ revealed a peak error less than $\pm 0.1\text{K}$ (29). Recently, a signal-conditioning circuit by generating a compensating, pseudologarithmic response function was proposed (30).

If the data are to be digitized and processed digitally, as soon as possible, it probably makes sense to perform any needed linearization in the digital domain. The techniques used in this case allow linearization to be done much more efficiently and accurately in software, and eliminate the need of tedious manual calibration using multiple and sometimes interacting trimpots. The principal techniques involve look-up tables and computational algorithms (20,31,32). A look-up table may be constructed, for example, by using a read only memory (ROM) hardwired to the analog-to-digital converter output. Each level from the converter corresponds to an address in ROM, and the word stored in that address is the linearized value. It can be constructed by using the device characteristics, available from the manufacturer. The Steinhart-Hart equation can be used to create the table, which implements a third-order linearization formula that provides high accuracy. If memory is limited, and the measurement is made infrequently, but rapid mathematics is available (as, e.g., in digital signal processing systems), a mathematical function that approximates the inverse of the nonlinear relationship, or the difference between the ideal signal and the actual signal, can be derived and stored in program memory. Then, whenever the measurement is made, the processor computes the correct value, based on its mathematical relationship to the measured input variable (23). In system

including microcontrollers, in many cases the mathematical functions may contain complex polynomial and exponential functions, placing a great burden on the program memory, RAM, and execution speed of most low cost devices. Digital piecewise linear interpolation may be a good choice for sensor linearization in such systems due to its fast execution speed, reduced program memory requirements, and easy of implementation (33).

ELECTRONICS FOR TEMPERATURE MEASUREMENTS

In the circuit project, simulation and analysis environment, SPICE subcircuits for thermistor modeling are useful, allowing for a realistic simulation of thermistor parameters for all standard analysis [transient, alternating current(ac), and dc]. Useful subcircuits have been described by Keskin (14), Hagerman (34) and Wangenheim (35), and are also commercially available (<http://www.catenauk.com>; <http://www.intusoft.com/products>). As discussed earlier, there are a variety of circuits in which thermistors may be used for temperature measurements. Caution must always be taken, however, to insure that the power dissipated in the thermistor is held at a minimum and that the current flow is insufficient to cause self-heating, since temperature measurements require that the thermistor be operated in a zero-power condition. The most common technique implies the use of a constant current source, and the measurement of the voltage developed across the thermistor.

Current Sources

In the section dedicated to the thermal characteristics of thermistors, it was shown that the use of current source

would prevent thermal runaway in thermistors. The simplest circuit that can approximate a current source is a high voltage source with a high resistance connected in series (voltage divider), as can be seen in Fig. 7. In this circuit, the output voltage is taken across the fixed resistor, and, the higher this resistor in relation to the thermistor resistance, and the higher the voltage, the closer this circuit will conform with an ideal current source. From the plot of the output voltage (Fig. 7b) it can be observed that there is a range of temperatures where the circuit is reasonably linear with good sensitivity. However, this simple circuit does not act like an ideal current source, since modifications in the thermistor resistance introduces alterations in current. An even better approximation to the desired current source would be obtained using standard circuits based on operational amplifiers (16,36). Integrated current sources are also useful, allowing for the configuration of regulated current sources of varying magnitudes. Fig. 8 shows a typical example, which is based on a device containing two low current regulators (37). One of current regulators supplies $100\ \mu\text{A}$ to the thermistor. The temperature of the thermistor is converted into a voltage that is increased by R_3 , filtered by R_2 - C_1 and amplified by U_{1B} . The second current source is used to provide the reference voltage in combination with R_1 and U_{1A} . This circuit is a useful framework for thermistor temperature measurements using analog-to-digital converters (37).

Wheatstone Bridges

The wheatstone bridge is a widely used means of measuring temperature using thermistors, since the bridge aids the linearization of the NTC (Fig. 5). The condition for the

Figure 7. Simple series circuit to approximate a constant current source (A) and corresponding output voltage (B).

balance of the bridge is $T_1R_2 = R_1R_3$. In a normal operation, R_3 is usually a variable resistor that is used to zero the bridge. If the bridge is excited with a constant dc voltage, the bridge output may be displayed in a dc meter, calibrated directly in temperature units. In medical care, it is often necessary to accurately determine very small temperature differences. For example, it may be necessary to measure the difference in temperature between two regions of an organ. In cases involving differential temperature measurements, matched thermistors are placed in the two voltage dividers. In Fig. 5, the second thermistor replaces R_3 . With this configuration, temperature differentials as close as 0.001°C can be readily detected.

Temperature-to-Frequency or Temperature-to-Time Interval Converters

For applications in which digital processors or microcontrollers are used for data acquisition and signal processing, the transducer response must assume a form suitable for conversion to digital format. Temperature-to-frequency or temperature-to-time interval conversions are convenient methods to measure temperature in this case, since they permit an easy and low cost interface, no ADC is needed and only one bit of input is necessary (6). Another advantage is that the optical isolation circuits used in this kind of application presents lower cost than that used in linear systems. Fig. 9 shows two simple circuits in which the frequency of oscillation varies with the temperature. Because a thermistor resistance varies with temperature, the RC time constant will change accordingly. And since the 555 timer determines the frequency corresponding to the RC time constant, the actual resistance is proportional to the number of counts recorded by the 555 timer (Fig. 9a). The frequency, or the number of counts in a given time window, can be easily converted to a temperature value (38,39). In the circuit described in Fig. 9(b), the thermistor is placed in the feedback loop of a hysteresis-based oscillator, and the output frequency is related to temperature,

according to the following relation (6):

$$f = \frac{\ln[(1 + \gamma)/(1 - \gamma)] \exp(\beta/T_0) \exp(-\beta/T)}{2CR_0} \quad (20)$$

where R_0 and C determine the nominal frequency and $(\gamma = R_2/(R_1 + R_2))$ enables small adjustments. Note that in both circuits described in Fig. 9, the frequency of oscillation varies nonlinearly with the temperature. Linear variations of temperature to frequency can be obtained using the circuit described in Fig. 6. Another example is seen in Fig. 10 (15), where the differential output of a bridge circuit employing an YSI 44018 linearized thermistor is amplified by an AD522 instrumentation amplifier, and converted to frequency by a 452L 100 kHz full-scale V/F converter. The circuit operates in a temperature range of 0–100 °C with accuracy to within 0.15 °C. The pulse transformer connected to the collector of the 2N2222A provides galvanic isolation.

Low Cost Systems

In handheld applications, accurate temperature measurement can easily be accomplished by interfacing a Wheatstone bridge including a thermistor and a digital voltmeter integrated circuit, as illustrated in Fig. 11. The IC is comprised of an analog-to-digital converter with built-in 3 1/2 digits LCD driver providing resolution of 0.1 °C. This digital thermometer makes it possible to achieve an overall system accuracy of ±0.4 °C from 0 to 100 °C. Anytime more than one thermistor temperature probe must be measured, a scanning digital panel meter may be a useful adjunct. Fig. 12 shows another simple circuit, using a microammeter in series with a potentiometer and a thermistor connected to a potential source. The meter can be calibrated in terms of temperature, providing a system usually used in low cost applications (6).

High Resolution Measurements

Very low modifications in temperature can be sensed by using lock-in amplifiers (40). These amplifiers are used to measure the amplitude and phase of repetitive ac signals buried in noise. It is achieved by their ability of acting as a narrow bandpass filter, which removes unwanted noise while allowing through the signal that is to be measured. The ac frequency of the signal to be measured is used as a reference signal to set the passband region of the filter, and must be supplied to the lock-in amplifier along with the unknown signal. Thus, ac must excite the thermistor. Studying perfusion changes associated with cerebral blood flow, Wei et al. (40) were able to detect temperature changes of 0.001 °C using lock-in amplifiers, Wheatstone bridges and matched thermistors.

Measurements without Physical Contact

Evans and Hajnayebi (41) developed a temperature acquisition system using proximity telemetry. The system consists of two units, a module that can be worn by the patient containing a temperature-to-pulse width converter (astable oscillator), and a handheld interrogator, which incorporates a radio frequency generator and an automatic-gain controlled (AGC) temperature readout (Fig. 13). Usually in

Figure 12. A simple low-cost circuit for temperature measurements based on a microammeter (from Interfacing Sensors to the IBM PC, by W. J. Tompkins and J. G. Webster, 1988, Reprinted by permission of Prentice-Hall).

measuring a patient’s temperature, the clinician must wait until the thermometer probe reaches body temperature and then log the readout. In some patients, however, frequent temperature measurement is essential, as, for example, in severe anemic patients undergoing slow blood flow transfusion where it may be necessary to monitor the body temperature each 15 min, for periods of up to 48 h. In such circumstances, the physical disturbance to the patient becomes extremely unpleasant. The system described in Fig. 13 does not require physical contact, allowing for thermistor to be interrogated by a handheld unit held in close proximity to the patient. Compared with conventional electronic clinical thermometers, such design has an additional advantage, since it does not require a separate display module for each patient.

Systems Based on Microcontrollers

The advent of low cost microcontrollers provides the design engineer new design possibilities for medical temperature measurement. Microcontrollers are comprised of a built-in microprocessor, analog-to-digital converter, RAM, and several digital inputs–outputs. The complete system utilizes the microcontroller, multiplexer, EPROM, digital display,

keypad, and display driver, being programmed in assembler language (www.microchip.com; www.motorola.com). These systems are relatively inexpensive to produce, yet offer high temperature accuracy and various software-controlled outputs (39,42). For example, a microcontroller system utilizing thermistor sensors can monitor the temperature in several locations in a patient. After programming, the microcontroller converts the resistance of the thermistor into a temperature reading by using the resistance versus temperature algorithm based on the Steinhart–Hart equation (33) or a look-up table, as discussed before.

Integrated Circuits

Recently, the electronic industry made available integrated circuits specifically dedicated to use with thermistors (43) and well suited for this task (19). The MAX6691 is a four-channel thermistor temperature-to-pulse-width converter that measures the temperatures of up to four thermistors and converts them to a series of pulses whose widths are related to the thermistors temperatures (43). This device can be readily connected to a variety of microcontrollers with a simple single-wire interface. Operating under the supervision of a microcontroller, the MAX6691 powers the thermistors only

when a measurement is under course. This minimizes the power dissipation in the thermistors, virtually eliminating self-heating. In the intervals between conversions, the MAX6691 falls into a $10\ \mu\text{A}$ (max) sleep mode, where the voltage reference is disabled and the supply current is at its minimum. In handheld healthcare systems, where power is at a premium, it may be an interesting characteristic. These integrated circuits also have internal voltage reference that isolates thermistor from power-supply noise, as described in the functional diagram presented in Fig. 14a.

The AD7711 is an integrated circuit from Analog Devices with signal conditioning and A/D conversion functions that is well suited for temperature measurement applications using thermistors (19). This integrated circuit includes a programmable gain amplifier, current sources and a voltage reference on the chip, allowing thermistors to be excited in either a constant current or voltage mode (Fig. 15a). The reference input is also differential, allowing ratiometric operation on the front end. The component can achieve >16 bits of peak-to-peak resolution and update rates of 100 Hz. Filtering is also provided as part of the $\Sigma\Delta$ process. This on-chip filtering may be useful when transducer excitation frequencies must be removed from the input signal. In addition, the filter profile also provides

(a)

Figure 15. Functional diagram (A) and typical application circuit (B) of the AD7711, 24-Bit Sigma-Delta, Signal Conditioning ADC. Reproduced from Ref. (19) with permission.

notches with 120 dB attenuation that can be placed at 50 or 60 Hz, minimizing line frequency components from the system. An example of the AD7711 use is presented in Fig. 15b. The on-chip 200 μ A current source acts as the excitation for the thermistor and generates the reference for the converter. In this case, the circuit is fully ratiometric, ensuring that changes in the excitation current will not affect the performance of the circuit. The diagram also shows a serial interface to a 68HC11 microcontroller, which may control the A/D converter, take data readings, and run a linearization algorithm.

Personal Computer Interfacing

Thermistors can be integrated to data acquisition systems and an IBM PC or compatible computer, in order to imple-

ment a flexible system for application is medical thermometry (6,44). These PC-based DAQ systems requires some signal conditioning hardware to interface the thermistor to the measurement device, such as a plug-in DAQ board (Fig. 16). The DAQ board or module performs the analog-to-digital conversion. A system to interface the thermistor and its output signal to this stage should include an excitation current or voltage source, signal amplification, low pass filtering and isolation signal conditioning hardware, which serves to electrically isolate the thermistor sensors from the measurement system, protecting the patient. Concerning the last topic, it is important to point out that electrical-safety codes and standards in health-care facilities must always be strictly followed (45). Several of useful circuits to perform these tasks were discussed earlier. A typical plug-in DAQ board has eight to 16 analog

Figure 16. Block diagram of a PC-based DAQ system for temperature measurements with thermistors (courtesy of National Instruments Corporation, Austin Texas, USA).

input channels. External multiplexing systems can be included if it is necessary to expand the number of input channels that can be connected to a DAQ board. The multiplexing system sequentially switches multiple channels to a single-input channel of the DAQ board. Software choices for controlling the data acquisition system include a general purpose programming language (e.g., C, Delphi, or Pascal, under DOS or Windows). Alternatively, the LabVIEW environment can be used to control the system. In this case, special routines for implementing the Steinhart–Hart equation to convert measured voltages from thermistors into temperatures are available.

EXAMPLES OF COMMERCIALY AVAILABLE THERMISTORS AND THERMISTOR PROBES

In the earliest days, thermistors acquired a reputation for being unpredictable and unstable devices, due to problems in manufacture and in application. Nowadays, however, with increased user familiarity with these devices and modern manufacturing technologies, they can be used with a great deal of confidence (15). A large number of companies produce NTC thermistors. Moreover, there is a great variety in the constructional characteristics and parameters of these components, depending on their use. In this section, a survey will be made concerning NTC thermistors for medical use manufactured by some companies. Detailed information can be found in available catalogs of the manufacturers or at the WWW pages listed at the end of this section.

Matched interchangeable thermistors eliminates the need for individual resistance temperature calibration, as well as permits the standardization of circuit components and simplification of design and replacement problems. Honeywell/Fenwall makes devices with interchangeability to within 0.2°C , from 0 to 70°C (Uni-Curve series, Fig. 17a) (10). Highly interchangeable thermistors are also manufactured by Alpha Sensors. These devices present tolerances to $\pm 0.1^{\circ}\text{C}$ over the medical temperature range (21).

The Honeywell/Fenwall LTN (Linear Thermistor Networks, Fig. 17b) series are designed to produce a resistance change or voltage output that varies linearly with tem-

perature (typical maximum linearity deviation of 0.256°C from -30 to 50°C). They consist of one twin thermistor and two precision resistors, and are also available in probe assemblies, providing a sensitivity that is hundred folds greater than that of thermocouples.

The standalone thermistor element is relatively fragile and cannot be placed in a rugged environment. In order to overcome this problem in biomedical applications, thermistor probes, which are thermistor elements embedded in protective tubes, are widely used. For example, Fig. 17c shows a pediatric probe for oral or rectal use (Ysi 423) with the sensor located at the tip of a semiflexible nylon tube. These probes can be disposable (Ysi 4400) or reusable (Ysi 400 ou 700). When disinfections are critical, autoclavable probes are also available for skin, esophageal, or rectal use in adult or pediatric measurements (Ysi 400AC probes, Fig. 17d).

For research or medical applications requiring small size and rapid response, as, for example, long-term subcutaneous measurement, thermal dilution, and flow measurement studies, Ysi manufactures catheter probes with time constant of 0.2 s, electrically isolated and operating in the temperature range of 0 – 70°C . Honeywell/Fenwall manufactures Small Bead Thermistors, that offer ultrafast time response (T.C. 1 s maximum) and are highly sensitive to electric power ($\delta = 0.1 \text{ mW}\cdot^{\circ}\text{C}^{-1}$ minimum). They are suited for usage in low heat capacity applications and their micro size (0.36 mm outer diameter) makes them adequate for using in extremely small assemblies, (e.g., catheter and hypodermic needles). In addition, they are also adequate for used in self-heat applications. If a standard probe does not fulfill the needs, custom design is available by several manufacturers (please, see WWW pages at the end of this article).

SOME FIELDS OF CLINICAL APPLICATIONS OF NTC THERMISTORS

As pointed out before, thermistors are probably the most widely used transducer for medical temperature measurements. Their characteristics have been contributing to

Figure 17. Examples of thermistors commercially available. Highly interchangeability devices (Uni-Curve® series) (A), linear thermistor networks (LTN® series) (B) (courtesy of Honeywell International Inc. 101, Columbia Road Morristown, NJ 07962, USA). facilitate clinically difficult measurements, that includes testicular temperature measurements in reproductive medicine (46), hypothermia (47), transcutaneous measurements during cardiopulmonary bypass (48), conti-

nuous monitoring of preterm infants (49), and personal heat strain monitoring in occupational medicine (50). However, beyond their utility in temperature measurements, these devices have found widespread use in a variety of

systems for clinical and research applications to measure flow, thermal conductivity and diffusivity of biomaterials, and to detect the presence of liquids. Therefore, this section intends to have a brief discussion about some of these applications, showing the branches of medicine where technology based on thermistor is used, and how this technology can assist each of them.

Cardiovascular Monitoring

Cardiac output, the volume of blood ejected by the heart each minute, is a key parameter in cardiovascular medicine, which is used to obtain diagnostic information about the heart and for continuous monitoring of heart function in critically ill patients. The thermodilution method uses thermistor type catheters to estimate this parameter. The tip of a Swan–Ganz catheter is inserted into a large vein, typically one in the right side of the neck, and advances through the right heart into the pulmonary artery (Fig. 18). Other sites can be used for catheter insertion (e.g., the groin or the arm). A cold saline or a dextrose solution, whose volume and temperature are known, is injected into the blood stream through one of the catheter lumens. The solution mixes with the blood in the right atrium and is diluted as it is carried downstream to a thermistor located at the surface of another catheter lumen. At the thermistor location, the temperature of the blood-injected mixture is measured over a period of time, and then the cardiac output (efficiency) is computed from this temperature–time response data.

At the level of the capillary network, the tissue blood flow (perfusion) is a primary factor in the local transport of heat, drugs, oxygen, nutrients, and waste products. This fundamental parameter holds the key to the diagnosis and subsequent treatment of numerous medical problems. The high sensitivity to small changes in temperature shown by

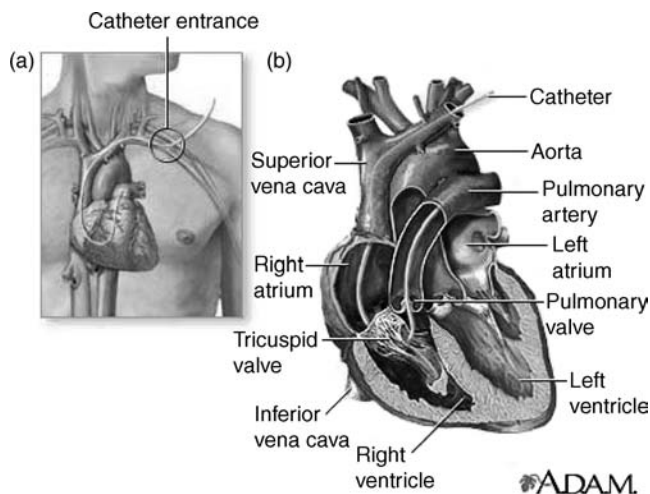

Figure 18. Placement of the thermistor-based catheter in the thermodilution method of estimating cardiac output. Overview (A), and a detail of positioning in the heart (B). This method involves the passage of a catheter into the right side of the heart to obtain diagnostic information about the heart and for continuous monitoring of heart function in critically ill patients. Figure 19. Example of thermal diffusion probe. It can be seen an active, heated thermistor, at the probe tip which produces a thermal measurement field that is dependent of the tissue thermal properties and the perfusion. The passive thermistor, mounted proximal to the probe tip, monitors the baseline temperature variations. Reproduced from (51) with permission of the IFMBE.

a thermistor can be employed to sense the small amounts of heat involved in the thermal techniques developed for the measurement of tissue blood flow (51). Minimally invasive probes constructed around two thermistors are usually applied in these techniques. An example of such probes is presented in Fig. 19. In these probes, one thermistor is used in the self-heat mode, operating as both a heat source and a temperature sensor. Changes in perfusion cause changes in its temperature, which is used as an indirect index of blood flow. As the baseline body temperature fluctuates, a second thermistor with the same size and electrical characteristics is used to measure and compensate for the changes in reference temperature. Systems like these may help clinicians in several application areas, providing early warning for ischemic events, targeting therapy rapidly and accurately, monitoring of patients in organ transplantations, and evaluating tumor and cerebral blood flow (51).

Respiratory Measurements

Obstructive and restrictive respiratory diseases present a huge public health problem. Prevalence rates of asthma and chronic obstructive pulmonary disease are $\sim 4\%$ each. These diseases are characterized by airflow limitation that results from modifications in lung parenchyma and airways. Thermal convection flowmeters measures the local speed of a fluid by measuring the heat loss from a heated element in the flow path (52,53). These instruments are used in respiratory medicine for gas flow analysis, and commonly thermistors are used as the sensing elements. They are also known as thermistor pneumotachometers (16). In these instruments, a small thermistor is placed in the flowing fluid. It operates in the self-heat mode in order to maintain an average temperature above that of the surrounding fluid. This is accomplished using a feedback circuit (16,52,53), as described in Fig. 20. A change in temperature tends to cause a variation in the thermistor resistance, which in turn affects the amplifier output voltage and the current through the sensor. Considering the

Figure 20. Feedback circuit used in thermal convection flowmeters. From *Medical Instrumentation: Application and Design*, by J. G. Webster. Reprinted by permission of John Wiley and Sons, Inc.

amplifier as presenting infinite constant gain and bandwidth, the bridge is always statically maintained balanced, and hence the thermistor resistance and temperature are constant. The sensor resistance is maintained constant equal to R_1 under any operating condition. This circuit operates satisfactory if ambient temperature is constant. If changes in ambient temperature are expected, a second unheated thermistor can be included in the circuit to compensate it (R_t in Fig. 20). One of the main advantages of this configuration is that the high negative gain feedback divides the sensor time constant by a factor equal to the loop gain, improving the frequency response (52). Thermistors lose heat at a rate dependent on the local mass flow, temperature, specific heat, kinematic viscosity, and thermal conductivity of the fluid. Thus, when a patient exhales through a breathing device in which the thermistor is mounted, it is cooled and the circuit needs to provide more electrical power to keep the thermistor temperature constant. This power is proportional to the airflow. When gas flow properties are sufficiently constant, the output voltage of these circuits is a nonlinear function of mass-flow rate only. Linear mass-flow relationships may be obtained using a linearization stage (Fig. 20), based on analog or digital implementations of piecewise linear or polynomial approximations (53).

Since the thermistor is cooled equally for both directions of velocity, the system with a single sensor provides an output of the same polarity, independent of the flow direction. This feature limits the use of these sensors to unidirectional flow, which can be satisfactory in some applications, as for example, in forced expiratory testes. Directional sensitivity can be provided by putting multiple sensors at separate points along the flow.

Speech Therapy

Spoken language is a highly developed skill. It involves the use of parts of the brain that deal with hearing, understanding speech, sound production, and conversion of the thoughts into speech. Patients suffering from cleft palate or similar defects exhibit a type of speech that is characterized by excessive nasal escape of air and by an abnormal resonance compared with normal speakers. This may be treated by plastic surgery, palatal prostheses, speech therapy, or even a combination of these treatments (54). Trained listeners and also experienced therapists have been already used to detect the presence of nasal air escape. These evaluations are, however, subjective and

hinder objective comparisons with previously made assessments, especially if these were made by another therapist (55). In order to allow a qualitative and quantitative analysis of nasal air escape, anemometers based on thermistors were proposed (54–56). Fig. 21 is a cross-section showing details of the device. The thermistor is positioned in the longitudinal path of the nasal airflow. The system uses a Wheatstone bridge; in one arm of the bridge a thermistor is connected, while in the opposite arm a second thermistor is used, as temperature-compensation element. In the practical use of this kind of system, clear differences were obtained when nonnasal and nasal subjects were asked to talk a nonnasal word (cheese) and a nasal word (missing) (54). The system can provide a numerical figure of merit to indicate the extent of the defect and the effectiveness of a treatment, as, for example, palatal training.

Sleep Medicine

One of the most used methods to sense breathing patterns is to detect airflow using a nasal thermistor sensor. The principle here is that of exhaled air ($\sim 37^\circ\text{C}$) being slightly warmer than inhaled air (room temperature), resulting in modifications in the thermistor resistance correlated with the respiration rate. The small size of the thermistor contributes to prolonged, minimally intrusive measurements of breathing pattern, which are particularly important for respiratory surveillance in newborn intensive care, biofeedback studies, and circadian rhythm analysis (57).

These characteristics also made thermistors a traditional device in the diagnostic of sleep-disordered breathing (SDB) (58), which is a widespread disease estimated to be present in $\sim 2\text{--}4\%$ of middle-aged adults. In these patients, the pharyngeal airway narrows with sleep onset, initially producing harsh respiratory breathing with some evidence of inspiratory flow limitation. Then, with further narrowing snoring is generated, and finally there is a complete collapse producing a full obstructive sleep apnea (OSA). Even if upper-airway obstruction is incomplete (hypopnea), increased upper airway resistance will still cause clinical symptoms similar to OSA because of respiratory effort-related arousals. Although rare compared to obstructive events, sleep apnea episodes can also be present in the absence of upper airway obstruction. In this case, known as central sleep apnea (CSA), the apnea events result from a decreasing in central controller output to the inspiratory pump muscles. The classic daytime manifestation of SDB is the excessive sleepiness, although other

Figure 21. Cross-section showing a thermistor in a mask used by speech therapists to evaluate nasal air escape (Reproduced from (54) with permission of the IFMBE).

symptoms, such as unrefreshing sleep, poor concentration and fatigue are commonly reported. Automobile and industrial accidents have been associated with a poor quality of sleep as well as hypertension and intellectual deficits. The severity of the disease is defined in terms of the apnea/hypopnea index (AHI). This measurement reflects the average number of apneas plus hypopneas observed per hour of sleep, and it is usually derived by identifying and counting each respiratory disturbance, with subsequent division of the sum by the number of hours slept. This way, scientific and diagnostic studies of sleep-disordered breathing are critically dependent of the performance of the measuring device used to detect abnormal respiratory events. Thermistors usually used in SDB diagnosis presents a long time constant (58). This way, they are not able to provide a good characterization of fast events like hypopneas. The effect of the thermistor high measurement time constant can be seen in Fig. 22, in which a simultaneous acquisition of the thermistor and a fast-responding system were done in a awake subject during spontaneous breathing. Fig. 22 shows that ventilatory details were lost by the thermistor system. This loss can be explained by the lowpass filter action of the thermistor, in which the higher order harmonics of the respiration process are discarded. This characteristic limits the accuracy of the clinical diagnosis based in thermistor in sleep studies, because it may introduce underestimation of hypopneas events. It happens because, during hypopneas, the respiratory flow tends to change from a quasisinusoidal (normal breathing) to an almost square-wave pattern. Similar limitation to describe dynamic respiratory events was also observed for thermistors used to monitor air stream temperatures in

exercising asthmatic patients (59). Recently, Togawa et al. (60) presented a technique that improved the accuracy of fluctuating temperature measurement by thermistors. This technique seems to present a great potential to improve the performance of these devices in the monitoring of fast events, a field still open to research.

Evaluation of the Thermal Properties of Tissue

The evaluation of thermophysical properties of tissue assume importance with the increasing use of hyperther-

Figure 22. Typical signal morphology obtained in studies with an awake subject during spontaneous breathing by the thermistor (bottom trace) and NPR systems (top trace). Note that respiratory details were lost by the thermistor signal (Reproduced from (58) with permission—© 2004, American Institute of Physics).

mia and therapeutic procedures based on heat delivery, such as radiofrequency, microwave, laser, and ultrasound (61). The thermal conductivity and the thermal diffusivity of biomaterials are measured using thermal probe techniques. Various thermal diffusion probe techniques have been developed from Chato's first practical use of the thermal probe (62). Physically, for all of these techniques, heat is introduced to the tissue at a specific location and is dissipated by conduction through the tissue and by convection with the blood perfusion. The similarity of these techniques is the use of a thermistor bead, either as a heat source or a temperature sensor. The probes are usually constructed by placing a miniature thermistor at the tip of capillary tubes. Fig. 23 shows one example of probe assembly (61). Four probes were used with one heated thermistor and three sensing thermistors in three different locations. The distribution of three sensing thermistors orthogonal to the central heating thermistor permits the determination of the directional nature of thermal properties. The probe is positioned invasively within the tissue of interest. Electrical power is delivered to the heating thermistor and the resulting temperature rise is measured by the sensing thermistors. An empirical relationship between the power delivered by the first thermistor and the temperature raise recorded by the sensing thermistors is used to evaluate the thermal conductivity along the line joining each of the thermistors. The delay between the application of a power pulse in the heated thermistor and the temperature pulse in the sensing thermistors is calculated by cross-correla-

tion and used to determine the diffusivity of the material in each direction. This system allowed the authors to measure the thermal properties of a swine left ventricle *in vivo*, as well as to investigate the effect of ablation. The thermal conductivity and the diffusivity of the tissue dropped after ablation. These data will help to generate three-dimensional (3D) thermal models of the ablation process.

Geriatrics

In the geriatric setting, the urinary incontinence is present in 7–15% of the elderly. The prevalence in elderly living in chronic care hospitals and nursing homes is considerably higher, up to 62% (63). The high sensibility and small size of the thermistor contribute to its application in the management of urinary incontinence, allowing for the development of monitors that can help to reduce elderly reliance on incontinence pads, both improving their quality of life, and reducing the cost of the treatment (64). These monitors are based on the changes in temperature produced by the urinary incontinence event, being developed for long-term ambulatory monitoring (63,64) and for home healthcare (65).

INTRODUCTION

Accurate temperature measurement is of utmost importance in many medical, biological, and biomedical applications. Technological development has increased both the performance and the range of equipment for temperature measurement, but at the same time the appetite for better measurements has increased as well. Opposite to what might be expected, this in fact increases the demands on the choice and especially the use of equipment for temperature measurement, as aspects associated with the particular application becomes relatively more important.

Despite the large variety of sensors and associated instrumentation, there is a very limited amount of principles or “physics” behind the different sensor types, at least when the most widely used sensors are considered (1); thermocouples, thermistors, and resistance based sensors (e.g., Pt-100). A thermocouple is an active sensor meaning that by itself it can give rise to a detectable signal. Thermistors and resistance-based sensors are passive as they demand an outer-power source. What all these sensors

have in common is that they only measure their own temperature. Thus, they interact thermally with the object to be measured, which can give significant measurement errors.

In order to carry out measurements with sufficient accuracy at a reasonable cost, several demands are put on the equipment and its use. All sensors and measurement systems have their benefits and limitations, and this should be taken into account together with the aspects of the present measurement situation when the measurement equipment is chosen. This process often involves analysis of accuracy, stability, time dependence, and environmental factors, for example, exposure to electromagnetic (EM) and thermal disturbances.

THEORY

Temperature Measurement and the Laws of Thermodynamics

Temperature measurement is based on the zeroth and first laws of thermodynamics. The zeroth law, as the name implies, was stated after the first and second laws, but it was considered to be of such importance that it was denoted the zeroth law. It states that if two bodies are in thermal equilibrium with a third body, they are also in thermal equilibrium with each other. For a further thermodynamic discussion see Ref. 2. From a temperature measurement perspective, it is interesting to replace the third body by a thermometer, for which the zeroth law can be restated as two bodies are in thermal equilibrium if they have the same temperature even if they are not in contact. The law thus tells us what we know from intuition, namely, that systems of different temperatures and in thermal contact with each others strive to equalize their temperatures. This is a very fundamental statement, although in many situations we must consider other aspects as, for example, heat transfer inside the considered systems and between the system(s) and the(ir) surroundings.

The above discussion emphasizes the importance of the first law of thermodynamics, which states that energy is conserved. In reality, all bodies are exposed to a thermal environment at another and often varying temperature that gives a time-dependent heat flux between the bodies and their environment. The difference and/or the variation in temperature and corresponding heat flux may sometimes be small; often, however, they are significant and can be considered as one of the main sources of measurement errors, which will be discussed in the next section. The principle of conservation of energy does not only cause trouble in the form of measurement errors, it can also be beneficial to use in the frequently used "lumped heat-capacity method" (see, e.g., Ref. 3).

Thermocouples

Thermocouple temperature measurement is based on the electrothermal phenomena known as the Seebeck effect after its discoverer T.J. Seebeck in 1821. If two dissimilar metals are connected in a circuit, as in Fig. 1, a temperature dependent electromotive force (EMF) arises in the circuit. The magnitude of the EMF is dependent on the materials and the temperature at the junctions.

Figure 1. (a) Closed and (b) open thermocouple circuits with conductors A and B and junction temperatures T_1 and T_2 .

Since the junctions are electrically connected and subject to different electrical potentials, a current will flow in the circuit; thus, thermal energy is converted into electric energy (see, e.g., Ref. 4). The current flow makes the Seebeck effect related to the Peltier and Thomson effects (see, e.g., Ref. 5). Peltier discovered in 1834 that if a current flows in a circuit made of two dissimilar conductors as in Fig. 1, one of the junctions becomes cold and the other junction hot. Thomson later found that for a circuit subject to a temperature gradient (heat flux), heat is rejected in any point where current and heat flows in the same direction, and is absorbed where the flows are countercurrent.

If a voltmeter is inserted in the circuit, as in Fig. 2b, it is possible to measure the EMF and relate it to the junction temperatures, as the voltage is dependent on the difference between temperatures T_1 and T_2 . Temperature measurement using a thermocouple is in fact measurement of a temperature difference between the two junctions.

It is important that the voltmeter has a sufficiently high resistance to keep the current small in order to eliminate disturbances related to the Peltier and Thomson effects (see, e.g., Ref. 5). This is normally not a problem, as modern voltmeters have sufficiently high impedance for these effects to be completely negligible.

Before modern measurement systems became available, the thermocouple was normally used by keeping one of the junctions (the reference junction) at a known temperature; typically an insulated ice bath that is very close to 0°C , whereas the other junction (the sensor) was used for temperature measurement. The measured voltage is proportional to the temperature difference between the junctions,

Figure 2. The simplest form of a thermocouple measurement circuit. The sensor measures temperature T_1 , whereas the reference junction temperature T_{ref} is integrated in the measurement system.

and since the ice bath temperature is known, the temperature of the other junction can be determined if the thermoelectric properties of the wires are known.

Today, the reference junction is more or less always integrated in the measurement system. The determination of the reference temperature is normally optimized for the instrument at room temperature (20–25 °C), although temperatures close to this interval can often be used accurately for most instruments. The circuit corresponding to a standard connection is given by Fig. 2, where the reference temperature is measured at the transition between the thermocouple leads (or extension leads) and the instrument connection. For two conductors A and B, the relation between the sensor temperature T_1 , the reference temperature T_{ref} and the measured EMF (voltage, V) follows the equation

$$V = \int_{T_{ref}}^{T_1} S_A(T)dT - \int_{T_{ref}}^{T_1} S_B(T)dT = \int_{T_{ref}}^{T_1} S_{AB}(T)dT \quad (1)$$

where $S_A(T)$, $S_B(T)$ and $S_{AB}(T)$ are the Seebeck coefficients (also called the thermoelectric power–sensitivity) for the respective conductors A and B, and the thermocouple AB. The EMF corresponding to more complex thermoelectric circuits is discussed in depth in Ref. 6.

If a commercial measurement system is not available or a designed circuit for inclusion in a larger system or stand alone is preferred, today there are special-purpose integrated circuits with built-in cold junction compensation (see, e.g., the example in Fig. 3).

Thermocouple Types

All metallic conductor pairs give rise to an electric potential, and thus have the potential to be used as a thermocouple. It is, however, convenient to use one of the standardized thermocouple types that has emerged, which offers obvious advantages, such as compatibility with commercial instruments, predetermined Seebeck coefficients, and a potential–temperature relationship and International Electrotechnical Commission (IEC)-specified tolerance classes.

There are about a dozen types of thermocouples that complement each other in terms of the measuring signal,

temperature range, and tolerance to different environments. Type K is the most commonly used and it is a good compromise of price and performance for many situations, although other types might be the choice for very high/low temperatures, hostile environments, and so on. Perhaps the most important difference between the various types is the output signal determined by the relative Seebeck coefficient of each material. Types S, B, and R contain platinum and are therefore more expensive than the others, but they are also more stable in, for example, e.g., oxidative environments.

There are organizations/national organizations that provide standards for thermocouples, but the standards of the IEC are internationally recognized and should be followed whenever possible. The IEC 584-1, last revised in 1995, contains reference tables and calculation polynomials for the output signals of the standardized thermocouple types as a function of temperature.

THERMOCOUPLE DESIGN

Wire Sensors

In its simplest form, a thermocouple element consists of a pair of wires that are connected together at a measuring junction. The junction must be electrically conducting and can be formed by soldering, crimping, or twisting the wires together, depending on what the situation requires. Wire sensors are mainly used to measure low temperatures in favorable environments. One limitation is imposed by the insulation material [e.g., poly(vinyl chloride) (PVC), nylon, Kapton or poly(tetra fluoroethylene) (PTFE)]. Another limitation is that the measuring junction is exposed to the atmosphere. The PVC insulation can withstand temperatures up to ~ 100 °C, whereas certain ceramic materials are tolerant of temperatures up to 1000 °C or more.

Sheathed Thermocouples

In sheathed thermocouples, the wires are normally insulated by densely packed magnesium oxide enclosed in a metal alloy suitable for the given thermocouple element.

Figure 3. An example of a circuit for temperature measurement using a thermocouple type K. The thermocouple controller AD597 (Analog Devices, Norwood, MA) contains a cold junction compensation circuit, and the OP-amplifier TS912ID (ST Microelectronics, Geneva, Switzerland) amplifies the output “V OUT” so that 0 V equals 0 °C and 5 V equals 100 °C with the present impedances. The thermocouple is connected to the “+IN” and “–IN” connections, and the low pass filtered voltage supply is connected at “V+”. There are several manufacturers of similar circuits; for details see the companies product-specific information.

Disadvantages associated with sheathed thermocouples are their relatively high prices and the absence of very thin sensor. Sheathed thermocouples have several advantages, such as (1) The metal sheathing is hermetically sealed, which makes the sensor useful in hostile environments. (2) It is tolerant to higher temperatures than wire sensor of corresponding size. (3) Sheathing can be easily bent to, and withhold, various shapes. (4) Vibration resistant.

Sheathing is available in different diameters and with exposed, grounded, and insulated measurement junctions (7,8). The exposed junction protrudes from the sheath and the tube is sealed, for example, by glass. The advantage is the shortest possible response time for sheathed thermocouples. However, several advantages of the fully enclosed sheathed thermocouple are lost; tolerance to high temperatures is one example. For the grounded junction, the wires are welded to the bottom of the sheathing tube. This gives a fairly fast response and good environmental protection, but sensitivity to ground currents. The insulated junction is not electrically connected with the sheath, which gives good protection against EM interference, but a slow temperature response.

MEASUREMENT ERRORS

Reliable temperature measurement is dependent on many factors that, more or less, inevitably leads to measurement errors. Consider, for example, a thermal treatment, such as radio frequency (RF) current ablation. During such a treatment, the temperature should ultimately be known in the entire heated area at every instant. However, this is obviously not possible. In practice, the temperature measurement is limited to a few single locations. In some situations, it might not even be possible to measure the temperature in any location inside the treatment area. In such cases, temperature information must be extracted from measurement outside of the treatment area, which gives space, time, and temperature uncertainties.

Insufficient Contact between Sensor and Measurement Object

Surface-mounted sensors are not only particularly sensitive to thermal shunting, but also to errors associated with an insufficient contact between the sensor and the measurement object. Suppose, for example, that a spherical sensor is placed in contact with a flat surface surrounded by air. Only a fraction of the circumference of the sensor will be in contact with the object to be measured, while the rest of the sensor is exposed to the temperature of the air. Thus, it is essential that the maximum possible contact surface be achieved between the sensor and the object to be measured, and/or that the sensor is thermally insulated from the surrounding.

Effects from adjacent hot or cold surfaces are especially treacherous as thermal radiation can effect the sensor temperature over relatively vast distances. An example is measurement of (hot) gas temperature in a chamber with cold walls; the walls will exchange energy with the sensor resulting in sensor temperature that is too low.

Thermal Shunting

A temperature sensor conducts heat, which gives what is called thermal shunting. The problem is particularly marked when the temperature is measured on pipes and other surfaces. The greater the temperature difference, the greater quantity of heat is “drawn out” of the body by the sensor. There is a sharp drop in temperature at the point where the sensor protrudes from the object to be measured. This is caused by a load being imposed on the object to be measured. The temperature drop is greatest when the object to be measured is a poor conductor of heat (low thermal conductivity). To overcome this measurement problem, the point at which the sensor leaves the body to be measured must be at a suitable distance from the measuring junction.

Temperature Gradients and Thermal Conduction

Heat losses through the probe occur when a sensor connects a warm zone with a colder one, especially if the sensor is the easiest path for the transfer of heat. Heat is conducted away from the object being measured to the probe. The heat flux gives a temperature drop and the sensor measures a lower temperature than the true value. Such losses can be effectively countered if we ensure that the thermal conductivity in the object and across the probe tip is much higher than it is along the sensor. In other words, more heat can be transferred to the sensor than conducted away by the sensor sheath.

Response Time

Since the sensor only measures its own temperature, there will almost always be a temperature deviation between the temperature of the sensor and its surrounding. In theory, the sensor temperature asymptotically approaches, but never reaches, the surrounding temperature. For practical purposes, the response time can be regarded as finite, but it can be both negligibly small and cause severe measurement errors.

The response time is defined as the time needed for the sensor to reach some fraction of a stepwise temperature change of the surrounding, often 90% or $1 - (1/e) = 67\%$. However, the response time of a sensor must be accompanied by information about the conditions under which the response time was obtained. The reason is that heat must be transferred from the surroundings to the sensor. This transfer takes some time, and the time needed differs greatly between different conditions, such as still air and stirred water. Too often, information of the conditions associated with a particular response time are left out, making the information useless. The response time is connected to the sensor and its surrounding and not the sensor itself.

Some critical factors affecting the response time of a sensor in contact with a body or medium include the following:

The heat capacity of the sensor. The greater heat capacity and mass, the longer response time.

The heat transfer in the materials. Air gaps and insulation, for example, reduce the heat transfer.

The contact surface between the sensor and the body or medium to be measured.

The response time can change over time; it can become shorter if for example, the junction of a sheathed probe is moved closer the sheath, or longer if, for example, a glue become brittle and porous and thereby gets different heat-transfer properties.

Self-Heating

Errors due to self-heating can be quite important in medical and biomedical applications depending on the small sensors often required (9). Resistance-based sensors and especially thermistors may be substantially affected by this type of error, but thermocouples are not affected as they are active sensors. All these types can, however, be affected by EM interference (see the sections Electromagnetic Interference and Electromagnetic Aspects).

Material Defects and Ageing

All types of thermocouple are subjected to varying degrees of wear and ageing depending on the environments in which they are used. It is therefore essential that all types of sensors are regularly inspected and calibrated. The type K thermocouple is the most widely used, and therefore the best documented (see, e.g., Ref. 7).

Use of Alternative Sensor Materials. Some thermocouples are expensive and it can therefore be tempting to use other materials as extension leads. As explained earlier, however, the Seebeck effect is created throughout the measuring circuit, so the use of other materials having a different Seebeck coefficient can give rise to a faulty output signal (7). There are materials, known as compensating leads, that have the same electrical properties as the thermocouple within limited temperature ranges, but it is always better to use thermoelectric material throughout the circuit. If this is not possible, compensating leads for the type of thermocouple used must be employed.

Alternative Probe/Junction Materials. Other materials are sometimes used for the measuring junction. A typical case is when the thermocouple wires are soldered to a tab, which is secured by screws at the required measuring point. This works if the tab has good electrical conductance and the temperature is the same at both ends of the wire. The wires must be as close together as possible so that they get the same temperature that constitutes the measured value.

Ageing. The ravages of time make their mark on all types of thermocouples. In general the process is accelerated by high temperatures ($\geq 200^\circ\text{C}$), vacuum, and various atmospheres. It is therefore of interest for only a limited amount of medical applications.

At high temperatures, short-range order (SRO) is a hysteretic phenomenon that is based on atomic migration inside the thermocouple, especially type K thermocouples.

Also type S thermocouples, which has wires of platinum–rhodium and pure platinum, are vulnerable to atomic migration. At high temperatures, the rhodium vaporizes and drifts across to the pure platinum wires, which results in a gradual fall in the output signal (see, e.g., Ref. 7.)

Connection Errors

Circuit Break (Open Circuit). A sensor wire has fractured, come adrift, or is making poor contact with the instrument. Modern instruments often trigger an alarm, for example, by Open appearing on the display.

Short Circuit. If the insulation has chafed and a short circuit occurs, a new measuring junction is created. The instrument will then display the temperature at the short circuit point, instead of at the tip of the probe. Sometimes, it can be very difficult to detect this type of error.

Reversed Polarity of Entire Measuring Circuit. If the polarity has been reversed, the instrument will also operate in reverse, that is, a temperature increase will be recorded as a temperature decrease.

Reversed Polarity within the Measuring Circuit. The extension lead must have the same polarity as the thermocouple wires. If the polarity of the thermocouple element is reversed, opposing voltages occur. The reading obtained will then be twice the temperature in the terminal head minus the temperature at the measuring junction.

Double Reversed Polarity. If the polarity of the extension lead has been reversed at both ends, the temperature at the ends will affect the output signal. The reading will be the temperature at the measuring junction less twice the temperature difference between the terminal head and the reference junction.

Electromagnetic Interference

Electromagnetic fields interact with materials inside the field. Thermocouples and other measurement sensors–probes are no exception, and the frequent occurrence of EM fields, especially in the medical–biomedical engineering sector, has contributed to many measurement errors.

The properties of an EM field change greatly with frequency. Interaction with the field is highly dependent on the geometry and the material of objects inside the field, which together with the great frequency spectrum of interest, makes evaluation of measurement interference multifaceted and intricate. Thus it is very difficult to predict and evaluate.

Measurement errors can arise due to direct effects, for example, induced current in the thermocouple wires (10). Remember that 1°C corresponds to $\sim 50\ \mu\text{V}$ for some typical thermocouples. Also, small currents can give significant measurement errors. Induced currents can also heat the wires and the measurement junction, leading to a too high temperature reading. Indirect disturbances can arise, for example, if the inserted probe disturbs the EM field. Such indirect effects are not only associated with metallic probes–material, but plastics as well (11).

THERMOCOUPLES IN MEDICINE AND BIOMEDICAL ENGINEERING

Thermal aspects, and thereby temperature measurement, are important in numerous applications in medicine and biomedical engineering. Thermocouple thermometry is still the dominant technique. Recent publications cover such varying fields as heating of pacemaker leads during magnetic resonance imaging (MRI) (12), estimation of brain protection during cardiopulmonary surgery (13), cryogen spray cooling (14), and thermal treatment using cryotherapy of breast fibroadenomas (15). Although the applications vary over a wide range, many of the fundamental questions are the same.

The following review discusses some applications in medicine and medical devices with a focus on temperature measurement during thermal treatment (treatment of disease and/or symptoms using heat or cold as one of the therapeutic agents). This is one of the major areas of interest for temperature measurement in medicine, and the application involves most of the interesting aspects, problems, and sources of errors associated with thermocouple thermometry. A more thorough review of the use and sources of errors of thermocouples in medicine can be found in Ref. 16, and some practical limitations are discussed in depth in Ref. 17.

Thermal Aspects

Methods, techniques, and equipments of thermal treatment cover a broad spectrum of applications, and the underlying medical as well as physical aspects are often substantially different. Many thermal and temperature measurement considerations are, however, equivalent, which is an important conclusion, as thermal aspects are often the dominant source of measurement errors (see, e.g., Ref. 18).

During thermal treatment, as in many other applications in medicine and elsewhere, it is often difficult to measure the temperature at the most important–interesting location(s). Furthermore, it is rarely a single or even a few temperature values that are solely of interest. More likely it is an entire temperature distribution: the temperature field. The temperature distribution is affected by many factors, and therefore is difficult to predict. During thermal treatment, time, temperature, and individually dependent blood perfusion are the most important and difficult aspects to consider. This is also the situation for other applications associated with human–animal temperature measurement at sites with a heterogeneous temperature distribution. Regardless of the application used, the relation between the measured temperature and the corresponding temperature distribution must always be taken under consideration.

An obvious example is functional neurosurgery using RF thermoablation. During such a treatment, the temperature is increased to 70–90 °C during 60 s in a small volume ($\sim 100 \text{ mm}^3$) surrounding the treatment electrode in order to destroy a malfunctioning tissue area. It is important to monitor the temperature in order to control the therapy, but practical difficulties have so far made intratissue

temperature measurement impossible. The thermocouple temperature reading is instead carried out inside the electrode that inevitably leads to both spatial and temporal temperature errors as both the maximum temperature and the interesting temperature distribution is located outside the electrode (19). The only possibility to carry out the treatment safely and efficiently is to map the temperature reading with the temperature distribution surrounding the electrode; experiments *in vivo*, *in vitro*, as well as modeling and computer simulations, can be useful tools (see, e.g., the review in Ref. 18).

Another major problem from a temperature measurement perspective is large temperature gradients that can give rise to measurement errors associated with uncertainty in probe positioning (20). Temperature gradients of $10^4 \text{ }^\circ\text{C}\cdot\text{m}^{-1}$ and even more are common during thermal treatment. The obvious effect is that an erroneous positioning of only a few tenths of a millimeter in such a steep gradient gives a measurement uncertainty of several degrees. This effect is particularly problematic since it by definition is an uncertainty and thus difficult to predict and compensate for.

Large temperature gradients also give multifaceted thermal conduction effects (21,22) as the probe in general has a different thermal conductivity compared with the measurement object (e.g., tissue). If the thermal conduction is larger in the probe compared with the tissue (as is the normal case), the probe will locally drain heat from the (heated) measurement location affecting the temperature distribution, while the probe itself experiences a temperature different from the adjacent tissue. Both these effects are highly time dependent; rapid temperature disturbances can initially be obtained during, for example, probe insertion and heating onset, although the probe-induced change of the temperature distribution can take much more time. Fortunately, it is possible to reduce the errors associated with these effects. The thermal conduction in the probe relative to the measurement object (e.g., tissue) can be estimated and compensated for, for example, by setting up a computer model that simulates the situation with and without the conduction effects (see the discussion in Ref. 18). Some theory of thermal conduction effects together with analytical, numerical, and experimental results, can be found in Ref. 23.

Electromagnetic Aspects

The use of EM energy for tissue heating purposes makes verification of the EM power deposition important. Since it is difficult to measure and model the EM distribution in general heterogeneous tissue and to obtain from this information an estimate of the corresponding heating effect, a more straightforward approach is by direct estimation of the heating deposition outgoing from the temperature measurement. This has been carried out using thermocouples in order to obtain information of the specific absorption rate (SAR), for example, in deep body regional hyperthermia (24).

When a probe is inserted in an EM field, a field perturbation followed by a changed power absorption in the vicinity of the probe might occur. This yields for all EM

fields, but the significance increases with the field strength that can cause troubles in, for example, thermal treatment and MRI. The volume occupied by a metallic material (probes) has substantially different electromagnetic properties compared with tissue. This can substantially change the field locally, and thereby also change the induced heating followed by an increased temperature.

Although thermocouples are not immune to either direct or indirect EM interference, the possibility to use very small sensors (conductor diameter ~ 0.1 mm) may for some applications keep this effect within reasonable or even negligible limits. In addition to the size, the shielding (11), the direction of the wires relative to the EM field (25), and the strength and frequency of the EM field, are all of importance to reduce EM interference. Perhaps the most serious source of direct EM interference is joule heating of the sensor-wires due to induced currents, which can cause heating of the sensor itself, as well as the surrounding tissue (21). Interference can also be reduced by an appropriate design of the measurement electronics and/or suppressed by filters (see, e.g., Refs. 10,16).

INTRODUCTION

The first documented application of infrared (IR) imaging in medicine was in 1956 (1), when breast cancer patients were examined for asymmetric hot spots and vascularity in IR images of the breasts. Since then, numerous research findings have been published (2–4) and the 1960s witnessed the first surge of medical application of the IR technology (5,6), with breast cancer detection as the primary practice. However, IR imaging has not been widely recognized in medicine nowadays, largely due to the premature use of the technology, the superficial understand-

ing of IR images, and its poorly controlled introduction into breast cancer detection in the 1970s (7).

Recently, advances in a couple of related areas have pushed forward series of activities to reappraise the role of IR imaging in medicine (7–12). These advances, including the development of the new-generation IR technology, smart image processing algorithms, and the pathophysiological-based understanding of IR images, will provide a cost-effective, noninvasive, nondestructive, and patient-friendly approach to health monitoring and examination, as well as to assisting diagnosis. These new developments are discussed in detail in this article.

Temperature is a long established indicator of health. The Greek physician, Hippocrates, wrote in 400 bc. “In whatever part of the body excess of heat or cold is felt, the disease is there to be discovered (13).” The ancient Greeks immersed the body in wet mud and the area that dried more quickly, indicating a warmer region, was considered the diseased tissue. The use of hands and thermometers to measure heat emanating from the body remained well into the sixteenth through the eighteenth centuries. Nowadays, we still rely on thermometers a lot when performing health examination.

All the above-mentioned methods are contact based. Since the British astronomer, Sir William Herschel, discovered the existence of IR radiation in 1800, major advances have taken place with IR imaging that do not need direct contact with the patient.

Infrared radiation occupies the region between visible and microwaves of the spectrum. All objects in the universe emit radiations in the IR region as a function of their temperature. As an object gets hotter, it gives off more intense IR radiation, and it radiates at a shorter wavelength (11). The human eye cannot detect IR rays, but they can be detected by using the IR cameras and detectors. Figure 1 illustrates the IR spectral band in finer scale. The boundaries between different IR spectral regions are not agreed upon and can vary. The boundaries that we adopt here are based on Refs. (14–18).

In general, IR radiation covers wavelengths that range from 0.75 to 1000 μm , among which the human body emissions that are traditionally measured for diagnostic purposes only occupy a narrow band at wavelengths of 8–12 μm (19). This region is also referred to as the long-wave

IR (LWIR) or body infrared rays. Another terminology that is widely used in medical IR imaging is thermal infrared (TIR), which, as shown in Fig. 1, covers wavelengths beyond $\sim 1.4 \mu\text{m}$. Within this region, the IR emission is primarily heat or thermal radiation, and hence the term thermography. The image generated by TIR imaging is referred to as the thermogram. The near infrared (NIR) region occupies wavelengths between 0.75 and 1.4 μm . The IR emission that we observe in this region is not thermal (17). Although the NIR and mid-wave IR (MWIR) regions are not traditionally used in human body screening, the new generation detectors have enabled the use of multi-spectral imaging in medicine, in which both NIR (20) and MWIR (21) are observed in different diagnostic cases.

In this article, we discuss IR imaging in medicine across the full IR spectral region with a focus on the thermal IR region, including the pathophysiological understanding of IR imaging, the development of new generation of IR imagers, and the advanced image processing algorithms of IR images.

PATHOPHYSIOLOGICAL-BASED UNDERSTANDING OF INFRARED IMAGING

Infrared imaging is a physiological test that measures the subtle physiological changes that might be caused by many conditions, for example, contusions, fractures, burns, carcinomas, lymphomas, melanomas, prostate cancer, dermatological diseases, rheumatoid arthritis, diabetes mellitus and associated pathology, deep venous thrombosis (DVT), liver disease, bacterial infections. These conditions are commonly associated with regional vasodilation, hyperthermia, hyperperfusion, hypermetabolism, and hypervascularization (19,22–27), which generate higher temperature heat source. Unlike imaging techniques, such as X-ray radiology and Computed Tomography (CT) that primarily provide information on the anatomical structures, IR imaging provides functional information not easily measured by other methods. Thus correct use of IR images requires in-depth physiological knowledge for its effective interpretation.

Human Thermal Models

The heat emanating on to the surface from the heat source and the surrounding blood flow can be quantified using the

Figure 1. The electromagnetic spectrum and the IR region.

Pennes' bio-heat equation (28). This equation includes the heat transfer due to conduction through the tissue, the volumetric metabolic heat generation of the tissue, and the volumetric blood perfusion rate whose strength is considered to be the arteriovenous temperature difference (29). The equation is given as

$$k \Delta^2 T - c_b w_b (T - T_a) + q_m = 0 \tag{1}$$

where k is conductivity, q_m is volumetric metabolic rate of the tissue, $c_b w_b$ is the product of the specific heat capacity and the mass flow rate of blood per unit volume of tissue, T is the unknown tissue temperature, and T_a is the arterial temperature. In theory, given the heat emanating from the surface of the body measured by TIR imaging, by solving the inverse heat transfer problem, we can obtain the heat pattern of various internal elements of the body. Different methods of solving the bio-heat transfer equation have been presented in literature (30,31). Although it is possible to calculate the thermal radiation from a thermal body by thermodynamics, the complexity of the boundary conditions associated with the biological body makes this approach impractical.

One of the biggest hurdles in the diagnosis using thermograms is the various thermal environmental conditions that could affect detection and evaluation to a great extent. A computer model was presented in (32) that aims to simulate the heat-transfer phenomenon within the human body and predict the internal temperature as well as the skin surface temperature, providing a reference model that thermograms taken under different thermal conditions can be converted between each other. Figure 2 illustrates the 16-cylinder-segment model this work is based on as well as the simulated body temperature profile.

Figure 2. Simulated human body temperature profile based on the 16-cylinder-segment model, after the first 60 min. The air temperature and mean radian temperature were maintained at 30 °C for 60 min, then changed to 24 °C and maintained at that temperature for another 60 min. The value in the parentheses is the temperature at the center of the segment. (Redrawn from Ref. 32.)

Figure 3. The thermal-electric analog.

The Thermal-Electric Analogue

Liu et al. (33,34) presented a new method for analyzing a thermal system based on an analogy to electric circuit theory; referred to as thermal-electric analog. This method does not require a direct solution to the inverse heat-transfer problem. Figure 3 illustrates the analogy between thermodynamics systems and the electrical circuit, where a battery with voltage U_S is used to simulate the heat source S inside the human body and the heat loss inside the heat source can be simulated as the heat loss on a resistor R_S . Hence, we can establish the correspondence between the temperature of the heat source and the voltage of the battery, as well as between the heat current and the circuit current. The set of R_i and C_i values correspond to the unit heat resistance and heat capacity along each radiation line. The circuit in Fig. 3 only shows the analogy for one radiation line. If the medium between the heat source (S) and the surface is homogeneous, then the radiation pattern sensed by the IR camera at the surface should have a distribution like Gaussian as shown in Fig. 3. If the medium is not homogeneous, then the surface radiation pattern can be represented as a linear combination of different Gaussian distributions.

This analogy can be used to estimate the depth of the heat source (34), and furthermore, help understand the metabolic activities undergoing within the human body, through a so-called slicing technique. The method has been used in early breast cancer detection and has achieved high sensitivity. It has also recently been used for the diagnosis of severe acute respiratory syndrome (SARS) patients, as reported in (35).

The Abnormal Thermogram Patterns

As mentioned before, one of the biggest hurdles in IR image interpretation is the lack of standardized image handling procedures. The human thermal model used in the section Human Thermal Models is one attempt in solving this problem. Fujimas also did some pioneer work (36) in 1998 by proposing eight thermophysiological expressions to identify abnormal thermogram patterns, referred to as the *thermatomes*.

Angiological *thermatomes*: Abnormal temperature regions caused by organic vascular abnormalities.

Functional angiological thermatomes: Abnormal temperature regions caused by vascular disfunctions.

Neurodermatomal thermatomes: Abnormal temperature bands caused by somatosensory neuronal disorders.

Myotomal thermatomes: Abnormal temperature regions suspected by abnormal muscular blood flow rate.

Metabolic thermatomes: Abnormal hot and/or cold spots caused by excessive and/or lower heat production and blood flow.

Dynamic thermatomes at environmental temperature stress: Regions with abnormal reactions when a patient received an applied thermal load.

Dynamic thermatomes at medication: Regions with abnormal reactions when a patient is given a medication.

Dynamic thermatomes at various kinds of stress: Regions with abnormal reactions when a patient receives a load (various in type).

IR Imaging in Early Breast Cancer Detection

Because IR imaging has been mainly used in breast cancer detection since its introduction to the medical field, in the following, we focus on the potential of IR imaging, especially TIR imaging, in *early* breast cancer detection.

Cancer cells are resulted from permanent genetic change in a normal cell triggered by some external physical agents such as chemical agents, X rays, ultraviolet (UV) rays, and so on. All types of cancer cells have an imbalanced metabolic activity that leads to the utilization of a large amount of blood glucose and the release of large amounts of lactate into blood. In addition, the high metabolic rate of cancer cells causes an increase in local temperature as compared to normal cells. These factors have enabled IR imaging as a viable technique to visualize the abnormality. The IR image provides more dynamic information of the tumor since the tumor can be small in size but can be fast growing making it appear as a high temperature spot in the IR image (37,38).

Many imaging modalities can be used for breast screening, including mammography using X-ray, IR, magnetic resonance imaging (MRI), CT, ultrasound, and positron emission tomography (PET) scans. Although mammography has been the baseline approach, it depends primarily on structural distinction and anatomical variation of the tumor from the surrounding breast tissue (7). Unless the tumor is beyond certain size, it cannot be imaged as X rays essentially pass through it unaffected. Other modalities like MRI and PET scan could provide valuable information to diagnosis, but they are not popularly adopted for various reasons including high cost, complexity and accessibility issues (12). Compared to mammography, MRI, CT, ultrasound, and PET scans that are also called the after-the-fact (a cancerous tumor is already there) detection technologies, IR imaging is able to detect breast cancers 8–10 years earlier than mammography (39,40). Keyserlingk reported in (7) that the average tumor size undetected by IR imaging is 1.28 cm versus 1.66 cm by mammography.

Samples of Other Advanced Interpretations

We would also like to mention two interesting work conducted recently although their influence on diagnosis is yet to be investigated. Alexjander and Deamer (41) propose to study the sound (rhythms and frequencies) made within the human body through the access of the IR frequencies of DNA bases. Imagine if we can “hear” the body, would a pleasing pattern to the ear indicate a healthy subject? Or would different patterns present a sign of a certain disease? Through nonlinear heat transfer modeling, Pavlidis and Levine (42) show that the periorbital blood flow in anxious states can be used to extract subtle facial temperature fluctuation patterns and thus assist in traditional polygraph examination. Perhaps if we go beyond imagination, more exciting applications of IR imaging can come into the light.

NEW GENERATION INFRARED TECHNOLOGIES

Infrared technology owes its origin to military research. Since IR imaging was first introduced to medical diagnosis in the 1960s, most of the IR equipment used has not been specifically designed for the medical market (23). Some of the problems associated with IR cameras at that time, for example, narrow field of view ($<20^\circ$) and low spatial resolution (~ 200 optical lines), although are not issues in military applications, they have affected the effectiveness and accuracy of diagnosis to a great extent. Some recent advances in IR sensor design expect to solve these problems and make IR sensors adequate for medical applications. In the following, we focus our discussion on the advances in the detector technologies, especially the uncooled camera development.

Cooled versus Uncooled Thermal Detectors

To some extent, the main factor that determines which wavelengths are included in which IR region is the type of detector technology used to capture IR radiation (17). The NIR radiations are observed in very similar way as the visible light, except that special IR detectors need to be used. On the other hand, TIR imaging generally requires the use of a cooling system in the form of a nitrogen or compressed air cooling bottle, which contains crystals like germanium whose electrical resistance is very sensitive to heat. Figure 4 shows the two main assemblies of the EYE-Z640 cooled FLIR (forward looking IR) camera from OPGAL Optronic Industries Ltd. (43). The detector is InSb cryogenically cooled and needs extra gadgets like the cooler and the dewar to support the cooling system. Compared to uncooled IR cameras, although cooled systems generally present better sensitivity, they consume more power, need a relatively longer cooling down time (e.g., a few minutes), and are more expensive. In addition, the average time that cooled IR cameras will function before failing is very limited (around a few thousand hours). Due to the size, weight, and complexity, these systems were limited to fixed deployment like tripod mounting.

The advance in solid state models has made a new class of sensors possible, the uncooled detector design. In the

Figure 4. EYE-Z640 InSb cryogenically cooled FLIR camera from OPGAL (44) with the electronic card (lower left corner) and the DDCE (upper right corner: Detector, Dewar, Cooler, and Electronics).

1980s, the Department of Defense (DoD) sponsored companies like Honeywell and Texas Instruments (TI) with large classified contracts to develop uncooled IR detector technology (45). Honeywell’s microbolometer and TI’s pyroelectric sensors are both successful deliverables from these programs. In 1999, the Defense Advanced Research Projects Agency (DARPA) issued a Broad Agency Announcement (BAA) (46) that solicits proposals for increasing the performance of the uncooled IR sensors to their theoretical limit. The objective for the thermal sensitivity is set at <10 mk with the pixel size less than or equal to 25 μm. As far as the array size, high performance arrays for long-range systems can be as large as 960 × 1280 elements, while arrays for microsensors may be as small as 240 × 320 elements (46).

Compared to other uncooled IR detector technologies, like ferroelectric and pyroelectric, microbolometer sensors are less expensive, providing higher dynamic range, broader spectral range, and lower cross-talk. Therefore, this type of uncooled sensors are more popularly used, especially after DoD declassified the microbolometer technology in 1992.

The microbolometer technology, which is thermalelectric in nature, converts IR energy to a change in resistance. Each microbolometer detector consists of a silicon nitride microbridge that lies above a silicon substrate and is supported by silicon nitride legs, as shown in Fig. 5. A bolometer is a thermal detector that is deposited on the bridge. When heated by incoming radiation, the bolometer detector can result in a temperature rise that is sensed as a change in the element resistance.

Figure 5. The microbolometer detector layout.

Figure 6. Bioyear’s PRISM 2000 thermal metabolic imaging system (Left: Gantry that hosts the FLIR camera. Middle: Console. Right: Bed). (Courtesy of Bioyear, Inc.)

Because the uncooled cameras do not require a cooling system, they are much lighter, smaller, more reliable and less expensive compared to the cooled cameras. Currently, the uncooled cameras are approaching to the thermal sensitivity of the cooled ones (0.05° or 0.02 °C of uncool vs. 0.01 °C of cool) and are very popular in breast imaging. Figure 6 shows the PRISM 2000 Thermal Metabolic Imaging system manufactured by Bioyear, Inc. (47), in which a FLIR microbolometer detector is installed on the gantry. The detector consists of 320 × 240 pixels with a sensitivity of 0.05 °C.

Although we have listed quite a few advantages of cooled IR cameras, the competition between uncooled and cooled detectors continues, especially with the recent development of the deeply cooled QWIP (quantum well photodetector) detectors. Wiecek conducted a brief comparison (48) between uncooled thermal detectors and QWIP and discussed the limits in both technologies.

Three Generations of Development

Since its first appearance, the development of thermal imagers has gone through three generations of evolution.

The first generation thermal imagers were fielded in the 1970s. They use a single detector or small-size linear array detectors. In order to generate the picture, two scanning mirrors are used. This generation imagers generally have the white out problem (or over saturation over high intensity sources). Although mechanical brightness controls are used later to address the problem, the images still lack clarity.

Second generation imagers appeared in the 1980s. They use a relatively larger linear array (~120 elements) or small two-dimensional (2D) focal plane array (FPA) (~64 × 64 elements) and the scanning mirrors are still used to generate the picture.

Third generation imagers upgrade the size of the 2D FPA a great deal, some of which contain as many elements as 1024 × 1024. In addition, the image processing capabilities are integrated on the FPA, hence the so-called on-chip image processing. According to Xenics’ definition (49), FPA is a matrix of detector cells that attached to a semiconductor chip. Each cell is responsive in IR wavelengths, in which it absorbs IR radiation, converts it into electrons, and sends a voltage signal in response to form an image. The FPA can capture multicolor images and brings great advantages to image capturing, including emissivity correction, lower

atmosphere influence on the temperature measurement, and so on. The third generation does not use mirrors that largely improves the image quality as the less moving part in the camera, the more reliable the system, and the less mechanical noise. Currently, the third generation FPA detectors can capture wavelength from 3 to 5 or 8–12 μm .

One of the most important features that distinguishes the third generation design is the employment of the time-delay integration (TDI) technique for image integration and enhancement. The TDI is a specialized detector readout mode. Instead of reading out the entire chip as a single large image, the image is read out continuously, line by line from the bottom of the detector chip. If the readout rate of the detector and the velocity of the object being imaged matches each other, then there will not be motion blurs.

Smart Image Processing Approaches to IR Images

Computer-aided diagnosis (CAD) has been playing an important role in the analysis of IR images, as human examination of images is often influenced by various factors like fatigue, being careless, and so on. The detection accuracy is also confined by the limitations of human visual system. On top of all these factors, a shortage of qualified radiologists also put an urgent demand on the development of CAD technologies. Currently, research on smart image processing algorithms on IR images tends to improve the detection accuracy from three perspectives: smart image enhancement and restoration algorithms, asymmetry analysis of the thermogram including automatic segmentation approaches, and feature extraction and classification.

Smart Image Enhancement and Restoration Algorithms

One of the problems with thermograms that has put IR imaging in a somewhat disadvantage situation is its lack of resolution due to blur compounded by rather high levels of noise. Snyder et al. (50) developed an algorithm to increase the effective resolution of thermograms by a 2:1 ratio while at the same time removing the noise and preserving edges in the image. This algorithm is based on a minimization strategy known as mean-field annealing, which takes into account processes of blur, noise, and image correlations, to make an optimal estimate of the missing pixels.

MIT's researchers attempt to enhance the resolution of IR images through another route. The Minimally Invasive Optical Biopsy System developed at MIT (51) uses IR light in conjunction with an intravenously injected dye and special computer software to create a clear, high contrast image that could easily allow physicians to detect breast masses and determine if they are benign or malignant.

Kaczmarek and Nowakowski (52) proposed the use of active dynamic thermography (ADT), commonly adopted in nondestructive testing of materials, to further enhance the image quality. ADT analyzes thermal transients after the application of external thermal excitation. Some preliminary results have shown the promise of this approach.

Asymmetry Analysis

Making comparisons between contralateral images are routinely done by radiologists. When the images are rela-

Figure 7. Case studies from Meditherm (53).

tively symmetrical, small asymmetries may indicate a suspicious region. From the human thermal model depicted in Fig. 2, the symmetry in temperature distribution between the left and the right part of the human body is very obvious. However, these small asymmetries might not be easy to detect and it is important to design an automatic approach to eliminate human factors. Figure 7 shows four case studies on how asymmetric thermal signatures have indicated different types of disease. These studies are originally conducted by Meditherm (53). Figure 7a shows a patient with complex regional pain syndrome (CRPS) in the right foot, which is developed after a fractured calcaneum 18 months previously. The thermogram indicates the right foot is 3.7 $^{\circ}\text{C}$ colder than the left foot. It is reported from the same study that some cases of CRPS are misdiagnosed as psychological or hysterical pain states but thermography is able to show characteristic changes. Figure 7b shows a patient with right knee surgery followed with a painful effusion in the early post operative period. In this case, thermography is able to confirm a significant inflammatory reaction and 30ml of blood-stained fluid was aspirated. Figure 7c shows a patient with the left wrist injured three years ago. Thermogram indicates obvious temperature change in the left wrist and hand.

Head et al. (54,55) recently analyzed the asymmetric abnormalities in IR images. In their approach, the image is segmented first by operator. Then breast quadrants are derived automatically based on unique point of reference, that is, the chin, the lowest, rightmost and leftmost points of the breast.

Qi and Head (56) developed an automatic approach to asymmetry analysis in IR images. It includes automatic segmentation and pattern classification. Hough transform is used to extract the four feature curves that can uniquely segment the left and right breasts. The feature curves include the left and the right body boundary curves, and the two parabolic curves indicating the lower boundaries of the breasts. Figure 8 shows the segmentation results of two patient images obtained using the Inframetrics 600M camera, with a thermal sensitivity of 0.05 K. The images are collected at Elliott Mastology Center. The results include the intermediate images from edge detection, feature curve extraction, to segmentation. From the figure, we can see that Hough transform can derive the parabola at the accurate location.

Mabuchi et al. (57) designed a computerized thermographic system, which would produce images of the distribution of temperature differences between the affected side and the contralateral healthy side. Because there is no standard skin surface temperature existed, the system

Figure 8. Segmentation results of two images. (a) results from cancerous patient. (b) Results from normal patient. From top to bottom: original image, edge image, four feature curves, segments.

measures the body-surface temperature of each pixel in the affected area and subtract from it the body-surface temperature of the corresponding pixel in the symmetrically located contralateral healthy area to generate the difference image.

Feature Extraction and Classification

Upon segmentation, different features can be extracted from the segments. Asymmetric abnormalities can then be identified based on mature pattern classification techniques. In this process, feature extraction is crucial to the success of computer-aided diagnosis (58) shows that the high order statistics (e.g., variance, skewness, and kurtosis) and joint entropy are the most effective features to measure the asymmetry, while low order statistics (e.g., mean) and entropy do not assist asymmetry detection. Jakubowska et al. (59) also addressed the importance of using statistical parameters (first and second order) in extracting thermal signatures for asymmetry analysis. From the figure, we observe that the high order statistics are the most effective features to measure the asymmetry, while low order statistics (mean) and entropy do not assist asymmetry detection. Figure 9 compares the effectiveness of the features used to analyze the symmetry of the segments derived in Fig. 8. The first data point along the x -axis indicates entropy, the second to the fifth points indicate the four statistical moments (means, variance, skewness, and kurtosis). The y axis shows the closeness metric we defined as the absolute difference between 1 and the ratio between the feature value from the left segment and that from the right segment. Hence, the smaller the difference, the more

Figure 9. Performance evaluation of different feature elements. Solid line: noncancerous image; Dash line: cancerous image. The five data points along the x axis indicate (from left to right): entropy, mean, variance, skewness, kurtosis.

symmetric the two segments. We observe from the figure that the high order statistics are more effective features to measure the asymmetry than low order statistics (mean) or entropy.

Szu et al. (60) proposed a new paradigm shift that uses at least two dual-band (mid and long) IR imaging cameras operating simultaneously on the patient. This system enables a smart brain-like neural network algorithm, the Lagrange Constraint Neural Network (LCNN), to achieve submillimeter scaling of the close-up breast imaging for the vascular and angiogenesis effects as well as stage-zero detection of ductal carcinoma *in situ*.

The Dynamic Area Telethermometry Technique

To be able to yield objective clinical diagnosis, Anbar et al. (61) proposed the dynamic area telethermometry (DAT) technique. It has been demonstrated to be applicable to any quantitative patho-physiological assessment. The authors demonstrated that using classical fast Fourier transform (FFT) and elementary statistics, the large amount of sequential observations can be reduced to a single quantitative diagnostic parameter without the participation of human experts. Other related work also reported in (62,63).

The above mentioned techniques are just samples of activities reported in recent conferences, workshops, and symposia. Another trend of effort that is worth mentioning is the transition of automatic target recognition (ATR) algorithms developed for military application to medicine. "From tanks to tumors" (64,65) has been the theme of this transition and the rich collection of ATR algorithms that the military has sponsored will greatly improve the state-of-the-art of CAD development.

Concept Validation

Concept validation is an important procedure in the promotion of IR-based breast screening where blind diagnosis

and clinical evidence are necessary. Although there have been a lot of clinical trials conducted so far (66), there has not been a well-designed, standard database created for the purpose of concept validation.

The Advanced Concept Analysis, Inc. located at Falls Church, VA was awarded in 2000 to manage the creation of such a database. The project is sponsored by the Deputy Assistant Secretary of the Army for Installations and Environment (Environmental Safety and Occupational Health), the Office of the Deputy Undersecretary of Defense for Science and Technology (ODUSD/S&T), the Air Force Research Laboratory (AFRL), and the Office of Naval Research (ONR). An Internet-based Virtual Distributed Laboratory (VDL) at AFRL will house >8000 images from >2000 patients provided by E.H.H. Breast Cancer Research and Treatment Center, Baton Rouge, LA and Ville Marie Medical Center & Women's Health Center, Montreal, Canada. Each center will use the collaboration tools and evaluation procedures on the VDL to conduct blind diagnoses of the images provided by the other. Blind test results will be compared with actual clinical evidence stored with the imagery. VDL access may be applied for at (67).

INTERNATIONAL IR IMAGING ACTIVITIES IN MEDICINE

Before this article is summarized let's take a quick scan of activities reported worldwide on the usage of IR imaging in medicine.

United States of America and Canada: Infrared imaging is beginning to be reconsidered in the United States, largely due to the factors discussed early, that is new IR technology, advanced image processing, in-depth pathophysiological understanding of IR images. Currently, there are several academic institutions with research initiatives in IR imaging. Some of the most prominent include National Institute of Health (NIH), Johns Hopkins University (JHU), University of Houston, and University of Texas. The NIH has several ongoing programs, such as vascular disorders (diabetes, DVT), monitoring angiogenesis activity (Kaposi Sarcoma, pain reflex sympathetic dystrophy (68), monitoring the efficacy of radiation therapy, organ transplant) perfusion, multispectral imaging, and so on (69–71). The JHU does research in microcirculation, monitoring angiogenic activity in Kaposi Sarcoma and breast screening, laparoscopic IR images for renal disease. University of Houston just created an IR imaging laboratory to investigate with IR the facial thermal characteristics for such applications as lie detection and other behavioral issues (fatigue, anxiety, fear, etc.) (42). There are two medical centers specializing in breast cancer research and treatment which use infrared routinely as part of their first line detection system, which also includes mammography and clinical exam. These are: EHH Breast Cancer and Treatment Center, Baton Rouge, LA. and Ville Marie Oncology Research Center, Montreal, Canada

China: China has a long-standing interest in IR imaging. More recently, the novel method Thermal Texture Mapping (TTM) (34,35) has added increased specificity to static imaging. It is known that this method is widely used in this country. Introduction of TTM has been made to

NIH. They have been using this method successfully in detection and treatment in Kaposi Sarcoma (associated with AIDS patients). There are further possibilities for high-level research for this method in the United States and abroad. The TTM technology developed by Bioyear (47) has also been adopted in the EHH Center and the Ville Marie Center mentioned above.

Japan: Infrared imaging is widely accepted in Japan by the government and the medical community. More than 1500 hospitals and clinics use IR imaging routinely (70). The government sets the standards and reimburses clinical tests. Their focus is in the following areas: blood perfusion, breast cancer, dermatology, pain, neurology, surgery (open-heart, orthopedic, dental, cosmetic), sport medicine, oriental medicine. The main research is performed at the following universities: University of Tokyo—organ transplant; Tokyo Medical and Dental University (skin temperature characterization and thermal properties); Toho University—neurological operation); Cancer Institute Hospital (breast cancer). In addition, around forty other medical institutions are using infrared for breast cancer screening.

Korea: Began involvement in IR imaging during the early 1990s. More than 450 systems have been used in hospitals and medical centers. Primary clinical applications are neurology, back pain/treatment, surgery, oriental medicine. Yonsei College of Medicine is one of the leading institutions in medical IR imaging research along with three others.

United Kingdom: The University of Glamorgan is the center of IR imaging; the School of Computing has a thermal physiology laboratory which focuses in the following areas: medical IR research, standardization, training (university diploma), "SPORTI" Project funded by the European Union Organization. The objective of this effort is to develop a reference database of normal, thermal signatures from healthy subjects. The Royal National Hospital of Rheumatic Diseases specializes in rheumatic disorders, occupational health (Raynaud's Disease, Carpal Tunnel Syndrome and Sports Medicine). The Royal Free University College Medical School Hospital specializes in vascular disorders (diabetes, DVT, etc.), optimization of IR imaging techniques and Raynaud's Phenomenon).

Germany: University of Leipzig uses IR for open-heart surgery, perfusion, and microcirculation. There are several private clinics and other hospitals that use infrared imaging in various applications. EvoBus-Daimler Chrysler uses IR imaging for screening all their employees for wellness/health assessment (occupational health). InfraMedic, AG, conducts breast cancer screening of women from 20–85 years old for the government under a 2 year grant and IR is the sole modality used.

Austria: Ludwig Boltzmann Research Institute for Physical Diagnostics has done research in IR for many years and it publishes the *Thermology International* (a quarterly journal of IR clinical research and instrumentation). The General Hospital, University of Vienna, does research mainly in angiology (study of blood and lymph vessels) diabetic foot (pedobarography).

Poland: There has been a more recent rapid increase in the use of IR imaging for medicine in Poland since the

Polish market for IR cameras was opened up. There are >50 cameras being used in the following medical centers: Warsaw University, Technical University of Gdansk, Poznan University, Lodz University, Katowice University and the Military Clinical Hospital. The research activities are focused on the following areas: Active Infrared Imaging, open-heart surgery, quantitative assessment of skin burns, ophthalmology, dentistry, allergic diseases, neurological disorders, plastic surgery, thermal image database for healthy and pathological cases and multispectral imaging (IR, visual, X-ray, ultrasound) (52).

Italy: Much of the clinical use of IR imaging is done under the public health system, besides private clinics. The ongoing clinical work is in the following areas: dermatology (melanoma), neurology, rheumatology, anaesthesiology, reproductive medicine, and sports medicine (72). The University of G. d'Annunzio, Chieti, has an imaging laboratory purely for research on infrared applications.

SUMMARY

This article discussed recent research achievements in medical thermography. The objective is to show that due to the advances in IR technology, image processing techniques, and the pathophysiological-based understanding of thermograms, IR imaging is mature to be used as a first line supplement to both health monitoring and clinical diagnosis. We have established a website (73) to facilitate researchers working in the field of medical thermography to exchange research findings. We welcome contributions to enrich this list of collections.

INTRODUCTION

High body temperature has been an indication of illness since the time of Hippocrates, when only the hand could be used to detect heat or cold. The development of thermometers as we know them was a slow process; it was not before the late 19th century that thermometry became an important tool in clinical practice (1). Medical thermometry is routinely used nowadays across the spectrum of medical specialties and in all environments, ranging from the home to the critical care unit. New techniques have

appeared, which allow the measurement not only of the core body temperature, but also of local temperatures or regional temperature distributions, which can be used as health indicators.

Catheterization for thermometry measurements is used in the thermodilution technique for the assessment of the cardiac output and in intracoronary thermography for the prognosis of atherosclerotic plaques. Non-contact infrared thermometry has been used in the screening of travelers for the severe acute respiratory syndrome (SARS), but also in rheumatic diseases, vascular disorders, and the detection of breast cancer. The most extensive use of thermometry, however, is in thermal therapies (hyperthermia and tissue ablation). The physical method used (RF and microwave radiation, lasers or ultrasound), the treatment site, the target volume size, and the anticipated temperature rise determine the temperature measurement technique. In fact, several practical requirements in this area have resulted in the recent technological advancement of medical thermometry.

SPECIFICATIONS OF A TEMPERATURE MEASURING SYSTEM

To achieve a fair comparison among the various temperature measuring systems and to choose the appropriate one for each application, a set of parameters has to be considered. In the following article, these characteristic parameters are defined as closely as possible to the international vocabulary of basic and general terms in metrology (2).

Accuracy is the ability of a measuring system to provide a value of temperature close to its true value. The *resolution* of a temperature measuring system is the smallest change in the value of temperature that causes a perceptible change in the corresponding indication, whereas the *resolution of a displaying device* is the smallest difference between indications of a displaying device that can be meaningfully distinguished. *Stability* is the ability of a temperature probe to maintain its metrological characteristics constant with time.

The concept of *time constant* has been replaced by the *step-change response time of a measuring system*. As a consequence, the response time of a temperature probe is the duration between the instant when the temperature at the input of the system is subjected to a step change between two values and the instant when the corresponding indication settles within 63% of the step change. The factors affecting the response rate of a temperature probe are

1. The mass of the probe surrounding the active temperature sensitive point.
2. The thermal conductivity of materials used in manufacturing the probe (e.g., sheathing, protective, or insulating coating).
3. The mass and conductivity of the measured material.

TYPES OF TEMPERATURE MEASURING SYSTEMS

Liquid-in-Glass Thermometers

Thermal expansion of fluids is a physical phenomenon that can be used for accurate temperature measurements, as is

manifested by the adoption of gas thermometers in the lower ranges of the current international temperature scale, ITS-90 (3). The expansion of solids finds an application not only in thermostats but also in bimetallic thermometers, which are used in industry (furnaces, hot water pipes, vapor chambers). In medicine the liquid-in-glass thermometer has dominated medical thermometry in the last few centuries. However, the use of liquid-in-metal thermometers is not unknown to the chemical industry, as they can present robust and accurate low-cost solutions in a hostile environment.

A liquid-in-glass thermometer comprises a capillary tube sealed at both ends supported in a stem with a suitable scale. At the basis of the tube, a tiny reservoir (bulb) contains the liquid, which expands inside the tube and raises its height, when it gets hot, because glass expands considerably less compared with it. For the liquid to expand without difficulty, the remaining space of the tube is either empty (vacuum) or filled with a compressible gas. The scale on the stem of the thermometer is calibrated in such a way that temperature is proportional to the liquid height. This requirement dictates the use of liquids, for which the volume increases linearly with temperature. Moreover, it implies that the capillary bore has to be of the same diameter. If, due to manufacturing uncertainties, the inner diameter of the capillary tube changes, inaccuracies can occur in temperature measurement.

The choice of the liquid depends on the use of the thermometer and the temperature range of interest. Mercury, alcohol, and some synthetic oils are most commonly employed. Intended use and safety against breakage (e.g., mercury is a toxic liquid) also play a role. The main advantages of liquid-in-glass thermometers are their low cost, user-friendliness, and credibility (their accuracy can be as low as $\pm 0.01^\circ\text{C}$, or even half of this value for laboratory thermometers). Their drawbacks can be summarized in their low resolution, which strongly depends on the operator, their slow response, and their fragility, which calls for an environment free of vibrations. Another disadvantage is that they have to be read locally, because they have to be in good contact with the measured medium (sometimes even fully immersed in it) and, in some situations, their size. Medical applications fall within the temperature range of both mercury (from about -30 to 500°C) and alcohol thermometers (from about -80 to 70°C).

Further details on the use of liquid-in-glass thermometers can be found in Reference 4.

Electrical Resistance Thermometers

The change of resistance with temperature in conductors is related to changes in free electrons' motion and atomic lattice vibrations. In fact, any conductor could be used in principle to build a resistance temperature detector (RTD). However, manufacturing limitations have led to the choice of specific metals, like copper, gold, nickel, silver, and platinum. The increase of resistance with temperature in metals is often expressed in the form

$$R_T = R_0(1 + \alpha T) \quad (1)$$

where R_0 is the conductor resistance at temperature of 0°C , T_R is the conductor resistance at temperature of T (in degrees Centigrade) and $\alpha(^{\circ}\text{C}^{-1})$ is the *temperature coefficient of resistance*, which is characteristic for the metal.

The accuracy of RTDs is very high, especially when constructed with metals like platinum, for which a high degree of purity can be achieved. This is why platinum resistance thermometers are used in defining ITS-90 in the range between the triple point of hydrogen (13.8033 K) and the freezing point of silver (1234.93 K), which comprises the biological temperature range. However, the characteristic curve of resistance against temperature is usually modeled as a higher order polynomial for standardization purposes. Assuming a linear relationship, like above, results in an error smaller than 0.4°C at 50°C in the temperature range 0 to 100°C (5).

The temperature sensor of an RTD consists of a wire wound on a ceramic core or a thick film coated on a ceramic surface. The sensor is encapsulated within a ceramic casing to form the temperature probe. The two ends of the wire are connected to a Wheatstone bridge (Fig. 1). The value of resistance R_V is varied until the indication on the digital voltmeter is zeroed, i.e., until it matches the unknown resistance of the temperature sensor. Therefore, the bridge imbalance, which indicates that resistance changes can be readily calibrated to reflect temperature changes by assuming a linear relationship. One problem with the circuit of Fig. 1 is that lead resistance also changes with temperature. Therefore, other arrangements of the lead wires should be implemented, which directly measure and subtract this latter resistance from the sensor resistance. Inaccuracies in RTDs can occur due to self-heating, because the current, which must be passed through the sensor to measure its resistance, causes ohmic heating. This kind of error can be minimized by reducing the flowing current and ensuring a good thermal contact between the sensor and the surrounding medium. As mentioned, RTDs can be very accurate. However, they have a large time constant and are relatively large in size for biological implantation. Moreover, they are fragile and have a high cost.

Thermistors

The principle of resistance changes with temperature is also used in thermistors. These were introduced to over-

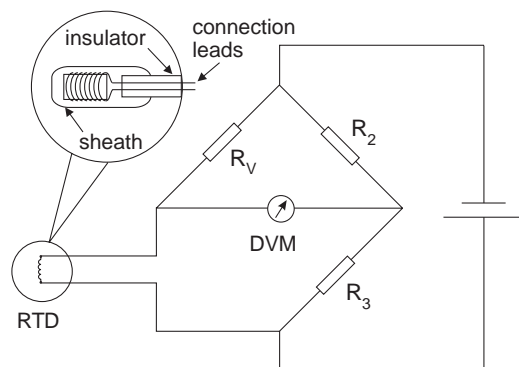

Figure 1. Schematic diagram of an RTD measuring circuit.

come the very small temperature coefficients of the cheaper metals used in RTDs. Thermistors are based on semiconductors, fabricated by mixing metal oxides (usually of manganese, nickel, chromium, and cobalt). The alteration of semiconductor resistance with temperature is founded on a different physical principle as compared with conductors. The exchange of electrons (and holes) from the bound valence band to the mobile conduction band depends exponentially on temperature, giving resistance changes of typically $1\ \Omega/0.01^\circ\text{C}$, whereas RTDs operate with changes on the order of $5\ \text{m}\Omega/^\circ\text{C}$.

Thermistors can present both reduction and increase of resistance with temperature. The change of resistance can be approximated by the relationship

$$R_T = R_0 e^{B\left(\frac{1}{T} - \frac{1}{T_0}\right)} \quad (2)$$

where R_0 is the resistance at temperature T_0 and B is a constant, which characterizes the thermistor material. The values of B are in the range of 3000 to 5000 K. Thermistors are specified by their resistance at 25°C , which ranges from several ohms to some kilohms.

They are manufactured in the shape of beads, disks, or rods with conducting leads attached to them and encapsulated in epoxy resin or glass sheaths. Beads are used most of the time; they are available in very small sizes with a diameter less than 0.1 mm. They have response times in the range of some seconds and an accuracy of ± 0.1 to $\pm 0.5^\circ\text{C}$.

A noteworthy development in thermistor fabrication took place in the mid-1970s, when R. Bowman introduced an elegant design of a temperature probe, which was highly insensitive to radio-frequency electromagnetic radiation (6). The probe had an outer diameter of 1 mm, with a thermistor of 0.5 mm in size, and a response time of 0.2 s. It was based on high-resistance, plastic readout-leads with resistances of about $160\ \text{k}\Omega/\text{cm}$, which secured a heating error in the lines of less than 0.005°C for a heating rate of $1^\circ\text{C}/\text{min}$.

The use of standard photolithography has made possible the creation of miniaturized thermistor probes. For example, the evaporation of amorphous germanium (a-Ge) on a Pyrex glass substrate has resulted in a temperature sensing area of $50\ \mu\text{m} \times 100\ \mu\text{m} \times 0.25\ \mu\text{m}$ with large resistance ($4\ \text{M}\Omega$) that needs only a 20 nA measuring current (7). The accuracy of this probe is close to 0.05°C in the temperature range 0 to 60°C and its response time only 14 ms.

Self-heating is a source of inaccuracy for thermistors, as it is for RTDs. However, the high resistivity of thermistor materials can allow for reductions in the measuring current, down to values that ensure the desired resolution. The high resistivity offers another advantage, namely that of eliminating the need for complicated circuitry configurations, because variation of lead resistance with temperature becomes less important. Thermistors need frequent calibration and may show a drift in their characteristics due to changes of the semiconductor materials. Their main drawback is their nonlinearity.

Thermocouples

The operation of thermocouples is based on the *Seebeck effect* or *thermoelectricity*, or the ability of heat energy to

Figure 2. The Seebeck effect (thermoelectricity) is the physical principle for the operation of a thermocouple.

free electrons from a metal's surface into the free state. When a pair of dissimilar metals is connected into the form of a loop and the junctions are kept at different temperatures, an electromotive force (emf) develops (Fig. 2). If the two junctions have the same temperature, then no net emf will appear. Therefore, if one junction is kept at a constant temperature and the temperature of the other is varied, the measured emf will be proportional to the temperature difference of the two junctions.

Many thermocouple material combinations are listed by Kinzie (8). The combination determines the magnitude and the polarity of the resulting emf. The criteria for selecting a thermocouple can include cost, temperature range, chemical stability, physical properties of the measured medium, and duration of measurement. The most commonly used metals for the construction of thermocouples are rhodium, copper, iron, nickel, chromium, and aluminum, as well as some of their alloys. Some metal combinations are standardized and designated by a letter (*T, J, E, K, N, B, S, R*).

Thermocouples of the *T, J, E,* and *K* types operate in temperature ranges, which include the temperatures of biological and medical interest. The first three types are assembled with constantan (an alloy of nickel and copper) as one of the metals. Although they have lower stability than other thermocouple types, they are inexpensive and show good linearity and moderate and sensitivity (30 to 50 $\mu\text{V}/^\circ\text{C}$) in the biological temperature range. Their dimensions can be very small. Two metal wires of some microns in diameter (70 to 140 μm in practice) are insulated (in PVC, Teflon, or glass fiber) and connected at their distant end (Fig. 3) to form the measuring (primary) junction, which is in the size of the two wires combined. The small

Figure 3. Schematic diagram of a thermocouple measuring circuit.

size of the wires and junctions allows for fast response times, especially when encapsulated in a thin sheath. Furthermore, it facilitates the introduction of thermocouples inside a hypodermic needle for interstitial temperature measurements more easily compared with thermistors and RTDs.

To operate a thermocouple, it is necessary to connect it to a voltage-measuring instrument. However, the connection to the readout module is usually achieved through the use of leads, which are made of a metal, different from the ones that make up the thermocouple. In the case of a type *T* thermocouple and copper leads, there is going to be one junction, namely that of thermocouple constantan to copper lead, which will introduce one more thermocouple junction. The advantage of the type *T* thermocouple is clear; for other types of thermocouples, for which none of the metals is copper, two new thermocouple junctions will be created at the connection of terminals to the readout module, whose emfs will be in series with the emf of the measuring junction. Therefore, the temperature of these secondary (Fig. 3) junctions (also called *reference* or *cold junctions*) must be stable and their emfs known to maintain the calibration of the primary junction. Historically, this used to be accomplished by immersing the reference junctions in an ice bath of 0°C , so that the total measured voltage was adjusted to zero when the probe temperature was also 0°C . A more convenient solution, however, is to provide an electronic bridge circuit between the secondary junction and the voltage measuring equipment. This circuit incorporates a resistance temperature device, whose voltage changes with temperature by the same amount as the reference junction, canceling out any variations of the latter (the temperature-sensitive device is connected in such a way that its voltage is subtracted from the emf appearing at the secondary junction).

Sources of uncertainty in temperature measurements with thermocouples include the spurious emfs from external electric and magnetic fields, temperature measurement of reference junctions, cable specifications, and drift and uncertainty of the voltage measuring instrument. Like in the case of RTDs and thermistors, thermal conduction along the metal readout wires gives another source of inaccuracy.

Interesting and practical information on thermocouple thermometry can be found in References 8 and 9.

Fiber-Optic Probes

The use of fiber-optic thermometers is necessary in situations, where electrical insulation for safety or electromagnetic immunity of the sensor is of concern. The most common medical applications for which these requirements are of paramount importance are cancer treatment with microwave or RF hyperthermia, temperature monitoring during Magnetic resonance imaging (MRI) and cardiac output measurement with the thermodilution technique. There are mainly three reasons for which conventional thermoelectric devices (RTDs, thermistors or thermocouples) should not be used inside electromagnetic fields:

1. The incident electromagnetic fields will be perturbed and scattered by the metal parts of the thermometer devices.
2. Currents will flow in the metal parts of the devices, resulting in their ohmic heating.
3. The currents in the devices can lead to spurious readings.

Fiber-optic sensors work on the principles of light absorption, reflection, scattering or interference, as well as with the effect of induced fluorescence. With respect to the implementation of the physical mechanisms, they either operate in the time domain or they involve intensity or wavelength modulation.

The simplest solution to temperature measurement with a fiber-optic probe is the use of a gallium arsenide (GaAs) crystal as the sensor. One implementation uses two optical fibers, a transmitting and a receiving one. The light transmitted by a light-emitting diode, after having been partially absorbed in the GaAs sensor at the tip of the probe, returns to the detecting module in the readout equipment. It is known that some of the light energy that gets absorbed in the crystal is used to raise electrons from the valence band to the conduction band. As the energy gap between the two bands is a known function of the crystal's temperature, the amount of absorbed power can be related to the temperature of the GaAs sensor. A second implementation with semiconductor sensors uses the same crystal and a dielectric mirror (Fig. 4) at the end of a single optical fiber and takes advantage of wavelength, instead of intensity, modulation due to temperature variations. The transmission spectrum of the crystal moves to larger wavelengths as its temperature rises (Fig. 5). This is known as the absorption/transmission shift and occurs because the energy of a photon is inversely proportional to its wavelength. When the temperature of the GaAs crystal increases, reducing the energy gap between the semiconductor's electron state bands, photons with less energy (longer wavelengths) are absorbed, making the transmission spectrum shift toward higher wavelengths. The advantages of this implementation include that the readout is independent of light intensity and, consequently, factors, which usually contribute to the attenuation in optical fibers, such as length, splices, and bending.

One of the first techniques that have been commercialized for fiber-optic probes is that of induced fluorescence. This technique makes use of the change in fluorescence decay time (lifetime) with temperature. At the tip of the probe, a thermosensitive phosphor sensor is located. This

Figure 4. Diagram of a fiber-optic probe.

Figure 5. The absorption/transmission shift with changing temperature in semiconductors.

sensor is stimulated by the red light of a pulsed light-emitting diode and emits light over a broad spectrum in the near infrared region. The time needed for this fluorescence effect to decay depends on the temperature of the phosphor sensor; the higher the temperature, the shorter the decay time. The fluorescent signal continues to be transmitted for some milliseconds through the same fiber back to a detector in the readout equipment, even after the stimulating light from the led is off. The fluorescent decay time is then measured by a multipoint digital integration of the decay curve. The use of the decay-time technique eliminates the need to reference the output light intensity to that incident on the sensor, a significant problem experienced in intensity modulation schemes.

Another approach to temperature measurement with fiber-optic probes is Fabry–Perot interferometry, in which two parallel, partially reflecting surfaces are brought very close to each other to form an optical reflecting cavity, also known as etalon. If the distance between these surfaces (due to different coefficients of thermal expansion of the materials they are made of) or the refractive index of the material between them changes, the reflectance spectra and the interference fringes change accordingly.

Apart from electromagnetic immunity, other advantages of fiber-optic probes include minimal thermal conduction along the probe and small size, down to 0.5 mm in diameter. Their temperature range is very wide, their accuracy can reach 0.1 °C, and their response time is in the order of several hundred milliseconds.

MRI Thermometry

The use of minimally invasive surgery is very attractive due to low costs and high effectiveness. It is usually conducted in the guidance of ultrasound imaging or MRI. Thermal therapies combined with MRI have gained recognition in the recent years and include laser-induced thermotherapy (LITT), RF ablation, hyperthermia, and focused ultrasound. In these techniques, it is not recommended to use temperature sensors with metal parts, due to the reasons described above. Instead, the signals collected to reconstruct the image in the MRI devices can be used to create temperature maps inside the patients in three dimensions.

The effect of temperature on physical parameters measured by MRI devices has been known for a long time; the first study on temperature measurement with such a

device appeared in 1983 (10). This first report was based on changes of the longitudinal relaxation time (T_1). In a space free of magnetic fields, the magnetic orientations of atomic nuclei in a biological sample are directed randomly. Once placed into a magnetic field, these nuclei take two different preferred orientations, aligned with or against the external magnetic field, and the sample becomes magnetized. The transition from the random distribution of the unmagnetized sample to a magnetized state requires some exchange of quantized energy. The process of magnetization is exponential, and the rate at which a sample becomes magnetized is characterized by a quantity known as the *longitudinal relaxation time* (T_1):

$$\vec{M}_z = \vec{M}_0(1 - e^{-t/T_1}) \quad (3)$$

If the availability of the exact energy required to flip the nuclei between their two energy states is low, then T_1 will be long. The energy for changing the magnetic state of nuclei is obtained from molecular motion, and thus, it depends on temperature. At absolute zero, where there is no molecular motion, T_1 approaches an infinite value. In fact, for the hydrogen protons, which are in abundance in a biological sample, the spontaneous state change would take place once every about 10^{25} years. Smaller molecules, like water, exhibit a great deal more motion than larger ones, although one should keep in mind the difference between the freely moving bulk water in tissues and that bound at surfaces of proteins and membranes, which is less mobile. The change in T_1 with temperature can be described by

$$T_1 = T_1(\infty)e^{-E_a/kT} \quad (4)$$

where E_a is the activation energy of the longitudinal relaxation process, k is the Boltzmann constant, and T is the temperature (K).

Temperature measurement with T_1 , using conventional sequences in MRI, suffers from long acquisition times, which would render the technique insufficient for most thermal procedures. Consequently, other sequences are used, like RF-spoiled gradient echo imaging, where the changes in T_1 can be assessed faster, but with limited signal-to-noise ratio (SNR). Another major problem of T_1 temperature measurements is the errors that occur from movement, which call for high-quality image registration.

Meanwhile, new measurement techniques have emerged based on two other parameters known to be affected by temperature, namely the diffusion coefficient and the proton resonance frequency (PRF) of tissue water. It is known that the diffusion coefficient D depends exponentially on temperature, because it relates the random Brownian motion of molecules with the diffusion process:

$$D \approx e^{-E_a/kT} \quad (5)$$

where E_a is the activation energy for water diffusion in this case. The problem with diffusion temperature mapping is that the motion of water in tissues is strongly dependent on the existence of biological structures, e.g., membranes. The permeability of these structures is dependent on temperature, making the diffusion process

nonlinear. Moreover, biological structures of larger dimensions, e.g., muscle fibers or myelin sheaths, lead to the anisotropic diffusion of water, which leads in a tensor for the diffusion coefficient, requiring the determination of its nine elements and long acquisition times.

The most popular technique for MRI temperature measurements is based on the PRF of water. The local magnetic field B_l , perceived by the hydrogen protons in a biological sample, relates to the main magnetic field of the MRI device B_0 , with the following equation:

$$B_l = (1 - \sigma_t)B_0 + \delta B_0 \quad (6)$$

where σ_t is the total screening constant of the proton and δB_0 includes all local deviations from B_0 , which are not temperature dependent. As the total screening constant increases linearly with temperature and the phase distribution in an image volume (slice) depends on the local field distribution, it is possible to obtain temperature information by directly subtracting phase images. According to the Larmor equation, the phase within a volume at temperature T is given by

$$\varphi(T) = \gamma T_E[(1 - \sigma_t(T))B_0 + \delta B_0] \quad (7)$$

where γ is the gyromagnetic ratio and T_E is the echo time of the gradient echo pulse sequence, which is used for the acquisition of the phase images. Therefore, the phase difference between two images at two different temperatures is

$$\begin{aligned} \Delta\varphi &= \varphi(T') - \varphi(T) = \gamma T_E[\sigma_t(T') - \sigma_t(T)]B_0 \\ &= \gamma T_E \alpha \Delta T B_0 \end{aligned} \quad (8)$$

where α is the proportionality constant of linear temperature dependence of σ_t , the value of which has been measured at approximately 0.01 ppm/°C (11). The main advantage of the PRF method is its independence of tissue composition. A potential artifact may arise from the presence of lipids, because the PRF of lipid hydrogen protons is independent of temperature. Nevertheless, lipids can be suppressed in gradient echo imaging by frequency-selective slice excitation. It is clear from equations 7 and 8 that the method is sensitive to changes in δB_0 between image acquisitions, due to drift of the external field, movement of the measured object, or change of magnetic susceptibility.

Comparisons among the three methods of MRI thermometry have shown that the PRF method is the one with higher precision (12). An accuracy of 0.5 °C with an estimated resolution of 0.3 °C could be reached in a heterogeneous human phantom (13).

Radiation Thermometry

The random agitation of electrical loads or dipoles in matter at a temperature above absolute zero is associated with the generation of an electromagnetic wideband noise signal with a spectrum extending from RF waves to gamma rays. *Infrared thermography*, i.e., the recording of the temperature distribution of the body using the IR radiation emitted from its surface, and some millimeters beneath it, exploits the wavelengths between 0.8 and

20 μm . *Microwave radiometry* uses the microwave energy emitted at larger wavelengths ranging from 1 mm to 1 m; this means that temperature is collected from a depth of some centimeters inside the body, requiring a huge amount of data to solve the inverse problem formulated (14).

By definition, a *black body* absorbs all radiation incident on it. Yet, if it is at an absolute temperature T , it emits electromagnetic radiation, which is described by the Planck's radiation law. According to the latter, the power P per unit area emitted into solid angle $d\Omega$ within the frequency bandwidth Δf is given by

$$P = \frac{2h f^3 \Delta f d\Omega}{c^2 [\exp(\frac{hf}{kT}) - 1]} \quad (9)$$

where h is Planck's constant and c is the speed of light. The emissivity ϵ of any surface at a given direction and frequency is then defined as the ratio of the power emitted through the surface to the emissive power through the black-body surface at the same frequency.

The major problem, when measuring temperature with radiation thermometers, is the knowledge of the surface emissivity, which depends on temperature. The techniques for measuring this value are complex and expensive. Apart from the uncertainty in the emissivity value, other sources of inaccuracy include the attenuation of radiation between the target and the thermometer (taking into account humidity and distance), the background radiation present (some of it will be reflected by the measured object) and errors in the radiation detectors. The latter can be either thermal detectors, using the absorbed electromagnetic energy to increase their temperature and sense a change in a physical property, such as resistance or dielectric constant, or photon detectors, which measure the direct effect of incident photons in matter with the excitation of electrons. For example, in a quantum well IR photodetector (QUIP), the incident photons produce electron-hole pairs, which are carried away by an applied voltage, giving rise to a pulse of charge.

Commercial IR cameras have a resolution of about 0.1°C at the biological temperature range and an accuracy of 2% of the temperature reading (in degrees Centigrade). With the use of continuous calibration techniques, the accuracy can reach 0.04°C (15). The most popular and controversial class of radiation thermometers are *infrared ear thermometers* or *infrared tympanic thermometers* (ITTs), which have been in the middle of a debate on both their accuracy (16) and their calibration (17).

More details on radiation thermometry can be found in Reference 18.

Electrical Impedance Tomography

The electrical impedivity (impedance of a unit cube) of tissue decreases by about $1.7\% \text{ }^\circ\text{C}^{-1}$ with increasing temperature, due to changes in ionic mobility (19) inside the intra- and extracellular fluids. Electrical impedance tomography (EIT) gives pictures of the conductivity distribution inside the body. Therefore, it can be used, in principal, to determine any variations induced to conductivity through temperature changes. The results in phantoms and *in vitro* were encouraging (20), despite poor resolution in central

regions, nonuniform sensitivity, and equipment interference.

However, the conductivity change with temperature in the living tissue is more complicated, because it involves temperature-induced changes in the interstitial fluid volume and the cell membrane. As a consequence of thermoregulation, vasodilatation can lead to changes in tissue conductance in the same order of magnitude as the changes due to ionic mobility of electrolytes (21). Nevertheless, *in vivo*, the method correlated with direct temperature measurements within 1.5°C , although large errors ($>5^\circ\text{C}$) did exist (22). The low cost and fast response of EIT are two reasons for which it seems reasonable to continue the effort of improving its application in temperature measurement, in particular for thermotherapy.

Ultrasound

Three methods can be used to estimate with ultrasound temperature changes inside tissues. The first one exploits the time shift of received echoes due to changes in tissue thermal expansion and speed of sound, which result in actual and apparent displacements of scattering regions, respectively. These displacements can be related to changes in temperature $\Delta T(z)$ along the direction of propagation z according to (23)

$$\Delta T(z) = \frac{c_0}{2(a - \beta)} \frac{\delta t(z)}{\delta z} \quad (10)$$

where $t(z)$ is the estimated time-shift at depth z , c_0 is the speed of sound before heating, a is the linear coefficient of thermal expansion, and the coefficient $\beta = (1/c_0)(\delta c/\delta T)$ describes the change in the speed of sound with temperature. It is assumed that the speed of sound varies linearly with temperature up to about 45°C , whereas the term $(a - \beta)$ depends on tissue type. It is clear that the limitation of the above method is the requirement for prior knowledge of the speed of sound and thermal expansion coefficients.

The second method is based on the changes of ultrasound attenuation with temperature, which, however, are more pronounced at temperatures larger than 50°C . Therefore, this technique is a good candidate for temperature monitoring in thermal ablation. The third method makes use of the changes on backscattered energy, which could be as much as 5 dB over the temperature range from 37 to 50°C for individual scatterers (24).

Although temperature measurements by ultrasound are a convenient and inexpensive alternative to MRI, the performance of all of the above methods needs to be evaluated *in vivo*, where sophisticated motion tracking techniques have to be employed to correct for tissue movement.

INTRODUCTION

Tissue ablation (literal translation “removal”) is the destruction of diseased (*pathologic*) body tissue, with the aim to cure a disease. Tissue destruction is achieved by thermal methods, or by application of chemical substances (e.g., ethanol). Thermal methods cause either local heating or cooling of the tissue to lethal temperatures (typically below -40°C , or above 50°C). A number of different physical principles are employed for heating and cooling tissue, such as radio frequency (rf) electric current, microwaves, laser, ultrasound, and cryogenic cooling.

Current clinical applications include treatment of heart arrhythmia, cancer (liver, lung, brain, kidney, bone, prostate), uterine bleeding, varicose veins, and enlarged prostate (benign prostate hyperplasia), with other emerging applications (see Table 1 for an overview). Typically, an applicator is introduced under imaging guidance [ultrasound imaging, fluoroscopy, computerized tomography (CT), magnet resonance imaging (MRI)] into the body, to the treatment site. Then the tissue region around the applicator is ablated, destroying the diseased tissue area.

This article describes physical principles, clinical devices, and applications of the different ablation modalities.

PHYSICAL PRINCIPLES OF TISSUE ABLATION

Thermal Ablation Methods

All thermal ablation methods rely on thermal conduction to some extent to heat or cool a region of tissue near the applicator. The problem of thermal ablation can mathematically be described by following heat-transfer equation:

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot k \nabla T + Q_A - Q_P \quad (1)$$

Energy Q_A ($\text{W}\cdot\text{m}^{-3}$) is applied to the tissue by the applicator, resulting in heating (or cooling) of the tissue. Some energy Q_P is carried away by blood perfusion; depending on tissue type, perfusion may be negligible (e.g., heart), or may have major impact (e.g., liver). The left-hand side of equation 1 describes how local tissue temperature T changes, depending on tissue density ρ and tissue specific heat c . The first term on the right-hand side describes how thermal energy is conducted through the tissue, depending on thermal conductivity k . Different models are available in the literature that approximate tissue perfusion, the

most widely used being Pennes' Bioheat equation (1). In the Bioheat equation, blood perfusion is modeled as a distributed heat sink term, according to

$$Q_p = \rho_{bl} c_{bl} w_{bl} (T - T_{bl}) \quad (2)$$

where ρ_{bl} ($\text{kg}\cdot\text{m}^{-3}$), c_{bl} [$\text{J}(\text{kg}\cdot\text{K})^{-1}$] and T_{bl} are density, specific heat, and temperature of blood, respectively. The parameter T is the tissue temperature, and w_{bl} is the blood perfusion ($1\cdot\text{s}^{-1}$).

Figure 1 shows the heat transfer problem on the example of cardiac radio frequency (rf) ablation.

For thermal ablation methods the resulting zone of tissue death is usually called *thermal lesion*, or *coagulation zone* (for heat-based methods). In cardiac ablation literature, *lesion* is the accepted term. The term lesion should be avoided in tumor ablation applications (though it is used, especially in earlier literature), since lesion is a general medical term referring to a pathological part of tissue (e.g., often tumors are called lesions).

Following each of the different ablation principles will be described. A comparison between thermal ablation methods is given in Table 2.

Figure 1. Heat transfer during cardiac rf ablation. Tissue close to the electrode is heated by resistive heating from rf current. Heat is then conducted thermally into the tissue. Heat is lost due to blood perfusion in the myocardium, due to thermal conduction through the electrode, and from convective cooling due to blood flow in the heart chamber. (From Ref. 2.)

Radio Frequency Ablation. Radio frequency ablation is the currently most widely used ablation method. The rf current in the frequency range of typically 450–500 kHz is applied to the tissue via the inserted electrode (catheter); a dispersive electrode (grounding pad) is required to serve as current return path. Inside the tissue electric current is carried by ions (mainly sodium, potassium, and chloride), that is, the ions oscillate due to the alternating electric field. The ion movement results in resistive heating (joule heating) of the tissue due to ionic friction, with most heat generated at the location of maximum rf current density (typically closest to the catheter). One parameter that is often used to characterize electrode performance is the specific absorption rate (SAR), expressed in units of $\text{W}\cdot\text{kg}^{-1}$. The SAR determines how much mass related power is deposited at a certain location in the tissue. To determine the SAR resulting from a specific rf electrode, we first have to solve the electric field problem to determine the electric field strength E in the tissue. The SAR can then be calculated from the local version of Ohm's law according to

$$\text{SAR} = \frac{\sigma}{\rho} |E|^2 = \frac{1}{\sigma \cdot \rho} |J|^2 \quad (3)$$

where σ is the electrical tissue conductivity, ρ is the tissue density, and J is the electric current density.

Figure 2 shows the tissue temperature distribution around a cardiac rf catheter after 45 s.

Maximum tissue temperature during rf ablation is limited to $\sim 110^\circ\text{C}$; above that temperature tissue water vaporizes, forming an electrically insulating barrier preventing further energy deposition. If too much rf power is applied, tissue around the electrode can char; this area of carbonization is electrically insulating and irreversible. Applied rf power therefore has to be controlled to prevent tissue charring (carbonization). In cardiac applications, maximum temperature is further limited to prevent tissue cavitation from rapidly expanding vapor.

There are three control methods currently used in clinical rf devices:

Power Control. Applied rf power is kept constant throughout the ablation procedure.

Temperature Control. The ablation catheter has one or more thermal sensors (thermocouples or thermistors) embedded in the electrode tip, or at a specified distance

Table 2. Comparison of Heat-Based Ablation Modalities

Modality	Advantages	Disadvantages
Radio frequency	Simple applicator design	Limited by tissue charring Dispersive electrode (ground pad) required Not usable under MRI (rf interference)
Microwave	High tissue temperatures Short application times Constructive interference of microwaves from multiple applicators	
Ultrasound	Directional applicators possible Can be used noninvasively	
Laser	Simple applicator design	Limited by tissue charring
Cryo	Iceball visible under ultrasound imaging Reversible tissue damage (for short application times)	

from the catheter. Applied rf power is controlled to keep the measured temperature constant.

Impedance Control. Applied rf power is controlled depending on tissue impedance, as measured between the active electrode and the grounding pad. Initially, impedance drops since electrical tissue conductivity increases with temperature due to higher ion mobility. As tissue vaporizes, an increase in impedance results. When impedance exceeds a certain threshold, rf power is temporarily shut down to allow vapor to settle, and then reapplied at a lower level. Figure 3 shows a typical time course of impedance during an impedance-controlled ablation procedure.

Microwave Ablation. Microwaves (MW) are electromagnetic (EM) waves in the frequency spectrum from 300 MHz to 300 GHz. During MW ablation, a MW antenna is inserted into the tissue, radiating microwaves into the tissue. These EM waves cause polar water molecules in the tissue to align with the applied alternating electric field. The resulting rotating water molecules cause frictional heating of the tissue. For MW ablation, microwaves

at frequencies of 915 MHz or 2.45 GHz are used due to Federal Communications Commission (FCC) restrictions, with wavelengths in the centimeter range inside the tissue. To determine the SAR during MW ablation, first the Maxwell equations have to be solved to determine the electric field distribution in the tissue. Then the SAR can be calculated using equation 3; note that the tissue conductivity σ is strongly dependent on frequency. Since the propagation of microwaves is not hindered by vapor or charred tissue, much higher tissue temperatures compared to rf (up to 150 °C) can be obtained (3).

Different antenna types have been proposed. The dipole antenna has been commonly used (see Fig. 4); other common antenna types are slot antennas and monopoles (4,5). Note that the SAR of MW antennas is dependent on insertion depth of the antenna, and it is significantly different at smaller insertion depths.

Contrary to other ablation methods, there has not been use of any advanced control methods to adjust applied power during MW ablation. So far, constant power (typically 40–100 W, depending on application) has been used. For MW ablation, impedance match between antenna and tissue is important. If there is mismatch in impedance, significant amounts of power are reflected, resulting in

Figure 2. Tissue temperature (computer simulation) after 45 s of cardiac rf ablation. Catheter is 2.3 mm in diameter, with 5 mm electrode length, and inserted 2 mm into tissue. Note that location of maximum temperature is ~ 1 mm distant from the electrode due to electrode cooling from blood flow in the heart chamber. Outer-most boundary (50°C) marks the thermal lesion boundary.

Figure 3. Typical time course of impedance Z (measured between electrode and grounding pads) during rf ablation. Initially, impedance decreases as electrical tissue conductivity increases from heating. When tissue starts to vaporize around the electrode (arrows), impedance rises. When impedance exceeds threshold (dotted line), power is shut down for 15 s, and then reapplied.

Figure 4. Cross-section of a dipole antenna for microwave ablation. Microwaves are radiated from the gap into the tissue.

undesirable heating of the antenna shaft and cable. Proper matching is complicated by the fact that tissue properties change significantly during heating.

Antenna Arrays. For all thermal ablation methods, the SAR is only significant very close to the applicator; most of the tissue heating is caused by thermal conduction. This can be a disadvantage when large tissue volumes need to be heated, or tissue close to large blood vessels is heated. Microwaves have an advantage in that regard; microwaves from multiple sources can produce constructive interference when the sources (i.e., antennas) are placed accordingly (6). Thereby, large SAR at far distances from the antennas can be achieved. Figure 5 shows the SAR of a square array of four microwave antennas, both for 915 MHz and 2.45 GHz microwaves. Depending on distance of the antennas and wavelength (i.e., frequency), different interference patterns result. An additional way to adjust the SAR pattern is to modify the phase angle at which the microwaves are supplied to the antennas in the array (7).

Ultrasound Ablation. Ultrasound as used in medical applications is typically in the frequency range of 0.5–20

Figure 5. Four dipole antennas are placed in an array 2 cm apart, and driven in-phase at frequencies of 915 MHz (a) and 2.45 GHz (b). The SAR is shown in linear scale (black = maximum). Note constructive interference at array center (*left*), and complex interference pattern with constructive and destructive interference (*right*) due to shorter wavelength at 2.45 GHz. (Images provided courtesy of Deshan Yang, University of Wisconsin-Madison.)

MHz. At high enough intensities, the absorbed mechanical energy results in tissue heating. There are two fundamentally different ways of delivering ultrasound energy to the tissue. Ultrasound can be applied noninvasively from the outside of the body, and focused at the treatment site (High Intensity Focused Ultrasound, HIFU). In addition catheters with integrated ultrasound transducers can be inserted into the tissue, similar to other ablative techniques (Interstitial Ultrasound Thermal Therapy, or Direct Ultrasound Ablation).

High Intensity Focused Ultrasound. Ultrasound has a high penetration depth, and can therefore be applied from outside the body and still reach deep tissue sites. Typically, an array of ultrasound transducers is placed outside the body, and the waves are coupled into the tissue by a gel. The ultrasound waves are focused at the desired location, resulting in high intensity and heating near the focal spot (Fig. 6). The location and depth of the focal spot can be adjusted by modifying the phase difference between the transducer elements. A large area can be ablated by moving the focal spot and “painting” the desired area. The transducer may be attached to a computer controlled mechanical positioning system (8).

Interstitial Ultrasound Thermal Therapy (Direct Ultrasound Ablation). One or more transducer elements are placed inside a catheter. Figure 7 shows the schematics of such a catheter, and Fig. 8 shows achieved coagulation zones at different power levels. The catheter is inserted invasively into the application site, and tissue close to the catheter is heated by ultrasound. Sector transducers that emit ultrasound at angles between 30° and 270° (10) can be used, allowing for directional ablation which is important in certain applications like prostate treatment; on the other hand rf, MW, and laser applicators provide typically uniform heating (axial symmetric) around the applicator. Another potential advantage of direct ultrasound ablation is the use of the transducer elements also for imaging; an ultrasound image from inside the treatment zone can be obtained allowing the monitoring of tissue heating.

Laser Ablation (Laser Interstitial Thermal Therapy, LITT). When high intensity laser light is applied to tissue, the light is absorbed, resulting in tissue heating. The penetra-

Figure 6. Schematic Diagram showing the principle of HIFU. An array of ultrasound transducers emits ultrasound waves into the tissue, which are focused and result in tissue coagulation around the focal point. The location of the focal point can be shifted by varying the phase between the array elements. (Image provided courtesy of Abhijit Sathaye, University of Wisconsin-Madison.)

tion depth is dependent on wavelength, where penetration increases with wavelength. The most widely used laser type, due to large wavelength and penetration is the Nd:YAG laser with 1064 nm wavelength (near-infrared, IR). This laser has a penetration depth of 3–4 mm. A quartz fiber with diffuser element at the tip is used to introduce the laser light to the treatment site. The transmission of the light into tissue changes during tissue heating. After tissue coagulation occurs, transmission is reduced to 69% of normal and further decreases to 15% of normal with onset of carbonization. Control of applied power to avoid carbonization is therefore essential. Typically, either constant power, or temperature feedback control where applied power is controlled so that the fiber tip is kept at constant temperature is used. Unlike most other ablation modalities, laser ablation has the advantage that the fibers are MRI compatible, allowing use of MR imaging (11).

Applicator Cooling. In the first heat-based ablation devices, the size of the achieved coagulation zone was insufficient for many applications like tumor ablation. Even today, there is a trend toward larger coagulation

zones to enable treatment of larger volumes. One successful method that has been applied to virtually all heat-based methods is cooling the applicator (e.g., catheter). In all catheter-based ablation methods, the highest SAR and subsequently highest temperature is obtained close to the catheter. In extreme cases, this can lead to tissue carbonization, which should be avoided as discussed earlier. Applicator cooling is achieved by circulating cooled water inside the catheter. Thereby, tissue close to the catheter is cooled and carbonization is prevented. Furthermore, the location of highest tissue temperature is more distant from the applicator (see Fig. 9). Since maximum tissue temperature is limited (e.g., to ~110 °C for rf ablation), this shift of maximum temperature results in an increase of the size of coagulation zone. The radial dimension of the coagulation zone can be increased by up to a factor of two when applicator cooling is used. Several commercial devices employ applicator cooling.

Cryoablation (Cryotherapy, Cryosurgery). Cryoablation is historically older than other ablative methods, and was introduced in the early 1960s (12). However, it

Figure 7. Catheter for Interstitial Ultrasound Thermal Therapy. An array of four transducers is used, and the catheter is cooled by circulating water. (From Ref. 9.)

Figure 8. Thermal lesion sizes obtained with cooled ultrasound applicator at different power levels. Directional ultrasound arrays are used, which allows for better control of the coagulation zone. (From Ref. 9.)

did not receive considerable interest until the 1990s, when the development of interoperative ultrasound imaging allowed guidance of probe placement and the monitoring of the procedure.

Cryoablation relies on cooling (freezing) tissue to cause injury. Contrary to most heat-based methods, cryoablation relies solely on thermal conduction. A cryoprobe (see Fig. 10) is introduced into the tissue, and cooled by circulating a cryogen inside. Cryogens used for cryoablation include liquified gases, such as nitrogen, argon, helium, and nitrous oxide. Liquid nitrogen has a boiling temperature of $-196\text{ }^{\circ}\text{C}$. Temperatures reached at the cryoprobe are down to $-160\text{ }^{\circ}\text{C}$, resulting in formation of an iceball around the cryo probe. Nitrous oxide has a higher boiling temperature of $-88\text{ }^{\circ}\text{C}$, but has the advantage of being safer in case of leakage into the body compared to other gases.

Cooling with argon and helium is based on the Joule–Thompson effect, which involves expansion of a gas

Figure 10. Internal structure of a typical cryoprobe based on liquid nitrogen (LN_2). The probe has vacuum insulation to prevent freezing of the probe shaft and subsequent destruction of normal tissue. The LN_2 changes phase when it hits the warm metal surface of the probe tip. Thus, a thin film of gas bubbles is formed on the metal surface resulting in lowest temperatures and largest ice ball near the tip. (From Ref. 13.)

through an orifice. The Joule–Thompson effect can produce either heating or cooling, depending on the type of gas, temperature, and pressure before expansion. For cryoablation, argon is decompressed from ~ 3000 psi (21,000 kPa) to ~ 150 psi (1000 kPa), resulting in cooling down to $-186\text{ }^{\circ}\text{C}$ (the boiling temperature of argon). Figure 11 shows a typical temperature distribution in tissue surrounding a cryoprobe.

One advantage of cryoablation over heat based methods is the visibility of the ice ball using ultrasound imaging (14). The interface between the ice ball and surrounding tissue is evident in ultrasound imaging (see Figure 12), and allows real-time monitoring of the ablation procedure.

Chemical Ablation. During chemical ablation a cytotoxic agent is injected into the tissue site to be treated, and diffuses into the tissue from the injection site. The most commonly used agents are ethanol and acetic acid. When ethanol is injected (ethanol ablation or percutaneous ethanol injection) into tissue, it causes cell death by cell dehydration, protein denaturation, and thrombosis of small vessels. Acetic acid has the ability to dissolve lipids

Figure 9. Tissue temperature (T) as a function of distance (D) from applicator. With catheter cooling, location of maximum tissue temperature is moved farther away from the applicator, resulting in an increase in diameter of the coagulation zone. Ablation zone dimensions are indicated by arrows as the regions with temperatures $> 50\text{ }^{\circ}\text{C}$. This image shows tissue temperature during rf ablation (from computer model), but the principle of cooling is applicable to all heat-based ablation methods.

Figure 11. Tissue temperature next to a cryoprobe after 12 min. Outer gray boundary represents the border of the ice ball. Dotted lines are 20 mm apart. (Image provided courtesy of Cheolkyun Kim, University of Wisconsin-Madison.)

(e.g., cell membrane) and possesses a higher toxicity than ethanol.

PRINCIPLES OF THERMAL TISSUE INJURY

Tissue Injury from Heating

The normal range of human body temperature is between 36 and 38 °C; with fever, body temperature can rise up to

Figure 12. Ice ball forming during cryoablation is visible under ultrasound imaging (arrows). (From Ref. 14.)

Table 3. At Elevated Tissue Temperatures Different Effects Take Place Depending on Temperature and Time

Temperature, °C	Tissue Effects
36–38	Normal physiological range
38–42	Fever
>42	Elevated rates of enzyme activity, cell death possible
45	Protein coagulation (after 1–2 h)
50	Protein coagulation (after 2–3 min)
60–100	Protein coagulation (instantaneous)
>100	Tissue vaporization, carbonization

42 °C, which is the maximum temperature a person can typically sustain. Significant cell damage occurs above 42 °C (hyperthermia) with possible cell death, depending on time duration for which temperature is increased (15).

There are several different cell responses to elevated temperature. At low temperatures (42–45 °C), a number of subtle changes in metabolic activity, pH, blood flow, and vascular permeability occur. From ~45 °C protein coagulation occurs after 1–2 h of elevated temperature. Above ~60 °C instantaneous protein coagulation occurs, and above 100 °C tissue vaporization takes place, with possible carbonization at even higher temperatures. Table 3 lists the different temperature ranges and effects on tissue.

Since very high temperatures in excess of 60 °C are obtained during ablative therapies, cell death (necrosis) due to coagulation (i.e., coagulative necrosis) is the most important mechanism of tissue damage; the region of cell death is practically the region where tissue coagulation occurs. From Table 3, we see that we can roughly define the region of cell death (the coagulation zone) as the region where tissue reaches temperatures >50 °C, since ablative therapies have application times of typically between 1 and 30 min. Figure 13 shows a typical coagulation zone in liver tissue, cut right after rf ablation.

To determine exactly whether cell death results at a certain location, the time history of temperature has to be taken into account. It has been shown in many types of tissue that there is an exponential relationship between cell death, temperature, and time. Above 43 °C, the time required to cause cell death is cut in half with each degree centigrade of temperature increase (18). Even though the time may vary between different tissue types, this exponential time–temperature relationship is the same for all tissues. Figure 14 shows the time required for cell death for different types of tissue, plotted on a double-logarithmic scale. The exponential time–temperature relationship can be modeled mathematically by the Arrhenius model. The time–temperature relationship can then be expressed by an isoeffect equation:

$$t_1 = t_2 \times R^{(T_1 - T_2)} \quad (4)$$

where t_1 and t_2 are the treatment durations at treatment temperatures T_1 and T_2 , respectively. The parameter R can be assumed a constant with a value of 0.5 above 43 °C, and 0.25 below 43 °C. Because the onset of appreciable tissue damage occurs at ~43 °C, it has been suggested by Sapareto and Dewey (18) to quantify tissue damage by a

Figure 13. Gross pathology of a coagulation zone created by rf ablation *In vivo* in porcine liver. Liver was sliced right after the ablation procedure. The hyperemic zone contains viable cells.

thermal dose at 43 °C. This thermal dose is expressed as cumulative equivalent minutes at 43 °C (CEM_{43}); that is, a certain thermal treatment has the same effect as keeping the tissue at 43 °C for CEM_{43} minutes. If we set T_1 to 43 °C in equation 4 and allow temperature to be changing with time (as it does during ablative treatments), we obtain

$$CEM_{43} = \int R^{[43-T(t)]} dt \quad (5)$$

Once CEM_{43} exceeds a certain critical value, the tissue can be considered to be destroyed (i.e., ablated). The critical value of CEM_{43} has been measured for many tissues, and is ~340 min for liver; that is, tissue with $t_{43} > 340$ min can be considered to be destroyed. Even though the relationship stated in equation 5 may show inaccuracies in certain cases (e.g., long application times), it is an accurate approximation for the time durations and temperatures that occur during thermal ablation procedures.

Tissue Injury from Freezing

There are two basic mechanisms of tissue injury due to very low temperatures, dehydration and intracellular ice for-

mation (19). In general, extracellular water will freeze before intracellular water. The salinity of the remaining extracellular water increases, resulting in water transport from intra- to extracellular space due to difference in solute concentration. This water transport causes *dehydration* of the cells, and may result in cell death. While mainly dehydration happens at lower cooling rates ($<50 \text{ }^\circ\text{C}\cdot\text{min}^{-1}$), *intracellular ice formation* occurs at higher cooling rates. Formation of ice crystals inside the cells results in damage of cell membranes, organelles, and ultimately cell death. Generally, it is assumed that a minimum temperature of $-40 \text{ }^\circ\text{C}$ is required to ensure cell death.

Other mechanisms assumed to contribute to cell death are loss of blood supply and bursting of cells due to water pouring back into the cells during thawing. Multiple freeze-thaw cycles are typically used during cryoablation to accentuate these effects. An animal study has shown that the iceball boundary visible under ultrasound correlates with the boundary of cell death within 1 mm (20).

CLINICAL APPLICATIONS AND DEVICES

In the following section, different applications of tissue ablation are discussed. The areas where ablative therapies are used most widely clinically are treatment of cardiac arrhythmia and cancer. For each application, we will briefly discuss the clinical background, describe devices, and review imaging modalities used for guidance and monitoring.

Cardiac Catheter Ablation

Cardiac ablation is now a standard treatment method for different types of *cardiac arrhythmia* (i.e., abnormal heart beats) (21). Even though other ablative methods have been investigated, rf ablation is the most widely clinically used technique. Recently, cryoablation systems have become commercially available and are clinically used. Microwave systems have also become available. Other modalities like laser, ultrasound, and chemical ablation are mainly found in the research literature with no commercial devices currently available.

One major difference between cardiac ablation and ablation at other sites is that the catheter electrode is in direct contact with the blood pool inside the heart chamber. High temperatures can result in blood clot formation,

Figure 14. Time-temperature relationship of cell death for different cell types. Note that all cell types exhibit the same exponential relationship (i.e., parallel lines), even though they have different sensitivity (i.e., different times to cell death). (From Ref. 17.)

Figure 15. Overview of rf ablation system for treatment of cardiac arrhythmia. An ablation catheter is inserted through a leg vein, and steered into the heart to the treatment site. The procedure is guided by X-ray fluoroscopy. (From Ref. 22.)

which has to be avoided. Blood flow inside the heart results in cooling of the electrode (see Fig. 1), resulting in varying sizes of thermal lesion depending on blood velocity at the specific location inside the heart.

Clinical Background. Cardiac arrhythmias result from abnormalities in the conduction pathways in the cardiac tissue. The types of cardiac arrhythmias treated by ablative methods can be broadly classified into two categories.

Regular Tachycardias with a Discrete Mechanism. This is the condition of the heart (atrium or ventricle) beating too rapidly, typically at a rate >150 beats·min⁻¹ at rest. In a normal heart, the excitation (and associated contraction) starts at the sinoatrial (SA) node, the heart's pacemaker. Tachycardia results from excitation originating from locations other than the SA node, or from circular conduction involving abnormal pathways. Tachycardia can further be divided depending on where it originates, into supraventricular [above the ventricle, meaning the atria, the atrioventricular (AV) node and the bundle of His], and ventricular tachycardia (within the ventricle or purkinje system). These tachycardias can often be treated successfully with ablation at a single point or small area of the heart.

Atrial Fibrillation. Atrial fibrillation (AF) is the result of disorganized excitation of the atria, resulting in irregular contraction of the ventricles. The blood flow through the atria is hampered, possibly forming blood pools in the atria. Eventually, a blood clot may form that could lead to a stroke or heart attack (myocardial infarct). Atrial fibrillation is the most common type of arrhythmia, with ~2.2 million people affected in the United States, and 160,000 new cases diagnosed each year. Atrial fibrillation appears to often originate with abnormal excitations from the entry points of the heart, most commonly the pulmonary (lung) veins and less often the systemic veins from the body. Continuation of AF may depend on large areas of the atria. Because of the complexity of both the initiation and maintenance of AF, ablation typically requires a much broader treatment area than that for regular tachycardias. Since its introduction in the 1980s, cardiac catheter ablation has become a standard treatment for many of these types of arrhythmias.

Procedure. The ablation and associated electrophysiology study are performed in a specially equipped laboratory. The patient is either anesthetized or awake with sedation to reduce discomfort and facilitate relaxation. Electrodes and sensors attached to the patient report blood pressure, blood oxygen saturation, and electrocardiogram (ECG). Next, the locations where multiple diagnostic catheters and the ablation catheter will be inserted (typically groin and/or neck) are locally anesthetized. The catheters are inserted into a blood vessel, and guided into the heart (see Fig. 15). The physician performs mapping as described below to determine the mechanism of the arrhythmia, and site of ablation. The primary imaging modality used for guidance is fluoroscopy, but other techniques are now used to assist in both guidance and mapping, as described below. The patient is typically discharged a few hours after the procedure, but may be monitored in the hospital overnight.

Devices

Radio Frequency Ablation. Figure 16 shows a typical rf ablation catheter tip with ablation electrode, and mapping electrodes for measurement of biopotentials from the heart. Most rf devices use temperature control, where power is controlled to keep the temperature measured by a thermocouple or thermistor embedded in the catheter tip constant (typically 60–80 °C). Typical application times are 45–60 s.

For treatment of atrial fibrillation, linear (i.e., elongated) thermal lesions are required. Linear lesions can be created by dragging or sequentially moving a standard catheter (Fig. 16), but some special multielectrode catheters can be

Figure 16. Cardiac rf ablation catheter (7F = 2.3 mm diameter) with ablation electrode (large arrow), and mapping electrodes (small arrows).

Figure 17. Cardiac multielectrode catheter for creation of elongated (linear) thermal lesions. Each electrode has two temperature sensors located near the edges for independent control. (From Ref. 23.)

more effective (Fig. 17). To keep all electrodes in the array at ideal temperatures, each electrode is controlled separately with multiple thermocouples placed at the edges of the electrodes.

Cryoablation. Cryoablation has the advantage of potential reversibility over heat based methods like rf ablation. For moderate hypothermic temperatures, tissue function can be restored after thawing. Thus, the correct location of a catheter can be confirmed by freezing at moderate temperatures (cryomapping). If the correct site is found (i.e., the arrhythmia stops or conduction is blocked), a longer freezing cycle with lower temperature is performed to destroy the tissue at that location. Once the tissue starts to freeze, the catheter sticks to the tissue (cryoadhesion), whereas with heat-based methods there is a risk of catheter movement. Other advantages include reduced complication rates compared to rf ablation. There should be minimal risk of tissue perforation, neighboring vessels like the coronary arteries seem to be preserved, and there is minimal risk of thrombus formation. Cryothermal lesion sizes are typically smaller than rf, and application times are longer (~4 min).

Microwave Ablation. Recently, microwave ablation catheters have become available for creating linear lesions (Microwave Ablation System Flex, Guidant, Indianapolis, IN), and are currently in clinical trials for treatment of atrial fibrillation. Microwave ablation has the potential benefits of directional heating, and deeper penetration compared to rf heating.

Cardiac Mapping and Imaging. Before ablation can be attempted, the treatment site in the heart has to be located, which is done by a procedure termed cardiac mapping. During the mapping procedure, local biopotentials known as electrograms are recorded typically from multiple catheters placed at different sites within the heart (Fig. 18). The ablation catheter itself has multiple mapping electrodes to record the electrograms (Fig. 16). This mapping procedure is performed under fluoroscopy to visualize the location of each catheter in the heart. These catheters can also be used for pacing the atria and/or the ventricles. From the temporal relationship between the electrograms, and from the relationship between these potentials and the ECG, the physician determines the mechanism of the arrhythmia.

During the mapping procedure, the mapping–ablation catheter is moved to locate the exact site that causes the arrhythmia, where ablation is then performed.

Multiple Electrode Mapping. Mapping using the above procedure can be long and cumbersome. Mapping with multielectrode catheters can speed up the mapping procedure by acquiring simultaneous electrograms, and enabling pacing from multiple locations. Fig. 19 shows the Constellation catheter (Boston Scientific), a basket-type catheter that is expanded within the heart, and can pace or record signals from 64 electrodes.

Another multielectrode catheter, the Ensite Array (St. Jude Medical), also employs 64 electrodes, but by using an inverse solution it estimates ~3000 signals on the interior (endocardial) surface of the heart chamber. It is deployed in without direct contact with the heart tissue (Figure 20). This has the advantage of not disturbing the beating heart and providing a highly detailed map, but is prone to errors since signals are extrapolated without direct tissue contact. Since fluoroscopy is not required during mapping, the radiation dose for the patient is highly reduced.

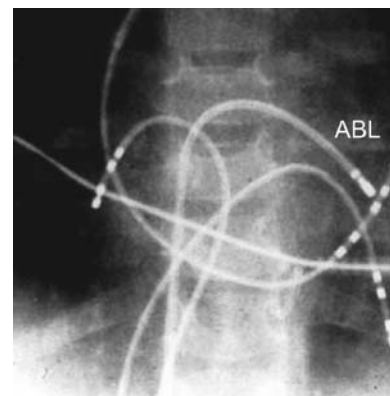

Figure 18. Mapping procedure using multiple catheters. This is an X-ray image of the heart showing the ablation catheter (ABL), and additional catheters for recording electrograms inside the heart. From the relationship between the electrograms at the different sites, the physician can determine the mechanism of the arrhythmia, and site of ablation. (Image provided courtesy of J. Phil Saul, Medical University of South Carolina.)

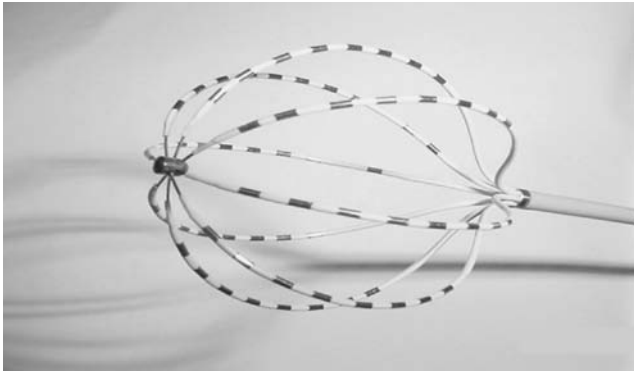

Figure 19. Constellation catheter has a total of 64 electrodes for cardiac mapping. The catheter is expanded inside the heart chamber. (From Ref. 24.)

Electroanatomic Mapping System. The CARTO system (Biosense-Webster) uses electromagnetic methods to determine the exact location of a specially designed catheter (25). A magnetic emitter employing three orthogonal coils is placed under the operating table, below the patient's chest. The reference catheter has a set of antennas located at the tip, which picks up the three magnetic fields. From the strength of the magnetic fields, the distance of the catheter from the magnetic emitter, the exact orientation of the tip (and subsequently the location in the heart) is determined. At each location, the reference catheter measures electrograms within the heart. By moving the catheter within the heart, a three-dimensional (3D) surface depicting the spread of activation through the heart (activation map) is created. From the activation map, the physician can determine the mechanism of the cardiac arrhythmia, and design a treatment plan. As with the Ensite Array, fluoroscopy dose can be markedly reduced with the CARTO system.

Figure 20. Ensite array catheter has 64 electrodes located on the surface of an expandable balloon catheter. The catheter records signals while floating inside the heart without contact. (Image provided courtesy of Endocardial Solutions.)

Impedance Mapping. The impedance signal between each catheter electrode and a set of reference electrodes can also be used to localize catheter positions. However, the accuracy of the location will depend somewhat on the variations in the impedance of the tissues through which the signal traverses. Two commercial systems, LocaLisa (Medtronic) and NAVEX (St. Jude Medical) use this technique to track catheter locations in real time, reducing mapping complexity and fluoroscopy time.

Tumor Ablation

After cardiac catheter ablation became clinically accepted, ablative methods were investigated for cancer treatment starting in the early 1990s. An estimated 70,000 clinical tumor ablation procedures had been carried out in 2004, with numbers still rising.

Clinical Background. The cancer type where tumor ablation was applied first is liver cancer. There was a need for a new treatment modality for liver cancer because surgery, the standard treatment, is only possible in ~15–20% of the cases, and chemotherapy does not work well for liver cancer.

As for many patients there was no viable treatment option, tumor ablation quickly became a standard treatment for unresectable (i.e., not treatable by surgery) liver cancer. More recently, tumor ablation techniques have been applied to other sites such as kidney, lung, and bone.

Tumor ablation can be performed during open surgery, using laparoscopy, or through a small incision in the skin (percutaneously). The treating physician is either a surgeon (open surgery, or laparoscopically) (26), or a radiologist (percutaneous approach) (27). Figure 21 shows a typical patient setup. The patient is either under conscious sedation, or light general anesthesia. The applicator is inserted under imaging guidance [typically ultrasound or computed tomography (CT)] into the tumor (in this case liver). Progress of ablation is monitored usually by ultrasound. Successful ablation is typically confirmed by CT. If

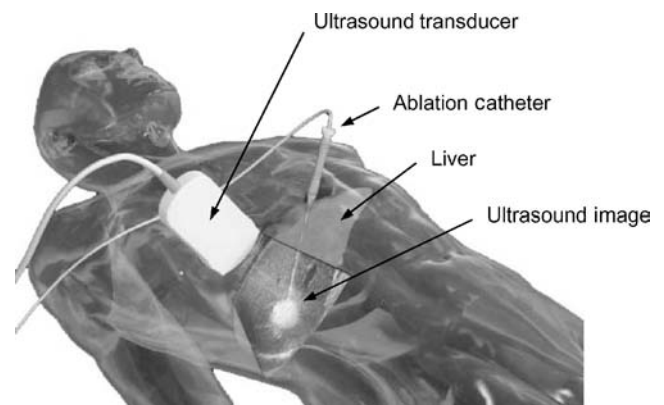

Figure 21. Patient setup for liver tumor ablation. The ablation catheter is inserted into the liver tumor through a small incision in the skin. Ultrasound imaging is used for guiding the electrode into the tumor, and monitoring the ablation. The white region in the overlaid ultrasound image represents areas of gas bubbles due to high temperatures. (From Ref. 28.)

Figure 22. Multiple overlapping ablation zones are required for large tumors to ablate tumor and a 1 cm rim of surrounding tissue. (From Ref. 28.)

the procedure is performed minimally invasively, the patient can leave the hospital the same or the next day.

To successfully treat a tumor, the whole tumor including a 1 cm surrounding zone of normal tissue has to be ablated. It has been shown that the chance of recurrence (i.e., regrowth of the tumor due to incomplete treatment) increases when <1 cm of surrounding tissue is ablated. A single ablation can only treat a limited volume of tissue. Therefore, for larger tumors, multiple overlapping ablations have to be performed (see Fig. 22). This can be done with multiple applicators, but for devices that only support a single applicator (like most rf devices), multiple sequential ablations have to be performed.

Currently, long-term results are only available for liver cancer. For small (<3 cm) primary liver tumors (hepatocellular carcinoma), complete tumor necrosis is achieved in typically 80–90% of the cases, with 3 year survival rates of $\sim 75\%$. Results are less favorable for metastatic cancer, where complete necrosis in 52–67% of small tumors is achieved, with 3 year survival of 40% (28). Treatment results are significantly worse with tumors >3 cm, where multiple sequential ablations are required.

Devices. Cryoablation was historically the first ablation method applied to cancer treatment. However, cryoa-

blation has been so far mainly limited to use during open surgery. Bleeding from the insertion site could result in internal bleeding if cryoablation were done minimally invasively. The first thermal ablation method that was applied minimally invasively through a small incision in the skin (percutaneously) was rf ablation (Chemical ablation was used even earlier). Today, rf ablation is the most widely used tumor ablation method, with competing device technologies, like MW ablation, emerging on the market.

Radio Frequency Ablation. There are currently three rf devices for tumor ablation commercially available on the U.S. market (29). They use applied power between 200 and 250 W, application times of 12–45 min, and create coagulation zones of 3–6 cm in diameter. All manufacturers employ different electrodes and power control algorithms. Figure 23 shows the different electrode types. Grounding pads (2–4) for rf current dissipation are typically located on the patient's thighs, equidistant from the rf electrode. One disadvantage of most current rf devices compared to other methods (MW, cryo, laser) is that only one electrode can be used at a time. This prolongs treatment of larger tumors (>3 cm diameter), with up to several hours procedural time. Below we compare the three most widely used systems.

RITA Medical. This system employs a tree shaped multiprong electrode (Fig. 23a). The prongs are stepwise expanded during the ablation procedure. Five of the prongs have thermocouples located at the prong tips that monitor tissue temperature. The rf power is regulated to keep tip temperatures ~ 100 °C. Different electrodes are available depending on tumor size. In one electrode design, saline is infused into the tissue during the ablation procedure. Local cooling and increase in thermal and electrical conductivity from the saline results in increased coagulation zones, up to 6 cm in diameter with 45 mins application time.

Boston Scientific. This system employs an umbrella shaped multiprong electrode (Fig. 23b). The prongs are completely expanded once the catheter is placed in the tumor. Power is controlled depending on impedance, which is measured between the electrode and the ground pad. If impedance exceeds a certain threshold resulting from tissue vaporization near the electrode, power is turned off for 15 s, and then applied at 70% of previous power level.

Figure 23. The rf electrodes of three manufacturers currently commercially available in the United States, and in clinical use. Multiprong electrodes by RITA medical (a), and Boston Scientific (b). Cooled needle electrode (single and triple cluster) by ValleyLab (c).

Valleylab. This system uses needle electrodes, which are cooled internally by circulating chilled water. Two types of electrodes are available (Fig. 23c): a single needle electrode and a triple-cluster electrode that achieve 3 and 4 cm coagulation zone diameters, respectively. This system employs impedance control, similarly to the Boston Scientific system. Treatment time is 12 min. Another recently introduced system originally developed at the University of Wisconsin, allows the use of up to three electrodes simultaneously, allowing rapid treatment of large tumors (30).

Cryoablation. Different cryoablation systems that employ either argon or liquid nitrogen cooling are clinically available. Cryoprobes in different sizes are available, though the general shape is often similar (Fig. 10). Cryoablation is mainly carried out during open surgery, though recently, small cryoprobes (17 gauge = 1.2 mm diameter) for minimally invasive treatment have become commercially available. Cryoablation has the advantage that the iceball is visible under ultrasound imaging, allowing real-time monitoring of the procedure (20).

Microwave Ablation. Microwave (MW) ablation has been used for small tumors with generic antennas in the Asian region for several years. Only recently has a MW ablation device for ablation of larger tumors become commercially available in the US (Vivant Medical, Mountain View, CA). Potential advantages over rf ablation are shorter treatment times and higher tissue temperatures in addition the possibility of use of multiple antennas takes advantage of constructive interference. Preliminary studies have indicated that MW ablation may show superior performance close to large vessels compared to rf ablation.

Imaging. Imaging serves different purposes during ablative treatment. Initially, the presence of a tumor is identified, typically by CT or MRI (though frequently additional tumors are found during interoperative ultrasound imaging, requiring change of the treatment plan). Figure 24 shows a contrast-enhance CT image of a patient with a liver tumor. Placement of the ablation applicator is typically guided by ultrasound imaging, and often confirmed by CT. Figure 25a shows an ultrasound image of

Figure 24. Tumor (arrow) can be identified from this contrast-enhanced CT image. Tumors are visible because they are typically hypervascular (i.e., have higher density of blood vessels than normal), and take up more of the contrast agent. (Image provided courtesy of Bradford J. Wood, NIH.)

a tumor with inserted rf electrode. Real-time monitoring of the ablation procedure is done by ultrasound imaging. Figure 25b shows the bright (hyperechoic) region resulting from microbubbles due to tissue heating during rf ablation; however, this bright area does not correspond to the zone of tissue destruction. Figure 12 shows the dark region (hypoechoic) depicting the boundary between frozen and unfrozen tissue during cryoablation. This boundary corresponds well with the boundary of cell death (20), which is one of the advantages over heat-based methods. After the ablation procedure, destruction of tumor and sufficient margin of normal tissue is confirmed by another CT scan or MRI.

Contrast agents for ultrasound imaging have recently become available in Europe (31), and should be available in the United States within the next years. These contrast agents employ microbubbles that are visible under ultrasound to visualize vasculature. Tumors are typically hypervascular, and show up using these contrast agents. As the tissue coagulates during ablation and blood perfusion stops, the contrast agent cannot penetrate the

Figure 25. Ultrasound imaging is typically used to guide and monitor the ablation procedure. (a) Shows the rf needle electrode (large arrow) inserted into the tumor (small arrow). (b) Shows bright area (arrow) due to formation of microbubbles as a result of tissue heating. (Images provided courtesy of Bradford J. Wood, NIH.)

coagulated areas anymore. Ultrasound imaging using contrast agents allows real-time monitoring of the ablation procedure contrary to CT and MRI, which can typically only be performed after the procedure.

Future Directions. A continuing trend in tumor ablation is toward larger coagulation zones and shorter treatment times. High tumor recurrence rates close to large vessels are still problematic, with improved applicators attempting to address this issue. Adjuvant therapies (e.g., radiation, chemotherapy agents) can kill cells at lower elevated temperatures (above $\sim 45^\circ\text{C}$) than heat alone (above $\sim 50^\circ\text{C}$). Thereby, the zone of cell death may be extended (cf. Fig. 13), which may be beneficial close to large vessels where it is difficult to achieve sufficient heating.

Unavailability of adequate monitoring of the extent of the coagulation zone is a major problem for all heat-based methods, especially when damage to nearby structures is to be avoided. This problem is partially addressed by ultrasound contrast agents as discussed above. Other potential imaging solutions include thermometry, using MRI or ultrasound imaging, and ultrasound elastography, which allows imaging of the coagulation zone due to change in elasticity after coagulation. Some companies are working on computer-assisted treatment planning systems that guide the physician in optimal applicator placement, and estimate coagulation zones.

Endometrial Ablation

Clinical Background. Ablation has become a standard procedure for women with dysfunctional uterine bleeding, with $\sim 30,000$ annual procedures. Endometrial Ablation (endometrium = lining of the uterus) is indicated for patients that do not respond to standard treatments like drugs and curettage (scraping tissue from the endometrium with a spoon-shaped instrument). Initially either laser or rf energy applied by a rollerball electrode was used; the physician had to manually direct the catheter to ablate the whole *endometrium*, which was time consuming. A number of newer U.S. Food and Drug Administration (FDA) approved devices that are more effective with shorter treatment times are now available (32). These second generation devices treat the whole lining at once, and provide success rates of 67–80%.

Devices. There are currently five second generation devices available on the U.S. market. Two devices use heated fluid to ablate the endometrium. In one device, heated saline ($80\text{--}90^\circ\text{C}$) is circulated within the uterine cavity for 8 min (Hydro Thermablator, Boston Scientific). Another device employs a balloon catheter, inside which heated Dextrose solution (5%) at 87°C is circulated for 10 min (Thermachoice UBT, Gynecare). One device uses cryoablation with a freeze–thaw cycle (10 min freezing) at two locations in the uterine cavity (Her Choice, AMS). The shortest treatment time is achieved by a device that uses bipolar rf ablation employing mesh electrodes (Novasure, Cytac Corp.; see Fig. 26). The rf energy is applied for 90–120 s, and controlled by tissue impedance. The last device uses microwave ablation at 9.2 GHz, and 42 W power for 3 min (MEA, Microsulis).

Figure 26. NovaSure catheter used for endometrial ablation. This catheter has an electrode consisting of multiple electrically isolated meshes, with rf energy applied bipolar between different meshes. Image provided courtesy of Cytac Corporation and affiliates.

Prostate

Clinical Background. Two types of prostate diseases are prevalent in men. Prostate enlargement (Benign prostate hyperplasia) is common in men >50 years of age. The enlarged prostate imparts pressure on the urethra resulting in restriction, at which point it has to be treated to reduce prostate size. Cancer is the second common disease affecting the prostate, and is the most common form of cancer affecting men.

Current standard treatment options for enlarged prostate include medication, surgery where part of the prostate is removed, and minimally invasive ablative methods. For prostate cancer, treatment options are surgical removal (radical prostatectomy) and external radiotherapy. Ablative methods are currently only used in cases when conventional treatment fails, or in cases with advanced disease to reduce tumor volume. Ablative treatment of prostate cancer requires more precise control of the ablation zone than for enlarged prostate, since the cancer is usually located in the periphery of the prostate (away from the urethra) making treatment from inside the urethra more difficult (33).

Commercial devices are available that employ cryo, rf, microwave, and ultrasound. Depending on the device, the prostate is treated by inserting the ablation catheter into the urethra, rectum, or through the skin in the region between the scrotum and anus (perineum). Urethra and rectum have to be protected from damage by cooling when heat-based devices are used, and by heating when cryoablation is used.

Devices for Enlarged Prostate Treatment

Microwave Ablation. Several devices are available that use microwave antennas inserted through the urethra.

Figure 27. Targis catheter for treatment of enlarged prostate. The different ports are used for inflating the balloon (arrow) inside the bladder, and for perfusing the catheter with cooling water. (Image provided courtesy of Urologix.)

Two devices (Targis and Prostatron, Urologix) use cooled antennas to avoid damage to the urethra. Figure 27 shows the Targis device. The balloon is inflated inside the bladder to facilitate proper positioning. The Thermatrix device (AMS) uses low energy and does not require cooling. The CoreTherm device (ACMI) employs temperature sensors to monitor tissue damage and control applied power. Treatment time is typically 30–60 min, and tissue temperatures are in the range of 45–50 °C.

Radio Frequency Ablation. The transurethral needle ablation device (TUNA, Medtronic) uses a catheter, from which two needle electrodes project from the urethra into the prostate. Maximum power of 30 W is applied for 4 min, so that tissue temperature as measured by sensors located within the needles tips reaches 100 °C. Since each needle ablates only a small tissue volume, multiple insertions are required.

Devices for Prostate Cancer Treatment

Cryoablation. While the rf and MW devices described above are used for treatment of enlarged prostate, cryoablation is used for treatment of prostate cancer. The probes are typically inserted into the prostate through the skin (percutaneously) in the region between the scrotum and anus (perineum). The diameters of current probes are between 1.22 (SeedNet, Galil Medical) and 3 mm (Cryocare CS, Endocare) for the two systems currently available in the United States. A warming catheter perfused with 40–42 °C saline is placed in the urethra to protect it from damage.

Ultrasound Ablation. Two devices that employ high intensity focused ultrasound are commercially available in Europe and Asia, though not yet FDA approved in the United States. Both systems (Ablatherm, EDAP; Sonablate, Focus Surgery) use catheters inserted into the rectum, and catheters have both imaging and treatment transducers. When the treatment transducer is activated, it creates a

single cylindrical thermal lesion ~20 mm long and 1–2 mm in diameter. The focal point is gradually moved according to a treatment plan to ablate the treatment region.

Radio Frequency Ablation. The same devices described under “Devices section for Tumor Ablation” are also under investigation for treatment of prostate cancer.

Endovascular Ablation

Clinical Background. Varicose veins are visibly dilated and twisted veins near the skin surface, most often affecting legs and thighs. Insufficiencies of the venous valves result in blood pooling and enlargement of the veins. Varicose veins affect ~10% of the population, mostly between ages 30 and 60.

Several treatment options are available, all aiming to close the affected veins. Veins can be treated using surgical stripping, sclerotherapy (injection of an agent that causes vein swelling, and closure), and ablation. During treatment, a catheter is introduced into the vein and the vessel wall is heated. The heat results in shrinkage of the collagen in the wall, eventually closing off the vessel.

Devices

Radio Frequency Ablation. A bipolar, multielectrode device (ClosurePlus, VNUS Medical) is commercially available (see Fig. 28) in two sizes (2 and 2.7 mm diameter). The catheter is inserted into a vein and advanced to the treatment location. The rf energy is applied between two sets of electrodes (2.7 mm catheter), or between outer electrodes and inner ball electrode (2 mm catheter). Power is controlled so that vein wall temperature, as measured by a thermocouple (located in the outer electrodes tips), reaches 85 °C. Heparinized saline is infused through the central lumen of the catheter to prevent blood coagulation. Once the target temperature is reached, the operator moves the catheter at a rate of 2–3 cm per minute while keeping

Figure 28. ClosurePLUS endovascular rf catheters for treatment of varicose veins in two sizes. The catheter is introduced with retracted prongs, and expanded at the treatment site. The rf current is passed between the center electrode, and surrounding prongs (left, smaller 2 mm catheter), or between two sets of prongs (right, larger 2.7 mm catheter), while catheter is pulled along the vein to shrink and close a section of the vein. the temperature within 3 °C of the 85 °C target. Treatment success is confirmed via ultrasound imaging, where no flow should be present.

Laser Ablation. The second commercially available device (EVLTL, Diomed) uses laser to produce heating, shrinkage of the vein. A laser fiber is inserted into a vein and advanced to the treatment location. Laser light of 810 nm wavelength at 14 W power is applied, while pressure on the vein ensures contact between fiber and vein. The fiber is advanced at a rate of 2–3 mm per second.

A study comparing the ClosurePlus and EVLT devices showed much higher temperatures when the laser device was used, resulting in vein perforations and reduced performance compared to the rf device (34).

Cornea Ablation

Clinical Background. Many vision disorders are a result of imperfections in the shape of the cornea. Conditions treated include astigmatism (cornea has oblong shape), myopia (nearsightedness), hyperopia (farsightedness), and presbyopia (blurred vision at close range, due to age-related loss of elasticity).

Treatment options are surgical treatment (part of the cornea is surgically removed), and ablative methods.

Devices

Laser Ablation (Laser Refractive Surgery). Laser is the most widely used ablative treatment method for corneal ablation. For most applications the excimer laser is used, which is an Argon laser operating in the ultraviolet (UV) range (193 nm wavelength); the laser is used in pulsed mode with 10–60 pulses (each a few ns) per second. The excimer laser does not cause tissue damage as described in the “Tissue injury from Heating” section, but causes the corneal tissue to vaporize. Part of the cornea is thereby removed, resulting in the desired change of shape.

In some applications, the Holmium:YAG laser is used, which operates in the IR region (2100 nm wavelength). This laser causes heating, and shrinkage of the collagen in the cornea, resulting in change of shape.

Radio Frequency Ablation (Conductive Keratoplasty). More recently, rf devices have become available for the treatment of hyperopia and presbyopia. RF energy is applied by fine electrode (90 μm diameter, 450 μm long) in pulsed fashion (exponentially damped rf pulses, pulse rate ~8 kHz), with power levels of ~1 W, and application times in second range. The rf heating results in collagen shrinkage, and change of cornea shape.

Intervertebral Disk Ablation

Degenerative diseases of the intervertebral disks are a major cause of lower back pain. Ablative techniques have been introduced in the late 1990s, and are now used in certain patient populations (35). Even though exact mechanisms of pain alleviation are not known, it is assumed that two mechanisms are responsible: shrinkage of the disk reduces pressure on nerve fibers, and destruction of sensitive nerve fibers. Currently, two devices are commercially available, both of which use rf ablation to heat tissue.

Other Applications

Ablative techniques are investigated for a number of other applications. Treatment of different types of cancer other than the ones discussed above such as in the breast and esophagus, are being investigated. In the brain, treatment of deep-seated tumors and other disorders, like Parkinson’s disease and Epilepsy, is examined. Ablation is investigated for treatment of chronic pain by ablating responsible nerve fibers. In dentistry, laser ablation is investigated as a potential replacement for mechanical drills.

TISSUE ENGINEERING

KRISTYN S. MASTERS
WILLIAM L. MURPHY
University of Wisconsin
Madison, Wisconsin

INTRODUCTION (1–4)

Definition

Tissue engineering represents a unique convergence of work from the worlds of clinical medicine, engineering, and basic science. The most commonly cited definition of tissue engineering originates from an influential 1993 paper by Langer and Vacanti (1): “Tissue engineering is an interdisciplinary field that applies the principles of engineering and the life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function.”

Although the term tissue engineering had existed for several years prior to this 1993 publication, and the concept of tissue engineering had existed for several decades, it is Langer and Vacanti's paper that is ultimately credited with stimulating broad awareness and acceptance of this description. This definition also served to unify seemingly diverse lines of research, as it encompasses three general strategies for the creation of new tissue, namely, the use of isolated cells or cell substitutes; tissue-inducing substances; or cells placed on or within matrices.

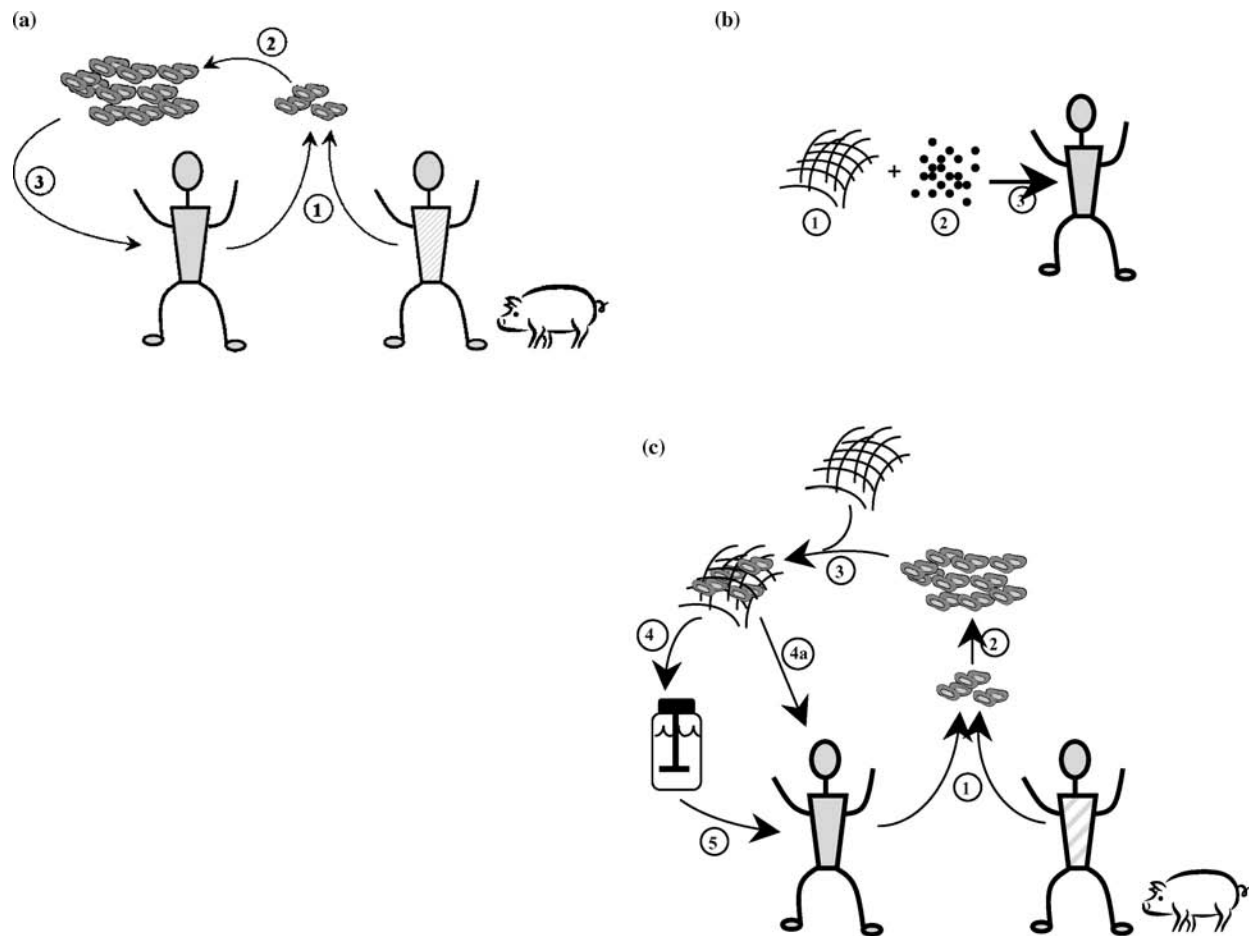

Figure 1. Depiction of three main tissue engineering strategies. In (a) cell transplantation, cells are obtained from a donor (1), who is either the patient themselves, another person, or an animal, then expanded *in vitro* (2), and reimplanted into the diseased/injured site (3). Regeneration via scaffold alone is represented by (b), where a degradable, and possibly bioactive scaffold (1) may be combined with inductive agents (2), and then implanted (3). Lastly, (c) depicts the implantation of cell-seeded scaffolds, as cells are isolated from a donor (1), expanded *in vitro* (2), and combined with a biomaterial scaffold (3), followed by either immediate implantation (4a) or further culture in an *in vitro* bioreactor (4b) prior to implantation (5).

Thus, tissue engineering includes a wide variety of therapies, including cell transplantation, the implantation of biomaterials alone as scaffolds for *in situ* cell growth, and the *in vitro* or *in vivo* development of cell-seeded materials; these strategies are depicted in Fig. 1. The choice of tissue engineering approach is dependent on the specific type of tissue to be repaired; factors, such as cell availability, tissue regeneration potential, and mechanical stresses in the tissue environment, are all important considerations in the selection of a tissue engineering strategy. Ultimately, the goal of tissue engineering is the formation of neotissues that are mechanically and biologically integrated in the patient's body.

Motivation

Therapeutic options for patients with diseased or dysfunctional tissues or organs are currently limited. While organ transplantation has become a successful means of replacing diseased organs, this option continues to be seriously

limited by problems with immune rejection and organ availability. Historically, the number of organs available for transplantation has been exceeded by the number of patients requiring an organ transplant, and this gap continues to widen. The number of needed organs continues to grow at an annual rate that is over twice the rate of increase of donated organs. Over 4000 people die each year while on the UNOS (United Network for Organ Sharing) transplantation waitlist, while 100,000 others die from organ failure without even qualifying for the waitlist.

Certain structural elements of the body (e.g., bone, blood vessels, and skin) may also be replaced via autologous tissue grafts. Such grafting procedures transfer the patient's own healthy tissue to a location that requires assistance with repair, thus circumventing immunogenicity problems associated with receiving tissues from other sources. However, tissue grafting is also accompanied by significant drawbacks and challenges, including limited availability of healthy donor tissue, donor site morbidity, and the need for multiple surgical sites. Grafted or reconstructed tissues are often

functionally inferior and less durable than the natural organs that they replace. Moreover, tissue grafting is appropriate for only select types of tissue.

Lastly, artificial prostheses and permanent implants have been developed to take the place of diseased or defective tissues, particularly in the areas of orthopedics and cardiovascular medicine. While these implants are capable of improving both the patient's lifespan and quality of life, tissue replacement with a permanent, artificial structure results in the loss of that tissue's natural biological functions. Most notably, artificial prostheses are unable to grow or remodel, meaning that they are often unsuitable for pediatric patients and are incapable of responding to changes in the body's needs or environment. Furthermore, significant issues arise from the permanent implantation of synthetic structures, and the types of tissues that can be mimicked by current prosthesis technology are very limited.

The field of tissue engineering holds the potential to overcome the aforementioned challenges associated with organ and tissue availability, immunogenicity, and retention of tissue function. Tissue engineering promises to provide a means of regenerating or replacing diseased or dysfunctional tissues and organs while leaving no permanent implant. While organ regeneration may be the most explicable motivation for the creation of engineered tissues, the objectives of tissue engineering as a field can be quite broad, as tissue engineering can be used to offer an alternative to drug therapy, gene therapy, and whole-organ transplantation; inspire or control the normal processes of tissue repair and healing; replace cells that are missing within an otherwise functional tissue or organ; use cellular control mechanisms to enhance drug delivery; lead to new models of human physiology.

The principal variables in the process of tissue engineering are (1) cell source; (2) scaffold type and properties; (3) method of tissue development (bioreactor design); (4) inclusion of inductive factors (i.e., cytokine delivery, gene therapy). This article will introduce and provide background on these key components of tissue engineering, and then discuss how tissue engineers have manipulated these variables in the development of two different types of engineered tissue: bone and cardiovascular tissue.

History

The National Science Foundation (NSF) (2) defines 1987 as the year that tissue engineering became formalized as a field; it is in this year that the NSF became consciously involved in tissue engineering. Although a defined label did not exist to describe their work, several pioneering researchers did perform tissue engineering research in the decades preceding the field's "official" emergence. In the vascular area, the concept of a resorbable vascular graft was introduced in the 1960s, with the first fully resorbable graft reported in 1979. In 1978, researchers observed improved healing after seeding synthetic vascular grafts with endothelial cells, and the first attempt to tissue engineer a vascular structure *in vitro* using collagen and cultured vascular cells was described by Burkel et al. in 1982 (see Ref. 3 for details). The origins of dermal tissue

engineering reach into the 1950s, when Billingham and Reynolds demonstrated that cultured epidermal cells could be applied to a graft bed to reconstitute an epidermis. By the 1970s, the ability to culture cells *in vitro* had significantly advanced, enabling the formation of multilayered epidermal sheets that could be transferred intact to a wound bed. The first living skin equivalent (LSE) was created using fibroblasts seeded on a collagen matrix and described in 1981 in a notable paper by Bell et al. (see Ref. 2 for details). In the area of orthopedics, the development of nondegradable biomaterial implants and the discovery of osteo- and chondrogenic cytokines and growth factors constituted the majority of pre-1987 tissue engineering work. Lastly, early (and current) tissue engineering of organs (e.g., the kidney, pancreas, and liver) was (and continues to be) hindered by the functional complexity of these structures and the difficulty of cellular expansion *in vitro*. Several types of cell-seeded, nonimplantable bioreactors were first developed during the 1970s to replace critical metabolic functions provided by these organs; however, there remains debate regarding whether such bioartificial devices fall under the definition of tissue engineering, as they are never incorporated into the body's reparative and homeostatic mechanisms.

In the years since these early forays into tissue engineering, the field has expanded substantially and has experienced some clinical and commercial successes. In 1988, Langer and Vacanti described a method of seeding cells on a resorbable polymer matrix for cell transplantation, which ultimately became the most important enabling technology for advancement, expansion, and recognition of the field of tissue engineering. This specific technique of seeding cells on a three-dimensional (3D), porous, biodegradable scaffold catalyzed an explosion of tissue engineering research in the late-1980s–mid-1990s. While the exploration of fundamental concepts underlying tissue engineering's viability generally took a backseat to the practice of tinkering with various combinations of cells plus materials, these investigations did significantly advance tissue engineering by enabling identification and a better understanding of the obstacles facing tissue engineers. By the year 2000, mainstream media outlets were touting the promise of this new field, with *Time* magazine proclaiming Tissue Engineer as the number one projected career in the twenty-first century.

Today's tissue engineering research sees the collaboration of engineers with clinicians, biologists, chemists, and many other scientists to effect the creation of numerous types of engineered tissues. Present tissue engineering ventures have addressed the regeneration or replacement of components found in every system of the body (cardiovascular, musculoskeletal, neural, endocrine, digestive, reproductive, and respiratory). While significant progress has been made toward the recreation of many complex tissues, the clinical and commercial success stories of tissue engineering represent less complicated structures (e.g., skin, cartilage, and the bladder). Yet, through the incorporation of emerging technologies, (e.g., the use of embryonic stem cells) the field of tissue engineering continues to evolve and progress in order to meet its promise of revolutionizing regenerative medicine.

COMPONENTS OF TISSUE ENGINEERING

Cell Sources (1,2,4–7)

As discussed in earlier sections, tissue engineering strategies may include the transplantation of cells alone or the seeding of cells upon implantable scaffolds. Cell sourcing is a formidable challenge in current tissue engineering techniques, as it is essential to select cells of appropriate origin and maturity for each tissue engineering application. In this section, cell sources for tissue engineering are arranged and discussed with respect to cell maturity, as the regeneration potential of a cell source is a crucial consideration in designing a tissue engineering strategy.

Mature Cell Sources. Mature cells are differentiated cells that are committed to performing given cell type-specific functions. These cells are generally obtained via primary cultures originating from small pieces of donor tissue. For example, a small skin biopsy may be performed in order to isolate keratinocytes and dermal fibroblasts, the two main cell types in skin. Once isolated, these cells may be cultured and expanded *in vitro* to yield the number of cells required for creation of tissue-engineered skin. However, the expansion potential of these cells is not without limit; over time, mature primary cells drift from their original phenotype, and will either die or become genetically unstable after a certain number of population doublings. One advantage of using mature cells in tissue engineering strategies is that it enables tissue–organ regeneration using the patient’s own cells, thus eliminating concerns of immunogenicity. Additionally, decades of research have concentrated on characterizing many mature cell types and their responses to various biological factors, thus facilitating the tissue engineer’s ability to predict and control cell behavior and tissue formation. Thus, in situations where a tissue sample of proliferative cells can be obtained using minimally invasive means, the use of primary cell lines as a component of the tissue engineering platform represents a viable strategy. The regeneration of cartilage via Carticel (Genzyme, Inc.) is an excellent example of the successful use of mature autologous cells in tissue engineering. In the Carticel process, healthy, mature chondrocytes are isolated from a patient with large articular cartilage lesions, propagated *in vitro*, and then reimplanted into the patient. Carticel is approved by the U.S. Food and Drug Administration (FDA) and has been clinically used on > 10,000 patients. Note, however, that isolation via primary culture and subsequent subculturing–expansion is not a feasible option for all cell types. For example, while cells from the liver (hepatocytes) readily regenerate *in vivo*, their *in vitro* growth is difficult and results in rapid loss of hepatocyte-specific functions. Furthermore, not all mature cell types are capable of regeneration. The cells of the adult myocardium (cardiomyocytes) are terminally differentiated and incapable of proliferation, even in the *in vivo* environment.

Immature Cell Sources. Historically, successful tissue engineering schemes have used mature, adult cells isolated from a specified tissue type as tools to produce their tissue

of origin. A common example, described above, involves use of dermal fibroblasts and keratinocytes to engineer skin tissue. This general strategy has gained a measure of success in cases where cells are accessible and expandable with minimal patient trauma, as in the case of skin and cartilage regeneration. However, many tissues do not contain readily accessible mature cells that can grow outside the body and remain capable of generating their corresponding tissue type. This limitation has led investigators to search for other cell types that are capable of generating functional tissues.

Various “stem cell” types have emerged as a potentially important cell source in tissue engineering (5). These cell types possess several properties that are ideal for regenerative applications, including: (1) an ability to make copies of themselves, or self-renew, which may allow for creation of an endless cell source; (2) the ability to differentiate into multiple mature cell types; and (3) the ability to differentiate in response to environmental cues. These capabilities, in principle, could allow for production of highly complex tissues and organs from a renewable stem cell source. However, the capabilities of stem cells are largely based on observation of natural stem cell activities *in vivo*, and recreation of these activities in engineered systems has been a significant challenge. The following paragraphs delineate the stem cell types in current use in tissue engineering and highlight important challenges in stem cell-based tissue engineering.

Adult Stem Cells. Several investigators are working toward generation of functional tissues using stem cells isolated from a multitude of adult tissues, including skin, skeletal muscle, retina, adipose tissue, dental pulp, blood vessels, and bone marrow. These cell types are often termed tissue-specific stem cells, to distinguish them from the more primitive and pluripotent embryonic stem cells (described in the next section). The bone marrow has been a particularly fruitful cell source, yielding two multipotent cell types: hematopoietic stem cells (HSCs), and bone marrow stromal cells. HSCs were initially defined by their ability to generate all of the mature blood cell types. However, recent studies indicate that these cells can also be coaxed to differentiate into nerve cells or liver cells when delivered to the central nervous system or the liver, respectively. Therefore, HSCs appear to have applications in engineering of several key tissue types. The marrow stromal tissue has also been an intriguing source of stem cell types. Cells from this source have been termed mesenchymal stem cells, bone marrow stromal cells, or marrow-derived mesenchymal stem cells, depending on their isolation and selection procedures. Marrow-derived cells have been used to generate bone, skeletal muscle, cartilage, adipose, and vascular tissues. It is important to note that similar mesenchymal stem cells have also recently been isolated from synovial joints, adipose tissue, and umbilical cord tissue, and have been driven to differentiate into mature cell types, including bone and cartilage cells. A subpopulation of the bone marrow-derived mesenchymal stem cells, which are termed multipotent adult progenitor cells (MAPCs), have recently demonstrated an ability to differentiate into an even more extended range of adult cell

types, including liver, nerve, blood, and lung cells. The identification of these cell types suggests that tissue-specific stem cells, which have historically been considered limited in their differentiation potential, may be capable of transforming into a wider range of mature cell types than anticipated. However, no adult stem cell type has been shown to be pluripotent, and therefore able to give rise to all types of specialized adult cells, and adult cells are more limited in their ability to self-renew in culture (< 60 population doublings) when compared with the more primitive embryonic stem cells (hundreds of population doublings), described in the next section.

Embryonic Stem Cells. Another stem cell type, the human embryonic stem cell (ESC), has also generated a great deal of excitement due to its potential use in tissue engineering applications. Human ESCs are pluripotent cells derived from the inner-cell mass of blastocysts generated via *in vitro* fertilization. These ESCs have also been isolated from embryos created *in vitro* via somatic cell nuclear transfer, which is often termed therapeutic cloning. In addition, similar cell types called embryonic germ cells have been isolated from the fetal gonadal ridge. Each of these cell sources produces cells that are capable of self-renewing for extended periods in culture without differentiating, and they are considered capable of generating all of the mature cell types in the body. It is therefore possible, in principle, to use ESCs as a renewable cell source to engineer any human tissue. Although this potential is intriguing, the use of ESCs in tissue engineering applications has not been extensive. These cells are primitive and often require complex signaling environments to direct them to become a specified mature cell type. Furthermore, the complex signals required to generate specified cell types are incompletely understood. These challenges, along with the social and ethical questions associated with ESC isolation and use, present significant roadblocks to ESC-based tissue engineering. However, recent studies have successfully utilized human ESCs combined with material carriers to generate a variety of adult tissue types. In addition, direct injection of human ESC-derived cell types into pathological sites is an active area of study. These efforts and others suggest that ESCs may be an important component of emerging tissue regeneration approaches.

Challenges. Each of the stem cell types described are being explored for stem cell based tissue engineering approaches, which have included (1) direct transplantation of the cells into a pathological location; (2) transplantation of cells upon or within a biomaterial carrier; or (3) differentiation of the cells in a cell culture bioreactor prior to implantation with or without a biomaterial carrier (Fig. 2) (6). A particular challenge in these stem cell based approaches is delivery of signals to stem cells to direct their differentiation and, in turn, new tissue formation. Stem cells are primitive by nature, and they therefore require instructions, which are provided in the natural stem cell micro-environment (or niche) (7). Many of the emerging approaches to stem cell based tissue regeneration attempt to adopt aspects of the natural stem cell niche to imitate natural tissue development. Design of new biomaterials and new inductive approaches, coupled with new insights about the signals that direct stem cell based tissue formation, may allow for a higher level of control over tissue regeneration in the future.

Biomaterials (8–12)

Tissue engineering strategies include the implantation of material scaffolds alone or in combination with cells. A material that can be used for tissue engineering applications must meet a number of requirements; namely, materials should be biocompatible; biodegradable to nontoxic products within appropriate time frame for application; easily processed to form complex shapes with appropriate porosity; able to support cell growth and proliferation; mechanically suited to an application. There exist numerous classes of biocompatible materials, and design and synthesis of new materials remain active areas of investigation. Several considerations and concerns are common to the design of all biomaterials, regardless of whether the material is derived from natural or synthetic sources.

Naturally Derived Biomaterials (8,10,11). Natural extracellular matrices (ECMs), which are protein-based matrices that surround most cell types in the body, can be considered the quintessential biomaterials. During natural tissue development and repair processes these natural ECMs serve many of the functions that are important for successful tissue engineering, including (1) provision of a space-filling scaffold for infiltration of cells and synthesis of

Figure 2. Schematic representation of current approaches to stem cell based tissue engineering. Stem cells are isolated from a variety of tissues, expanded in culture, and implanted into a tissue defect with or without a biomaterial carrier. In some cases, the cells are induced in culture to differentiate into a particular mature cell type prior to implantation.

a new tissue; (2) delivery of signals that influence cell activity during new tissue formation; and (3) the ability to degrade and remodel while a new tissue forms. It is therefore not surprising that a large fraction of biomaterials used in tissue engineering are derived directly from the natural ECM (8). Most of the natural biomaterials used currently are derived from connective tissues, including ligaments, tendons, blood vessels, skin, and bone. More specifically, the most common natural materials in general clinical and scientific practice include collagen (both native and chemically modified), fibrin, hyaluronic acid, and alginate. The following paragraphs provide a brief description of each of these biomaterials.

Collagen. Collagens are a class of vertebrate proteins (with >25 variations) that fold into a characteristic triple helical structure. In skin, tendon, and bone tissues the predominant type of collagen is Type I, and it is this type that is used extensively in tissue engineering applications. Type I collagen can be formed into a cross-linked hydrogel network, a fiber mesh, or a porous sponge, depending on the processing method. Therefore, it is a tremendously flexible base material, and applications have included skin, bone, cartilage, nerve, and liver tissue engineering. Collagen-based materials can also be readily mixed with cells, proteins, or plasmid DNA during processing, which has led to the use of collagen scaffolds in cell-based and inductive tissue engineering strategies.

Fibrin. Fibrin is an integral protein component of clots that form during blood coagulation. It is in this context that fibrin provides a temporary matrix during natural wound healing. Therefore, the natural function of fibrin demonstrates its potential use in wound healing and tissue engineering applications. Fibrin is capable of forming a hydrogel upon protein cross-linking, and these hydrogels adhere strongly to connective tissues, promote cell attachment and wound healing, and degrade in response to protease activity. Therefore, fibrin-based hydrogels serve as excellent matrices for blood vessel ingrowth and healing of connective tissues (e.g., skin, bone). In addition, synthetic biomaterials have been designed to mimic the biological properties of fibrin, including cross-linking, cell adhesion, and protease degradation. These biomimetic approaches highlight the importance of natural biomaterials as templates for design of synthetic biomaterials.

Hyaluronic Acid. A critical component of the extracellular matrix in many tissues, hyaluronic acid (HA) (10) is a relatively simple, yet unusual, high molecular weight polysaccharide. Hyaluronic acid is present in all mammals, playing a vital role in embryonic development, extracellular matrix homeostasis, wound healing, and tissue regeneration. This acid possesses unique biological and mechanical properties due to its hydrophilic, polyanionic composition, and the influence of HA on cell function is highly dependent on its molecular weight. Degradation of HA may occur via several cell-secreted enzymes, or nonenzymatically via free radicals or other various treatments. The intrinsic physicochemical and biological properties of HA have generated widespread use of this molecule in

clinical therapies, and many HA-based products have been approved by the FDA for clinical use in osteoarthritis, ophthalmology, wound healing, gastroenterology, and prevention of postsurgical adhesions. Due to the integral involvement of HA in tissue regeneration and the ease of chemically modifying HA to form numerous derivatives, the use of HA has also been extensively investigated in a wide array of tissue engineering applications. Moreover, as HA plays a crucial role during the morphogenesis of many organs, it may be capable of providing specific signals to cells to initiate tissue or organ regeneration. Derivatization or chemical cross-linking of HA yields HA-based materials with a wide range of mechanical, chemical, and biological properties. These scaffolds can take numerous physical forms including fibrous meshes, sponges, microspheres, and hydrogels.

Alginate. Alginate is a natural polysaccharide isolated from seaweed. In the presence of divalent cations (e.g., calcium) or multivalent polymers (e.g., polylysine) alginate chains become cross-linked into a network hydrogel with intriguing properties. The utility of alginate hydrogels in biomaterials and tissue engineering applications is largely a result of their ability to repel proteins. Proteins do not intrinsically interact with alginate hydrogels and, in turn, cells do not bind to these gels. Therefore, alginate hydrogels provide useful platforms for presentation of specific molecules to cells, allowing these gels to be used as controllable synthetic matrices. In addition, alginate hydrogels do not bring about a substantial immune response, so they are useful in applications designed to shield cells or tissues from the immune system (e.g., pancreatic islet delivery). Another attractive property of these hydrogels is their ability to gel *in situ* without the use of harsh cross-linking agents. This allows for minimally invasive implantation of a material, and may enable minimally invasive cell, protein, and gene delivery. Alginate hydrogels have been used in applications ranging from cell encapsulation to bone tissue engineering.

Other Naturally Derived Materials. Numerous other naturally derived materials have demonstrated promise for tissue engineering applications, including chondroitin sulfate, gelatin, agarose, chitosan, and dextran. A more detailed discussion of the role of naturally derived materials in tissue engineering is available in several reviews (8,10–12).

Limitations. Clearly, natural polymers can be used in a wide variety of tissue engineering applications, as they are generally biocompatible, biodegradable, and easy to process. However, there are limitations to the use of these materials. There is often substantial batch-to-batch variation in the properties of these polymers, which can be dependent on the species and tissue of origin or the harvesting procedure. In addition, because these materials are protein or polysaccharide based they are typically not amenable to standard polymer processing schemes that involve high temperatures or harsh organic solvents. In addition, the nature of protein-based natural materials makes them vulnerable to immune responses *in vivo*,

particularly in cases where the proteins are implanted into a host species that differs from their source. These concerns and others provide an impetus to develop synthetic biomaterials that exploit the advantages of natural materials and limit their disadvantages.

Synthetic Materials (9,11,12). Although synthetic materials lack the inherent bioactivity and biologic recognition possessed by natural substances, their advantages are numerous. In a broad sense, the primary advantage associated with synthetic materials is the researcher's ability to accurately control material characteristics. Controlled alterations in material chemistry, polymerization, or method of scaffold formation can produce changes in the type and time of material degradation, porosity, stiffness–elasticity, texture, shape, hydrophilicity, and bioactive ligand presentation. The ability to construct synthetic materials from scratch enables researchers to tailor material properties to the desired specifications required for a specific application. While many such manipulations are also possible with natural materials, it is widely accepted that synthetic materials are more amenable to modification. This section will discuss several of the most prevalent synthetic materials used in tissue engineering applications.

Poly(α -esters). Poly(glycolic acid) (PGA) and poly(lactic acid) (PLA) remain the most widely used synthetic materials for tissue engineering. These polymers are produced via a ring-opening polymerization of glycolide ($R = H$) or lactide ($R = CH_3$), respectively (Fig. 3).

Poly(glycolic acid) is a highly crystalline, hydrophilic poly(α -ester) that was used as early as the 1960s as the first biodegradable suture material. Simple, random hydrolysis of the ester bonds leads to bulk degradation of PGA, with the degradation rate dependent on the degree of PGA crystallinity. The degradation product of PGA is glycolic acid, which is processed through normal metabolic pathways in the body and ultimately eliminated via the respiratory system as carbon dioxide. Because the degradation products of PGA act as components of the body's natural metabolic pathways, this polymer may be classified as a bioresorbable material. For tissue engineering applications, PGA is most often processed via extrusion to form a 3D, porous mesh structure composed of uniform PGA strands or fibers. Cells seeded on these scaffolds readily adhere to the PGA fibers, then spread, proliferate, and produce extracellular matrix proteins. The PGA has proven to be an excellent carrier for numerous cell types and other biological agents. Due to its rapid degradation and poor mechanical properties, however, use of PGA alone is not suitable for many applications.

Figure 3. Ring-opening reaction of glycolide ($R = H$) or lactide ($R = CH_3$) to form PGA or PLA, respectively.

Figure 4. Copolymers of PGA with PLA can be synthesized to form poly(lactic-co-glycolic acid) (PLGA), whose characteristics represent a combination of the two original polymers.

Similar to PGA, PLA is a resorbable poly(α -ester) that degrades via hydrolysis to generate a product (lactic acid) that is readily metabolized by the body. However, PLA is more crystalline and hydrophobic than PGA, resulting in significantly slower degradation characteristics. The PLA is exceptionally strong for a biodegradable material and its superior strength makes it particularly well suited for regeneration of load-bearing tissues (e.g., bone and cartilage).

The synthesis of PLA–PGA copolymers (PLGA, Fig. 4) has yielded tissue engineering scaffolds with a wide range of mechanical and degradation characteristics. Because of their excellent biocompatibility and versatility, PLGA scaffolds have been widely used in tissue engineering applications with much success. The polymers PGA, PLA, and PLGA are all highly processable; scaffolds may be fabricated via extrusion, injection molding, compression molding, or solvent casting. They can be formed into complex structures, and there exist numerous methods for introducing pores. Nanofibrous scaffolds have also been fabricated from PLGA and PLA. These scaffolds mark an interesting advancement in the design of matrices for tissue engineering, as their physical structure (an array of fibers 50–500 nm in diameter) mimics the structure of fibrillar collagen, a component of the native extracellular matrix. A further reason that PGA and PLA remain the materials of choice for tissue engineers is that they are among the few synthetic scaffold materials approved by the FDA. The primary drawbacks of the poly(α -ester) family of polymers are their brittleness and tendency to crumble, lack of chemical functionalities other than end-groups, and production of acidic degradation products that often cause inflammation.

Poly(Anhydrides). Poly(anhydrides) are notable as a scaffold material for tissue engineering in that they undergo surface degradation via hydrolysis of the anhydride group, as opposed to the bulk degradation experienced by poly(α -esters). Poly(anhydrides) are also the first new synthetic degradable material approved by the FDA in >20 years. Poly(sebacic acid) (SA) and poly(*p*-carboxyphenoxyhexane) (CPH) are two commonly synthesized poly(anhydrides) for tissue engineering and drug delivery applications (Fig. 5).

Because homopolymers of SA degrade over a period of days, while polymers based upon CPH degrade over periods of months to years, copolymerization of SA with CPH offers a means of creating poly(anhydride) materials with a wide range of controlled surface-erosion characteristics. Surface-degrading materials have better retention of mechanical strength than those that degrade via bulk mechanisms; scaffold structural integrity is compromised early in the bulk degradation process, and the majority of mass loss occurs toward the end of the degradation process,

Figure 5. Polyanhydrides, such as SA (a) and CPH (b) are commonly used in tissue engineering and drug delivery applications.

often resulting in inflammation following the sudden burst of acidic degradation products. Such drawbacks make surface-eroding polyanhydrides advantageous for several tissue engineering related applications. Polyanhydrides have proven to be excellent vehicles for drug delivery, and are therefore particularly appropriate for the scaffold-only approach to tissue engineering, where these materials provide a structural platform that elicits *in situ* tissue ingrowth and regeneration through the release of bioactive and tissue-inductive agents. The tissue engineering potential of this class of materials was recently enhanced through the modification of SA and CPH to contain photopolymerizable moieties, meaning that the starting monomers are cross-linked to form scaffolds via exposure to a certain wavelength of light. As discussed in following sections, formation of scaffolds via photopolymerization affords several advantages over many other polymer processing techniques.

Poly(Ethylene Glycol) and Poly(Vinyl Alcohol). Hydrogels synthesized from poly(ethylene glycol) (PEG) or poly(vinyl alcohol) (PVA) represent yet another major class of biomaterials used in tissue engineering applications. An interesting feature of both PEG and PVA is that they are relatively biologically inert, meaning that they are resistant to protein and cell adhesion. While it may appear counterintuitive that nonadhesivity makes these materials attractive for tissue engineering purposes, the reason that tissue engineers value this property of PEG and PVA comes back to the need to control the biomaterial environment. Both PEG and PVA ultimately provide tissue engineers with a “blank” template that can be systematically modified in a controlled manner to possess a wide range of defined chemical, mechanical, and biological properties.

Unlike the polyesters and polyanhydrides described earlier in this section, PEG and PVA are not inherently degradable. However, PEG and PVA can be easily modified to contain either enzymatic or hydrolytic degradation sequences, or both. Thus, not only can the tissue engineer tailor the hydrolytic degradation time for a PEG scaffold, but they may also incorporate moieties that are sensitive to cell-secreted enzymes in order to facilitate creation of a system where scaffold degradation coincides with tissue growth.

Figure 6. (a) Poly(ethylene glycol) may be chemically modified with vinyl groups (b) to form a material that is polymerized into hydrogel structures via exposure to light (photopolymerized PEG). (c) Bioactive molecules may also be covalently incorporated into these structures by modifying one end group of photoactive PEG with a biological ligand.

Fabrication of PEG and PVA scaffolds is commonly performed via photopolymerization. The end groups of these polymers are modified to contain vinyl groups (Fig. 6) that enable light-induced polymer crosslinking and hydrogel formation under specified conditions. Unlike other processing methods, the conditions of photopolymerization are very mild and can be executed in the presence of cells and sensitive bioactive agents. Photopolymerization may be performed *in situ*, thus offering a minimally invasive method of implanting biomaterials into the site of desired tissue repair. Moreover, the photopolymerized material can assume complex shapes, as it can fill irregularly sized defects *in situ* without complicated molding or shaping techniques. The hydrogel structures that result from photopolymerization are transparent in appearance and possess varying mechanical properties that are dependent on polymer molecular weight and concentration. These materials may also be covalently modified to present various bioactive agents that stimulate cell adhesion to the scaffolds, as discussed in later sections. The PEG and PVA hydrogels possess excellent biocompatibility and are very successful in supporting cell viability, growth, and function. Disadvantages of these materials include their poor tensile strength and relatively small pore size.

Other Synthetic Materials. Numerous other synthetic materials have demonstrated promise for tissue engineering applications, including poly(acrylamides), poly(urethanes), poly(orthoesters), poly(lactones), poly(propylene fumarates), and poly(phosphazenes). A more detailed discussion of the role of synthetic materials in tissue engineering is available in several reviews (9,11,12).

Limitations. Synthetic materials alone cannot provide biological cues to influence cell behavior and tissue formation; these materials serve as only structural supports for cell growth. Thus, it is difficult to recreate a cell's natural biological environment using only synthetic materials. Moreover, issues with material biocompatibility persist. Biocompatibility of scaffolds and their degradation products remains a significant obstacle in the development of new synthetic materials. Furthermore, biocompatibility does not necessarily imply hemocompatibility (blood compatibility), creating further challenges in the creation of materials for blood-contacting applications. Finally, because most synthetic materials degrade via hydrolysis,

tissue engineers continue to struggle with the problem of tailoring material degradation to tissue regeneration such that the material remains for a sufficient period of time to support tissue growth, but not so long as to inhibit tissue formation.

Bioreactors

The previous sections highlighted the importance of isolating cells that are capable of generating new tissues and creating materials that can support new tissue growth. Once the appropriate cell types are procured and material scaffolds are constructed, what is the optimal manner in which to combine these components to generate new tissues? Furthermore, what is the appropriate environment for cultivation of a new tissue as it develops? These are critical questions in tissue engineering approaches, and a variety of bioreactor (13,14) systems have been built to control and optimize cell engraftment cell survival, and proper cell function within biomaterial scaffolds.

Cell Seeding. An initial challenge posed in cell-based tissue engineering schemes involves simply placing cells within a biomaterial construct, a process termed cell seeding. In most strategies, it is important to encourage as many cells as possible to engraft within a biomaterial scaffold to promote generation of new tissues and to avoid squandering valuable cellular components. More efficient cell seeding limits the size of a biopsy needed for cell sourcing and may also reduce the extent of cell expansion necessary to produce adequate cellular components. In addition, studies aiming to generate cartilage, bone, and cardiac tissues have demonstrated that cell seeding density and homogeneity directly influence the growth of new tissues. Higher cell densities lead to enhanced tissue formation, while more homogeneous cell seeding distributions result in more uniform tissue formation. In view of these previous results, investigators have developed a variety of strategies to encourage efficient and homogeneous cell seeding.

The simplest method of cell seeding, termed static seeding, involves simply adding a cell suspension onto a scaffold construct and passively allowing the suspension to permeate the material. This method often leads to inefficient cell seeding and heterogeneous cell distribution. In fact, static seeding approaches often result in growth of only thin $\sim 100\ \mu\text{m}$ layers of tissue due to limitations in cell seeding density and homogeneity as well as limited nutrient diffusion. The limitations of this static approach have led to development of more active cell seeding approaches, which include stirred bioreactor systems, direct perfusion bioreactors, and rotating wall bioreactors. In a stirred bioreactor, a dilute suspension of cells is continuously stirred around a stationary, porous scaffold construct, allowing for convective flow. Similarly, direct perfusion bioreactors encourage infiltration of cells by directly flowing a cell suspension through a stationary porous scaffold. Rotating wall bioreactors encourage mixing of cells with scaffolds by rotating the entire bioreactor casing around a central axis. Each of these strategies has enhanced the efficiency and

homogeneity of cell seeding, resulting in more copious and uniform new tissue development.

Mass Transport. Encouragement of mass transport to and from a developing tissue is among the most formidable challenges in tissue engineering. This challenge is particularly daunting *in vitro*, where a developing tissue cannot be exposed to a functional vascular network. Mass transport is vital in tissue engineering approaches, as it provides a means for delivery of oxygen and nutrients to cells within a developing tissue. Tissues that are grown in the absence of facilitated mass transport typically contain a shell of viable tissue surrounding an inner core of necrotic tissue. The thickness of healthy tissue is commonly $< 1\ \text{mm}$, which is not an appropriate scale for a majority of intended tissue engineering applications. To address this limitation several investigators have developed bioreactor systems that encourage mass transport throughout a developing tissue. These systems use mechanisms that are similar to the aforementioned cell seeding bioreactors, and in this case convective flow is used to transport oxygen, nutrients, and wastes during new tissue development. The result is a significant increase in the total amount of tissue grown, both *in vitro* and *in vivo*. Bioreactor systems that enhance mass transport have become important in bone, liver, and skeletal muscle tissue engineering approaches, and the clear benefit of mass transport during tissue development *in vitro* has motivated strategies aimed at increasing mass transport *in vivo* (e.g., by promoting vascular tissue in growth).

Inductive Signaling. Efficient and homogeneous cell seeding and optimal cell survival have a substantial impact on the success of a tissue engineering approach. However, it is also important to expose growing tissues to signals that direct their development into functional tissues. This is particularly crucial in emerging stem cell-based tissue engineering schemes, in which cells must be exposed to signals that direct differentiation and induce formation of the tissue of interest by cells capable of generating multiple mature tissue types. Therefore, there is a need to develop bioreactor systems that provide a range of signals to cells to encourage functional tissue growth *ex vivo*. To that end, investigators have developed bioreactor systems that are capable of delivering both biochemical signals (e.g., protein growth factors) and mechanical forces (e.g., fluid shear forces, compressive forces). As a result, new bioreactor systems allow for growth of tissues that more effectively mimic natural tissue structure and function. Illustrative examples include cartilage, bone, skeletal muscle, ligament, and cardiovascular tissues.

Of course, in many cases the most effective bioreactor system for new tissue development is actually the *in vivo* implantation site. Therefore, an important consideration in tissue engineering is how long, if at all, a cell-scaffold construct should be cultured *ex vivo* prior to implantation. For example, several recent approaches have focused on encouraging vascular tissue infiltration *in vivo* to address the challenge of mass transport to and from a developing tissue. For tissues that are particularly dependent on high oxygen tension (e.g., liver tissue) inducing vascular tissue

ingrowth *in vivo* may be a more effective strategy when compared with convective fluid transport in a bioreactor *ex vivo*. However, for poorly vascularized tissues (e.g., cartilage) that rely heavily on the local mechanical environment during their development, the mechanically and biochemically controlled environments of a bioreactor system may allow for optimization of tissue development *ex vivo*. Other tissue types may benefit from an initial culture period *in vitro* for cell expansion and early tissue development, followed by implantation into a supportive *in vivo* site. The amount of *in vitro* culture time that is appropriate prior to implantation of a tissue engineered construct is an important open question in several approaches.

Mechanical Signaling. The mechanical environment is a key factor during development of several tissue types, and mechanical forces become important as early as the eight-cell stage of embryonic development. Similarly, mechanical forces are important parameters during development of several engineered tissue types. Numerous physical factors have been shown to influence growth of engineered cartilage tissue, including hydrodynamic forces and cyclic mechanical compression and tension. In addition, systems for application of tensile stresses to growing skeletal muscle influence the ultimate contractile properties of the engineered muscle tissue. Mechanical forces also have a clear effect on bone development, repair, and regeneration, and investigators have taken advantage of these effects to build bioreactors that provide mechanical stimulation (see the section Case Studies in Tissue Engineering). To address the importance of mechanics, several investigators have generated instrumentation for application of biomechanical forces to developing tissues. Bioreactors can be designed to include screws to apply static strain or motorized load cells for dynamic actuation, and the biomechanical components are engineered to interface with other bioreactor components, including stirring tools for mass transport and media containing inductive agents. Biomechanical forces have played a particularly prominent role in emerging functional tissue engineering approaches, which often aim to provide factors that directly mimic the characteristics of the corresponding *in vivo* environment and improve the properties of the engineered tissue.

Emerging Designs. Although they are beyond the scope of this article, it is important to note that new concepts are emerging in bioreactor design at the cellular and subcellular scale. Several investigators are actively developing microfluidic systems that are capable of culturing multiple cell types simultaneously in highly controlled environments. These systems are being customized for coculture of multiple cell and tissue types (often termed organ-on-a-chip approaches), as well as highly controlled drug delivery. Microfluidic systems can also be interfaced with biomaterials to provide a powerful platform for highly controlled tissue development *ex vivo*. These approaches and others are enhancing the level of complexity that is possible in bioreactor design, and may allow for more direct mimicry of natural microenvironments.

Figure 7. Schematic representation of inductive tissue engineering approaches. Cells are exposed to 3D environments that are engineered to contain covalently linked or soluble agents. The agents are chosen to influence cell activity, ultimately leading to induced growth of a desired tissue.

INDUCTIVE APPROACHES

A variety of investigators have designed 3D matrices to interface directly with mammalian cells, and these materials were described in the biomaterials section above. Both natural (e.g., collagen gels) and synthetic [e.g., poly(L-lactic acid)] materials have been used for decades as scaffolding to support tissue formation from cells *in vitro* or *in vivo*. These materials have historically been passive, in that they have not exerted a high level of control over the signals presented to resident cells. In the past decade, matrices have been designed to interact with cells via specific cell attachment ligands, or designed to deliver soluble signals, so that characteristics of the cell's microenvironment can be tightly controlled (Fig. 7). Bioactive matrices have been used to delineate the effects of specific cell attachment ligands, material properties (e.g., mechanics), and soluble signals on attachment, proliferation, migration, and differentiation of a wide variety of mature cell types. These strategies are often termed inductive approaches, as they are designed to induce a particular cell activity (e.g., tissue formation). The following paragraphs describe inductive schemes that have been used to add a bioactive component to biomaterial matrices.

Covalent Modification of Biomaterials

One widespread approach used to confer bioactivity involves covalently linking biologically active molecules to a biomaterial (15). In this general approach, a biological molecule is engineered to include a chemically reactive group, which is then reacted with a functional group within a biomaterial. The result is a material that has physical properties defined by the original material, and with biological properties defined by the linked biological molecule. This approach has been primarily used to link peptide sequences that promote cell attachment, including RGDS, RGDY, YIGSR, and IKVAV. For example, synthetic PEG hydrogels and natural alginate hydrogels, which do not intrinsically interact with cell surface receptors, can now be readily modified with peptides that promote cell attachment and desired function. In addition to these methods that deliver signals to cells, investigators have also developed materials that respond to cell activity. One example of this general approach is materials that are held together, or cross-linked, by biochemically labile chemistries. These

materials are designed so that their labile linkages are degraded in response to enzymes that are produced by resident cells. Thus, by creatively designing these linkages investigators have been able to generate materials that respond to cell migration and differentiation, resulting in materials that can effectively "listen" to cells. Taken together, the inductive biomaterials created by covalent modification can be considered truly cell interactive, as they are able to deliver signals (e.g., cell adhesion ligands) to cells, and respond to cell activity (e.g., by degrading).

Delivery of Soluble Factors

Another important focus of recent tissue engineering approaches has been delivery of proteins, called growth factors, which can directly modulate cell activity (16). Traditional growth factor delivery approaches have focused on embedding proteins in plastic micron-scale spheres or suspending proteins in highly hydrated gels. In each case, the protein is released via diffusion as the carrier materials degrade, resulting in a high local concentration of the protein. The advent of these technologies has had a revolutionary effect on medicine, and the worldwide market for drug delivery technologies is expected to exceed \$100 billion by 2005. Although these technologies have been useful in a wide variety of biomedical applications, their application to tissue engineering is pragmatically limited. Plastic microspheres do not provide a structural matrix for tissue ingrowth and are difficult to process into structural matrices while maintaining the biological activity of the embedded protein.

Hydrated gels are also nonideal carriers, as growth factors typically diffuse out of the gel matrix rapidly, resulting in limited signaling. Investigators have recently developed innovative approaches to address the limitations of these systems and allow for longer term protein release within structural matrices that support tissue development. For example, plastic microspheres have been engineered to form aggregates with cells or to form a matrix with interconnected pores, and these new strategies allow for inclusion of biologically active proteins. The proteins are then released into the cell population in a sustained manner as the material degrades. These methods are flexible in the type of growth factors that can be included, and have recently been extended to delivery of multiple active growth factors simultaneously. Another recent approach involves covalent immobilization of active growth factors within a hydrogel matrix to locally contain growth factors and limit diffusion out of the hydrogel. This approach has been applied to delivery of vascular and neural growth factors, and could potentially be applied to other proteins, provided they maintain biological activity when covalently immobilized. Taken together, these approaches have been quite successful in actively influencing cell activity within structural matrices during new tissue development. The next generation of protein delivery approaches is likely to exert a higher level of control over where and when cells are exposed to inductive signals. Spatial patterning and tightly regulated timing of protein delivery are routine in natural tissue development, and may be similarly important in complex tissue engineering applications.

Gene Delivery

Another set of inductive approaches does not rely on delivery of peptides or proteins to cells from a synthetic system, but instead focuses on genetic manipulation of cell activity (17). Investigators have developed a variety of strategies to deliver genes to cells, and the genes are typically designed to induce cells to secrete inductive proteins. The gene delivery approaches often utilize the same core technologies that have been used for protein delivery, including sustained release from polymer scaffolds and release from hydrogel matrices, but they substitute plasmid DNA for proteins. Plasmids are circular strands of DNA, which typically contain a single gene under the control of a promoter, which is chosen to enable production of an encoded protein in the target cell type. The encoded protein, often a protein growth factor, is chosen to influence cell activity. Therefore, this approach generates cells that act as bioreactors to produce an inductive protein, and the protein, in turn, encourages new tissue development. This gene delivery approach has been successfully applied to engineering of bone, skeletal muscle and vascular tissues, and the general concept could find broad applicability in engineering of essentially any tissue type.

CASE STUDIES IN TISSUE ENGINEERING

Bone Tissue Engineering Strategies

Vertebrate bone tissue is a dynamic organ with a range of vital functions. Bone serves as a storage depot for mineral ions, a protective barrier for internal organs, and a solid support for muscle actuation. Perhaps the most unique and intriguing property of bone is its ability to continuously regenerate its structure, thereby maintaining consistent structural and mechanical properties. A coordinated set of cell and molecular activities mediates this dynamic remodeling process, and these activities are orchestrated by biochemical, mechanical, cellular influences. The dynamic nature of natural bone tissue makes it perhaps the ultimate "smart material", and the characteristics of natural bone have served as an inspiration to chemists and materials scientists who aim to develop stimulus-responsive and self-healing materials. Furthermore, the constant generation of new bone tissue in natural systems serves as an excellent model for tissue engineering, a field that similarly strives to regenerate natural tissue structure and function. Therefore, bone can be considered an exemplary system for a variety of tissue engineering approaches, including conductive, inductive, and cell-based strategies.

It is perhaps surprising that there is any need for engineered bone tissue at all in view of the efficiency of bone regeneration in vertebrates. However, there are several pathological conditions that result in permanent bone loss or damage. Costs of musculoskeletal conditions represent an average of 3% of the gross domestic product of developed countries (an estimated \$254 billion annually in the United States) and >600,000 inpatient fracture reduction procedures are performed in the United States annually. Furthermore, bone and joint diseases account for one-half of all chronic conditions in people over the age

of 50. The predicted doubling of this age group's population by 2020 suggests that the tremendous need for novel bone repair and replacement therapies will continue to grow rapidly. Regeneration of natural tissue represents a promising approach to replace bone, and could both supplant many of the current metallic hardware-based bone replacement methods and expand the range of bone loss conditions that can be effectively treated. Filling of bone voids in non-union fractures or maxillofacial deformities, bridging of gaps in spine fusion surgeries, and stabilization of vertebral compression fractures provide illustrative potential targets for new bone tissue engineering approaches. Current clinical strategies aimed at repairing or replacing natural bone tissue are typically passive, relying on mechanically sound hardware (e.g., titanium, polyethylene) to replace the structural properties of natural bone. These approaches do not exert a high level of control over the process of new bone formation in a defect site. Limitations in these approaches invoke new therapies for bone replacement, including bone tissue engineering (18–20). The following paragraphs give a brief description of representative tissue engineering approaches that have been developed to repair or replace bone tissue. A more focused and detailed treatment of this topic is given in several outstanding review papers (18–20).

Cell Sources. Osteoblasts are the chief bone-forming cells in natural bone tissue. Based on the regenerative capacity of natural bone tissue it seems obvious that mature osteoblasts would be an excellent candidate as a cell source for bone tissue engineering. These cells can be isolated from the patient (autologous transplantation) or from a donor (allogeneic transplantation), and the typical donor sites are the calvaria or the iliac crest. Investigators have used osteoblasts seeded within various biomaterial scaffolds to engineer bone tissue. However, there are significant limitations to the use of these differentiated cell types. Isolation procedures result in a limited number of autologous or allogeneic osteoblasts, and these cells are difficult to expand in culture. In addition, allogeneic cells harbor the potential to bring about unwanted immune responses. These limitations have led rapidly to the identification and use of alternative cell sources in bone tissue engineering.

The best characterized cell sources in common use in current bone tissue engineering approaches are bone marrow derived fibroblasts. These cells include the aforementioned mesenchymal stem cells, as well as other more committed osteoblast precursors, called preosteoblasts, isolated from bone marrow. These cell types, which are typically distinguished from other cells that reside in the marrow based on their ability to attach and form colonies on standard cell culture substrates, have a long history of use in bone biology and orthopedic regeneration. Between 1968 and 1974, Friedenstein and co-workers (see Ref. 5 for details) undertook a series of studies on the bone-forming capacity of bone marrow derived cells. The studies resulted in isolation of a specific cell type, termed the colony-forming unit fibroblast, which was characterized by its ability to attach to standard cell culture substrates and form isolated colonies in culture. It was not until two decades later that

these cells were further characterized by Caplan and co-workers (see Ref. 5 for details) and called mesenchymal stem cells (MSCs). The pioneering work of Caplan's laboratory in skeletal tissue engineering using MSC sources, coupled with a high profile publication by Pittenger et al. (see Ref. 5 for details) describing the tremendous multipotential of these stem cells, has facilitated use of these cells in bone tissue engineering applications. Recent studies have also identified other adult precursor cells that are capable of forming bone tissue, including skin-, adipose-, and dental pulp-derived mesenchymal stem cells. Investigators are now using each of these cell types as integral components in bone tissue engineering schemes.

Biomaterials. Natural long bones (e.g., the femur) develop upon a cartilage template matrix during a process termed endochondral ossification. In many ways, this natural cartilage template serves as an ideal support for development of new bone tissue. The cartilage matrix: (1) is porous and therefore allows for infiltration of bone-forming cells and vascular tissue; (2) is capable of withstanding the mechanical environment in an orthotopic location; (3) provides a substrate that is conducive to new bone formation; (4) is biodegradable and can be remodeled by infiltrating bone cells; and (5) contains signals that induce new bone formation. These natural characteristics mirror the parameters that are important for design of natural and synthetic scaffolds for bone tissue engineering, including pore structure, mechanical properties, degradability, osteoconductivity, and osteoinductivity. Osteoconductivity is generally defined as the ability of a material to support formation of bone by bone-forming cells (e.g., in a bone defect), while osteoinductivity is defined as the ability of a material to induce formation of bone tissue in conditions that are not otherwise conducive to bone formation (e.g., in a nonorthotopic location). Investigators have developed several classes of biomaterials to address these parameters and to successfully engineer functional bone tissue.

A broad range of natural and synthetic materials have been explored in bone tissue engineering, including poly(anhydrides), poly(fumarates), self-assembling peptide amphiphiles, and alginate hydrogels. Although these materials are well characterized in the context of bone engineering, the most commonly used bone tissue engineering scaffolds have been poly(α -hydroxy esters), type I collagen-based materials, and calcium phosphate based minerals. Each of these base materials can be processed into porous scaffolds that degrade into nontoxic byproducts, allowing for formation of new bone tissue in concert with material degradation. In addition, the mechanical properties of these matrices are dictated by their structure and composition, allowing for significant mechanical tailoring. A particular advantage of calcium phosphate based materials is a property known as bioactivity, which is the ability of these materials to serve as an excellent template for synthesis of mineralized tissue by bone cells and bone precursor cells *in vitro* and *in vivo*. For example, mesenchymal stem cells differentiate and form bone tissue more readily on calcium phosphate materials when compared with other types of scaffold, including polyesters and

protein-based hydrogels, and this phenomenon is attributed to calcium phosphate bioactivity. Many bone tissue engineering approaches exploit this bioactivity by processing or synthesizing new types of calcium phosphate based materials, including both natural (e.g., coralline hydroxyapatite) and synthetic (e.g., sintered hydroxyapatite) scaffolds. Recent approaches have also combined natural and synthetic polymers with calcium phosphate minerals to create hybrid materials for bone tissue engineering. These materials directly mimic the organic–inorganic composite structure of the natural bone extracellular matrix, and they have shown substantial promise as supportive scaffolds for new bone formation.

Bioreactors. *In vitro* engineering of bone tissue has been an active area of study for over a decade. However, early attempts at bone tissue engineering demonstrated limitations that highlight the importance of bioreactor design. Previous studies indicate that growth of bone tissue within 3D scaffolds in static culture conditions is limited to the outer 200–800 μm of a scaffold construct. The poor tissue growth and cell death observed at locations deeper within these scaffolds was likely caused by poor nutrient transport into the developing tissue. These studies and others have provided an impetus to create new bioreactor systems that enhance mass transport and allow for development of more homogeneous bone tissue *in vitro*. Spinner flasks and rotating wall bioreactors have been shown to substantially enhance bone synthesis by mesenchymal stem cells cultured within 3D polyester scaffolds. In addition, perfusion culture systems successfully enhanced generation of bone tissue by osteoblasts and bone marrow-derived precursor cells *in vitro*. In each case, the success of these approaches is attributed to improved nutrient transport within the developing tissue, which is generated by fluid flow.

Other *in vitro* bioreactors have been designed to understand and manipulate the effect of mechanics on engineered bone tissue growth. Mechanical forces have a well-known influence on remodeling of adult bone tissue and, in turn, regulation of bone strength over time. Mechanical stimulation is also vital to proper early development of cartilage and bone, and the mechanical properties of developed bone tissue can be correlated to the load applied during development. In view of these mechanical effects on bone maintenance and development, it is not surprising that mechanical forces have a pronounced effect on bone formation by osteoblasts and osteoblast precursor cells in cell and tissue culture. Culture systems that apply compressive or shear forces to bone-forming cells have shown that the cells respond to mechanical stress by enhancing synthesis of bone matrix.

Inductive Approaches. It is clear that protein growth factors are a vital component of natural bone development and repair processes, due to their effects on bone forming cells and blood vessel ingrowth. Based on these observations, investigators are developing several novel delivery systems that allow for controlled delivery of protein growth factors to bone defect sites to improve or accelerate bone healing. The most potent known growth factors related to

bone regeneration are the class of molecules known as bone morphogenetic proteins (BMPs). Discovery of the unique ability of demineralized bone matrix to induce bone tissue formation in extraskeletal sites led to the isolation and discovery of BMPs as inductive factors. Since their discovery, BMPs have been delivered from several materials to induce formation of new bone tissue in a variety of skeletal and extraskeletal sites. The BMP delivery vehicles examined thus far include demineralized bone matrix, polyester scaffolds, β -tricalcium phosphate, and hydroxyapatite. In each case, BMPs in conjunction with a natural or synthetic carrier material *in vivo* induced dramatic increases in the quantity and functionality of regenerated bone tissue when compared with the carrier materials alone.

Recent inductive approaches have also addressed the importance of angiogenesis in natural bone growth, development, and repair. Bone does not grow, develop, or heal properly when angiogenesis is artificially blocked. However, until recently there had been little interest in specifically inducing ingrowth of a functional vascular supply to support developing bone tissue. Studies have recently demonstrated that delivery of growth factors that induce blood vessel ingrowth (e.g., vascular endothelial growth factor) can substantially increase bone repair and regeneration. These studies provide a new mechanism for actively inducing bone regeneration.

Inductive gene delivery strategies have also been explored in bone tissue engineering. Investigators have delivered plasmid deoxyribonucleic acid (DNA) encoding bone morphogenetic protein-4 (BMP-4) and parathyroid hormone from collagen-based scaffolds. Localized delivery of these plasmids led to the formation of local bone foci similar to natural bone. In addition, multiple studies have achieved transfection of fibroblasts with a gene encoding for bone morphogenetic proteins, resulting in more extensive bone formation. These genetic approaches will likely gain more significance and acceptance with the emergence of more efficient methods for gene transfer, and they could be used in conjunction with novel stem cell based approaches.

Combination Approaches. In this section, bone tissue engineering components are separated into distinct categories to facilitate the readers understanding of the field. However, it is important to note that the vast majority of strategies for bone tissue engineering involve a combination of multiple components, including materials, cells, and biological molecules. In fact, emerging tissue engineering schemes almost exclusively utilize combinations of two or more of the categorized components in this section, and it has become more common for investigators to unite materials, molecules, cells, and highly controlled bioreactor environments to direct bone tissue development. Development of combined approaches requires a more complete understanding of the interdependence of distinct components. For example, the combination of BMPs with a carrier material is critical, and the identity of the carrier material can significantly influence BMP activity. In addition, surface characteristics and geometry of the scaffold material significantly influence induction by BMPs. The complex interplay between substrates and growth factors in synthetic tissue engineering scaffolds emulates the

cross-talk between extracellular matrix signals and soluble signals in natural tissue development and regeneration. Indeed, as the complexity of bone tissue engineering systems increases, researchers may approach the intricacy and control demonstrated during natural bone development and regeneration.

Cardiovascular Tissue Engineering Strategies (21–23)

Cardiovascular disease is a significant cause of morbidity and mortality in the United States and developed countries. Successful treatment has often been limited by the poor performance of synthetic materials utilized for tissue replacement, as hemocompatibility remains a significant challenge in biomaterial design. A lofty goal for cardiovascular tissue engineering is the development of a completely tissue engineered heart. Progress toward this goal will likely be made through the parallel development of effective tissue engineered components of the cardiovascular system. These individual components include blood vessels, heart valves, and cardiac muscle. Each of these structures will be briefly discussed with respect to the cell source, biomaterial, and bioreactor considerations.

Heart Valves. The human heart contains four valves, each with slightly different characteristics and each experiencing a different hemodynamic environment. While heart valves are relatively small, thin structures (on the order of a few hundred microns thick), their composition is surprisingly complex. Valve dysfunction may occur via a variety of mechanisms, and the current treatment for diseased valves is predominantly valve replacement. Over 290,000 people received heart valve replacements in 2003; this number has been steadily rising over the last decade and is expected to reach 850,000 by 2050. Currently available valve substitutes have enabled these patients to experience an enhanced quality of life and have extended patient survival. Yet, in 50–60% of patients with substitute valves, complications associated with these valve replacements necessitate reoperation or cause death within 10 years postoperatively. Present heart valve substitutes consist of either mechanical prosthetic valves or tissue valves that are derived from either human or animal tissue. Perhaps the greatest shortcoming of current valve substitutes is their inability to grow or remodel in response to the physiological environment. Valve replacement is particularly challenging for pediatric patients, who not only outgrow mechanical valves quickly, but also experience rapid calcification (pathological hardening) of transplanted tissue valves. Valve replacement in the elderly has also become more complex; as the average life span increases, but the age at which heart valve disease occurs does not, patients > 65 now need valves that will last 20 years, not just 10. Fabrication of a tissue engineered valve using a biodegradable scaffold may enable the creation of functional valve tissue capable of growth and remodeling in response to changes in its physiological environment. Significant advances have recently been made toward the creation of a functional tissue engineered heart valve via the immobilization of cells within a variety of natural and synthetic matrices, as will be briefly discussed here. A

durable, nonobstructive, nonthrombotic, self-repairing tissue valve that would grow with the patient and remodel in response to *in vivo* stimuli is the current goal for tissue engineered heart valves.

Cell Sources. The source of cells to use in valve regeneration remains a significant concern. Valvular interstitial cells (VICs) comprise the majority of the cell population in heart valves, with a thin layer of endothelial cells (ECs) providing the valve with a nonthrombogenic surface. The adaptive, complex, and dynamic structure of heart valves can be primarily attributed to the VICs, which are responsible for valve extracellular matrix production as they constantly remodel and repair the valve. The organization and relative proportions of the valve matrix are paramount to valve function, thus emphasizing the importance of these interstitial cells. Although these cells readily proliferate and function in *in vitro* culture, they are very difficult to obtain from a patient or living donor. Other mature cell types, such as smooth muscle cells, dermal fibroblasts, and myofibroblasts, can perform some of the functions of VICs, but ultimately do not exactly mimic all of the properties of VICs. Recent studies suggest that marrow stromal cells may be a viable immature cell source for valve tissue engineering. Embryonic stem cells also hold promise as a cell source for VICs, although the method of inducing their differentiation to VICs has not yet been identified.

Construction of fully functional heart valves will also require endothelialization of the valve surface. The ECs play a critical role in both the maintenance of valve homeostasis and the pathogenesis of valvular disease. Mature cell sources for ECs include dermal microvascular endothelial cells (HDMECs), which are isolated from human foreskin, and endothelial cells isolated from human umbilical veins (HUVECs). However, neither of these sources provide autologous cells for a patient in need of valve replacement. Mesenchymal stem cells have recently been shown to differentiate into ECs, indicating that MSCs are a promising source for autologous ECs. Researchers have also identified techniques to induce the differentiation of ECs from embryonic stem cells.
