Biomaterials. Construction of a tissue engineered heart valve requires a material that is readily processed into a complex shape, can withstand harsh hemodynamic stresses, and yet is flexible enough to allow for valve opening and closure. To this end, synthetic scaffolds have been constructed using PGA, PLGA, polyhydroxyalkanoate (PHA), or poly-4-hydroxybutyrate (P4HB). Studies using PGA/P4HB in particular have been very successful in large animal models. Much work has also focused upon using decellularized native valves as a scaffold material; in this approach, immunogenicity of a donor valve is lessened by removing the cells, leaving only the extracellular matrix structure. The primary advantage of this strategy is that the appropriate matrix composition of the valve is already present and does not have to be reconstructed. These valve scaffolds can then be recellularized with autologous (non-immunogenic) cells, with the goal of restoring the valve's regenerative capacity. Finally, hydrogels made from

several naturally derived materials, such as collagen or hyaluronic acid (HA), have also been used for heart valve tissue engineering. Although HA-based valve scaffolds have not yet progressed to *in vivo* studies, the use of HA is particularly exciting, as this polysaccharide is required for cardiac morphogenesis and native heart valve formation.

Bioreactors. Because it is difficult to survive with only a partially formed or semifunctional heart valve, tissue engineered matrices must first be cultured in a bioreactor environment prior to implantation. Culture of tissue engineered valves in bioreactors aims to create mechanically stable and reliable valve tissue with significant (or complete) degradation of the material scaffold prior to implantation. In addition to providing appropriate nutrients to the cell-seeded scaffolds, such bioreactors are intended to provide physiologically relevant flow and shear stresses in order to condition the tissue for *in vivo* implantation and function. Furthermore, tissue engineered heart valves exposed to pulsatile fluid shear stresses *in vitro* display improved function over constructs cultured in bioreactors without a mechanical signal. Investigators working on tissue engineered heart valves have made significant advances in bioreactor design, and these bioreactors may have utility for the culture of other tissues that require pulsatile stresses.

Cardiac Muscle. Because adult cardiac muscle cells (cardiomyocytes) cannot regenerate, myocardial damage induced by a myocardial infarction (heart attack) or other injury results in loss of cardiac function and progressive deterioration leading to congestive heart failure. Necrotic cardiomyocytes in infarcted ventricular tissue are replaced by fibroblasts, leading to the formation of scar tissue and creating regional contractile dysfunction. Current treatments consist of mechanical support using left ventricular assist devices and, ultimately, heart transplantation. The incidence of heart failure at 1 year postheart attack is >20%, and the 1 year postheart attack mortality rate (~30%) did not change from 1975–1995, highlighting the lack of effective treatments to combat this problem. Multiple tissue engineering strategies, including cell-only transplantation, inductive approaches, and implantation of cell-seeded scaffolds have been investigated in order to generate a viable method of repairing damaged heart tissue.

Cell Sources. Cardiomyocytes (CMs) are highly differentiated cells that comprise 70–80% of the heart's mass, yet only 20–30% of the total cardiac cell number. The remaining cell population consists of cardiac fibroblasts and endothelial cells, although CMs are primarily responsible for the contractile activity of the heart. Electromechanical coupling between CMs enables the transduction of electrical signals into muscular contractions. Use of mature autologous cells is feasible for some tissue repair applications, but is likely not possible for myocardial repair, primarily because adult CMs do not proliferate, and removal of any cardiac tissue to obtain CM progenitor cells could impair the function of the already-injured heart.

Cellular cardiomyoplasty (CCM) is a promising therapy that has recently emerged for the repair of damaged cardiac muscle and involves the injection of a suspension of cardiac-related cells into the injured heart (cell transplantation). The therapeutic goal of CCM is the replacement of dead heart muscle with functionally competent and contractile myocardium. Sources for these injected cells have included skeletal myoblasts, fetal cardiomyocytes, hematopoietic stem cells, mesenchymal stem cells, embryonic stem cells, and endothelial progenitor cells, yet the functional fate of these cells following transplantation remains unresolved, and normal electromechanical coupling between implanted cells and host myocardium has been absent. While CCM has been shown to augment myocardial function, there exists debate about whether the transplanted cells are actually functioning as cardiomyocytes. Strategies that do not involve regeneration of cardiomyocytes are limited to rescuing injured tissue and are unable to contribute directly to the restoration of contractile function or increase systolic function. Hence, if the transplanted cells are not differentiating into cardiomyocytes, then contractile, electrically coupled, fully integrated cardiac tissue is not being regenerated, leading to suboptimal improvement of cardiac function. Furthermore, because only 20% of the heart's cells are CMs, stem cells injected into the heart simultaneously receive developmental cues from many different cell types, making it difficult to predict the differentiation pathway that the transplanted cells will follow. Because researchers currently cannot regulate the differentiation factors to which cells are exposed *in vivo*, transplantation of stem cells that are committed to the cardiomyocyte lineage may be a more effective method of regenerating CMs *in vivo*. These cell sourcing issues observed with cellular cardiomyoplasty also extend to the tissue engineering strategy of implanting cell-seeded biomaterial constructs.

Biomaterials. While cellular cardiomyoplasty has been successful in augmenting cardiac function, it has still not been proven to reliably regenerate cardiac muscle. Thus, many researchers are combining cardiac-related cells with biomaterials in order to develop an approach that enables greater control over tissue formation. Numerous synthetic, natural, and biomimetic materials have demonstrated promise for cardiac tissue engineering applications. Seeding of cardiomyocytes on PGA- or PLGA-based materials has produced cardiac grafts whose *in vitro* structural and electrophysiological properties approach those of native heart muscle. However, the acidic degradation products and brittleness of these materials have hindered their *in vivo* success. Several collagen-based matrices have been used to create small myocardial structures that morphologically resemble and possess many of the properties of native myocardium, while alginate matrices also show good promise as scaffold materials for cardiac repair. Bioactive or inductive materials may also be used in a scaffold-only approach for cardiac tissue regeneration; recent studies have demonstrated the existence of a small number of cardiac progenitor cells within heart muscle, and implantation of a bioactive material containing appropriate agents may recruit these myocardial progenitors to the site of injury. While the number of polymers that have

been used to develop cardiac muscle is small at this point compared to the number used for other tissues, (e.g., bone, skin, and blood vessel) this number is likely to increase over the next decade as the push to develop a completely tissue engineered heart increases.

Bioreactors. *In vitro* development of cardiac muscle requires the use of appropriate nutrient delivery systems. Cell-seeded constructs cultured in perfusion bioreactors contain more uniformly distributed cells with enhanced differentiation. While direct perfusion of cell-scaffold constructs has been shown to be beneficial, culturing the constructs under laminar flow rather than turbulent flow has also been found to enhance engineered cardiac muscle. Laminar flow conditions can be provided by using a rotating bioreactor rather than a spinner flask. Another approach for *in vitro* culture of cardiac muscle is to subject cell-scaffold constructs to mechanical stimuli, such as pulsatile flow and cyclic stretch, as would be experienced *in vivo*. Bioreactors that combine perfusion mechanisms with mechanical signals, such as compression or stretching, significantly improve cardiac tissue formation and function over perfusion-only systems. The nutrient requirements for cardiac tissue are quite high, and this tissue is particularly sensitive to ischemic conditions. The thickness of a tissue engineered myocardial construct that can be developed using current techniques is limited to 100 μm , contrasting the 1 cm thickness of native heart muscle. Recent developments in the design of bioreactors for heart valves, which employ adjustable pulsatile flow and varying levels of pressure, may be applicable to the culture of engineered myocardium.

Large Diameter Blood Vessels (>6 mm). Vascular disease is a prominent problem in the United States, with approximately 500,000 coronary artery bypass surgeries performed each year. Natural tissues, primarily saphenous veins or internal mammary arteries, are generally used for coronary artery replacement. In general, the results have been quite favorable for these procedures. Unfortunately, as discussed earlier, the availability of donor vessels and issues with donor site morbidity often preclude the use of natural tissue grafts. Moreover, grafted vessels are often unable to adjust to the increased pressure and wall shear stress in the grafted position, resulting in inadequate vessel performance. Blood vessel replacements composed of entirely synthetic materials were first developed in the 1950s using polymers, such as polyesters, polyethylene terephthalate (PET, Dacron), and expanded polytetrafluoroethylene (ePTFE, Gore-Tex). However, implantation of these materials is permanent, with no regeneration of the biological blood vessel. Furthermore, several problems such as platelet adhesion and activation, and decreased mechanical compliance compared with adjacent arterial tissue, are also frequently associated with synthetic grafts. These problems have motivated investigations of tissue engineered alternatives.

Cell Sources. Blood vessels consist of three cell types: fibroblasts, smooth muscle cells, and endothelial cells. Most tissue engineering endeavors focus upon the smooth muscle and endothelial cells, which are generally obtained

from harvested autologous blood vessels. However, issues, such as donor site morbidity, vessel availability, and performance of an invasive surgery complicate the use of these mature, autologous cells. A solution to these problems may lie in the use of mesenchymal stem cells, which are capable of differentiating into vascular smooth muscle cells and endothelial cells, and may therefore represent an excellent cell source for vascular tissue engineering.

Biomaterials. Attempts to tissue engineer blood vessels date back to the 1970s, and the number of different materials that have since been used in these endeavors is numerous. Construction of a tissue engineered blood vessel requires a material that is resistant to platelet adhesion (nonthrombogenic), can withstand transmural pressure acting normal to the vessel wall and tangential shear stresses, and has similar mechanical properties to that of the adjoining native vessel. Much research has focused upon the use of collagen gels for vascular tissue engineering. Although collagen gels have poor mechanical properties, proper alignment and function of vascular cells in these gels has been observed. The PGA Polymer has been used alone and in combination with other synthetic materials (polyhydroxyalkanoate) to form tissue engineered vessels that remained functional for several months following implantation in an animal model. Recent research has focused upon the use of PEG hydrogels as vascular tissue engineering scaffolds, as the physical and biological properties of these materials are well suited for vascular applications. Finally, a unique vascular tissue engineering approach used no material, but instead rolled sheets of vascular cells into tubular shapes and observed excellent mechanical and functional properties of the tissue.

Bioreactors. With respect to shear stresses, flow, and application of appropriate mechanical signals, the bioreactor culture of tissue engineered vascular grafts possesses many similarities to the other cardiovascular applications discussed above. Application of fluid shear stresses is necessary in order to generate the cellular alignment found in native vessels and to stimulate proper function of vascular cell types. Because *ex vivo* studies of native intact vessels often have similar culture requirements as tissue engineered vascular grafts, a diverse range of researchers has been involved in the development of such bioreactors, yielding numerous configurations and approaches. Variables in the design of vascular bioreactors include constant or pulsatile flow through the vessel lumen, application of longitudinal strain, and perfusion of exterior surface of the vessel.

INTRODUCTION

Tomotherapy is intensity-modulated rotational radiotherapy utilizing a photon fan beam (1). The term tomotherapy derives from *tomographic radiotherapy*, literally meaning “slice” radiotherapy. Tomotherapy treatment delivery is conceptually similar to computerized tomographic (CT) imaging where a three-dimensional (3D) image volume is acquired as a stack of two-dimensional (2D) cross-sectional images. By analogy, a tumor volume can be subdivided into a stack of slices that are independently irradiated to achieve a 3D conformal dose distribution. Dose conformation is achieved by modulating the intensity pattern of the incident X-ray beam during rotation of the X-ray source using a fan-beam multileaf (MLC) collimator whose leaves are pneumatically driven to achieve near instantaneous leaf transitions between open and closed states. As shown in Fig. 1, the table motion can be incrementally stepped the width of the fan beam after each completed arc (serial tomotherapy) (2,3) or it can be

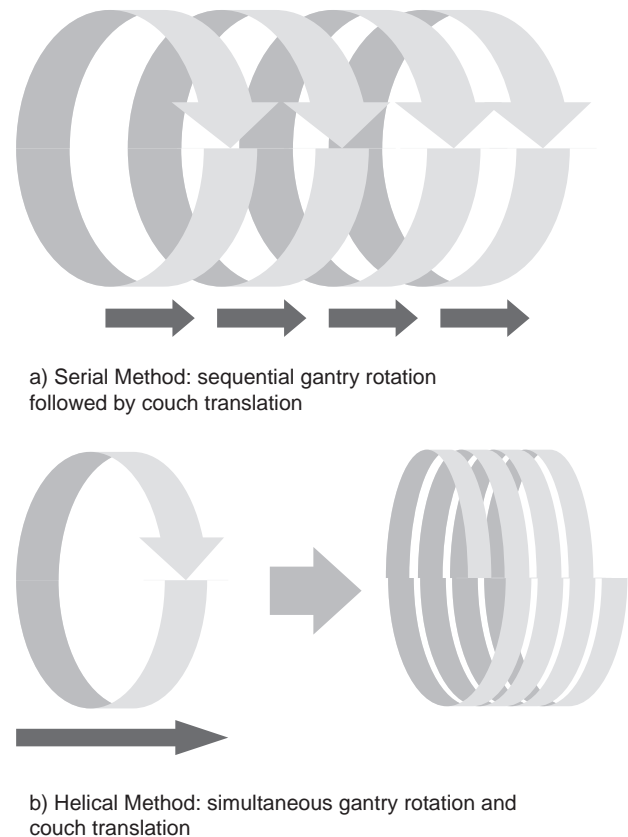

Figure 1. Tomotherapy methods: (a) serial tomotherapy, (b) helical tomotherapy.

Figure 2. Components of the NOMOS Peacock System: (a) gantry mounted MIMiC binary MLC and controller, and (b) table mounted precision positioner for accurately stepping the table between gantry rotations. (Photos courtesy Jim Hevzi, PhD, Cancer Treatment and Research Center, San Antonio, TX.)

translated simultaneously with continuous source rotation (helical tomotherapy) (4).

Two types of tomotherapy, serial and helical, have been developed and implemented clinically. Serial tomotherapy, embodied in the NOMOS Peacock System (North American Scientific - NOMOS Radiation Oncology Division, Cranberry Township, PA) is an add-on component for conventional C-arm medical linac gantries (Fig. 2a). It is feasible to deliver non-coplanar serial tomotherapy treatments using this implementation. Alternatively, the Hi-ART II helical tomotherapy system (TomoTherapy, Inc., Madison, WI) is a dedicated radiotherapy treatment unit built upon a helical CT ring gantry. The constraint of a ring gantry is minimal since few patients are treated with noncoplanar radiation fields and IMRT diminishes the need for these types of field arrangements. Most importantly, a ring gantry is a very stable platform for CT scanning and is used in all diagnostic CT scanners.

Both tomotherapy implementations have a high level of system integration with common components being (1) an inverse treatment planning system, and (2) computer controlled beam modulation using a pneumatically driven multileaf collimator (Fig. 3). One major difference between the two implementations is the integration of MVCT image guidance into the treatment delivery process of the Hi-ART II (5). The MVCT imaging is primarily used for daily target location to improve precision and accuracy of IMRT treatments. In addition, the detector can be used for machine quality assurance, and for reconstructing daily estimates of delivered dose using measured profiles of X-ray fluence

transmitted through the patient during treatment delivery (6). This latter capability, called *dose reconstruction* is useful to the process of *adaptive radiotherapy* wherein a daily discrepancy between planned and delivered dose due to errors in patient setup or changes in gross tumor volume can be corrected in future treatments.

HISTORICAL BACKGROUND ON THE DEVELOPMENT OF TOMOTHERAPY

Rotational treatment techniques were very popular in the era of orthovoltage (250 kVp) X rays prior to the development of megavoltage photon sources. Rotational delivery allowed improved dose at the tumor relative to the surface compared to treatments using a few fixed-beams portals. This was a consequence of the peak dose for orthovoltage X rays occurring at the skin surface, which for nonrotational deliveries was the dose-limiting feature of the treatment. The development of high energy photon beams from Co-60 and medical linear accelerators reduced the need for rotational treatments since the peak dose was shifted below the skin surface resulting in improved skin sparing when few field techniques were used. As a consequence, treatment techniques shifted almost exclusively to simpler few field beam arrangements, typically of opposed beams, that were easy to verify using planar radiography. This in turn eventually led to the development of dual energy medical linear accelerators, or linacs, with two X-ray energies: a low X-ray energy (4, 6 MV) for treatments in the

Figure 3. Tomotherapy binary MLCs: (a) the NOMOS MIMiC design has 20 pairs of opposed leaves that allow two slices to be treated per rotation. (b) The TomoTherapy binary MLC design consists of 64 interdigitating leaves that are used to treat a single slice per rotation. (Photo courtesy TomoTherapy, Inc, Madison, WI.)

head–neck region, and a high X-ray energy (10 MV or greater) for treating deep seated lesions in the trunk and pelvis. In situations where a single low energy machine was the only treatment unit available, rotational techniques were often used for deep-seated lesions, owing to the fact that the relative shape of the rotational dose distribution is insensitive to the X-ray energy used.

In 1988, Anders Brahme of the Karolinska Institute published an article that described the advantages of using nonuniform beam profiles to achieve conformal dose distributions of arbitrary shape (7). A key feature of this work was the application of a mathematical optimization method to determine the nonuniform profiles for few-field delivery. Subsequent efforts by Bortfeld et al. (8), Webb (9), and Holmes et al. (10) applied iterative tomographic image reconstruction methods to inverse planning of intensity modulated beams with the latter two investigations providing methods applicable to rotational IMRT. Webb's application of the simulated annealing algorithm for planning rotational IMRT (9) was implemented in the first commercial inverse treatment planning system, PeacockPlan (NOMOS Corp., Sewickley, PA), to support serial tomotherapy. The work of Holmes et al. (10,11) and Swerdloff et al. (12) under the direction of Dr. T. R. Mackie at the University of Wisconsin Department of Medical Physics began the formulation of a dedicated helical tomotherapy unit (1).

SERIAL TOMOTHERAPY: NOMOS PEACOCK SYSTEM

The Peacock System was developed during the early 1990s by the NOMOS Corporation under the leadership of Mark Carol, a neurosurgeon who became interested in the radiation therapy problem during his medical training (2,3). This system was designed as an add-on device to existing medical linear accelerators, many of which in the early 1990s lacked the features of a computer controlled MLC and a record and verify system needed to perform IMRT delivery. The first serial tomotherapy treatments were performed at the Methodist Hospital, Baylor College of Medicine, in March of 1994 under an Investigational Device Exemption with clearance from the Food and Drug Administration (FDA) coming in 1996. Since then, >100 systems have been installed clinically with over 10 thousand IMRT treatments completed successfully.

The Peacock System consists of four components: (1) CORVUS: an inverse treatment planning system; (2) MIMiC: a computer controlled multileaf collimator; (3) the controller: a dual computer system for control and continuous checking of the MIMiC; and (4) the Auto-Crane: a computer controlled table positioner. The latter three components are shown in Fig. 2.

CORVUS was the first commercial implementation of inverse treatment planning for IMRT. The planning system consists of (1) tools for import and fusion of CT and MRI images for subsequent contouring of treatment and avoidance regions including organs at risk; (2) a finite-size pencil beam 3D dose computation model; (3) an optimization engine based on simulated annealing and gradient-based optimization algorithms; (4) algorithms to convert optimized X-ray intensity maps to multileaf collimator field

shapes and their associated treatment times; and (5) tools to map patient treatments onto dosimetry phantoms for treatment plan delivery verification.

The MIMiC is a binary multileaf collimator. It consists of 20 pairs of opposed tungsten leaves that are 8 cm tall and project to nominally 1 cm wide at 100 cm from the radiation source. The leaves move quickly in and out of a fan beam to provide the intensity modulation. The motive power for the leaves was compressed air pushing and pulling on pistons. The binary collimator was licensed from the University of Wisconsin patent invented by Swerdloff et al. (12). The opposed leaf design allows two adjacent treatment slices to be treated simultaneously during a single arc producing a more efficient delivery. The treatment slice width can be set to 1 or 2 cm using mechanical stops, or to 0.4 cm using a tertiary collimator called the BEAK. The maximum size of the "modulated" volume is a 20 cm diameter cylinder whose length is determined by the longitudinal motion of the treatment table.

Tomotherapy treatments typically require an order of magnitude greater number of monitor units than conventional 3D conformal radiotherapy, consequently the leakage characteristics of the collimation system and the treatment unit are of concern as they influence the whole body dose equivalent received by the patient and the risk of a second malignancy that might occur as a consequence of treatment (13,14). Leakage transmission through a MIMiC leaf and through the gap between leaves is <1%; the leakage transmission outside of the defined slice is determined by the leakage characteristics of the treatment unit jaws and head shielding, which is typically 0.1%. These leakage characteristics were improved upon in the development of the dedicated helical tomotherapy unit described in the next section.

Attached to the MIMiC housing is a pc-controller. This device is a dedicated record and verification system used to monitor the (1) the angular position of the treatment gantry using onboard inclinometers, and (2) the open and closed state and transition times (<140 ms maximum) of the MIMiC leaves during treatment delivery. During treatment delivery, the gantry angle defines the open–close state of each leaf as defined by the treatment plan, which is created assuming constant dose rate and gantry rotation speed. Unacceptable changes in gantry speed will be detected by the controller causing treatment interruption by tripping the interlock circuit of the treatment room door thereby terminating the radiation beam. The controller also verifies the integrity of the plan data, which is stored on a 3.5 in. password protected floppy disk that is originally created by CORVUS as a means of transferring the plan to the controller. Data integrity is ensured using CRC check sums of the data files on the floppy disk. Modification of a plan requires the user to decommission the floppy disk using a password while inserted in the CORVUS planning station.

A continuous gantry rotation is modeled as a set of fixed beams spaced at 10° intervals from ~±160° from the vertical gantry position. A 10–15° interval is required at startup to allow the gantry speed and beam output to stabilize before leaves are opened to modulate the beam. Intensity modulation is achieved by opening a leaf for a

fraction of the interval with opening and closing occurring at angles symmetrical to the center of the interval. For example, a 50% modulation is achieved by opening the leaf at -2.5° and closing it at $+2.5^\circ$ about the center of a 10° interval. Typically, 10 intensity levels are used to approximate an intensity profile so leaf transitions occur at 1° boundaries within the 10° interval.

Serial tomotherapy requires precise positioning of adjacent treatment slices at the submillimeter level to avoid unacceptable dosimetry errors in the abutment region between slices (15). In recognition of this issue, the initial implementation of the Peacock System used a manual table positioner called the Crane that was a professional grade photography studio stand (Cambo BV, Kampen, The Netherlands) modified to attach to the treatment table side rails with table position determined by high precision digital linear scales. This device was subsequently replaced by a computer-controlled positioning device called the Auto-Crane, that was originally developed as the Xlator by the University of Texas Health Sciences Center, San Antonio, TX (16).

HELICAL TOMOTHERAPY: TOMOTHERAPY, INC. HI-ART II

Figure 4 shows a TomoTherapy Hi-ART II tomotherapy unit (TomoTherapy, Inc., Madison, WI) with its covers off and its various subsystems labeled. The linac is a 30 cm long, 6 MV, S-band (nominal 3 GHz) magnetron-powered device with a gridded-gun and a solid-state modulator. The linac is used for both CT imaging and treatment delivery, with imaging carried out using a lower beam current to reduce patient dose, and lower X-ray energy to improve image contrast. Given its compact size, the linac is aligned parallel to the beam axis with the flattening filter removed to increase output to 8–10 Gy/min at the gantry rotation axis located 85 cm from the fixed target. Elimination of the field-flattening filter improves the energy spectrum of the

Figure 4. Helical tomotherapy unit in a factory test cell. The major components are: (a) linac, (b) binary MLC, (c) couch, (d) detector, (e) RF system, (f) modulator, (g) gantry control, and (h) RF power.

beam and reduces scatter outside the field boundary, thereby simplifying treatment beam modeling and CT image reconstruction.

In recognition of the increased number of monitor units required for tomotherapy delivery, the treatment head shielding was designed to limit the primary leakage to 0.01% of the primary beam, or one-tenth the limit (0.1%) used for conventional radiotherapy treatments. The shielding includes integrated primary collimators that are used to define field widths from 5 to 50 mm (nominal). Below the primary collimators resides the binary multileaf collimator module, consisting of 64 leaves made from 10 cm high tungsten with leakage $<0.5\%$. A 13 cm thick lead counter weight is attached to the ring gantry opposite the treatment head that acts as a rotating primary barrier or beam stop.

Each binary MLC leaf completely blocks a portion of the fanbeam with a projected shadow of 6.25 mm (nominal) at the gantry rotation axis. The 64 leaves define a 40 cm diameter treatment field of view, which combined with up to 160 cm (nominal) couch travel enables very large treatment volumes to receive IMRT. Intensity modulation is achieved using pneumatic control of the binary MLC leaves by rapidly (~ 20 ms) switching the open-closed state of leaves during gantry rotation. As in the MIMiC collimator, the intensity level is proportional to the time a leaf is open and effectively there are ~ 50 intensity levels that that can be delivered.

The linac and gantry systems of the tomotherapy system are highly favorable for CT imaging where mechanical stability of the source-detector positions during rotation and a small source size are desirable. The gantry sag of the tomotherapy system is ~ 0.1 mm so no sag corrections are required in the CT reconstruction algorithm. The size of the electron beam on the target is ~ 1 mm so that the resolution is ~ 1.2 – 1.6 mm, which is comparable to a conventional CT scanner for high contrast objects. Operating at an average dose to the patient of 1–3 cGy, the images produced have soft tissue contrast of 2–3%, which is poorer than a modern CT scanner, yet are of sufficient quality for adaptive radiotherapy processes. The tomotherapy unit's xenon gas detector elements have tungsten septa separating ionization cavities. In addition to the ionization collectors, the tungsten plates are embedded photon converters intercepting the megavoltage photons and yet are thin enough to let an appreciable fraction of the electrons set in motion to deposit energy in the xenon gas. The interception of the beam by the tungsten means that the quantum efficiency of the system is $\sim 25\%$, which is much more than the few percent collection efficiency of modern portal imaging systems.

Modeling the treatment delivery process requires discretization of the continuous motions of the gantry and table as well as the continuous intensities of the modulated beams. Proper sampling reduces the chance for computational aliasing that can produce “streak” or “thread” artifacts in the dose distribution (17). Consequently, each 360° gantry rotation is modeled as 51 beams spaced at 7.06° apart: a number chosen to allow a 40 cm diameter target volume to be homogeneously treated with a 2.5 cm completely blocked central avoidance structure (18). Following

optimization, the intensity levels are discretized for treatment delivery, with 50 levels chosen to reduce the uncertainty in the target dose due to intensity discretization to <0.1%. Discretization of couch travel is determined by the pitch ratio: the ratio of the couch travel distance per rotation to the field width defined at the axis. In helical tomotherapy delivery, the pitch is usually set to be less than one-half to avoid thread-like dose artifacts developing near the edge of the field becoming clinically significant (17). Given a typical pitch of 0.3 for a 25 mm field width, the table motion is modeled by offsetting adjacent beams by 0.147 mm (e.g., $0.3 \times 25 \text{ mm}/51$) increments parallel to the direction of table motion.

A Hi-ART II treatment delivery typically takes <5 min for small target volumes like a prostate and <10 min for larger volumes such as head and neck. Mackie et al. (19) provided an expression for estimating the irradiation time given the target length L , the beam width W , the prescribed dose D , the average dose rate at the target R , and the modulation factor M :

$$T = MD(L + W)/WR \quad (1)$$

The modulation factor is a user selectable planning parameter along with the beam width and pitch. It is defined as the ratio of the maximum leaf open time of any leaf to the average leaf opening time of all the nonzero values, and is typically selected in the range of 1.5–3.0. As an example, a 7 cm prostate volume irradiated at an average dose rate at the target volume of 4 Gy/min by a 2.5 cm wide fan beam with a modulation factor of 2.5 would yield a beam-on time of ~ 4.75 min.

THE HI-ART II CT IMAGING SYSTEM

The detector resolution of the Hi-ART II unit projected to the axis of rotation is ~ 0.6 mm in the transverse direction and equal to the slice width in the longitudinal direction. The rotation period of the Hi-ART II helical tomotherapy unit is 10 s (6 rpm) and the typical slice thickness used is 4 mm, however, a small slice width (e.g., 2 mm) could be used for the fine resolution needed for small target volumes. The unit takes ~ 800 projections (or views) per rotation. For each rotation, two CT slices can be obtained. Pitches of 1, 1.5, and 2 are available, which means that up to 0.8 cm length can be scanned in 10 s. A typical tumor of 8–10 cm length would take as little as 2 min to acquire 25 CT slices. Longer lengths and smaller pitches take more time proportionately. Acquisition occurs on the fly so there is little delay following acquisition for the images to be analyzed. Pixel resolution at the center of the image is dominated by the detector resolution and at the edge of the circle of reconstruction by the number of projections. The reconstructed images shown in Fig. 5 indicate that the Hi-ART II is capable of resolving 1.2–1.6 mm objects near the edge of a 30 cm diameter phantom.

The verification CT uses an ~ 3.5 MV beam, which means that the photons interact almost exclusively by Compton interactions so that the linear attenuation coefficient is linear with the electron density of the medium (20). Metal artifacts arise in conventional CT scanners because the attenuation of the metal is greatly enhanced due to the photoelectric effect. In helical CT, the beam is penetrating enough to eliminate artifacts arising from metal objects like hip prostheses and dental filings. This means that the

Figure 5. Verification CT at megavoltage (MV) energies of a RMI Solid Water CT phantom. The 3% contrast plug is clearly seen as are the 1.2 mm and 1.6 mm air holes in the solid water phantom. The dose was estimated at 3 cGy at the center of the phantom.

Figure 6. Verification CT of a lung patient. The panel on the left is a soft-tissue window and the panel on the right is a lung window. The difference between muscle and fat and bone and soft tissue is clearly distinguishable. Some of the vascular structures are visible in the lung. The tumor boundary in the lung is discernible, but its extension into the mediastinum is not visible. The dose to the patient was ~3 cGy.

representation supplied by a verification CT is a more reliable CT system for patients with metal implanted appliances. Figure 6 illustrates that bone has less contrast than a conventional CT scan, but it is still clearly discernible on the Hi-ART II unit. The boundary of lung with internal major airways and vascular structures are evident. The boundary between fat and muscle is clearly distinguished, which means that the breast and prostate are discernable. Other organs such as the kidney and

bladder are visible. Unlike the highest quality conventional CT scanners, the contrast between white and gray matter in brain is not visible.

The CT imaging is performed prior to each treatment to reduce the possibility of a geometrical miss of the target and sensitive structures. An automated comparison of verification and planning image sets is carried out immediately following image acquisition to guide the adjustment of the patient setup. The patient is assumed to be a rigid object requiring translations and rotations to bring the target anatomy and important sensitive structures into alignment with the treatment plan. The patient is positioned by aligning the patient's skin marks with lasers located outside of the bore of the unit. A sagittal representation of the patient's planning CT is shown on the operator console to aid in selecting the slices to be scanned. A verification scan is taken and reconstructed during the acquisition. The patient is then transported to the same position outside of the gantry bore while the verification image set is fused onto the planning image set and the translation and rotation offsets are reported. Typically the image fusion is first done automatically using a mutual information algorithm (21). Following automated registration, the patient registration can be fine-tuned manually. This allows the operator to take into account, as best as possible, the nonrigid nature of the transformation. Once

Figure 7. The registration window for a prostate patient. The gray squares are from the planning CT. The verification CT is shown in the upper left and the planning CT is in the lower left. The yellow squares in the large panel are from the tomotherapy verification CT. The rectal boundary and the fat pad surrounding the prostate are clearly aligned on these transverse images. Note that the skin boundary and the leg bones are not as well aligned as the prostate. Regions of interest and the dose distribution obtained from the planning system can be superimposed on the images, but these capabilities have been turned off in this presentation. The translational alignments suggested were 0.0 mm lateral, -0.6 mm longitudinal, and -1.5 mm vertical.

the image registration is completed, the offsets also describe how the patient must be adjusted. Figure 7 shows an example of the graphical user interface for the registration utility being used to register a prostate patient.

If the patient requires adjustment the patient can be translated accordingly. The Hi-ART II CT couch has automated vertical (elevation) and longitudinal translations, and automated gantry start angle adjustments to account for patient roll. The couch top can be manually adjusted in the lateral direction (x direction). Yaw and pitch rotations can be accommodated using angularly calibrated immobilization and positioning aids, which are especially useful for the head and neck. The Hi-ART II includes a set of moveable CT-simulator lasers so that the modified position of the patient can be confirmed.

IMAGE GUIDANCE AND ADAPTIVE RADIOTHERAPY

Adaptation of future treatments from information gleaned from past treatments is a further refinement based on daily CT verification. The daily CT image set forms a model of the patient that can be used to compute an estimate of the dose delivered for that treatment. *Dose reconstruction* is a determination of the dose delivered superimposed on the CT at the time of treatment (6). The CT detector runs at the time of treatment recording the treatment beam exiting through the patient and couch. Using the CT image set acquired just before treatment, the energy fluence incident on the patient can be computed and used to estimate the dose distribution in the patient using the same convolution-superposition method used for helical tomotherapy treatment planning. The total dose delivered up to the current treatment is analyzed for regions of under- and overdosage and these regions reoptimized to bring them inline with the original plan with the corrections applied in one or more future treatments: a process called *adaptive radiotherapy*.

The CT imaging capability of the Hi-ART II has proven extremely useful for reducing daily geometrical misses, which are the most important errors that can compromise treatment efficacy. The increased confidence provided by daily CT setup verification has allowed clinicians to reduce geometrical margins that account for setup uncertainty, and to explore accelerated treatment protocols using a larger dose per fraction than conventional treatments (22). It is expected that CT image guidance technology will facilitate further changes in radiotherapy practice in the coming decade as more facilities adopt this capability.

TONOMETRY, ARTERIAL

JOSEPH S. ECKERLE
 SRI International
 Menlo Park, California

INTRODUCTION

The arterial tonometer is an instrument for measuring arterial blood pressure. It differs from the familiar sphygmomanometer in that, rather than measuring the pressure only at greatest contraction and greatest heart dilation (systolic and diastolic), it provides continuous measurement throughout the heart's pumping cycle. Typically, the instrument sensor is placed over a superficial artery; the radial artery pulse point at the wrist is one convenient site for tonometer measurements. Figure 1 shows how a tonometer sensor would be placed for measurements at this site.

A catheter can be used for accurate, continuous measurement of blood pressure, but the instrument is invasive and numerous risks are associated with its use. In contrast, the noninvasive tonometer can provide an accurate, continuous blood pressure measurement with negligible risk.

Sphygmomanometric instruments of several types are available for noninvasive blood pressure measurements. However, these instruments are generally not capable of continuous blood pressure measurement, nor is their long-term use feasible. The familiar blood pressure cuff hinders venous return and results in peripheral edema. In contrast to sphygmomanometric instruments, the tonometer can be used for beat-by-beat blood pressure measurement over long periods of time with minimal edema. Important disadvantages of the tonometer include its sensitivity to sensor placement and movement artifacts, effects of anatomical variations, and the greater complexity and cost relative to a conventional sphygmomanometer.

In what follows, the physical principles that form the theoretical basis for tonometric blood pressure measurement are first presented; these include techniques for identifying the location of an artery beneath a tonometer sensor and for adjusting the force with which the sensor is

Figure 1. Arterial tonometer sensor on radial artery.

pressed against the skin. Next, the technical evolution of tonometer transducers is discussed, leading to a description of modern, multiple-element transducers. This is followed by discussion of several considerations that are unique to tonometric measurements, and may influence the usefulness of the technique for certain applications. Various applications of tonometry, particularly surgical monitoring and cardiovascular evaluation, are discussed next. Finally, the measurement accuracy of tonometry is addressed.

PRINCIPLES OF OPERATION

General Principles

The fundamental principles underlying arterial tonometry are similar to those for ocular tonometry (1,2). Figure 2 shows an idealized model that helps illustrate these principles. In Figure 2, P represents the blood pressure in a superficial artery and F is the force measured by a tonometer transducer. The membrane is the artery wall. Figure 2b is a "free body diagram" showing all the forces and moments acting on the frictionless piston of Fig. 2a. As shown in Fig. 2b, an ideal membrane transmits only a tensile force, T , and does not transmit any bending moment. The tension vector shown, T , is perpendicular to the pressure vector, so the force, F , is independent of T and depends only on the blood pressure and the area of the frictionless piston, A . Following common practice, the integrated effect of arterial pressure acting on the segment of arterial wall is represented by a vector of magnitude PA , oriented perpendicular to the wall. Thus, measurement of the force, F , permits one to directly infer the intraarterial pressure.

Figure 3 shows a superficial artery and a tonometer sensor in cross-section. The tonometer sensor is represented schematically, and is modeled as an assemblage of springs with spring constants, K , as shown. By careful design of the tonometer sensor and selection of an appropriate superficial artery, it is possible to satisfy several conditions:

Figure 2. Idealized model for a tonometer.

Figure 3. Schematic diagram of a tonometer sensor and a superficial artery.

1. The artery is supported from below by bone (e.g., the radius).
2. The hold-down force, F_1 , flattens a portion of the artery wall, but does not occlude the artery.
3. The thickness of the skin over the artery is insignificant, compared to the artery diameter.
4. The artery wall behaves essentially like an ideal membrane.
5. The arterial rider is smaller than the flattened area of the artery, and is centered over the flattened area.
6. The spring constant of the force transducer, K_T , is large compared to the effective spring constant of the artery.

When all these conditions are satisfied, Pressman and Newgard (3) showed theoretically that the conditions of Fig. 2 apply where the arterial rider of Fig. 3 corresponds to the frictionless piston of Fig. 2. Thus, the electrical output signal of the force transducer is directly proportional to the intraarterial blood pressure.

The arterial tonometric measurement depends on the membranelike behavior of the artery wall. Drzewiecki et al. (4) have shown analytically and by experiments with an excised canine femoral artery (5) that the desired behavior can be obtained, provided that the artery is flattened sufficiently. This work provides an important theoretical foundation for the arterial tonometer and helps to explain the observations of several prior *in vivo* studies.

Multiple-Element Sensors

A major practical problem with the simple arterial tonometer of Fig. 3 is the requirement that the arterial rider be precisely placed over the superficial artery. Reliable measurements can be obtained only after painstaking adjustment of the sensor location by a trained operator (6). Apparently, there are differences of opinion concerning the severity of this positioning problem and these are discussed in greater detail below.

To ameliorate this problem, multiple-element tonometer sensors, shown schematically in Fig. 4, have been developed (7-9). The sensor worn by the patient actually consists of a multiplicity of individual sensors. Typically, the sensors are arranged to form a linear array of force transducers and arterial riders. The array need only be

positioned with enough precision so that some element of the array is centered over the artery. A computer then automatically selects the sensor element that is correctly positioned over the artery.

One algorithm for selection of the correct element from the multiple-element sensor array exploits two characteristics of the pressure distribution in the vicinity of the artery (8). The first is that the pulse amplitude (i.e., the pressure difference between the systolic and diastolic points on the transducer output waveforms) exhibits a broad maximum over the artery. The algorithm searches for the largest pulse amplitude; the corresponding sensor element will then be within about one artery diameter of the center of the artery. However, this element will, in general, not be precisely centered over the artery.

To identify the centered sensor element more precisely, the algorithm then exploits a second phenomenon, illustrated in Fig. 5. This figure shows a multiple-element tonometer sensor and the underlying, partly compressed artery. For purposes of illustration, assume that the diastolic pressure in the artery is 80 mmHg (10.7 kPa). At the instant of diastole, the pressure measured by each element of the sensor is shown plotted at the top of the figure. Elements 4-6, which all lie over the flattened part of the artery wall, measure the intraarterial pressure [80 mmHg (10.7 kPa)] with good accuracy. However, the pressures measured by elements 2, 3, 7, and 8 are all significantly greater than the intraarterial pressure. This higher pressure can be explained by noting that the artery wall is bent to a very small radius in the regions below the latter elements. As a result, large bending moments are transmitted by the artery wall and are manifested as increased

Figure 4. Multiple-element arterial tonometer.

Figure 5. Illustration of pressure distribution near a superficial artery.

pressure on the adjacent sensor elements. A more detailed treatment of this phenomenon can be found in Drzewiecki et al. (4). The element-selection algorithm exploits this phenomenon by searching for a (spatial) local minimum in diastolic pressure (e.g., element 5 of Fig. 5) in a region near the maximum pulse amplitude. The term “local minimum” has a precise meaning in mathematics: When moving in either direction from a local minimum, the value of the function increases. The sensor element corresponding to the local minimum is then assumed to be centered over the artery and blood pressure is measured with this element (10).

Recently, there have been several efforts (11–13) to improve the basic algorithm described above. One algorithm or another might be most effective depending on numerous factors, such as the application, the patient population, and the precision of the sensor and associated amplifiers.

To further ameliorate the positioning problem, Shinoda and others (14,15) have developed motor-driven mechanisms to move a multiple-element sensor laterally within a larger housing strapped to the wrist.

Hold-Down Force

Adjusting the tonometer sensor’s transverse location with respect to the artery is not enough; the degree of arterial flattening is also important for accurate tonometric pressure measurement. Arterial flattening depends on the interaction of anatomical factors with the value of the hold-down force, F_1 , in Fig. 3. The appropriate value of the hold-down force must be determined for each subject before accurate tonometric measurements can be made. The procedure commonly employed involves increasing (or decreasing) the hold-down force gradually while recording the signal from the tonometer sensor. Figure 6 is an example of such a recording (16). In Fig. 6, hold-down force decreases with time through regions A, B, and C. Region B, where the pulse amplitude is greatest, is considered (3,16,17) to be the region where the most accurate blood pressure measurements are made. This region corresponds to flattening of the artery (as shown in Fig. 5) that is insufficient to cause its occlusion.

Drzewiecki et al. (5) discuss the effects of hold-down force from a theoretical perspective. Eckerle (18) developed algorithms for automatic identification of the center of region B (Fig. 6) and for recognition of difficult subjects (see below) based on various parameters that define this region. Briefly, the algorithm fits a third-order polynomial to the data of Fig. 6. The locations of the regions of Fig. 6 can then be directly computed from the polynomial coefficients. Recently, alternative algorithms (19,20) to control hold-down force have been developed. Again, the optimum algorithm may depend on factors such as application, population, and equipment precision.

TONOMETER SENSOR DESIGN

The size and precision requirements for tonometric blood pressure sensors are severe. Eckerle et al. (21) conclude that, ideally, the arterial rider should be less than ~ 0.2 mm wide and the associated transducer should be accurate to better than ± 2 mmHg (270 Pa). For multiple-element sensors, at least 25 elements with interelement spacings of ~ 0.2 mm are desirable. As of 1984, these design goals had been approached but not met (21). Then, in 1990, an integrated circuit (IC) based tonometer sensor array was

Figure 6. Effect of hold-down force on a tonometer output signal.

reported (9) that substantially achieved these goals. The silicon-and-glass sensor die included 31 tonometer sensor elements in a linear array ~ 6 mm long.

The first single-element tonometer sensors were constructed of aluminum. Strain gages were attached to miniature beams supporting the arterial rider (3). This approach made effective sensors, but they suffered from the positioning problems previously discussed. Subsequently, various workers devised alternative single-element tonometric sensors. Bigliano et al. (22) reported a pressure sensor with a thin membrane that controlled air flow through a narrow passage. Stein and Blick (23) used a modified myographic force transducer to record blood pressure waveforms from the radial artery. Bahr and Petzke (17,24) used a semiconductor pressure transducer placed over the radial artery. Kelly et al. (6) used a pressure sensor intended for insertion via a catheter. This sensor was mounted in the tip of a pencil-shaped probe, which was then applied to the skin. Borkat et al. (25) placed a pressure capsule, consisting of a rubber bladder attached to a pressure transducer, over the radial artery. Borkat's device is probably the most inexpensive and simple of these alternatives, but it fails to meet the size and stiffness requirements that apply for accurate tonometric measurements.

Multiple-element tonometer sensors have been fabricated from a monolithic silicon substrate using anisotropic etching to define pressure-sensing diaphragms about $10 \mu\text{m}$ thick in the silicon (26). The IC processing techniques are then used to create piezoresistive strain gages in the diaphragms. External circuitry measures the resistance of the strain gages to determine the pressure exerted on each sensor element. Figure 7 is a photomicrograph of an eight-element sensor fabricated in this way. The diaphragms are square and are arranged in two staggered rows of four each. Note the scale in the figure. The arterial riders in this device are 0.75×0.75 mm. Figure 8 is a further magnified view of one element of the Figure 7 sensor. Two radial and two tangential piezoresistive strain gages can be seen together with aluminum metallization used for connection to external circuitry. The performance of these sensors is representative of the best that had been achieved (for tonometers) as of 1984 (21) and is summarized in Table 1.

Achieving the size and accuracy requirements for multiple-element tonometer sensors noted above (21) is difficult, even using the latest advances in IC sensor fabrication. One fundamental problem involves the difficulty of placing independent pressure sensors side by side while minimizing interaction between them. In 1990, Terry et al. (9) reported a clever configuration to address this problem. Briefly, a multiplicity of independent pressure transducers shared a single, long, narrow silicon diaphragm. Some performance parameters of this sensor are also shown in Table 1. This sensor was the first to substantially achieve the size and precision requirements proposed by Eckerle et al. (21).

While the single-diaphragm sensor of Terry et al. (9) has superior performance, relative to the Fig. 7 device, it requires a more complex manufacturing process, and is therefore more expensive. For cost-sensitive applications, a sensor such as Fig. 7 may be preferred. Other groups are

Figure 7. Eight-element tonometer sensor.

investigating fiber-optic transducers (27) and capacitive transducers (28,29) for use in multiple-element tonometer sensors.

Proper mounting of an IC tonometer sensor is very important. The mounting arrangement must protect the fragile sensor while faithfully transmitting the pressure of the patient's skin to the sensor. Consideration should be given to measurement drift caused by thermal effects or material creep. Finally, the shape of the mounted sensor can be chosen to conform to the local anatomy (e.g., the nearby radius in the case of a radial artery tonometer). Fujikawa and Harada (30) and others (31,32) developed

Figure 8. Pressure-sensitive diaphragm of tonometer sensor.

Table 1. Typical Performance of Silicon Tonometer Sensors

Parameter	Typical Value ^a		Units
	Ref. 26	Ref. 9	
Number of elements	8	31	Each
Element spacing	0.75	0.2	mm
Sensitivity	25	25–50	$\mu\text{V}/\text{V mmHg}$

methods for mounting IC sensors for tonometry in clinical environments.

A clinical tonometer instrument, incorporating many of the features described above, is shown in Fig. 9. Comparable instruments may be obtained from suppliers such as Colin Medical Technology Corp., Komaki, Japan; Hypertension Diagnostics, Inc., Eagan, Minnesota; and AtCor Medical, Sydney, Australia.

MISCELLANEOUS CONSIDERATIONS

One significant advantage of the arterial tonometer is its ability to make noninvasive, nonpainful, continuous measurements for long periods of time. There are several reasons for this superiority over the sphygmomanometer:

1. The sensor is adjusted to partly flatten, but not occlude the radial artery. In contrast, sphygmomanometric systems typically occlude the artery in order to determine systolic pressure.

2. The part of the tonometer sensor representing the arterial riders and side plates of Fig. 3 is ~ 20 mm in diameter. There may be occlusion of some veins beneath this part of the sensor, but numerous parallel venous paths in the remainder of the wrist allow return venous flow. [The reader may wish to try the following experiment: Place a dime (a U.S. coin ~ 18 mm in diameter) over your radial artery pulse. Holding your wrist with your free hand, press down on the dime with the thumb to occlude the radial artery. You are now experiencing greater venous occlusion than a tonometer sensor would cause.]
3. There are several venous paths through the wrist. Some of these pass between bones that apparently help protect them from pressure that may be applied externally to the wrist by the mounting strap and other parts of the tonometer sensor.

These factors all help to minimize development of edema distal to a tonometer sensor. Discomfort and development of edema will depend on factors, such as subject-to-subject

Figure 9. Clinical tonometer instrument.

variations in wrist anatomy, measurement duration, and the hold-down force used. In a study involving 20 conscious, healthy subjects (33) the blood pressure waveform was monitored continuously by tonometry for more than 30 min. The subjects reported no significant discomfort due to the tonometer sensor.

The tonometer's ability to measure blood pressure continuously with minimal distraction to the subject makes it attractive for ambulatory blood pressure monitoring. This application should be feasible in the future, but present instruments do not have sufficient artifact-rejection capability for reliable measurements on ambulatory subjects (21). This is not to say that the arterial tonometer is unusually sensitive to movement artifacts. In a study involving 20 subjects (34), the tonometer was found to be less sensitive to subject movement than photoplethysmographic, quadrapolar impedance plethysmographic, and sphygmomanometric sensors.

Eckerle et al. (35) have taken the first step toward an ambulatory tonometer for blood pressure by developing an ambulatory pulse rate sensor using tonometry. By use of a curved spring, the sensor can be mounted unobtrusively in a watchband <8 mm thick.

Taking an analog signal-processing viewpoint, the blood pressure can be described as the sum of an alternating current (ac) component and a direct current (dc) component. Briefly, the ac component is more easily measured by tonometry than the dc component. More specifically, under clinical conditions, the six conditions listed above may not always be satisfied. When this happens, the tonometer sensor often continues to measure the ac component with good fidelity, while the measurement accuracy of the dc component (on which the familiar systolic and diastolic depend) becomes degraded. Shinoda and others (36–38) have used sphygmomanometric measurements of blood pressure to correct errors in the dc component and thereby produce an output with good waveform fidelity (ac component) and accurate measurement of systolic and diastolic (dc component).

The radial artery is not the only site at which a tonometer may be applied, but most research to date has used this site. Other sites suitable for tonometric measurements include the brachial artery at the inner elbow (the antecubital fossa), the temporal artery in front of the ear, the carotid, and the dorsalis pedis artery on the upper foot.

Anatomical variations of the wrist can make the location and support of the radial artery unsuitable for tonometric

pressure measurement. Unsuitability occurs in only a small fraction of the population and such difficult subjects can be recognized by the computer used with multiple-element sensors. In one study involving 6 subjects (7,8) there was one difficult subject, while in another involving 20 subjects (33) there were none.

As described above, a single-element tonometer sensor, such as Fig. 3, can be used for tonometric blood pressure measurement if six conditions are met. The multiple-element tonometer was developed to help simplify tonometric measurements for the clinician (relative to a single-element instrument). Many clinicians (39–45) have reported using multiple-element instruments. Many other clinicians (6,46–54) have used single-element instruments. Chen et al. (44) have used both types. They observe that "Although [the hand-held, single-element tonometer]...was probably adequate for brief steady-state data, manual recording was too unstable for accurate pressure tracking during hemodynamic transients, and it introduced an element of user dependence and thus potential bias to the data. The automated [multiple-element tonometer] system circumvented these limitations." We may also observe that the two groups are generally pursuing different applications, suggesting that the choice of optimum sensor type is application dependent.

APPLICATIONS

Perhaps the first clinical application of tonometry was for blood pressure monitoring in surgery and other procedures. Stein and Blick (23) used radial artery tonometry during a catheterization procedure. Kemmotsu et al. (39) used a multiple-element tonometer for surgical monitoring. Several others (40–43,55) have also evaluated the instrument under various surgical and postsurgical situations.

Figure 10 shows a typical blood pressure waveform, obtained with an arterial tonometer from the radial artery of an adult male. Note that systolic and diastolic pressures, as well as pulse rate and dicrotic notch information, can be obtained from the waveform. The subject performed a Valsalva maneuver at the time indicated. The attendant changes in blood pressure and pulse rate are quite clearly indicated. Of course the tonometer measures only the pressure in the underlying artery, not central arterial

Figure 10. Intraarterial blood pressure waveform.

(aortic) pressure. Central aortic pressure is useful for clinical applications, so there has arisen a desire to calculate central aortic pressure based on a radial pressure obtained with a tonometer.

A brief discussion of circulation dynamics may now help reveal the motivation for some other tonometer applications. Physiologists have long struggled to devise a useful physical model for the circulatory system. Briefly, two complementary models have arisen, a windkessel model and a pulse wave velocity (PWV) model (56,57). In the windkessel model, the circulatory system is represented (often using an electronic analogy) as a small number of lumped elements such as capacitors, inductors, and resistors. In the PWV model, the circulatory system is represented as one or more pipes in which a pulse wave, generated by the heart, travels at a certain velocity. Physiologists and clinicians seek to determine the values of the lumped elements and the magnitude of the PWV by means of noninvasive measurements. Various aspects of the ac component of the pressure waveform of Fig. 10 can be used to estimate the windkessel parameters and PWV.

Focusing on the windkessel model, one can devise a transfer function that relates the pressure at a peripheral site (e.g., the radial) to an input pressure waveform in the aorta (58,44). It is then straightforward (in theory) to compute the inverse of this transfer function. Using this inverse transfer function, one may then calculate the pressure waveform in the aorta based on the peripheral waveform. This technique is potentially very powerful because it allows making a previously invasive measurement (the aortic pressure waveform) by using a noninvasive instrument: a radial artery tonometer.

Several investigators (44,46,58) have evaluated the above technique to determine aortic pressure by mathematical manipulation of a radial artery pressure determined by tonometry. Others (47,59) have evaluated a similar technique to determine aortic pressure from a tonometric carotid pressure measurement.

Numerous investigators (48–51) have used tonometry to estimate windkessel parameters, particularly arterial elasticity. Other investigators (45,52–54) have used it to estimate PWV.

For certain applications, it is sufficient to measure relative, rather than absolute, blood pressure. These include polygraph (lie detector) tests and studies of the physiological effects of various cognitive and physical stressors (e.g., weightlessness and high $-g$ aircraft maneuvers). A multiple-element tonometer designed specifically for relative blood pressure measurement has been developed by Eckerle et al. (33) and tested extensively on 20 subjects of both sexes. Subjects were subjected to stressors such as mental arithmetic and cold pressor, and their blood pressures were recorded continuously for periods in excess of 30 min.

MEASUREMENT ACCURACY

Because the accuracy of tonometric blood pressure measurements depends on the size and positioning of

the sensor, the value of hold-down force, and the accuracy of the sensor itself, some variability in reported tonometer accuracy can be expected when these factors are not well controlled. In nearly all of the measurements reported prior to 1987 hold-down force was adjusted manually, and in many the tonometer was manually positioned as well. Some improvement in tonometer accuracy and repeatability can be expected from automatic sensor positioning and hold-down force adjustment.

An early validation of the principles of tonometry (60) involved comparison of pressures measured in an exposed canine femoral artery by both a tonometer and an intraarterial catheter. One series of tests involved 15 animals with blood pressure changes being induced by drug injection and vagal stimulation. For this entire series of tests, the difference between pressures measured by the two instruments was never $> 5\%$.

Stein and Blick (23) compared tonometric measurements with direct arterial blood pressures on 20 patients undergoing cardiac catheterization. They found that the tonometer reproduced both the intraarterial waveform and any abrupt changes in pressure caused by various interventions with remarkable fidelity. Specifically, during interventions that increased or decreased systolic pressures by as much as 30%, the tonometric pressure measurement followed the direct arterial pressure within 10% in 92% of the observations.

Weaver et al. (8) compared sphygmomanometric blood pressures with those obtained with a multiple-element tonometer sensor on five subjects of both sexes ranging in weight from 135 to 225 lb (61–102 kg). The standard deviation between the two measurements of systolic and diastolic pressures was 6.5 mmHg (870 Pa), indicating that the tonometer was at least as accurate as the sphygmomanometer.

In 1989, Kemmotsu et al. (39) reported the accuracy of an automated, multiple-element tonometer instrument used for monitoring during surgery. The tonometric measurements showed good correlation ($r = 0.94$, $P < 0.001$ for systolic) with invasive measurements on the contralateral radial artery. Kemmotsu subsequently performed additional studies (40,41) involving surgical monitoring. In the later study (41), involving 60 patients, the mean absolute value of error ranged from 3.6 to 6.6 mmHg (480 to 880 Pa). Standard deviations ranged from 4.5 to 6.2 mmHg (600 to 830 Pa).

Other investigators (42,43,55) have evaluated multiple-element tonometers for surgical and postsurgical monitoring. They found standard deviations ranging from 1.7 (for a single patient) to 14.2 mmHg (230 to 1960 Pa).

Sato et al. (61) evaluated the accuracy of a multiple-element tonometer instrument on conscious subjects subjected to a Valsalva maneuver and a tilting test. This study is of particular interest because they directly addressed the question of frequency response of the tonometer/tissue/artery system. Good frequency response is important for computation of windkessel parameters or PWV as described above. Sato et al. found the frequency response of the tonometer/patient system to be essentially flat from 0 to 5 Hz.

ALI MÜFTÜ
Tufts University
Boston, Massachusetts

INTRODUCTION

The relations among forces, motion, and deformation are studied in the field of mechanics. Biomechanics seeks to understand the mechanics of living systems (1). The teeth and jaw perform the critical function of initiating the digestion by breaking the food into smaller sizes. This increases the surface area of the food and improves the effectiveness of the enzymes involved in digestion. *Mastication* is defined as the action of chewing foods. The masticatory system is composed of

1. The dentition
2. The bones (the maxilla the mandible, and the temporal bone),
3. The ligaments
4. The muscles
5. The temporomandibular joint (TMJ):

The periodontal ligament (PDL), which attaches the teeth to the bones, the articular disk, and the cartilage, which are located on the articulating surfaces of the TMJ, and the other soft tissues such as the blood vessels and the nerves are also parts of this complex. The three main functions of the masticatory system are chewing, swallowing, and speech. This system also helps in expression of emotions and respiration. The temporomandibular system is controlled by the nervous system, and its successful function requires a harmonious relation of these components. Biomechanical investigations of the mastication system aim to understand the fundamental relations between anatomy and function and thus either aid the available treatment modes or help design new ones.

During function (mastication) or rest, various components of the temporomandibular complex work together. Explanation of the complex interrelations between the components of the masticatory system, requires knowledge of the functions of each component. A comprehensive review of the biomechanics of tooth and jaw was given in Reference 2 up to 1988. The aim of the current article is to review the recent developments in this field. In the last few years, the cost and the speed of performing analysis using computational techniques has improved dramatically (3). Thus, many new investigations were enabled particularly by, but not limited to, using the finite element method. This article reflects some of these new analyses. In general, this article is divided into three sections related to the biomechanics aspects of the anatomy, function, and treatments of the masticatory system.

The article starts with an overview of the functional anatomy of the mastication system. Brief anatomical

descriptions of the dentition, the skeletal components, the musculature, the temporomandibular joint/disk, and the connective tissues, such as the ligaments, are given. The monographs given in References 4 and 5 can be consulted for more detailed information.

Next, the biomechanical models of mastication are introduced. This involves investigating the relations between the forces applied by the muscles, and the reaction forces that develop on the teeth, the TMJ, and the ligaments, as well as the deformations of the mandible. In-depth understanding of these relations help treatment of TMJ disorders (such as bruxism), design of endosseous implants, reconstructive prosthetics, and various tooth replacement modalities. Definitions of key engineering concepts such as external and internal forces, internal stresses and strains, and elastic material (stress-strain) behavior are provided. The material properties of all components of the masticatory system are briefly reviewed. The biomechanical fundamentals of mastication are introduced by using force balance relationships, where the mandible is treated as a rigid body. In addition, investigating the deformations of the mandible is briefly covered. The monographs given in References 3,4 and (6–11) are only some of the many references that review these topics in more detail.

Many treatment modalities involving the masticatory system benefit significantly from the studies performed in the fields of biomechanics and biomaterials. These include,

but are not limited to, prosthodontic and orthodontic treatments, reconstructive surgery, and reconstructive prosthetics. In this article, the biomechanical considerations in prosthetic dentistry, including dental implant treatments, intracoronary and extracoronary restorations, and fixed and partial dentures, are reviewed.

DENTITION AND SUPPORTIVE STRUCTURES

Human dentition is composed of a total of 32 teeth (Figs. 1 and 2). Each tooth has a part that is visible, called the *crown*, and a part located inside the bone called the *root* as shown in Fig. 3. The teeth are attached to the bone by a soft tissue called the PDL, which serves to connect the tooth to the surrounding bone and distributes the occlusal loads to the bony tissue. On the superior aspect (top portion) of the masticatory system, 16 teeth are attached to the maxillary arch. Likewise, on the inferior aspect (bottom portion), 16 teeth are attached to the mandibular arch. As the sizes of the maxillary teeth are larger, the teeth in the maxilla are situated on a larger arch.

The teeth on each jaw can be classified in four groups, according to their function as shown in Fig. 2. The *incisors* are used to cut the food into smaller pieces. They are located on the anterior (frontal) section of the mouth. The incisors have a relatively small cross-section; there-

Figure 1. Lateral view of the skull showing the skeletal components of the masticatory system. (From Sobotta Atlas of Human Anatomy, Vol. 1, 13th ed.).

Figure 2. (a) The mandibular dental arch and (b) the maxillary dental arch. (From Sobotta Atlas of Human Anatomy Vol. 1, 13th ed.).

Figure 3. Schematic representation of an incisor tooth showing tooth socket and periodontium. (From Sobotta Atlas of Human Anatomy, Vol. 1, 13th ed.).

fore, they can apply large pressures on the food to provide effective cutting. Four incisors are located on the maxilla and the mandible, each. The *canines* are the long teeth whose function is to tear the food. In humans they mostly function as the incisors and cut the food. There are two incisors on the mandible and two on the maxilla. The *premolars* crush the food to smaller sizes during rhythmic, repetitive phases of mastication. Six maxillary and six mandibular *molars* are located at the ends of lower and upper dental arches. Molar and premolar teeth have multiple cusps and groves, which provide a relatively large surface area, enabling more effective crushing of the food.

The Teeth

Each tooth has two main sections, a *crown* and a *root* or roots as shown in Fig. 3. Each section is further subdivided to crown, cervix (neck), root, and apex. The tooth is solid except for the *pulp cavity* centered within it. The major portion of the tooth is made of *dentin*. A layer of *enamel* covers the crown portion of the tooth mostly above the gum line. A thin layer of *cementum* covers the root set in the bony tissue. The *cementum* is true bone. The pulp cavity may be divided into

two portions; the *pulp chamber*, which is mostly in the crown, and the *pulp canal* traversing the interior of the root, ending in a constricted opening at the root apex. The pulp cavity contains the *dental pulp*, a soft tissue containing connective tissue, blood vessels, and nerves (12).

Both the dentin and the enamel contain collagen, hydroxyapatite (HAP) (an inorganic molecule), and water. However, the distributions of these constituents are different in these structures: The dentin contains 47% HAP, 30% collagen, and 23% water; and; the enamel contains; 92% HAP, 2% organic material, and 6% water, by volume. The microstructure of the enamel is characterized by parallel rods of HAP. In the dentin the tubules are connected by organic material. Because of the difference of HAP content and the microstructure, the modulus of the enamel can be as much as four to six times as high as that of dentin (4). See Table 1 for a summary of the elastic properties of the tooth and the periodontium.

The PDL

The general name given to the attachment mechanism of the teeth is the *periodontum*, which consists of the

Table 1. Elastic Properties of the Enamel, Dentin Layers of a Tooth and the PDL

	Elastic Modulus E [GPa]	Poisson's ratio ν	Tensile Strength [MPa]	Compressive Strength [MPa]	Shear Strength [MPa]
Enamel	80 ^{b,c}	0.3 ^b	10 ^a	288–400 ^a	8 ^a
Dentin	14 ^d , 15 ^b , 18 ^a , 20 ^b	0.15 ^d , 0.31 ^{b,c}	48 ^a	232–297 ^a	20 ^a
PDL	0.002 ^c , 0.003 ^a , 0.05 ^b , 10 ^d	0.45 ^c , 0.49 ^{b,d}			

^aFrom Toparli et al.(13)^bRees and Jacobsen (14)^cArola et al.(15)^dImanishi et al.(16)

cementum, the PDL, the alveolar bone, and a portion of the gingiva (Fig. 3) (4). The PDL is a connective tissue present between the root of the tooth and the alveolar bone, whose function is (1) to provide support for the teeth and (2) to control the distribution of the occlusal loads on the bony tissue (5). Its thickness varies between 0.15 and 0.38 mm, in humans. Perhaps a good indication of its function can be observed when it is realized that the magnitude of occlusal loads affects the thickness of the PDL, where increased load results in thickening of the PDL.

Among other cellular components of the PDL are the osteoblast and osteoclast cells associated with the alveolar bone; cementoblast and cementoclast cells that associated with the cementum; and fibroblast cells that are responsible for collagen generation. The extracellular components of the of the PDL are the collagen fibers, oxytalan fibers, nerves, vessels, and the ground substance, which is composed of hyaluronic acid, glycoproteins, proteoglycans, and water (4).

Approximately 65% of the PDL's volume is occupied by dentoalveolar fiber bundles. The collagen molecules (type-I and III) of PDL are wrapped into collagen *fibrils* (55 nm diameter), which are wrapped into *fibers*. The fiber bundles are arranged into networks having a complex three-dimensional overlapping arrangement (4). These fiber bundles provide the load-bearing capacity to the PDL.

It has been mentioned that one of the primary functions of the PDL is to distribute the forces acting on the teeth to the bony tissue. The force–displacement relationship of the PDL is nonlinear. When a tooth is subjected to an external force, its initial displacements are caused by relatively small forces until the force magnitude reaches 1 N. Thereafter, increasingly higher forces are required to displace the PDL. The PDL is stiffer under axial loads acting on the tooth as compared with tangential loads. The same level of load applied tangentially causes a larger displacement of the PDL, as compared with the axial load. Like similar connective tissues, the PDL also shows viscoelastic material behavior.

THE SKELATAL COMPONENTS

The major bones of the human skull that are involved in mastication are the *mandible*, the *maxilla*, and the *temporal* bone. The *maxilla* is composed of two parts that are connected at the midpalatal suture, as shown in Fig. 2b. A large portion of the facial bone is composed of the maxillary bones. On the frontal plane, the maxilla is connected to the

zygomatic bone and the *nasal bone*, and on the sides of the skull, it is connected to the temporal bone as shown in Fig. 1. The teeth on the maxillary arch are connected to the maxilla on the alveolar ridges. These teeth are considered to be the fixed part of the masticatory system, as the maxilla is fixed to the skull.

The *mandible* is the arch-shaped bone that forms the lower part of the facial skeleton and the masticatory system as shown in Fig. 2a. On the posterior (back) sides, the mandible extends vertically. This vertical (ascending) extension of the mandible is the *ramus*. The *mandibular angle* located at the posterior (back) part of the ramus is shown in Fig. 1. The superior (top) extension of ramus forms two processes: The anterior (frontal) one is the *coronoid process*, and the posterior (back) one is the *condyle*. These two processes make critical attachments to the rest of the masticatory system. The mandible is connected to the temporal bone at the condyle through the TMJ. The TMJ allows pivoting and sliding of the mandible with respect to the fixed part of the masticatory system, and it consists of various ligaments, the articular disk, the synovial capsules, and the synovial fluid. The articulating surfaces of the bones in the TMJ, namely, the condyle and the fossa, are covered with a fibrous tissue called the *articular cartilage*. The coronoid process serves as one of the endpoints of the temporal muscle. Various muscles and ligaments are attached to the mandible, enabling the mastication function. On the front part of the mandible, the teeth are connected through the *alveolar ridges*.

Two *temporal* bones are located on each lateral side of the human skull as shown in Fig. 1. The temporal muscles are connected to the wide area called the squamus part of the temporal bone. The mandible articulates in the concave part of the temporal bone called the *mandibular fossa*, located below the squamus part and near the zygomatic process as shown in Fig. 1. The mandibular fossa is also called the *articular fossa*; or the *glenoid fossa*. The *articular eminence* is located immediately in front of the mandibular fossa. The condyle of the mandible articulates on the maxilla through the TMJ. In the initial phases, of the opening of the jaw, the condyle rotates in the mandibular fossa; however, in the later phases; it moves forward and slides along the articular eminence. The thickness of the bone in the posterior part of the mandibular fossa is relatively thin, whereas thicker bone is found in the anterior part and in the articular eminence. This is an indication of the load-bearing nature of these surfaces, where bone thickness is larger in sections subjected to larger stresses.

THE MUSCULATURE OF THE MASTICATION SYSTEM

The masticatory muscles are divided into *depressor* and *elevator* groups (6). The depressors are the *digastric*, *suprahyoid*, and *infrahyoid* muscles, and the elevators are the *temporal*, the *masseter*, the *medial pterygoid*, and the *lateral pterygoid* muscles (5).

The depressor muscles are located in the floor of the mouth. The supra- and infrahyoid muscles connect the hyoid bone to the mandible. The digastric muscle connects the mastoid process of the skull with the mandible, and it is attached to the hyoid bone through a tendon. These muscles are primarily involved during jaw opening and swallowing.

The three muscles, which form the fan-shaped muscle, shown in Fig. 4a, are collectively called the *temporal muscle*. The *anterior (front) temporal muscle* is composed of vertically oriented muscle fibers. The fibers orientation turns gradually toward the horizontal direction in the *middle temporal muscle* and the *posterior (back) temporal muscle*. The muscle fibers are attached to the temporal bone on the open part called the squamus of the temporal bone. These fibers come together as they descend downward through the zygomatic arch and form a tendon. This tendon attaches to the coronoid process and anterior border of the ascending ramus of the mandible.

The temporal muscle is both an elevator and a positioner. It can function unilaterally, bilaterally, or in sections to position and elevate the mandible. In bilateral closure, this muscle moves the condyle into the mandibular fossa. In unilateral action, the posterior temporal muscle moves the mandible toward the active side.

Figure 4. The elevator muscles of mastication: (a) the temporalis, (b) the masseter, (c) the medial pterygoid, and (d) the lateral pterygoid. (Modified from Temporomandibular Disorders and Occlusion by Okeson JP, 5th ed., Mosby, 2003.)

The *masseter* is located on the distal (outer) lateral sides of the ramus of the mandible, as shown in Fig. 4b. This muscle extends from the angle of the mandible upward and attaches to the zygomatic arch. The masseter is the most powerful elevator muscle in the masticatory system, and it is responsible for the high loads in the molar area. The crushing forces on the molar area could become high when the masseter acts together with the internal pterygoid and the anterior temporal muscles.

The *medial (internal) pterygoid* muscle is the internal counterpart of the masseter as shown in Fig. 4c. The fibers of this muscle originate from the *pterygoid fossa* of the *sphenoid bone*, located internally in the mouth, extend downward, internally, and connect to the internal face of the mandibular angle, as shown in Fig. 4c. The medial pterygoid and the masseter function in a coordinated manner, and together they can generate high loads. Although the primary function of the medial pterygoid is to elevate the mandible, it can also move the mandible medially (toward the center).

The *lateral pterygoid* muscle: is the collective name of the two muscles: the *upper (superior)* and *lower (inferior) lateral pterygoid*, as shown in Fig. 4d. The upper lateral pterygoid muscle originates from the sphenoid bone located internally in the mouth, extends horizontally, and attaches to the condylar neck, the capsular ligament, and the articular disk. This muscle is active along with the elevator muscles during closing the teeth together for chewing or clenching. The upper lateral pterygoid muscle is a weaker muscle as compared with the lower.

The lower lateral pterygoid muscle originates at the pterygoid plate (Fig. 4d). It extends backward and upward connecting to the neck of the condyle. Bilateral contraction of the right and left lower pterygoids pulls the condyles down, out of the articular eminences, and the mandible moves forward, as shown in Fig. 4d. Unilateral contraction causes movement of the mandible to the opposite side.

THE TMJ

The relative motion of the mandible with respect to the temporal bone takes place at the TMJ, as shown in Fig. 5a. This is where the condyle of the mandible sits against the temporal articulating surfaces of mandibular fossa and the articular eminence. The TMJ is composed of the condyle of the mandible, the articulating surfaces of the temporal bone, the articular cartilage and disk, the ligaments, and the muscles. The articular disk is considered to act as a non-ossified bone, between the mandibular fossa and the condyle; hence, the TMJ is considered a compound joint of the human body.

The articular disk deserves special attention, as it facilitates the relative motion to take place without direct bone-to-bone contact. The disk is located between the condyle and the temporal fossa. This is a fibrous tissue, which does not have blood vessels and nerves for the most part. The articular disk is mainly a mesh of *collagen fibers* whose interstices are filled with *proteoglycans*. In the TMJ disk, the collagen fibers help maintain its shape during loading, whereas the elastin fibers function to recover the form after

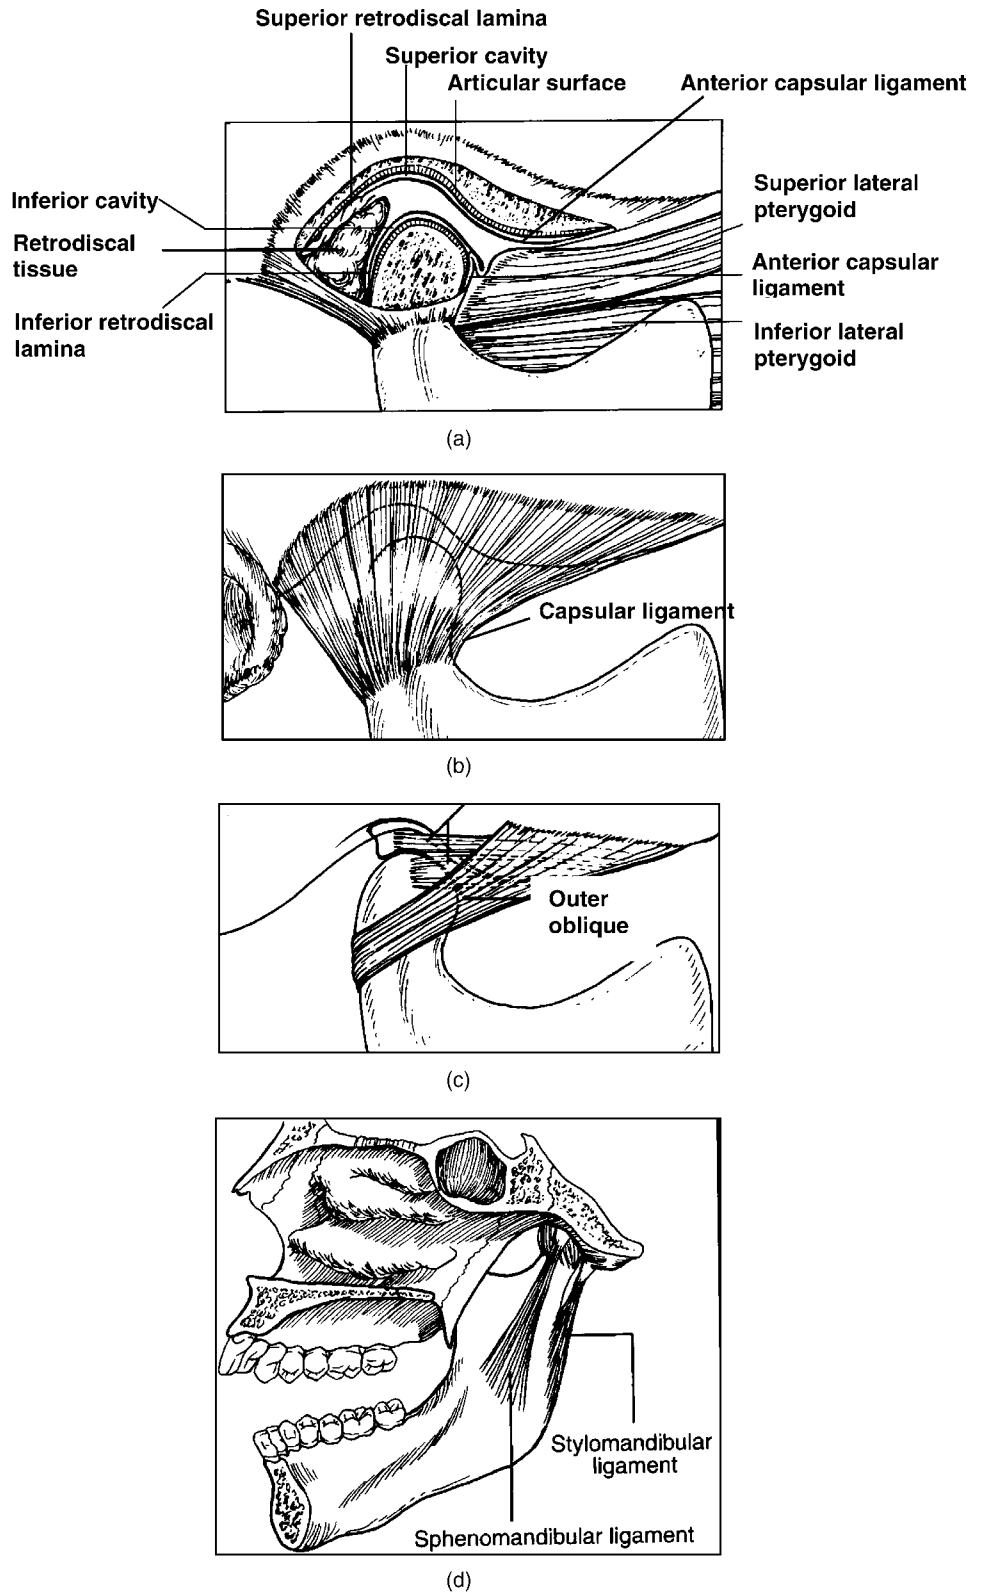

Figure 5. Schematic representation of the articular disk and the ligaments of the masticatory system: (a) the articular disk and its connecting tissues, including the collateral ligaments; (b) the capsular ligament; (c) the tempo-romandibular ligament; and (d) stylomandibular and sphenomandibular ligaments. (Modified from *Temporomandibular Disorders and Occlusion* by Okeson JP, 5th ed., Mosby, 2003.)

unloading. The mechanical properties of the articular disk strongly depend on the collagen fiber and the proteoglycan composition and organization (17). Experimental evidence suggests that the elastic modulus of the articular disk increases with age (18). The load-displacement (stress-strain) behavior of the articular disk is nonlinear and

viscoelastic. A poroelastic material behavior model where the solid matrix behavior was hyperelastic showed several similarities with dynamic indentation tests of articular disks (19).

The articular disk is mainly supported by ligaments, as shown in Fig. 5a. In the posterior (back) region of the TMJ,

the articular disk is attached to a loose connective tissue named the *retrodiscal tissue* (RT). The superior (top) portion of the RT is attached to the tympanic plate by the *superior retrodiscal lamina*, and its inferior (bottom) part is attached to the condyle by the *inferior retrodiscal lamina*. The medial, lateral, anterior, and posterior surfaces of the articular disk are attached to the *capsular ligament*, which surrounds most of the surfaces of the condyle and the articular surface of the temporal bone. In the front, the articular disk is also attached to the superior (upper) lateral pterygoid muscle (5).

The capsular ligaments divide the joint into the *upper* and *lower cavities*. The internal surfaces of the cavities are covered with endothelial cells. The cavities are filled with *synovial fluid* produced by these cells. The synovial fluid serves as a lubricant in the TMJ and reduces the frictional forces between articulating surfaces. Depending on the joint speed and load, different lubrication regimes are thought to be responsible for this effect (7). These include *boundary lubrication*, *elastohydrodynamic lubrication*, and *hydrodynamic* lubrication modes (20). Another effect, which possibly contributes to joint lubrication, is the *weeping lubrication*, which takes place as the synovial fluid, retained in the articular cartilage, is forced out of the cartilage into the synovial cavity, under sufficient normal pressure. The weeping lubrication is thought to be more prevalent during elevation and clenching (5).

Two- (21) and three- (22,23) dimensional finite element models of the quasi-static opening of the jaw that included the contact relations among the articular disk, the condyle, and the articular eminence showed that the disk moves together with the condyle. These models predicted that the superior lateral pterygoid muscle and the ligaments attached to the disk do not play a significant role in the disk movement during jaw opening (21,23). The biconcave shape of the disk is sufficient to move the disk with the condyle. These studies also showed that the articular disk is primarily loaded in its intermediary (central) region.

THE LIGAMENTS

Ligaments are the connective tissues between the bones. The main function of the ligaments of the masticatory system is to prevent the mandible from undergoing extreme relative motion. Ligaments also protect the nerves and the vessels that connect to the mandible. In the masticatory complex, there are five main ligaments as shown in Fig. 5: the *collateral (discal) ligament*, *capsular ligament*, the *temporomandibular ligament*, the *sphenomandibular ligament*, and the *stylomandibular ligament*.

The *collateral ligaments* attach the medial (inner) and distal (outer) surfaces of the articular disk to the condyle of the mandible. These attachments along with the anterior (front) and posterior (back) attachments of the articular disk to the capsular ligament create the *synovial cavities*. The attachment of these ligaments permit the motion of the articular disk front-to-back, or in the anterior-posterior direction. Therefore, this ligament allows the disk to travel with the condyle.

The *capsular ligament* encloses the entire TMJ, as shown in Fig. 5b, and thus it provides a sealing function for the synovial fluid. The entire circumference of the articular disk is also attached to this ligament. The capsular ligament is attached superiorly (top) to the temporal bone and inferiorly (bottom) to the neck of the condyle. This ligament resists lateral or inferior (downward) forces.

The *temporomandibular (TM) ligament* consists of an inner *horizontal* and an *outer oblique part*, as shown in Fig. 5c. The TM ligament plays an important role in the pivoting action of the TMJ. Both parts of the TM ligament originate from the zygomatic arch. The inner horizontal part extends from the zygomatic arch horizontally and attaches to the anterior (frontal) neck of the condyle. The outer oblique part extends from the zygomatic arch and attaches to the posterior (back) part of the neck of the condyle, as shown in Fig. 5c. The outer oblique part of this ligament resists excessive dropping of the mandible. During the initial phase of the mouth opening, the condyle can pivot around a fixed point, while this ligament is becoming stretched. When the stretching of this ligament reaches its limit, then the condyle moves downward and forward across the articular eminence to continue opening. It is believed that the *inner horizontal part* of this ligament limits the backward (posterior) movement of the condyle and the articular disk.

The full effect of this ligament in limiting the motion of the articular disk has been debated (9); biomechanical models of the disk movement during mandibular opening and closing have shown that the disk could move in the anterior and posterior directions due to the favorable contact conditions provided by its bicuspal shape (21,24).

The *sphenomandibular ligament* extends from the sphenoid bone and attaches to the *lingula* on the inner (medial) surface of the ramus as shown in Fig. 5d. The function of this ligament is not well understood. However, its main function could be protection of nerves and blood vessels from dislocation and trauma, and it can prevent extreme anterior and lateral dislocations (4).

The *stylomandibular ligament* is another accessory ligament. It is located between the styloid process and the back of the ramus as shown in Fig. 5d. It limits excessive protrusive movements of the mandible (4).

MASTICATION AND ITS BIOMECHANICAL MODELS

Mastication is the action of chewing foods. Mastication involves rhythmic and repetitive motion of the mandible with respect to maxilla. The mastication cycle starts with the *opening phase*, followed by the *crushing phase* and *grinding phase*, which occur during closure, as shown in Fig. 6a. The motion of the mandible during mastication is a three-dimensional, complex motion, which has been described as having the shape of a teardrop or a pear. When the motion of the incisors in an idealized mastication cycle is viewed from the frontal plane (Fig. 6a), this analogy becomes clear. During the opening phase, the mandible drops vertically for about 15–18 mm; thereafter, it moves

Figure 6. The mastication cycle viewed from (a) the frontal plane; and (b) the sagittal plane. (Modified from Temporomandibular Disorders and Occlusion by Okeson JP, 5th ed., Mosby, 2003.)

laterally and the closure phase begins. During the initial phase of closure, the incisors move 4–5 mm laterally while crushing the food. This phase lasts until incisors are located 3–4 mm laterally and 3 mm vertically with respect to their initial (intercuspal) condition. During the grinding phase, which follows, the food is sheared between the cusps of the incisors. The view of the motion of the incisors from the side (sagittal) plane on the working side, shown in Fig. 6b, shows that during the opening phase, the incisors move slightly in the frontal (anterior) direction, followed by a posterior motion during closing. The TMJ and the premolars also follow a path similar to that of the incisors in the sagittal (side) plane on the working side.

The amplitude of the anterior and the lateral movement of the mandible depend on the stage of mastication. During the initial phases, the incisors are used to cut the bolus (food) and the anterior and lateral movement are relatively large. During the later phases, the posterior teeth are used more, and the lateral movement of the teeth is reduced. The consistency of the food also affects the lateral movement, where harder foods require larger lateral movements and more chewing cycles, as shown in Fig. 7.

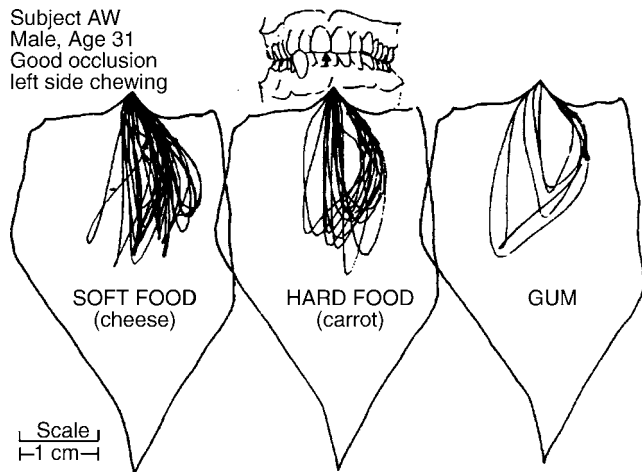

Figure 7. Frontal view of the chewing stroke from a 31-year-old man with good occlusion, for soft food, hard food, and chewing gum. (From Advances in Occlusion, by Lundeen HC, Gibbs CH, Boston, 1982).

In biomechanical analysis of mastication, static analysis are carried out to determine maximum clenching forces that can be applied by the muscles; dynamic analysis, on the other hand, provides information about the muscle TMJ interactions during the open and close cycles, as well as laterodeviations. In these analyses, the mandible is modeled as a rigid body, and the muscle forces are modeled as concentrated forces, as shown in Fig. 8. The attachment points and the three-dimensional vectorial orientations of the muscles are typically, carefully, measured from cadaver specimens. The biomechanical analysis of mastication also considers the deformations of the mandible due to external forces.

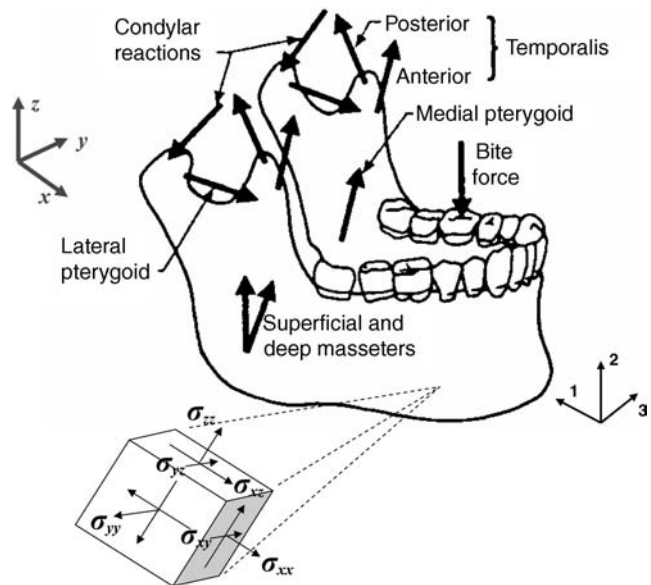

Figure 8. The locations and directions of the muscle force vectors, the bite force vector, and the condylar reaction force vectors are shown schematically. The x -, y -, and z -coordinate system indicates the coordinate system in which the forces are measured. The 1-, 2-, and 3- coordinate system indicates the transversely isotropy directions for material properties of the mandible. The small stress cube indicates the internal stresses generated at a point inside the mandible in response to external loading. (Modified from Faulkner et al., “A three dimensional investigation of temporomandibular joint loading,” *Journal of Biomechanics* 1987;20:997–1002.)

In the next section, a classification of the internal and external forces acting on a deformable body will be described. The material property definitions and deformation behavior of the tissues involved in the masticatory system is described next. Finally, some static, dynamic, and elastic models of mastication developed in the last 20 years will be described.

In general, the forces acting on a structure can be classified as *external forces* and *internal forces*. The external forces can be further classified as *surface tractions* (external pressure), *concentrated forces*, and *body forces*.

External Forces

Surface tractions are external forces distributed over a finite area, on the surface of the structure. For example, the contact pressure between the condyle of the mandible and the articular disk takes place over a relatively large area. This contact pressure is a normal traction acting on the mandible (and the disk). Note that distribution of this traction can vary from point-to-point. In the metric system, the unit of traction is Pascal (Pa), where $1 \text{ Pa} = 1 \text{ N/m}^2$.

Concentrated force is a term used for an idealized traction acting over an infinitesimally small area. In the metric system, the unit of the concentrated force is Newton (N), where $1 \text{ N} = 1 \text{ kg}\cdot\text{m/s}^2$. Use of concentrated forces is common in mechanics as they simplify the analysis in many instances. For example, in many mechanical models of the mandible, the forces exerted by the muscles, the forces experienced by the teeth during clenching or mastication, and the reactions on the condyle are idealized as concentrated forces as shown in Fig. 8. While idealizing the muscle forces, investigators spend a great deal of effort to ensure that the idealized forces represent the (actual) tractions in a mechanically equivalent manner.

Both surface tractions and concentrated forces are transferred from one body onto another through physical contact. Forces exerted by muscles on the bones are in this category. On the other hand, a *body force*, such as that due to gravity, is a force that acts over a distance, without requiring direct physical contact. For example, if it was not for the slight state of contraction of the clenching muscles, the mandible would stay open due to the effect of gravity.

Internal Forces and Internal Stresses

The internal forces develop inside a structure in response to external forces and enable the structure to stay together. The internal forces can only be "visualized" by taking a virtual cross-section of the structure. Depending on the location and orientation of the cross-section, the internal forces will vary in magnitude and direction. The resultant of the internal forces acting on an infinitesimally small cross-sectional area (dA) of the structure can be decomposed into a *normal force* (dF^n) acting perpendicular to the cross-section and a *shear force* (dF_s) acting in the plane of the cross-section. *Stress* at a point inside the structure can then be defined as the limit of the internal forces acting on the area dA as it becomes infinitesimally small. In general, the internal stress state of a structure can be expressed by six independent stress components σ_{xx} , σ_{yy} , σ_{zz} , σ_{xy} , σ_{xz} , σ_{yz} as shown in Fig. 8. (Note that six indepen-

dent stress components assume that no internal twisting moments exist in the structure. In case these exist, then nine stresses are necessary for this description) Note that in this representation, the first subscript refers to the direction of the normal of the plane on which the stress is acting, and the second subscript refers to the direction of action of the internal force. Thus, σ_{xx} , σ_{yy} , and σ_{zz} are the *normal stress* components, and σ_{xy} , σ_{xz} , and σ_{yz} are the *shear stress* components. It is important to remember that internal stresses are defined at a point inside the structure, and in general, they can vary from point-to-point. Whether they do vary depends on many factors such as the shape of the structure, external force distribution, and material properties. In the metric system, like the tractions, the unit of stress is Pascal.

Deformation and Strain

In general, a structure that is properly fixed on its boundary will deform in response to external forces. The deformation of a point on the structure can be characterized by its displacements. In general, a point P^- before deformation will be displaced to a new location P^+ after deformation. For small displacements, the displacement vector d^- can be expressed in a Cartesian coordinate system. The components of d^- along the x -, y -, and z -axes are u , v , and w , respectively.

Relations governing the mechanics of deformable bodies are expressed in terms of strain, rather than the displacements. In general, *strain* is a nondimensional measure of deformation at a point. The *normal strains* ϵ_x , ϵ_y , and ϵ_z represent the change in length per unit of initial length, along the x -, y -, and z -axes, respectively. The *shear strains* γ_{xy} , γ_{xz} , and γ_{yz} represent the decrease in the right angle initially formed by the sides parallel to the x - y , x - z , and y - z axes, respectively (26).

Material Properties

The load-displacement behavior of a structure depends on the type of material involved. In general, the material properties of a structure are determined by uniaxial tension test, shear test, and hardness test. A uniaxial tension test and a pure-torsion test establish the relations between, for example, σ_{xx} and ϵ_x and σ_{xy} and γ_{xy} by Hooke's law:

$$\sigma_{xx} = E\epsilon_x \quad \text{and} \quad \sigma_{xy} = G\gamma_{xy} \quad (1)$$

where the proportionality constants are the elastic (or Young's) modulus E and the shear modulus G . In general, the three-dimensional stress-strain relations are expressed with the generalized Hooke's law, which can be given in matrix form as

$$\{\sigma\} = [E]\{\epsilon\} \quad \text{or} \quad \{\epsilon\} = [C]\{\sigma\} \quad (2)$$

where the *stress vector* is $\{\sigma\} = \{\sigma_{xx} \ \sigma_{yy} \ \sigma_{zz} \ \sigma_{xy} \ \sigma_{yz} \ \sigma_{xz}\}^T$, the *strain vector* is $\{\epsilon\} = \{\epsilon_x \ \epsilon_y \ \epsilon_z \ \gamma_{xy} \ \gamma_{yz} \ \gamma_{xz}\}^T$, the *elasticity matrix* is $[E]$, and the *compliance matrix* is $[C] (= [E]^{-1})$. The elasticity matrix of an *anisotropic* material has 21 independent components. In case the material has three orthogonal planes of symmetry, the material is said to be *orthotropic*. The compliance matrix for an orthotropic

material is defined by nine independent material properties (27):

$$[C] = \begin{bmatrix} 1/E_1 & -v_{21}/E_2 & -v_{31}/E_3 & 0 & 0 & 0 \\ -v_{12}/E_1 & 1/E_2 & -v_{32}/E_3 & 0 & 0 & 0 \\ -v_{13}/E_1 & -v_{23}/E_2 & 1/E_3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1/G_{23} & 0 & 0 \\ 0 & 0 & 0 & 0 & 1/G_{31} & 0 \\ 0 & 0 & 0 & 0 & 0 & 1/G_{12} \end{bmatrix} \quad (3)$$

where E_i are the Young's moduli, G_{ij} are the shear moduli, and v_{ij} are the Poisson's ratios in the respective directions, with the restriction that $v_{12}/E_1 = v_{21}/E_2$, $v_{13}/E_1 = v_{31}/E_3$, and $v_{32}/E_3 = v_{23}/E_2$. The number of independent elastic constants is reduced to five for a *transversely isotropic* material, such as the bone, where each plane through a longitudinal axis is a plane of elastic symmetry. For fully *isotropic* materials, the material properties are the same in all directions, and two independent properties (E , ν) are sufficient to describe the stress-strain relationship.

Mechanical Properties of Bone

Bone is composed of collagen, water, hydroxyapatite mineral, and small amounts of proteoglycans and noncollagenous proteins. Collagen is the structural protein that gives the flexibility and tensile strength, also found in ligaments and the articular disk. Hydroxyapatite, $\text{Ca}_{10}(\text{PO}_4)(\text{OH})_2$, is a crystal with hexagonal symmetry located within and between collagen fibers, found in the form of needles, plates, and rods. The internal structure of bone is porous. Two distinct porosity ranges give rise to the *cortical* (compact) bone with low porosity (5–10%) and the *trabecular bone* with 75–95% porosity. The interstices are filled with marrow, a tissue composed of blood vessels, nerves and various types of cells (28).

Among these cells are the *osteoclasts*, which are responsible for formation of new bone, and *osteoblasts*, which are responsible for resorption of bone. *Remodeling* of bone involves repair of internal cracks, and so on, due to coupled activity of osteoclasts and osteoblasts. In addition to self-healing, the bone also has the ability to *adapt* to variations in imposed stresses (Wolff's law). It has been hypothesized that the strain in the bone tissue stimulates the biological response resulting in adaptation (28). The physiologic loading zone has been reported to be in the 1000–3000 microstrain range (28). Bone adaptation has significant biomechanical consequences, in design of endosseous implants, and prosthetics. The loading conditions created in the bone by these should be carefully considered to prevent excessive or insufficient loading.

The cortical bone is a transversely isotropic material, as two of its principal material directions have similar mechanical constants. The stiffest direction of the mandibular cortical bone is along a tangent to the parabolic curve of the mandible, i.e., direction -3 in Fig. 8 (29). The mechanical properties of the *cortical bone* depend on several fac-

Table 2. Elastic Properties of Cortical and Trabecular Bones Measured for a Transversely Isotropic Material Model

	Transversely Isotropic

tors, including the porosity of the bone, mineralization level, bone density, collagen fiber organization, and rate of deformation (28). The ultimate stress of the cortical bone has been reported to be higher in compression (170 MPa) than in tension (100 MPa) (28).

The mechanical properties of the *trabecular (cancellous) bone* depend on the porosity, the orientation of the trabecular architecture, and the material properties of the tissue in the individual trabeculae (28). The strength of the trabecular bone has been reported to be the same in tension and compression, and it is approximately 2–5 MPa (28).

Experimental data for the transversely isotropic material properties of the cortical bone of the mandible were obtained by Carter as reported by Hart et al. (30). These values are reported in Table 2. This table also contains the trabecular bone properties measured for human tibia. In other studies, many investigators assumed that the jaw bone deforms in an isotropic manner. The elastic modulus values used in these finite element analysis models ranged between 11 and 20 GPa for the cortical bone and between 0.2 and 7.9 GPa for the trabecular bone. The Poisson ratio was typically taken in the range of 0.3–0.33 (31–35).

Mechanical Properties of the Cartilaginous Tissue of the Masticatory System

The cartilagenous tissue of the masticatory system is the *articular cartilage* on the articular surfaces of the TMJ and the *articular disk*. In general, this type of tissue is composed of cells (chondrocytes) imbedded in intercellular matrix, permeated by a system of fibers (1). Depending on the function of the cartilage tissue in the body, the appearance and the nature of the intercellular matrix can be different. For example, the *yellow elastic fibrocartilage* is found in external ears and larynx; the *hyaline cartilage* is found in nasal, tracheo-bronchial, and articular surfaces; and the *white fibrocartilage* is found in intervertebral and articular disks (1).

In indentation experiments, the cartilage tissue shows an instantaneous recovery, followed by a time-dependent creep deformation, when it is released after compression. Full recovery to the initial state takes place in a finite amount of time. Such material behavior is termed *viscoelastic*. The cartilage tissue is porous, and the synovial

fluid fills the interstices of the tissue. Under compressive stress, the fluid can move out of the tissue, and upon relaxation, it will return to interstitial openings. This fluid flow provides lubrication to the joints as well as nutrients to the cartilage cells (1). The viscoelastic behavior is due to (1) the inherent viscoelastic nature of the solid matrix and (2) the velocity differences between the solid matrix and the liquid (11).

The mechanical response, biomechanical function, and biological integrity of the cartilaginous tissue are governed by the movement of the interstitial fluid (1) *within* cartilage and (2) *across* the articular surface. The synovial fluid is transported through the porous membrane due to a pressure gradient across the tissue. Flow also occurs due to the deformation of the cartilage matrix; the pressure of the fluid internal to the matrix rises in response to deformation. The resulting pressure gradient with respect to the articular surface causes the fluid flow. The biphasic model for the mechanical behavior of the articular cartilage was formulated by Mow et al. (36). In this model, the tissues are modeled as consisting of a soft, permeable, elastic solid, mixed with water. The fluid and the solid phases are coupled through the pressure. Experimentally observed viscoelastic behavior of the articular cartilage can be explained by this biphasic model (36).

Although the articular cartilage behaves as a viscoelastic material due to its poroelastic nature, it can undergo large deformations. Experimental evidence further suggests that the material properties are nonhomogeneous and anisotropic. The experimental measurements of the load-displacement behavior of the articular cartilage of the rabbit TMJ have indicated that the elastic modulus (E) depends on the location with respect to the joint, varying between 0.95 and 2.34 MPa (37). These values are on the same order of magnitude as that reported by Woo et al. obtained for bovine humeral articular cartilage (11). The elastic modulus and Poisson's ratio of the articular cartilage of the temporal joint from these references are given in Table 3.

The articular cartilage is a connective tissue that provides very small frictional resistance to the sliding motions of the joints, in general. Experimental studies to determine the coefficient of friction (COF) show that the presence of the synovial fluid plays a significant role in its low level. Although it has been found that the COF can be as low as 0.005, it has also been shown that it depends on the level of the normal stress and the motion of the joint. In general, under large normal stress values, the COF is found to increase. Moreover, the static friction coefficient is larger

than the dynamic friction coefficient (1,18,38). This behavior is in contrast to the behavior of the COF between most other materials (20).

Tension and compression tests of human *articular disk* show nonlinear stress-strain behavior (14,39). Chin et al. measured the viscoelastic properties of human TMJ disks (40). Chen et al. (39) assumed that the solid matrix of the articular disk can be modeled as a hyperelastic material of the Mooney–Rivlin type (41), where the strain energy of an incompressible rubber-like material is expressed as

$$U = c_1(I_1 - 3) + c_2(I_2 - 3) \quad (4)$$

where I_1 and I_2 are the first and second invariants of the Cauchy–Green deformation tensor and c_1 and c_2 are empirically determined constants (41). Chen et al. used $c_1 = 27.91$ MPa and $c_2 = -20.81$ MPa, based on experimental data obtained from dog articular disks (39).

More recently, Tanaka et al. obtained experimental results for human articular disks (18). Although their data show the same trend predicted by the Mooney–Rivlin type of hyperelastic behavior, they approximated the curve by a single elastic modulus calculated at 2% strain level, and used a linear FEA. Chen and Xu (42) and Hu et al. (37) used a linear piecewise continuous material model. Other investigators assumed that the articular disk behaves strictly in a linear-elastic manner (19,21,43). The data for elastic modulus (E) used in these work are reported in Table 4.

Mechanical Properties of the Ligaments

The physiological function of a joint ligament is to provide stability to joints and to limit their range of motion (45). Ligaments can resist only tensile forces. The structural component responsible for the tensile strength of ligaments is the protein, collagen. Other components of this tissue are elastin, proteoglycans, and glycoproteins. The basic molecular collagen unit is a left-handed molecule. Collagen molecules are wound into super-helices, microfibrils, and fibrils in a hierarchical manner. At each level, the orientation of the helix is reversed. This alternating helix direction is useful in converting the axial tension to circumferential compression, and it is a contributing factor to the strength of the ligaments (45).

The load-displacement curve of the ligament under tensile loading initially displays nonlinear behavior with tangent modulus increasing with increasing strain. Increasing the strain even further, eventually a linear

portion is reached. The post-yielding region shows a decreasing tangent modulus with increasing strain. The elastic modulus (E) of the nuchal (neck) ligament is 7.5 MPa, the ultimate strength, and the ultimate strain are 2.4 and 1.25 MPa, respectively (45). Chen and Xu used nonlinear springs, which can only carry tension, to model the upper, and lower posterior ligaments and the anterior ligament (42). They used data from the talofibular ligament of human ankle and assumed that the stiffness of the ligament would be proportional to its cross-sectional area. Thus, they calculated spring stiffness values that are on the order of 10.9–16.35 kN/m.

Static Models of Mastication

Static models of mastication aim to develop an understanding of the maximum forces applied by muscles of mastication. These models typically treat the mandible as a rigid body. The motion of a rigid body is fully described by the displacements and rotations of its center of mass. During occlusion, the external loads acting on the masticatory system are the forces on the TMJ, the ligaments, the teeth, and the muscles, as shown in Fig. 8.

The static equilibrium, for example, in clenching, requires that the sum of the external force and moment vectors be in balance. Considering the subdivisions of the muscles of mastication (i.e., anterior, medial, posterior temporalis; superficial and deep masseter; superior and inferior lateral pterygoid; and, the medial pterygoid), it can be observed that there will be $N_m = 16$ muscle force vectors ($\vec{F}_i^{(m)}$) acting on the mandible, where N_m is the total number of muscles. Note that the subscript i ($1 \leq i \leq N_m$) is an integer counter used to identify each muscle. Similarly, the reaction force vectors due to the ligaments, due to the contacting teeth, and at the joints of the TMJ are indicated by $\vec{F}_i^{(l)}$, $\vec{F}_i^{(t)}$, and $\vec{F}_i^{(j)}$, respectively. Note that these forces can only attain positive values; muscles only apply tensile forces; the ligaments provide no appreciable resistance when they are compressed; and when the TMJ and the teeth are in contact, the reaction forces are considered to be positive. The static equilibrium of external forces is ensured by the following vector equation:

$$\sum_{i=1}^{N_m} \vec{F}_i^{(m)} = \sum_{i=1}^{N_l} \vec{F}_i^{(l)} + \sum_{i=1}^{N_t} \vec{F}_i^{(t)} + \sum_{i=1}^{N_j} \vec{F}_i^{(j)} = 0 \quad (5)$$

where N_l , N_t , and N_j are the total number of force vectors related to the ligaments, teeth, and joint reaction forces. The location of each force vector is represented by a location vector $\vec{r}_i^{(l)}$. Each force vector causes a moment with respect to the origin of the location vector represented by the vector cross-product $\vec{r} \times \vec{F}$. The moment balance with respect to the origin is expressed by the moment equilibrium equation:

$$\sum_{i=1}^{N_m} \vec{r}_i^{(m)} \times \vec{F}_i^{(m)} + \sum_{i=1}^{N_l} \vec{r}_i^{(l)} \times \vec{F}_i^{(l)} + \sum_{i=1}^{N_t} \vec{r}_i^{(t)} \times \vec{F}_i^{(t)} + \sum_{i=1}^{N_j} \vec{r}_i^{(j)} \times \vec{F}_i^{(j)} = 0 \quad (6)$$

Equations 5 and 6 are a compact representation of the force and moment vectors. In a Cartesian coordinate system, each vector is represented as the vector sum of its components acting along the x -, y -, and z -axes. Thus, equations 5 and 6 each represent three equations of equilibrium along these axes, resulting in a total of six equations.

As mentioned, there are four elevator muscles on each side of the skull. Some investigators consider only these eight muscles during function; therefore, they use $N_m = 8$ (46). In other studies, depending on the level of detail, the total number of muscle forces used can vary up to $N_m = 26$ (47). Similar comments apply for the number of forces on the ligaments, teeth, and joints. Thus, it can be easily recognized that the six equations of equilibrium, represented by equations 5 and 6, are not sufficient in solving for the magnitudes of the numerous unknown forces. Such systems are statically indeterminate.

To find a solution for a statically indeterminate system, additional equations and assumptions are necessary. Osborn and Baragar (47) assumed that the *strain sensors* in the muscle tissue and pressure sensors in the TMJ are activated at a rate proportional to the magnitude of the muscle tension and joint reaction forces. The total output f of these sensors then becomes

$$f = \sum_{i=1}^{N_m} c_i^{(m)} |\vec{F}_i^{(m)}| + \sum_{i=1}^{N_j} c_i^{(j)} |\vec{F}_i^{(j)}| \quad (7)$$

where $c_i^{(m)}$ and $c_i^{(j)}$ are the sensor output rates specific to the muscles and joints, respectively. They further postulated that the central nervous system minimizes the output of the (cost) function f . Thus, the problem of finding the reaction forces in mastication is transformed into a problem where the cost function in equation 7 is minimized subject to satisfaction of equations 5 and 6 and conditions $|\vec{F}_i^{(m)}| \geq 0$ and $|\vec{F}_i^{(j)}| \geq 0$. This defines a *linear programming* problem, typically encountered in economics, and it can be handled with various available approaches (48). Osborn and Baragar investigated the effects of minimizing only the joint forces ($c_i^{(j)} = 1$, $c_i^{(m)} = 0$) or only the muscle forces ($c_i^{(m)} = 1$, $c_i^{(j)} = 0$).

The following muscle groups were considered in their study: the masseter (superficial, deep, anterior, and posterior), the medial pterygoid (anterior and posterior), the temporalis (anterior, medial, and posterior), the lateral pterygoid (superior, upper, inferior), and the digastric. Thus, they had $N_m = 23$. They neglected the effect of ligaments ($N_l = 0$), and assumed a single reaction force ($N_j = 1$) acts on each TMJ. The bite force on different teeth were treated as known external forces. They showed that the model where the cost function involves only the minimization of muscle forces results in more realistic mastication force scenarios. Their model predicted that muscle elements with longer moment arms relative to the joint are activated first. As the bite force increases, a ripple activity spreads into muscles with shorter moment arms.

Hatcher et al. investigated the muscle forces involved in unilateral clenching by using a model that is symmetrical around the mid-sagittal plane, including six muscles: the posterior and anterior temporalis, the deep and superficial masseter, the medial pterygoid, and the lateral pterygoid (49).

Due to the assumption of symmetry, $N_m = 6$. They assumed that the left and right TMJ forces were identical ($N_j = 1$). They compared the mathematical results with the results obtained from an *in vitro* model of a skull. The muscle action in the *in vitro* model was simulated by applying external forces, and occlusal and TMJ forces were measured. The study concluded that more realistic results are obtained in the case where the applied force magnitudes are based on the cross-sectional area of the muscles and the electromyogram (EMG) data, in contrast to when they are solely based on the cross-sectional area of the individual muscles. In a different study, the same authors predicted that the balancing side condylar reaction force is larger than the working side, when occlusion occurs on either one of the molars (25). They also showed that the ipsilateral (same side) condylar reaction force varies considerably as the occlusion direction varies in the parasagittal plane.

Smith et al. used a total of six muscles: the right and left lateral pterygoid, the right and left temporalis, and the right and left masseter/medial pterygoid muscle complex (46). They considered the TMJ load and one bite force. They used a minimization technique in which their cost function was the root-mean-square of the TMJ reaction force. This analysis predicted that the TMJ is loaded over the normal functional range of bite force positions and angles. The magnitudes of the reaction forces on the TMJ were found to vary between 5% and 60% of the occlusal force depending on which teeth the occlusion takes place.

Koolstra et al. (50) considered the effects of the eight clenching muscles: the deep and superficial masseter; the medial pterygoid; the anterior, posterior, and deep temporalis; and the superior and inferior lateral pterygoid. They treated the left and the right sides as being independent; hence, a total of 16 muscles were included. The magnitudes of the TMJ reaction forces and the muscle forces were unknown, but their directions of application were measured from the skull. The bite force, on the other hand, was treated as a known quantity. The total number of unknowns were 18, and the linear programming technique was used. The cost function f was based on the postulation that the relative activity of the most active muscle among all muscles should be as small as possible. The relative activity $|\vec{F}_i^{(m)}|$ of a given muscle i was defined as

$$|\vec{F}_i^{(m)}| \leq \mu |\vec{F}_i^{(m)}|_{\text{Max}} \quad (8)$$

where $|\vec{F}_i^{(m)}|_{\text{Max}}$ is the maximum possible for of the muscle and μ is a coefficient defined below. The maximum muscle force of a muscle element is assumed to be proportional to its physiological cross-section, and it is a known quantity. The objective function was given as

$$f(|\vec{F}_i^{(m)}|) = \mu \quad (9)$$

subject to N constraints defined by equation 8. Using this model, the maximum possible bite forces, for which the masticatory system can remain stable, were predicted. Thus, biteforce and joint-force envelopes for mastication at different teeth were evaluated. *In vivo* validation of these results were carried out by Koolstra and van Eijden (51). An overall good agreement between measured and predicted values was observed.

Dynamic Modeling of Jaw Opening and Closing

Biomechanical analysis of the jaw opening and closing was modeled by Koolstra and van Eijden (24,52–54). The dynamic modeling of the jaw opening and closing involves equations of dynamic equilibrium, where the jaw is considered rigid. Thus, the motion of the mandible can be determined by six degrees of freedom of its center of mass; the three rigid-body displacements $\{u\} = \{u_x, u_y, u_z\}^T$ in the x -, y -, and z -directions, and the three rotations $\{\theta\} = \{\theta_x, \theta_y, \theta_z\}^T$ about the x -, y -, and z -axes. The six equations of motion are given in the general matrix form as follows:

$$[M]\{\ddot{u}\} + [C_u]\{\dot{u}\} = \sum \vec{F} \quad (10)$$

$$[\bar{I}]\{\ddot{\theta}\} + [C_\theta]\{\dot{\theta}\} = \sum \vec{M}_G \quad (11)$$

where $[M]$ is the mass-matrix, $[C_u]$ is the damping matrix for the displacements, $\{\dot{u}\}$ is the velocity vector, $\{\ddot{u}\}$ is the acceleration vector, $[\bar{I}]$ is the rotational inertia matrix calculated with respect to the center of gravity of the mandible, $[C_\theta]$ is the damping matrix for the rotations, $\{\dot{\theta}\}$ is the angular speed vector, and $\{\ddot{\theta}\}$ is the angular acceleration vector. The sum of the external forces ($\sum \vec{F}$) and the sum of the moments ($\sum \vec{M}_G$) with respect to the center of mass are calculated using the same relations given in equations 5 and 6 (55).

In Reference 52 the muscle forces are treated as known external forces. This restriction is removed in later studies. The forces on the TMJs and the teeth were calculated based on contact constraints. This aspect of the model makes it nonlinear. The condyle was approximated as a sphere, and the shape of the articular fossa and articular eminence were approximated by a third-order polynomial, based on the dimensions measured from a skull. The cartilage was modeled as a nonlinear spring. Damping of the jaw motion due to friction, which originates from surrounding soft tissues, was included in the model. The forces on the ligaments were neglected.

Using this model, Koolstra and van Eijden performed simulations of *jaw-closing* as a result of isotonic forces (10 N) generated by various pairs of masticatory muscles (52). This model demonstrated that the normally observed swing-slide condylar movement along the articular eminence can be generated by various masticatory muscles. However, different parts of the masseter and the medial pterygoid muscle seemed to be most suitable for this motion (52).

The mastication forces are controlled by the central nervous system, and they are modulated by the physical limitations of the sarcomeres, the force generating units of the muscles (53). The force generated by the sarcomeres depends on the length and contraction velocity of the sarcomeres. In addition, a passive elastic force is generated depending on the amount of stretching. These are determined empirically and expressed as the force-length (F_L), force-velocity (F_v), and stretching (F_p) factors (53). The magnitude of the instantaneous muscle force $F(t)$ can then be formulated as (54):

$$F(t) = F_{\text{max}}[A(t)F_L(t)F_v(t) + F_p(p)] \quad (12)$$

where $A(t)$ is the activation level of the muscle.

The jaw-opening and closing simulations were performed by Koolstra and van Eijens using equation 12 in their dynamic model (54). In this work, they included the jaw-opening muscles, in addition to the closing muscles. The activation level $A(t)$ was kept constant, and all muscles were activated simultaneously. It was found that the level of activation of the temporalis muscle parts was critical in jaw-closing movements. The amount of jaw opening was limited by the passive forces of the jaw-closing muscles. However, the amount of jaw closing was not significantly influenced by the passive forces of the jaw opening (54). The TMJ remained loaded throughout the jaw movements. They also concluded that the average moments generated by the jaw-closing muscles, with respect to the center of mass of the mandible, are responsible for stable operation of the TMJ (52,54).

The lateral deviation of the jaw from the closed position was also modeled by Koolstra and van Eijens (24). They found that laterodeviations that conform to the naturally observed ones could be generated by unilateral muscle contractions. Their analysis concluded that movements of the jaw predominantly depend on the orientation of the contributing muscles with respect to the center of mass, and not on the TMJ ligaments or passive elastic muscle properties (24).

Deformations of the Mandible

Forces applied to the mandible cause internal stress response within the mandible. Highest masticatory loads are experienced when the maxillary and mandibular teeth are in contact. During typical chewing, such high load contacts last on the order of 0.1 s for chewing strokes and longer for swallowing. At the end of the day, 15–30 min of high loads are experienced by the masticatory system. Persons with parafunctional habits, such as bruxism, may experience longer durations of high levels of loading (4).

The stress and strain distribution in the mandible change in response to the loss of teeth (30), mandibular reconstruction (56,57) TMJ reconstruction, presence of dental implants (58), or prosthesis (59); consequently, the mandible changes its geometry and material property distribution (30). Analysis of the internal stresses in the mandible has, therefore, a potential to aid treatment. The deformations and internal stresses of the masticatory system could be evaluated by modeling the mandible as a curved beam (60), using the photoelastic method (4) or by strain measurements. The nonuniformity of the cross-sectional area and that of the trabeculae of the mandibular bone, and the presence of the teeth, prevent the beam theory from being an accurate tool of analysis. On the other hand, the photoelastic method provides a good visualization of the internal stress distribution (4). But the trabecular architecture is generally not included in the photoelastic models. The strain measurements *in vivo* or *in vitro* can only be performed on the surface of the bone.

The finite element method offers a suitable alternative to model the geometric and material variations of the mandible. Detailed analysis using FEA comes at a high computational expense. However, combined with experimental strain measurements and the photoelastic method,

for verification purposes, the FEA can be a useful tool; and, it has been used to analyze the internal stress distribution in the mandible (30,61–63). The FEA of a partially edentulous mandible, by Hart et al., showed that the strain distribution in the mandible is extremely complex (30). This work showed that an asymmetrically edentulous mandible could experience different condylar reactions even in bilateral loading. The anterior portion of the ramus, the coronoid process, and the attachment locations of the muscles experience relatively high tensile stresses under various loading conditions. The condyle experiences relatively high compressive stresses. In general, these results were found to be in agreement with photoelastic stress analysis (4,30).

BIOMECHANICAL PROPERTIES OF TOOTH REPLACEMENT MODALITIES

The treatment objectives of prosthodontic services include maintaining and enhancing quality of life by providing the function, comfort, and aesthetics that is compromised or lost due to oral disease. Amount of damage to oral structures and properties of materials are two important factors that dictate treatment techniques. *Restoration* is a broad term applied to any material or prosthesis that restores or replaces lost tooth structure, teeth, or oral tissues (17). Patient desires and expectations aside, depending on the extent of damage or loss, treatment options may be classified as (1) intracoronal restorations, (2) extracoronal restorations, (3) fixed partial dentures, and (4) removable partial dentures. Each of these treatment modalities has several different choices that can be used by the clinician. In addition to these treatment options, dental implants offer an anchoring function for single tooth replacement or support for various denture scenarios.

To meet functional, biological, and esthetic requirements, a “fixed” restoration (filling, crown, bridge) must remain firmly attached to the tooth. In general, *retention form* indicates the feature of a tooth preparation that resists dislodgement of a crown in a vertical direction or along the path of placement, whereas *resistance form* is the feature to resist dislodgement in all other directions. Tooth preparation also involves removal of sufficient tooth material (reduction) so that the “replacement material” can have enough bulk for structural durability.

Intracoronal Restorations

Absence of tooth structure due to caries (decayed tissue), trauma, or developmental defects is the main indication for *intracoronal* restorations. Before placement of such a restoration, a damaged tooth is “prepared” by the dentist to a certain geometric form to remove all caries, to protect the remaining tooth structure, and to minimize the chances of dislodgement of the restorative material during function (i.e., eating and swallowing) and parafunction (i.e., tooth grinding and clenching).

Metal direct filling materials are gold foil and silver amalgam, which are supplied in many different compositions. *Esthetic direct filling* materials, composite resins, are BISGMA acrylic resins filled with inorganic materials.

The preparation of the teeth for metal direct filling restorations is different than for composite resins. Mechanical locks and undercuts provide retention and resistance to gold foil and amalgam restorations. Preparations are usually extended into the dentin layer to have at least 1–1.5 mm thickness of the material and to take advantage of the elasticity difference between dentin and enamel. Composite restorations, on the other hand, require less invasive preparations. Analyses of preparation designs for various clinical scenarios via photoelastic or finite element studies, as well as bench tests on extracted teeth, have been conducted to provide insight to the optimum preparation form for a specific material to protect the tooth from further damage. Strength (15), wear characteristics (64,65), and reaction to temperature changes are examples of important factors that have been investigated.

Inlays are alternatives to direct filling materials. Preparations for this type of restoration require occlusally diverging walls because these restorations are made indirect and require a path of insertion. Gold alloys, composite resins, or porcelain can be used as inlay materials. This type of restoration is indicated in non-stress-bearing, two-surface preparations (mesio-occlusal, disto-occlusal). Their use in stress-bearing, three-surface (mesio-occluso-distal) situations has been associated with a “wedging” effect, risking cusp fractures.

Increased tooth loss or extensive caries necessitates modification of preparations from ideal forms. At this point, the clinician has to either employ auxiliary retention methods for direct fillings via retentive pins or choose cuspal coverage with indirect restorations (onlay, crown).

Extracoronary Restorations

As the damage to a tooth gets more extensive, an extracoronary type restoration (crown and dowel) is indicated. Major factors that affect retention of a crown include, but are not limited to, the degree of taper of the walls of the prepared tooth, total surface area of the luting cement, area of the cement under shear forces, and roughness of the tooth surface. The resistance form of a crown includes consideration of length of the preparation, tooth width, and taper. Crowns can be made of gold alloys, porcelain, or a combination of both (porcelain fused to metal).

Very often an endodontically treated tooth has a very limited amount of coronal dentin. This is in part due to the required access opening to perform the root canal, and in part to previous tooth loss, i.e., existing fillings. In such situations, foundation restorations are indicated. Frequently, these restorations require utilization of *dowels* (posts). A dowel is fitted into a prepared root canal of a natural tooth. When combined with an artificial crown or core, it provides retention and resistance for the restoration. Many different geometric configurations (e.g., custom cast, prefabricated tapered, parallel sided, threaded), materials of different strength and fatigue characteristics, and corrosion resistance properties (gold alloy, stainless steel, titanium alloy, carbon, ceramic, fiber) have been manufactured for this purpose. The effects of post length and diameter on retention have been widely studied.

Fixed Partial Dentures (Bridges)

Fixed partial dentures (FPDs) can be used to replace missing teeth. Whether these FPDs are supported by natural teeth or dental implants presents different biomechanical issues. On natural teeth, variables such as pericemental support of the abutments (teeth that support the FPD), crown-to-root ratio, configuration of the roots (i.e., single vs. multiple and converging vs. diverging) are among the biomechanical factors to be considered. Available space could become an issue, as the span of the restoration, which is dictated by dimensions of the missing tooth/teeth, is inversely proportional to the strength of the restoration. Similarly, height of the abutment teeth influence height of the connector (part of the bridge where missing tooth replacement, pontic(s), connect(s) to the retainers) and its strength. Hence, material selection is very important. Difference in mobility of abutment teeth may affect seating of the restoration. Another clinical scenario involves the presence of an intermediate abutment when a natural tooth located between terminal abutments serves to support a fixed prosthesis. Under occlusal loads, this “pier” abutment acts as an undesired fulcrum, and the abutment with the least retention fails. To overcome this issue, segmental bridges have been used.

Horizontal components of bite forces are transmitted in part from posterior to anterior directions, because of proximal contact of teeth within the same arch. These forces are well tolerated by the bridge system. However, forces that create movement toward buccal or lingual side (cheek or tongue side) may be detrimental.

When implants are used to support and retain a fixed prosthesis, the difference in mobility of implants is less of a concern, because successful osseointegration is assumed and mobility is more likely related to deformation of bone. However, passive fit of the restoration is a difficult task to achieve due to limitations of materials and techniques. Misfit of restorations is reported to cause more maintenance problems, rather than jeopardizing osseointegration. Unlike natural teeth-supported FPDs, the dentist has the control over the number, size, and location of implant placement when an implant-supported FPD is planned (Fig. 9).

Removable Dentures

Removable dentures are used in complete and partial edentulism. Indications for removable partial dentures include, but are not limited to, situations where the edentulous span is very long, periodontal support is reduced, posterior abutments are absent, and tissue loss is excessive. Typically, a removable partial denture has a cast metal framework, which extends from one side of the dental arch to the other, regardless of the location of the missing teeth. This “cross arch stabilization” by the rigid framework helps reduce detrimental horizontal forces on the abutment teeth.

Components of a removable partial denture (RPD) framework include major connectors, rests, direct and indirect retainers, and minor connectors. One of the most important aspects of removable partial denture fabrication involves design of the framework to achieve retention,

Figure 9. Schematic representation of an osseointegrated, endosseous implant with the abutment and the restorative crown. (From “Single tooth implants,” by Misch CE, in *Implant Dentistry*, 2nd ed., Mosby, 1999).

support, stability, comfort, function, and aesthetics. Removable partial dentures are subject to a combination of forces arising from three different fulcrums on horizontal, sagittal, and vertical planes. As described for other treatment modalities, planning is aimed at directing forces along the long axes of the teeth as much as possible. Factors that influence the amount of stress transmitted to abutment teeth include length of the edentulous span, quality of the ridge support, clasp design flexibility and material, and occlusal harmony.

Tooth loss in an arch varies significantly in number and location; therefore, removable partial dentures are often designed based on available support (tooth supported, or tooth–tissue supported). When the tooth loss pattern allows a tooth-supported RPD, design issues are less complex. However, posterior “free end” scenarios present specific problems because the denture will be supported both by teeth and tissues. Under function, healthy teeth may be displaced as much as 0.2 mm, whereas tissue may be displaced 1.0 mm or more. Thus, prevention of moments on the terminal abutment teeth (teeth that are next to the edentulous space) has been a major concern for tooth–tissue-supported prosthesis. To minimize moments, various clasp assembly designs, resilient precision attachments, and “stress breaking” mechanisms have been proposed.

Recently dental implants have been used to assist RPDs in retention and support.

Complete dentures are indicated in total edentulism. For patients that cannot adapt to complete dentures, use of dental implants is indicated. Retentive mechanisms for implant-assisted dentures vary from individual attachments to bar systems, joining multiple implants. There are many variations to individual attachments as well as to

bar systems. These result in different levels of retention, support and freedom, and lack of movement in a specific plane.

Dental Implants

A dental implant is a prosthetic device of alloplastic material implanted into the oral tissues beneath the mucosa and periosteal tissues and into the jaw bone to support a fixed or removable prosthesis. A dental implant system serves as the anchor for the prosthetic reconstruction of missing teeth by supporting a fixed or removable prosthesis. The system mainly consists of an implant and an abutment. A *prosthetic attachment* is typically fixed on the *abutment* by one of the following methods: cementation, use of an occlusal screw, or a socket arrangement that allows retention of a removable prosthesis.

The *implant* is the component implanted into the bone tissue and serves the function of the root. Upon surgical placement of the implant, a healing period of 2–6 months is allowed during which osseointegration takes place. *From the patient's point of view*, “a fixture is considered osseointegrated if it provides a stable and apparently immobile support of a prosthesis under functional loads, without pain, inflammation or loosening” (66). During osseointegration, new bone forms in contact with the implant and a direct structural and functional connection is established, without initiating an immune response (rejection). Mineralized tissue is found to be in contact with the implant surface over most of the surface within nanometers (66). Relative movement (micromotion) between the implant and the bone at the time of placement is more likely to favor development of a fibroosseous interface (28). The presence of the implant modifies the mechanical environment in its surrounding, by altering the normal physiology, distribution of the fluids, and force transmission (28). Nevertheless, dental implants have high long-term success rates (67,68) due to careful bioengineering of the choice of materials (69), surface topography and coatings, overall size and shape of the implant body, and thread shape.

The *abutment* is the component that supports and/or retains the prosthesis (70). The abutment is secured to the implant with a mechanical attachment method, and ideally, it should stay fixed with respect to the implant throughout the life of the implant. Currently, three methods are used to attach an abutment onto an implant. In the most common mechanical attachment method, an abutment retaining-screw is used to fix the abutment with respect to the implant (70). The mechanics of this type of screw attachment are analyzed by classic methods (71) and the FEA (72). Another approach is to use a screw with a relatively large tapered end (73). Finally, in some implant systems, a tapered interference fit between the abutment and the implant is also used to provide the connection (74,75).

From a bioengineering perspective, an important issue is to design the implant with a geometry that will minimize the peak bone stress caused by standard loading (76). The complex geometry of the implants prevents the use of closed-form solutions in stress analysis, where simple formulas relate the effect of external loads to internal stresses

and deformation. The FE method has been applied to the dental implant field to predict stress distribution patterns in the implant–bone interface not only by comparison of various root-form implant designs (76–80), but also by modeling various clinical scenarios (1,58,81,82) and prosthesis designs (32,83–85). This method offers the advantage of solving complex structural problems by dividing them into smaller and simpler interrelated sections by using mathematical techniques (41).

FEAs, which investigate the relation between implant design and stress distribution, have addressed the overall shape and size of the implant body, implant neck geometry, and thread geometry for threaded implants. Rieger et al. showed that a tapered design made of a material with high elastic modulus would be most suitable to serve as a free-standing implant (78). Holmgren et al. suggested considering application of oblique load to FEAs, indicating that these were more realistic occlusion directions capable of causing the highest localized stress in the cortical bone (77). These authors found the stepped implant design to exhibit a more even stress pattern than a straight cylindrical design.

Threaded implants exhibit geometric variations in terms of thread pitch, shape, and depth. Threads are used to increase the surface area of the implant (86). Use of different thread configurations for different bone qualities has been proposed as thread geometry may play an important role in the type of force transmitted (70,87–89). Chun et al. showed that the maximum stress in compact bone is higher for the plateau design compared with the triangular or square designs and their variations. According to these authors, screw pitch had a significant impact on the stress distribution (90).

The transosteal region of the implant body has been defined as the “crest module” (86). For most systems, this neck portion of the implant is smooth. Different designs include parallel, converging, and diverging sides. One particular implant investigated by Hansson using the FE method included both taper and retention elements up to the crest of the implant and was found to have much lower interfacial shear stresses compared with a smooth neck design (76).

TRACER KINETICS

EDWARD V. R. DI BELLA
University of Utah
Salt Lake City, Utah

INTRODUCTION

Tracer kinetics refers to the changing distribution of a tracer that provides information regarding a biological system. The tracer may be introduced by injection into the bloodstream, or inhaled, or in some cases be native. By definition, the tracer is present in relatively small (trace) amounts so that it has little or no effect on the system being studied.

A large variety of tracers, along with methods for their measurement, are employed daily in numerous medical applications. Imaging function with tracers can provide complementary or more relevant information than anatomical imaging. For example, positron emission tomography (PET) and single photon emission computed tomography (SPECT) imaging can track radiolabeled tracers to detect and stage cancer, to assess neural function, to follow response to therapy, and to detect heart disease. Magnetic resonance imaging (MRI) with paramagnetic contrast acting as a tracer is a rapidly growing area, as is ultrasound with tracer-like microbubbles. Over 1 million patients are imaged annually in the United States for oncology applications. Over 7 million/year have a cardiac SPECT scan, mostly for the diagnosis of coronary artery disease.

How do these tracers work? Two brief examples will help to illustrate the process. The first example is of tracer applications that are suitable for analysis at equilibrium. That is, the kinetics portion of Tracer Kinetics is not used directly, but rather serves only to bring the tracer to some equilibrium state. The second example is of a radiolabeled glucose analogue, which is most often analyzed as if it were at equilibrium, but offers more information when its changing distribution over time is considered as well. This will provide a feel for the field of tracer kinetics and for the controversy sometimes surrounding the use of tracer kinetics with quantitative modeling methods, compared to visualization of static images of tracer distribution.

“Static” Tracers

By far, the bulk of clinical radionuclide studies use static images acquired while the tracer distribution is changing slowly or is fixed. Microsphere-type tracers are the simplest case of this type of tracer. These tracers provide a static distribution after their first pass and may be, for example, ^{99m}Tc-labeled albumin, or in studies with animals that will be sacrificed, 10–15 μm diameter carbonized microspheres tagged with radioactive or fluorescent labels. Such tracers lodge in capillaries in proportion to flow. The microspheres must be infused into the left atrium or left ventricle or will all be trapped in the lungs. Absolute flow values in milliliters per minute per gram (mL/min/g) can be computed using these tracers. However, the amount of tracer in the region of interest must be known. For animal studies with microspheres, this is done by excising the

regions of interest after sacrifice. The small tissue regions are counted in a type of well counter if radiolabeled microspheres were used, or digested and read in a fluorimeter if fluorescent microspheres were used.

Absolute flow calculation with microspheres also requires knowledge of the flow to a “virtual” organ. This virtual organ can be at the aortic valve at the output of the left ventricle, in which case it is known that the full amount of tracer enters the virtual organ at a flow rate equal to the cardiac output. Thus if cardiac output is known and the number of microspheres is known, then flow to any region of interest can be computed as cardiac output x (number of microspheres in region)/(number of microspheres injected). The units will be milliliters per minute (mL/min), which can be made into mL/min/g after dividing by the weight of the region of interest.

The virtual organ could instead, for example, be in the femoral artery if a catheter was inserted into the artery and a blood sample withdrawn at a known flow rate during the first pass of the microsphere injection. This knowledge of number of microspheres in the virtual organ given a known flow rate allows computation of the flow rates in other regions.

Other tracers that lodge in position in proportion to flow can provide relative flow measures though it is difficult to provide absolute flow measures. One example of a widely used study is ^{99m}Tc -sestamibi SPECT. Sestamibi is injected after exercise or pharmacological vasodilation, and rapidly equilibrates with deposition in proportion to flow. The distribution then changes very slowly, as it is “stuck” in the myocardium. The timing of the SPECT scan is then not critical. The half-life of radioactive decay of ^{99m}Tc is ~ 6 h, so decay is not a central issue in the imaging. These myocardial perfusion SPECT scans are done at exercise or with a vasodilator in order to be sensitive to stenosed coronary vessels. An excellent reference for the use of tracers in Nuclear Cardiology, including a chapter on tracer kinetics, is found in Ref. 1.

Dynamic Tracers

In general, a thorough understanding of the kinetics of the particular tracer of interest leads to the best method for processing the measurements of the tracer. Consider fluoro-deoxyglucose (^{18}F FDG); ^{18}F FDG is a positron emitting tracer of glucose. However, ^{18}F FDG is trapped at a certain stage in the glycolysis cycle (Fig. 1). As with glucose, hexokinase catalyzes its conversion from ^{18}F FDG to phosphorylated ^{18}F FDG, ^{18}F FDG-6- PO_4 . However, ^{18}F FDG-6- PO_4 does not continue along the glycolysis pathway as does glucose-6- PO_4 , and very little of it leaks back into the interstitial space and vasculature. The changes in ^{18}F FDG concentration over time in an area can be represented with a physiological three compartment model as seen in Fig. 1. Compartment models are defined in detail in the next section. The use of dynamic (time series) images of ^{18}F FDG acquired with PET requires the application of tracer kinetic principles to provide semiquantitative or quantitative absolute measurements of regional metabolic rate of glucose usage. A mathematical model that can predict or fit the PET data and provides estimates of

Figure 1. Three-compartment model. For FDG, k_1 represents uptake into a free compartment outside the vasculature. The parameter k_2 is the washout of free FDG back into the vasculature; k_3 represents the rate constant of phosphorylation of FDG to FDG-6- PO_4 ; and k_4 represents the rate constant of dephosphorylation and is relatively small. Note the concentration measured in the tissue, $C_t(t)$ in the text, is $C_t(t) = C_2(t) + C_3(t)$ (illustrated by the largest box).

meaningful physiological parameters is needed. Such models require the arterial input function (AIF), which is the time–activity function the tissue of interest sees as supplying itself.

Yet, in typical clinical ^{18}F FDG PET scans, one tomographic volume image is acquired over ~ 5 – 30 min, at a time point when the distribution of FDG is changing only slowly. Thus the dynamic data is not used. The images are simply analyzed visually by an experienced reader. Thus at least to date, the complexities of acquiring the data dynamically and measuring an accurate input function and performing the required processing seemingly outweigh the gain of having a quantitative measure of the metabolic rate of glucose usage. This is not the case with some other dynamic tracers such as radiolabeled water, where visual analysis is not useful and kinetic analysis is nearly essential.

Nomenclature

The study of tracer kinetics began prior to 1950, and, due to its myriad applications in a breadth of fields, has had a number of different terms used to describe the same things. Some unified nomenclature was proposed for use with tracer kinetics for biomedical research in 1990 (2). The paper includes a 170 term glossary, but has not prevented the field from having a rich array of discrepant notation and terminology.

Tracer kinetics have been rapidly growing in use with MRI applications. Sufficient research has been published using dynamic contrast enhanced (DCE) MRI with confusing terminology to motivate a paper by MRI researchers regarding terminology for the popular two compartment Kety–Schmidt model. The paper proposes using K^{trans} and k_{ep} for the washin and washout rate constants in the two compartment model (see Fig. 2 and the section on two compartment models below).

Pharmacokinetics is a large related field of study that uses tracer kinetic techniques, sometimes with different nomenclature. The pharmacokinetics field generally seeks to understand drug and biochemical delivery patterns. Drugs of interest may be radiolabeled or tagged with fluorescent or other substances so that they can be tracked and their spatiotemporal behavior identified.

Figure 2. A compartment model type view of a section of capillary (lower two segments) and a section of tissue. The arrows represent the exchange that would occur with an extracellular tracer such as gadolinium. Water would distribute throughout all four regions shown.

COMPARTMENT MODELING

By kinetic modeling we refer to using any of a number of quantitative approaches to extracting information from a time series of data. All of these approaches invoke some sort of mathematical model in order to parameterize the data. The idea is that the parameters can provide more information than processing without models or simple visual examination of the data can provide.

Depending on the type of tracer or contrast agent used, and on the fidelity and resolution of the signal, appropriate models can be selected. That is, the models should not include detail that cannot be discriminated by the measured data, even if it is known to exist physiologically. In practice, almost all models will be required to be simplified versions. The models also need to have useful parameters for the task at hand. Compartment models are widely used for a number of applications due to their relative simplicity and physiological relevance.

A compartment refers to a well-mixed volume in a system of interest that can be considered to have a homogeneous concentration of the tracer. A widely used compartment model of interest is the two compartment model (Fig. 2). This case is often an extremely useful approximation to the system of interest. For example, one compartment is considered to be the vasculature, and one compartment is the tissue of interest. The washin and washout rate constants k_1 and k_2 (or K^{trans} and k_{ep}) govern the concentration in the tissue compartment. The driving compartment, the arterial input function, is usually considered to be measured or otherwise known. For this reason, some authors call this a one compartment model.

Note that a compartment model is often used even in the analysis of multiple heterogeneous regions. Typically, it is assumed that all are driven by the same input function. That is, the blood “compartment” is the same for all of the regions, but the tissue kinetic parameters of uptake and washout of each region may vary. The model remains the same, but the parameters are different for each region.

Kety Model

The roots of compartment modeling approaches are found in Kety’s seminal work in the 1940s (3,4). Kety and

Schmidt were the first to successfully determine the cerebral blood flow (CBF) and oxygen consumption in a relatively noninvasive way. They had normal volunteers breathe air with a ~5–10% concentration of nitrous oxide. The nitrous oxide that was used as a tracer is an inert gas that is soluble in the brain tissue. They then applied the Fick principle to determine CBF. The Fick principle is simply mass balance for convective systems. Use of the Fick principle gives

$$Q_b(t) = CBF \int_0^t C_a(\tau) - C_v(\tau) d\tau \quad (1)$$

where Q_b is the mass quantity of tracer per 100 g in the brain, CBF is the flow of the tracer (and of the blood) in mL/(min·100 g), C_a is the concentration of the tracer in g/mL, and C_v is the concentration of the tracer in the venous blood. Alternatively, for experiments with radiolabeled tracers, Q could instead be in terms of activity in Bequerels and concentration in terms of activity/milliliters.

Rearranging and evaluating at a time $t \sim 15$ min when the system is at equilibrium gives the equation Kety used for global CBF:

$$CBF = \frac{Q_b}{\int_0^t C_a(\tau) - C_v(\tau) d\tau} = \frac{\lambda C_v(t)}{\int_0^t C_a(\tau) - C_v(\tau) d\tau} \quad (2)$$

Here the venous concentration times λ , which is the solubility constant or partition coefficient for nitrous oxide, is used as a measure of the amount of tracer in the brain at equilibrium. The partition coefficient refers to the concentration of the tracer in the tissue divided by the concentration in the blood at equilibrium (at equilibrium arterial and venous blood ideally have the same concentration). Another way to consider the partition coefficient is as a virtual volume, relative to the volume the tracer distributes in a unit of blood. Thus λ is also called the distribution volume. For water, $\lambda = 1$. For nitrous oxide $\lambda = 0.48$ mL/mL. The parameter λ is also sometimes given in units of g/g or mL/g when the density of blood is ~1.06 g/mL or the specific gravity of gray or white matter ~1.05 are used.

For an extracellular tracer such as gadolinium-diethylenetriamine penta-acetic acid (DTPA), $\lambda \sim 0.3$. Figure 2 shows a graphic interpretation of the distribution volume for gadolinium.

In practice, venous measurements of nitrous oxide concentration are taken from an internal jugular vein, and arterial concentrations from a peripheral arterial line. This gives an accurate measure of whole brain CBF, ~50 mL/(min·100 g) in normal humans.

PET H₂¹⁵O Compartment Model

Interestingly, at first glance Kety’s use of the Fick principle does not appear to link to most of today’s compartment models. The approach today is often to write a system of differential equations to describe the behavior of the tracer, and then solve the equations to get a form such as:

$$C_t(t) = C_a(t) \otimes k_1 e^{-k_2 t} \quad (3)$$

where \otimes denotes convolution, and the arterial input function $C_a(t)$ convolved with one or more exponential terms is

fit to the measured image data $C_t(t)$. Though the Kety form has no derivatives or convolutions, Kety's Eq. 2 can be rearranged in a similar form. This rearrangement is illustrated by describing the use of a two compartment model for PET $H_2^{15}O$. Water rapidly diffuses across capillary and cellular membranes, so one can postulate based on Fig. 2 that the rate of change of concentration in the tissue compartment is equal to the input to the compartment (the rate constant k_1 times the arterial concentration) minus the output from the compartment (C_t times the rate constant k_2).

$$\frac{dC_t}{dt} = k_1 C_a - k_2 C_t \quad (4)$$

For the tracer water, $k_2 = k_1$ since the capillary membrane appears symmetrical to this tracer and the distribution volume is 1. Solving this first-order differential equation gives Eq. 3. Note that integrating both sides of Eq. 4 gives the form seen in Kety's Eqs. 1 and 2.

The model can be made more general for tracers that are not freely diffusible everywhere (as water is) by including the partition coefficient. That is, for the more general case of diffusible tracers, $k_1 = F$ and $k_2 = F/\lambda$. This formulation allows estimation of both flow to the region of interest (perfusion) and the volume of distribution of the tracer. Both of these measures can be useful clinically.

Tracer Kinetics of Gadolinium Measured with MRI

Less straightforward tracers, such as the paramagnetic moiety Gd-DTPA used in dynamic contrast MRI, can also be approximated with the two compartment model. Gadolinium diffuses out of the vasculature into the interstitial space, but does not enter cells. Thus the distribution volume reflects the size of the interstitial space. This lack of distribution into cells also creates complications when water exchange is considered. That is, Gd-DTPA is not detected directly with MRI as is the case with radionuclide detection. It is detected by how it changes the relaxation rates of hydrogen in its local microenvironment by interaction of its electrons and the hydrogen protons in blood or tissue (5). So, if water (hydrogen) is moving between where the Gd-DTPA is in the interstitial space and the intracellular space free of gadolinium, it experiences different microenvironments and thus different relaxation rates. Assuming the rate of exchange of water molecules across the cell membrane is rapid, one can neglect this effect on the image signal intensity. Otherwise, more complicated modeling including the water exchange is needed.

Another interesting example of tracer kinetics is the use of gadolinium contrast enhanced MRI for determining if an area of cardiac muscle is dead or alive. A static scan ~15 min after contrast injection can show that gadolinium is present at a higher concentration in infarcted tissue compared to normal tissue. This delayed enhancement is most easily understood through a tracer kinetics approach. Figure 3 shows the time curves from a normal and abnormal region and one can see the abnormal region washes in more slowly, but the washout is a slower process. Another way of interpreting this is the distribution volume is larger. This corresponds intuitively to the agent having more

Figure 3. (a) Time curves from measured uptake in region corresponding to arrow in the middle image, distribution volume $v_e = 0.58$ mL/g. The blood input is from a region of interest drawn on the left ventricle cavity. The fit is from a two compartment model for gadolinium-DTPA. (b) “Delayed” image of a short axis slice of the heart (right ventricle on left, left ventricle the large doughnut structure with its endocardial wall traced in green) from MRI acquired ~15 min after contrast injection, showing subendocardial inferior infarct (arrow). (c) Curve from a remote normal region, $v_e = 0.37$. The magnitude and spatial distribution of v_e may help characterize the infarct better than delayed enhancement alone.

volume to distribute in within regions where cell membranes have been destroyed, since gadolinium is an extracellular tracer.

The volume/g of tissue that is occupied by cells in the heart muscle is estimated as ~70%. The interstitial space, or distribution volume for Gd-DTPA, has been reported as $v_e \sim 0.3$ mL/g in healthy tissue, where v_e stands for volume of extracellular extravascular space and is used in place of the symbol λ . This distribution volume increases if cell membranes are disrupted as in acute myocardial infarction (heart attack). Scar tissue, composed of a collagen matrix, will still accumulate gadolinium if it is still perfused. This is likely because the collagen matrix has more interstitial space, but is still not completely understood (6).

Another issue for most tracers is that tissue regions of interest contain on the order of 10% of their volume as vasculature. Thus the time curve $C_t(t)$ is biased by a contribution from something similar to $C_a(t)$. [Due to hematocrit changes in smaller vessels and delay and dispersion, it may not be exactly $C_a(t)$.] One method of accounting for this is to include another parameter in the fit to estimate the blood volume in the region of interest:

$$C_t(t) = C_a(t) \otimes k_1 e^{-k_2 t} + v_b C_a(t) \quad (5)$$

The v_b parameter can also be used to model blood signal in tissue that arises from partial volume effects. Figure 4 illustrates the use of v_b to account for blood spillover into the tissue in a dynamic cardiac MRI study.

Intravascular tracers that do not leave the vasculature may be used to obtain measures of blood volume and to

Figure 4. Short axis dynamic cardiac MRI time series study. (a) MRI image precontrast. Epicardial (light blue) and endocardial (orange) regions that give the tissue curves in (b) and (c) are marked. Parts (b) and (c) use the same blood input function and should have similar flows as implied by the K^{trans} ($K^{\text{trans}} = k_1$) values given. The point here is that due to partial volume effects, typical upslope or percent enhancement semiquantitative measures would incorrectly give very different flow indices for the two regions. The model used Eq. 5 to obtain blood volume v_b values to compensate for partial volume effects.

measure flow and can be analyzed as

$$C_t(t) = C_a(t) \otimes h(t) \quad (6)$$

where in this case $h(t)$ is not parameterized and the peak value of $h(t)$ can be shown to reflect flow (7).

Impulse Response

The response of a system to the input of an impulse, or a delta function $\delta()$, completely characterizes the system if it is a linear time-invariant system. Equation 3 shows that the impulse response for a two compartment model with rate constants k_1 and k_2 is $k_1 * \exp(-k_2 t)$.

While many physiological systems are not linear time invariant, linear time-invariant systems often serve as a good approximation. Examples of nonlinear systems include enzyme kinetics, saturable receptors, or any process that saturates (as the input continues to double the output does not). Too much of any tracer may force a system to nonlinearity, or at least to some abnormal physiological state. For example, at some point there could be so much FDG in the blood stream that doubling the amount only changes the uptake in the tissue by a small amount. More complicated nonlinear and time-varying models are needed for processes such as insulin kinetics (8).

Three or More Compartments

More complex systems, for example, when a tracer diffuses out of the vasculature and may either diffuse back, or

remain freely available in the interstitial space, or undergoes a chemical trapping such as phosphorylation, requires a more complex model. The two compartment model may not be sufficient since the tissue now has two different pools of nonuniform concentrations. Note that these pools generally are not measured separately (Fig. 1). The two compartment model can still be used as an approximation, but a three-compartment model (Fig. 1) is likely more appropriate. A more complex model with four compartments has also been proposed for the case of FDG uptake in skeletal muscle (9).

Order of Model

How does one determine if the lower order model or the higher order model is best to use? This is certainly very task dependent, and is an open question. One approach is the Akaike Information Criteria, or AIC (10). This measure is based on the intuitive notion that as the number of parameters increases, the fit to the data should improve in proportion ($\text{AIC} = \text{residual sum of squares} + 2 * P$, where P is the number of parameters being fit).

If the tracer kinetics are not well understood and the order of model to use is unclear, more exploratory methods such as spectral analysis are appropriate. Spectral analysis models the impulse response as a summation of a number of exponentials (11). That is, spectral analysis is a type of generalized compartment model where the impulse response is a linear combination of N decaying exponentials: $h(t) = \sum_{i=1}^N \alpha_i \exp(-\beta_i t)$. For example, if the data truly is from a two compartment model, then only one of the exponential terms will have a nonzero coefficient. The drawback, or advantage, depending on one's viewpoint for a particular problem, is that the coefficients are fixed so that the problem becomes linear as only β 's need be estimated. The selection of the spectrum of exponential decay rates can thus be quite important. A logarithmic distribution of β has been used in PET (11).

Even if the model is well-known, spectral analysis may be a desirable approach since the linearized fitting can be more rapid than standard nonlinear compartment modeling. Several published studies in PET and SPECT have found high correlations between compartment modeling and spectral analysis methods. Such studies are reviewed in Ref. 12.

A higher level of realism can be obtained by using a distributed model of multiple parallel pathways of capillaries feeding the tissue region of interest. XSIM is freely available software useful for modeling such distributed systems where blood-tissue exchange units form basic building blocks that can have differing delays or flows or permeability (13). Most often the measurement system, particularly medical imaging, does not have the spatial and temporal resolution and is too noisy to robustly use such a complex model. Such models are, however, of great importance in understanding the underlying physiology (8,13).

Model-Free Methods

It is not required to use a specific model. Some "model-free" methods are easier to use or have the advantage of making fewer assumptions regarding the tracer distributions. The

downside is that the parameters may not offer as much insight into physiological mechanisms underlying the imaging results.

The mean transit time is a measure of how long the tracer requires to pass through the capillary bed from the arterial to the venous side. One can consider the impulse response as a histogram of transit times through the region. The expected value of the impulse response provides the mean transit time if there is no recirculation [$\tau = \int th(t)dt$]. Or, for a short bolus, the area divided by the height at time zero of the tissue uptake time curve gives τ .

$$\tau = \int_0^{\infty} C_t(t)dt/C_t(0)$$

The mean transit time is on the order of 5 s for nondiffusible intravascular tracers in the brain, and on the order of minutes for diffusible tracers (14). Or one can define the mean transit time as the inverse of the washin rate constant, $1/k_1$ (14).

Other easily computable parameters such as maximum upslope, percent signal enhancement, area under the curve, or the time until peak signal have been suggested and used as model-free approaches.

ESTIMATING KINETIC PARAMETERS

Weighted Least Squares

The estimation of kinetic parameters from noisy data is a well-studied problem. The errors in the parameters can be estimated based on the variance in the data. The model can be written as:

$$C_t(t) = h(t) \otimes C_a(t) + \varepsilon \quad (7)$$

where ε is an additive noise process. The impulse response can be cast in a toeplitz matrix H and the equations expressed

$$\mathbf{y} = H\mathbf{b} + \varepsilon \quad (8)$$

where $\mathbf{y} = C_t(t)$, possibly for multiple regions, and $\mathbf{b} = C_a(t)$, and the unknowns are the parameters \mathbf{p} that form H . The weighted least-squares fitting process minimizes $\mathbf{y} - H\mathbf{b}$, weighted by the data covariance matrix $\Phi = \text{cov}(\mathbf{y})$:

$$\min_{\mathbf{p}} (\mathbf{y} - H\mathbf{b})^T \Phi^{-1} (\mathbf{y} - H\mathbf{b}) \quad (9)$$

If the measured data \mathbf{y} have uniform Gaussian noise then Φ^{-1} will be a diagonal matrix with on the diagonal and will not be any different from an unweighted fit. Technically, Φ should be the covariance matrix of the residuals $\mathbf{y} - H\mathbf{b}$, since \mathbf{b} is typically a measured quantity with noise. Huesman and Mazoyer compared the results with the use of $\text{cov}(\mathbf{y})$ and $\text{cov}(\mathbf{y} - H\mathbf{b})$ as the weighting function in the fitting of dynamic PET data with a noisy arterial input function (15).

One can consider the system of equations (Eq. 8) in the more "standard" form of $\mathbf{y} = A\mathbf{p}$, where \mathbf{p} are the unknown parameters. If we assume the model is linear in the para-

eters (i.e., $d\mathbf{y}/d\mathbf{p} = A$) then the best linear unbiased estimate, the estimate with minimum variance (16), is given by

$$\mathbf{p} = (A^T \Phi^{-1} A)^{-1} A^T \Phi^{-1} \mathbf{y} \quad (10)$$

This gives the parameters that minimize the $\text{cov}(\mathbf{p})$ matrix $E[(\mathbf{p} - \hat{\mathbf{p}})(\mathbf{p} - \hat{\mathbf{p}})^T]$. The point is that given this form, one can show that the resulting cov matrix of the parameter estimates is the Fisher information matrix

$$\text{cov}(\mathbf{p}) = (A^T \Phi^{-1} A) \quad (11)$$

where A are the partial derivatives with respect to the parameters of the model, also called the sensitivity matrix.

More commonly, and for the case of a compartment model, the matrix A will be a function of the parameters. So the model will be nonlinear in the parameters. Equation 11 still holds if A is evaluated at the true parameters \mathbf{p} , and the measured data are Gaussian (17).

The $\text{cov}(\mathbf{p})$ is the combination of the sensitivity matrix A and the data covariance matrix Φ . In addition to providing a way to estimate the error in the fitted parameters, one can also compare data acquisition strategies in this manner. Mazoyer and Huesman compared input function shapes and temporal sampling strategies by comparing the determinants of their information matrices (17).

Note that Eq. 8 need not only represent a single measured region. The measured curves \mathbf{y} and impulse responses can be stacked to form a larger system of equations using the same AIF \mathbf{b} and different parameters for each region. (see, e.g., Ref. 18).

Bayesian Approaches

Two quite different Bayesian approaches have been published. One class of methods combines tomographic reconstruction with compartment models (19,20). The method in (19) assumes the AIF is known a priori and then encourages the reconstructed time courses of each voxel to fit a two compartment model. The reconstruction is performed simultaneously to satisfy the tomographic reconstruction criteria that the projections of the estimated image match the measured projections. The method was applied to dynamic teboroxime SPECT data and resulted in improved washin estimates.

Another type of Bayesian approach is to use multiple (normal) regions to estimate the kinetic parameters using a two step process (21). The first iteration calculates the parameters for the regions independently. These are then averaged and their covariance matrix computed and used in the second step in a penalized least squares, or Bayesian, formulation:

$$\min_{\mathbf{p}} (\mathbf{y} - H\mathbf{b})^T \Phi^{-1} (\mathbf{y} - H\mathbf{b}) + (\mathbf{p} - \mu)^T \Omega^{-1} (\mathbf{p} - \mu) \quad (12)$$

where \mathbf{p} are the parameters to be estimated, μ is the average of the parameters estimated in the standard fashion, and

$$\Omega = 1/M \sum_{m=1}^M (\mathbf{p}^m - \mu)(\mathbf{p}^m - \mu) + 1/M \sum_{m=1}^M (A^m \Phi^{m-1} A^{mT})^{-1} \quad (13)$$

That is, Ω is the standard deviation of the parameters estimated in the first step and the estimated uncertainty

of the parameter estimates. The parameter M is the number of regions (assumed homogeneous) and m is used to index the M regions. This approach is equivalent to a specific case of ridge regression (22). These Bayesian methods represent a new class of analysis techniques for tracer kinetics.

IMPROVING AND AUTOMATING ANALYSIS OF THE KINETIC TRACER CURVES

While some applications have sufficient signal-to-noise ratio (SNR) to perform pixelwise analysis of the kinetic tracer curves, other applications can benefit greatly from spatial averages of the data. Methods such as factor analysis and clustering can be useful for automatically identifying blood and tissue curves from the image series data (23). This approach may give better kinetic parameter estimates and be more automated than manual delineation of regions.

Factor Analysis

Factor analysis, also termed FADS, which stands for Factor Analysis of Dynamic Structures, has been somewhat widely used in nuclear medicine applications (24–27). The FADS is essentially principal components analysis followed by a “rotation” to satisfy nonnegativity conditions. While this does not provide a unique solution, several different FADS methods have been validated as clinically useful for certain tasks. As well, a number of modifications to the basic method to incorporate additional information have been proposed, for example, (27).

Clustering

Clustering is becoming a popular method for a data-driven approach to choosing the regions. K-means clustering, also termed c-means clustering, groups alike time–activity curves (or time-concentration curves) by computing a distance between each pair of curves and grouping curves into the cluster that they are closest to. The cluster centers are updated (continuously or at discrete intervals). Most often a Euclidean distance is used to determine to which cluster a voxel belongs.

It is still an open issue to make factor analysis, clustering, and automated approaches robust and clinically practical. Quantitative imaging finds particular importance for longitudinal studies. These studies also need robust registration and processing methods to perform well.

Since a number of the analysis methods are nonlinear, it is typically left to empirical task-specific studies to determine if specific image processing methods can significantly impact the accuracy or robustness of the results.

ISSUES WITH THE ARTERIAL INPUT FUNCTION, AIF

Importance of an Accurate AIF

In order to obtain accurate absolute measures of kinetic parameters, it is important to use an accurate arterial input function. This is critical for any of the models or model-free approaches that use the AIF. Accurate input

functions, or at least some measure of what the tissue “sees” is essential for obtaining quantitative parameters and is intrinsic to model-based methods. Many “model-free” methods also rely on measures of input and output to obtain the mean transit time from the images. As other issues key to acquiring good quality dynamic data (scanners, computer speed, and memory) are surmounted, more effort is being focused on estimating the AIF more accurately and automatically.

In many situations, it is difficult to obtain an accurate AIF. If the tracer of interest binds to red blood cells or plasma proteins, then the AIF obtained from the images does not reflect the concentration of the tracer that is available for uptake by the tissues. Or the contrast agent in MRI may be saturated and not provide a true measure of gadolinium concentration when the concentration is high, or there may be flow effects that change the MRI signal. Arterial blood samples and subsequent processing are required to obtain accurate AIFs in these settings.

Methods for Improving the AIF Measurement

A number of techniques for improving the AIF have been proposed. For example, in contrast MRI studies of the brain, either a cluster or a single voxel that meets certain criteria can be automatically obtained and used as the AIF. In MRI cardiac studies, either a small bolus given before the main bolus to give the shape of the AIF curve without saturation, or a pulse sequence modification to obtain a nonsaturated AIF are current methods to improve AIF estimation.

Blind Deconvolution—Methods for Estimating an Unmeasured AIF

There have recently been efforts to estimate the arterial input function jointly with the parameters of interest. That is, given the measured data y , estimate both H and b in the equation:

$$y = Hb + \epsilon \tag{14}$$

In the field of telecommunications, this is termed blind estimation or blind deconvolution, since the input is not known (28). While this is not possible given a single region of interest, multiple regions with differing kinetic parameters, driven by the same input, can provide a system of equations with sufficient measurements to estimate the AIF within a global scale factor. Then, Eq. 14 is composed of a number of stacked matrices (18). Another way to see this is to consider two regions without using the matrix formulation:

$$\begin{aligned} y_1(t) &= b(t) \otimes h_1(t) \\ y_2(t) &= b(t) \otimes h_2(t) \end{aligned} \tag{15}$$

Then convolving both sides of Eq. 16 with $h_2(t)$ and substituting from Eq. 12 gives the “cross-relation” expression (29):

$$\begin{aligned} h_2(t) \otimes y_1(t) &= h_2(t) \otimes b(t) \otimes h_1(t) \\ y_1(t) \otimes h_2(t) &= y_2(t) \otimes h_1(t) \end{aligned}$$

This last expression can be solved for \mathbf{p} (recall h is a function of \mathbf{p}) with no knowledge of the AIF! The solution is unique with a two compartment model and the use of two different regions, to within a global scale factor (18). A three-compartment model requires more than two regions (or the use of other constraints) to obtain a unique solution (30).

The blind deconvolution method is sensitive to noise (18). Future hybrid approaches incorporating some measurements and other a priori information such as population expectations with the blind deconvolution technique will likely result in less sensitivity to noise and artifact.

FUTURE ISSUES

The last few topics—the Bayesian fitting approaches, factor analysis, clustering, and blind deconvolution represent cutting-edge directions for analysis of tracer kinetics data. These techniques need more research and validation before being widely used in clinical applications.

More and more dynamic studies of tracer kinetics will be performed as the equipment (in particular computer speed and disk space) allows dynamic acquisition and processing with smaller penalties. While the analysis of the studies will be task dependent, insight into the fundamentals of acquiring and analyzing tracer kinetics will be applicable to all fields.

Tracer development is perhaps in its highest gear ever since the largest advances, particularly in molecular imaging, are likely to result from new, more specific, and more physiologically relevant tracers. A hot area is the design of tracers to follow genes of interest, reporter genes, and to track stem cells and disease processes (31).

While the ideal tracer may go in proportion to the site of interest and be stuck there so that static imaging provides full information, it is much more likely that tracers will continue to exhibit complex properties. Thus research into optimal acquisition and analysis of the temporal and spatial distributions of the tracer will remain an important field and will likely even grow in significance. Analysis of dynamic data can offer quantitative and possibly even absolute measures of many clinically important parameters. The use of tracer kinetic principles and image time series from modalities such as optical, MRI, ultrasound, PET, and SPECT will continue to have very important application to cardiac, brain, renal, liver, and other dynamic systems.

TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION (TENS)

ANJU MADNANI
 SANJAY MADNANI
 RANDALL CARK
 JASON WELLS
 LSU Medical Centre
 Shreveport, Louisiana

INTRODUCTION

The field of pain management is a rapidly expanding one, and new treatment modalities are being discovered or rediscovered. Electroanalgesia has a long and sometimes dubious history, dating back to the ancient Egyptians. However, the publishing of “the gate control theory” of pain transmission in 1965 by Melzack and Wall transformed our understanding of pain, its transmission, and how it is modulated. With this discovery, electroanalgesia underwent a revolution, and transcutaneous electrical nerve stimulation (TENS) was developed and is continually being refined. Today, our understanding of the mechanism by which TENS produces analgesia continues to expand does its potential applications.

This article provides a review of pain, its definition, types, and physiology. It provides background information and theories surrounding the mechanism of analgesic action of TENS and the development of electroanalgesia. It discusses the usage, design, applications, and warnings surrounding TENS.

WHAT IS PAIN?

Pain is an unpleasant sensory and emotional experience associated with actual or potential damage, or described in terms of such damage. Pain serves as an essential defense mechanism to protect one’s body from potential damage. Indeed, the disastrous consequences of diminished or

absent pain signaling become readily apparent in diseases and conditions that result in partial or complete damage of the nerves that innervate the extremities (e.g., diabetic neuropathy, tabes dorsalis, tuberculoid leprosy, and many others). While serving an essential function, pain can often present for physiologically inappropriate reasons, continue far past the removal of noxious stimuli, remain long after wound healing, or even present for purely psychological reasons. This maladaptive and uncontrolled pain cycle afflicts an estimated 40 million Americans (1), and research into the causes and cures of pain is a rapidly expanding branch of medical science and forms the basis for a multibillion dollar a year, multidisciplinary industry.

Pain can be categorized either temporally as in acute or chronic pain or by the mechanism. Nocioceptive–inflammatory pain is produced after an appropriately perceived tissue injury. Neuropathic pain, however, is produced by nerve injury that is inappropriately perceived due to neuroplasticity. Often described as a burning or electric sensation, neuropathic pain can persist long after an injury or for completely idiopathic reasons. Even simple light touch or changes in temperature are enough to trigger severe bouts of extreme pain, lasting seconds to hours or longer (i.e., trigeminal neuralgia).

Phantom limb pain is another incompletely understood neuropathic phenomenon and occurs in 50–67% of postsurgical amputation patients (2). It is often described as a minor-to-severe cramping or, less commonly, as a burning sensation (3). While this commonly subsides with time, in ~10% of patients, this pain persists and is often refractory to NSAID or opiate therapy, traditional first and second line agents in the treatment of pain.

THE PHYSIOLOGY OF PAIN

The process of nociception is complicated, but can be divided into four distinct physiological processes transduction, transmission, modulation, and perception. Transduction, the translation of noxious stimuli into electrical activity at the sensory endings of nerves, occurs at unspecialized mechano-, thermo-, or polymodal (thermal and chemical) nociceptors, as well as at unspecialized nerve endings.

Polymodal nociceptors respond to a variety (i.e., chemical, mechanical, and temperature extremes) of intense noxious stimuli. Thermonociceptors are distinct from thermoreceptors that transmit non-noxious temperature information. This class of nociceptors functions from temperature ranges of roughly <5 to >45 °C. Mechanonociceptors are activated when intense pressure stimulates them; as with thermonociceptors, the mechanonociceptors are distinct from the receptors that transmit non-noxious light and strong touch, vibratory information, and so on. Additionally, visceral “silent” nociceptors exist in a default dormant state and are usually activated only in the presence of inflammatory mediators. These silent nociceptors likely are involved in hyperalgesia as discussed below.

In the peripheral nervous system, small unmyelinated C polymodal nociceptive fibers, as well as the larger,

lightly myelinated A δ mechano- and thermonociceptive fibers transmit noxious stimuli to the dorsal horn of the spinal column. The small C fibers are responsible for what is termed slow pain and transmit data at under 2.5 m·s⁻¹. These small fibers outnumber the larger, lightly myelinated A δ fibers, responsible for fast pain, which conduct at a rate of 4–30 m·s⁻¹, by a ratio of ~7:1 in the epithelium. The concept of slow and fast pain is easily conceptualized by a hypothetical injury of one stepping on a nail. The initial sharp sensation, or fast pain, is transmitted by the larger A δ fibers, while the nagging dull ache, or slow pain, is transmitted by the smaller, unmyelinated C fibers (Fig. 1).

The A δ fibers synapse with projecting neurons in lamina 1 of the dorsal horn of the spinal cord. In addition to this

Figure 1. Propagation of action potentials in sensory fibers results in the perception of pain. (Modified from Ref. 4). (a) This electric recording from a whole nerve shows a compound action potential representing the summated action potentials of all the component axons in the nerve. Even though the nerve contains mostly nonmyelinated axons, the major voltage deflections are produced by the relatively small number of myelinated axons. This is because action potentials in the population of more slowly conducting axons are dispersed in time, and the extracellular current generated by an action potential in a nonmyelinated axon is smaller than the current generated in myelinated axons. (b) First and second pain are carried by two different primary afferent axons. First pain is abolished by selective blockade of A δ myelinated axons (middle) and second pain by blocking C fibers (bottom).

Figure 2. Nociceptive afferent fibers terminate on projection neurons in the dorsal horn of the spinal cord. Projection neurons in lamina I receive direct input from myelinated (A δ) nociceptive afferent fibers and indirect input from unmyelinated (C) nociceptive afferent fibers via stalk cell interneurons in lamina II. Lamina V neurons are predominately of the wide dynamic-range type. They receive low threshold input from the large-diameter myelinated fibers (A β) of mechanoreceptors, as well as both direct and indirect input from nociceptive afferent fibers (A δ and C). In this figure the lamina V neuron sends a dendrite up through lamina IV, where it is contacted by the terminal of an A β primary afferent. A dendrite in lamina III arising from a cell in lamina V is contacted by the axon terminal of a lamina II interneuron. (Adapted from Ref. 4.)

direct, afferent input, these projecting neurons receive indirect input from the stalk cell neurons in lamina II. These stalk cell interneurons of lamina II receive their afferent input from the C fibers that synapse with them. The projecting neurons of lamina V receive afferent input from the large myelinated A β , non-noxious, sensory fibers via dendritic synapse in lamina IV, from synapse with A δ fibers in lamina V, and project both to lamina III as well as higher cortical centers (5,6) (Fig. 2).

In the dorsal horn of the spinal cord at the synapse level, the afferent pain signal can be modulated to either lessen or amplify the body's response to the pain signal. Serotonin as well as norepinephrine act either directly presynaptically to inhibit the propagation of the pain signal or via activating inhibitory interneurons. The enkephalins, endogenous δ and μ opiate receptor agonists, function at this level to serve a similar inhibitory function. The neuromodulator peptide, substance P is released, along with glutamate from the C fibers, and both work allosterically to amplify the pain signal transmission to higher levels.

Once in the dorsal horn of the spinal cord and after synapse, the afferent pain signal is transmitted to higher cortical centers via either the spinothalamic, spinoreticular, spinomesencephalic, cervicothalamic, or spinohypothalamic pathways. Perception is the final process where all above processes as well as prior physical and psychological experiences interact and create the final subjective and emotional experience of pain. The opioids, both endo-

Figure 3. Three of the major ascending pathways that transmit nociceptive information from the spinal cord to higher centers. The spinothalamic tract is the most prominent ascending nociceptive pathway in the spinal cord. (Adapted from Ref. 7.)

ogenous and exogenous, function to alter perception of pain at the cortical level, as well as to activate inhibitory interneurons in the periaqueductal gray area (Fig. 3).

HYPERALGESIA AND SENSITIZATION

In certain situations, nociceptors can become exquisitely sensitive to stimulation or activated in greater numbers than usual. This results in hyperalgesia and is termed sensitization; this process occurs via distinct mechanisms both peripherally as well as centrally. While peripheral sensitization occurs in both acute and chronic phases of injury, central sensitization generally occurs in the chronic phase of insult, after repetitive noxious events.

Upon peripheral injury, for example, an epithelial incision, inflammation is affected via a large number of chemical mediators, such as prostaglandins, leukotrienes, bradykinin, serotonin, substance P, histamine, potassium, and others, released from both damaged, as well as surrounding tissues (5). These inflammatory mediators serve not only to result in inflammation, but also serve to decrease the threshold to stimulate surrounding nociceptors. This can be done by directly acting to affect sensitization or by working in tandem to sensitize nociceptors via another chemical mediator. For example, bradykinin is an important and extremely potent mediator of hyperalgesia.

It works not only to directly sensitize the nociceptive fibers (i.e., C and A δ fibers), but also serves to stimulate local tissue to produce prostaglandins, which themselves result in sensitization. In addition to bringing about sensitization of nociceptors, some chemical mediators directly activate nociceptors, for example, histamine activating polymodal nociceptors (Table 1).

With continued C fiber pain signal transmission due to persistent noxious insult, increased glutamate is released from their end plates in the dorsal horn. With this increased glutamate release, continued opening of postsynaptic calcium ion channels results. This is mediated by postsynaptic *N*-methyl-d-aspartate (NMDA)-type glutamate receptors. This process, termed "wind-up", results in a continual increase in dorsal horn neuron response to the pain signal. This is an example of pain signal modulation. In addition to this progressively increasing response to the pain signal, dorsal horn neurons can become more easily excitable to a lesser peripheral signal. This process, termed central sensitization, is also mediated by NMDA-type glutamate receptors. Additionally, there is an upregulation in production of a variety of neurotransmitters, neurohormones, and their receptors. Effectively, these changes of excitability and magnitude of C fiber response constitute a pain "memory" and also result in progressively larger areas of peripheral tissue coverage of the dorsal horn neuron. Central sensitization with resultant

Table 1. Naturally Occurring Agents that Activate or Sensitize Nociceptors^a

Substance	Source	Enzyme Involved in Synthesis	Effect on Primary Afferent
Potassium	Damaged cells		Activation
Serotonin	Platelets	Tryptophan hydroxylase	Activation

Histamine	Mast cells		Activation
Prostaglandins	Arachidonic acid–damaged cells	Cyclooxygenase	Sensitization
Leukotrienes	Arachidonic acid–damaged cells	5-Lipoxygenase	Sensitization
Substance P	Primary afferents		Sensitization

^aModified from Ref. 4.

hyperexcitability helps explain allodynia, the perception of a non-noxious stimulus, such as light touch, as a painful stimulus. In light of these changes, it is obvious not only why chronic pain can be so difficult to treat, but also why it is important to break pain “cycles” before chronic changes begin to occur.

Allodynia is classically seen in several different chronic neuropathic pain syndromes for reasons that are not always completely understood, but likely stem from the chronic changes outlined above. Herpes zoster is perhaps the best known of these conditions with many sufferers reporting a severe dermatomal burning pain long after the peripheral nerve damage has healed. Allodynia is common following an attack, and severe bouts of pain can be precipitated from the friction between ones shirt and ones skin. Trigeminal neuralgia is another such chronic condition where allodynia is common. In this condition, lightly stroking one’s cheek or the process of eating can precipitate attacks of severe, stabbing transient pain, followed by longer periods of a moderate to severe burning sensation.

PSYCHOLOGICAL ASPECTS OF PAIN

As mentioned earlier, perception of pain is an individualized phenomenon. It is affected by culture, mood, and individual experiences (8,9). Chronic pain can be termed as pain that persists for a certain period, usually ~6 months, after an injury has healed or when the noxious source is idiopathic and central sensitization has occurred. The field of pain management employs a diverse, polymodal disciplinary strategy toward treating pain that extends far beyond simple pharmacotherapy. It includes interventional therapy, physical therapy, meditation, biofeedback, acupuncture, psychiatric therapy, electroanalgesia, and many other treatment modalities. There is a definite psychological component to chronic pain that can cause it to be perceived as much more severe than acute pain and make it refractory to traditional therapy, and chronic pain is frequently associated with depression.

THEORIES OF PAIN

Gate Control Theory

The gate control theory, published in 1965 by Ron Melzack and Pat Wall (10), was the theory from which modern electrotherapy has evolved and that has helped revolutionize

treatment and our understanding of pain. The theory states that pain perception depends on the balance of large, afferent sensory A β and small diameter afferent nociceptive A δ and C fiber activity. According to the theory, non-nociceptive sensory fibers can activate neurons in the substantia gelatinosa. These neurons can decrease or inhibit the pain signals of nociceptive neurons prior to higher level transmission. This theory explains the common practice of rubbing an acute wound to lessen pain. It is worth noting that the inhibitory effect of nonnociceptive neurons is a local one. No analgesic effect exists when rubbing one’s toes after an injury to one’s fingers (Fig. 4).

The theory’s emphasis on the modulation of inputs in the spinal dorsal horn and the dynamic role of the brain in pain processes had a clinical, as well as a scientific impact, and after this theory several methods were developed to modulate the input. Physical therapists and other health-care professionals began developing and refining different modulation techniques, such as implantable dorsal spinal electrostimulation, and later transcutaneous electrical nerve stimulation devices as well as rediscovering old ones, such as acupuncture. After this discovery, TENS became an important part in treating the acute and chronic pain. See below for a much more thorough discussion of the history of electroanalgesia.

Figure 4. Schematic diagram of the Melzack–Wall gate control theory of pain mechanisms. Large- (L) and small-diameter (S) afferent fibers project to the substantia gelatinosa (SG) and first central transmission (T) cells. The inhibitory effect (–) of SG on the afferent terminals is increased (+) by activity in L fibers and decreased by activity in S fibers. A specialized system of L fibers (the central control trigger) activates certain cognitive processes that influence the modulating properties of the apinal gating mechanism via descending fibers. (From Ref. 10 R. Melzack and P. D. Wall, *Science*, 150:971–979, 1965, © 1965, AAAS.)

Other Theories Regarding TENS' Analgesic Effect

Other theories have been developed to explain the effectiveness of TENS, namely, the enkephalin and endorphin theories, and likely all three contribute to the analgesic effect. Multiple studies have demonstrated an increase in dorsal horn enkephalin production (11,12) as well as have demonstrated that blockade of opiate receptors lessens or even prevents analgesia from TENS (13–15). As briefly described earlier, enkephalins are μ and δ opiate receptor agonists and function as inhibitory neurotransmitters. Release of enkephalins from inhibitory interneurons decrease Ca^{2+} influx into the nociceptive neuron, thereby preventing, or lessening depolarization time, prevents or lessens excitatory neurotransmitters, such as glutamate, release, thereby negatively modulating the pain signal. Additionally, enkephalins function postsynaptically to activate K^+ conductance, thereby hyperpolarizing the dorsal horn projecting neuron and inhibiting pain transmission to further higher cortical centers (Fig. 5).

While enkephalins have a short half-life and function locally, recent studies (16–18) have demonstrated increased levels of circulating endorphins. In contrast to enkephalins, endorphins are circulating μ agonist neurohormones. As such, they act not only on the μ receptors in the dorsal horn of the spinal cord, but also function on central μ receptors to alter the perception of pain and negatively modulate the signal. The discovery that TENS increases endorphin levels is significant. The effect of increasing enkephalins produces a transient effect that lasts only as long as the electrical signal is applied, as is with direct nonnociceptive stimulation as described in the gate theory. However, use of TENS produces an increase in circulating endorphins that is proportional to usage. The net effect is an analgesic effect that persists after the TENS unit is removed and increases in potency and duration with repeated usage.

The Evolution of Electroanalgesia

The use of electroanalgesia is an ancient practice, and to thoroughly understand the theory and application of TENS, it is important to understand the evolution of electroanalgesia. The powers of certain fish, namely, the Nile Catfish (*Malopterus electricus*), Torpedo Fish (*Torpedo mamorata*), and the Electric Eel (*Gymnotus electricus*) to deliver electrical shocks resulting in paralysis and temporary sensory loss in affected limbs has long been known. The Nile Catfish appeared on walls of various Egyptian tombs, dating from ~2750 bc, and represents the earliest known documentation of this phenomenon of electrical discharge. While it is not known exactly when ancient man discovered the analgesic or anesthetic properties of such fish, it is quite likely that since their discovery by primitive man, these properties were readily apparent.

Exactly when the electrical properties were used for medicinal benefit is unclear, but the earliest known writings describing this benefit were made by made in ad 46 by Scribonus Largus, a Roman physician who described the usage of the torpedo fish as a treatment for intractable gout and headache pain (19). Quoting from his treatise *Compositiones Medicae*, Largus describes these remedies.

For any type of gout a live black torpedo should, when the pain begins, be placed under the feet. The patient must stand on a moist shore washed by the sea and he should stay like this until his whole foot and leg up to the knee is numb. This takes away present pain and prevents pain from coming on if it has not already arisen. In this way Anteros, a freedman of Tiberius, was cured (20).

“Headache even if it is chronic and unbearable is taken away and remedied forever by a live torpedo placed on the spot which is in pain, until the pain ceases. As soon as the numbness has been felt the remedy should be removed lest the ability to feel be taken from the part. Moreover several torpedoes of the same kind should be prepared because the cure, that is, the torpor which is a sign of betterment, is sometimes effective only after two or three” (21).

As time progressed, the usage of electroanalgesia spread as a treatment for varying medical conditions. Pedanius Dioscorides around 80 ad describes the usage of the torpedo fish for rectal prolapse. This represents likely the first description of electrical stimulation for intentional muscular contraction (19). Likewise, these treatments were used and espoused by Galen in the second century.

The knowledge of the usage of the electrical properties of such fish was not limited to Europe. Ibn-Sidah, an Islamic physician described placing an electric catfish on someone suffering a seizure sometime in the eleventh century (21). The use of the electric fish continued to grow and by the sixteenth century the number of remedies had expanded and included treatments for various arthralgias, myalgias, headaches, epilepsy, vertigo, and for inducing sleep both by European, Indian, and Middle Eastern physicians. By the seventeenth century the application of artificially generated electricity was made possible by the development of the electrostatic generator by Otto Von Guericke.

Major revolutions in electroanalgesia came in the mid-nineteenth century from Guillaume Benjamin Amand Duchenne. He introduced the usage of moistened electrodes, as opposed to the more painful dry electrode, as a means of delivering electroanalgesia for treatment of neuropathic pain. His focus on muscle contractions from electrotherapy and making strides toward to a somewhat standardized system of electrode placement were important advances as well.

Throughout the world, electrotherapy became increasingly popular toward the end of the nineteenth and beginning of the twentieth centuries. However, with this rise in popularity came a rise in dubious to downright fraudulent applications and practitioners treating all manners of maladies from skin ailments to weight loss. With an ever increasingly savvy public, the rise of fraudulent applications, the rise of modern pharmacotherapy, X rays, and the like, electrotherapy begin to fall out of favor, or at least popularity, in the early twentieth century (19).

However, technological advances in electrical storage and delivery along with new understandings of pain have produced a resurgence in application and research in electroanalgesia. Shortly after the publishing of the gate control theory, a flurry of exciting discoveries in this

Figure 5. Local-circuit interneurons in the superficial dorsal horn of the spinal cord integrate descending and afferent pathways. (a) Possible interactions between nociceptor afferent fibers, local interneurons and descending fibers in the dorsal horn of the spinal cord. Nociceptive fibers terminate on second-order spinothalamic projection neurons. Local enkaphalin-containing interneurons (ENK) exert both presynaptic and postsynaptic inhibitory actions at these synapses. Serotonergic and noradrenergic neurons in the brain stem activate the local opioid interneurons and also suppress the activity of spinothaiamic projection neurons. (b) 1. Activation of nociceptors leads to the release of glutamate and neuropeptides from sensory terminals in the superficial dorsal horn, thus depolarizing and activating projection neurons. 2. Opiates decrease the duration of the nociceptor’s action potential, probably by decreased Ca²⁺ influx and thus decrease the release of transmitter from primary afferent terminals. In addition, opiates hyperpolarize the mambrane of the dorsal horn neurons by activating a K⁺ conductance. Stimulation of the nociceptor normally produces a fast excitatory postsynaptic potential in the dorsal horn neuron opiates decrease the amplitude of the postsynaptic potential.

realm took place starting with the 1967 demonstration by Sweet and Wall that *In vivo* electrostimulation of peripheral nerves produces analgesia as well as Shealy and Long’s work in the area of dorsal and anterior spinal cord surgically implanted stimulators. Shealy and Long discovered that peripheral nerve stimulation done in surgical candidates prior to an electrospinal implant placement produced nearly comparable analgesia to the actual dor-

sal horn implant (17)! This discovery laid the foundation for TENS development and widespread utilization today (22,23).

While somewhat beyond the scope of this article, it is worth noting that electroacupuncture experienced a widespread rediscovery in China in the 1950s. Though based on a different system of understanding of human physiology than traditional western medicine, this modality of

Figure 6. This represents one of the earliest families of stimulators, with the original model seen on the *left*. The original sponge electrodes are depicted in the *foreground*.

electroanalgesia is beginning to garner increasing interest interest in western medicine (19).

Transcutaneous Electrical Nerve Stimulation

Today electrotherapeutic treatment is one of the most important parts of multidisciplinary approach to treat acute and chronic pain. The TENS units themselves have undergone an evolution from large bulky units to the much smaller units of today. While there are numerous units available, each generally consists of one or more channels for electrodes, a display (either analog or digital), and various options to adjust the various parameters of the electrical current.

One of the First TENS Units Created (below)

The unit (*left*) is one of the first TENS unit available and is large and bulky with an all analog interface. Subsequent units (*center and right*) still remain analog but were more compact, though nowhere near the level of today's units (Fig. 6).

Several Modern TENS Units (below)

Pictured are just several of the numerous commercially available TENS units. Note the compact size of the models compared to older units as well as the digital TENS unit (*bottom*) (Fig. 7 and Table 2).

Electrode

The discovery that transcutaneous peripheral nerve stimulation provided nearly identical analgesic levels as dorsal root stimulation revolutionized electroanalgesia, and it almost goes without saying that the noninvasive, easy to employ nature of TENS is one of the modality's biggest assets. The electrode, the interfacing agent between the skin and machine, has undergone almost as much evolution as the TENS unit itself. The very nature of peripheral transcutaneous nerve stimulation is such that electrical currents must be applied for longer periods of

Figure 7. Several commercially available TENS units.

time in greater amounts. While the process of transferring an electrical current from machine to peripheral nerve may seem relatively simple on the outside, several notable problems present ranging from the actual transfer of the current to skin irritation to cost. Several distinct solutions currently are in use, and all present with a variety of tradeoffs (Table 3). Generally speaking, properties of a good electrode for TENS use include low cost/use ratio, good adhesion, comfortable, nonirritating to skin, good electrical conductivity, and easy to use.

Standard EKG or EEG electrodes were initially used for TENS with limited success, as these were designed for much lower amperage and much shorter usage than is needed for effective TENS. It quickly became apparent based on excessive skin irritation and poor adhesion and subsequent nonuniform current distribution that new electrode solutions were needed. One of the most popular current solutions involves silicone impregnated with carbon (Table 3). These carbon silicone electrodes provide the best cost/use ratio of the commercially available electrodes and can often last for months if properly cared for. However, a tradeoff exists in terms of convenience with these carbon silicone pads, as electroconductive gels, rich in suspended ions to facilitate the transfer of electric current from the TENS unit across the epidermis, must be applied

Table 3. Basic Types of Electrodes

General electrode Type	Number of Uses	Typical Retail Cost Electrode (pair)	Typical features			
			Adhesion and Conduction	Composition Materials	Advantages	Disadvantage
Disposable	1 use	Under \$3.00	Pressure-sensitive tape surrounding conductive area (wet get in sponge)	Nonwoven Foam	Easiest to use Very good adhesion Comfort	Cost/use Skin irritation Poor electrical performance
Semireusable	3–10 uses	\$5.00–10.00	Conductive adhesive over entire surface	Foam Plastic film Carbon silicone	Ease of use Low skin irritation Comfort	Weak adhesion Care and storage Medium cost per use Good electrical performance
Reusable	>100 uses	\$4.00 ^a	Requires addition of conductive gel and tape adhesion	Carbon silicone	Very good electrical performance (if applied properly) Lowest cost per use	Most preparation to use Skin irritation Messy Requires gel and tape Skill required for optimal performance Poor adhesion Not as flexible in use

prior to each usage. The electrodes must then be affixed with tape to the skin. This process can be laborious if not impossible for the end user to do, depending on electrode location as well as physical disability. While numerous medical tapes exist, care must be taken in their selection. Some users display mild-to-severe allergic reactions to adhesives in various tape products. Likewise, certain adhesive tapes adhere too firmly to the skin and can result in injury with repeated application and removal.

In applications where cost is no object, sterility is needed, or convenience must be maximized, single use adhesive electrodes are used that consist of thin, porous material impregnated with adhesive electroconductive gel covered with cloth or plastic on one side to prevent adhesion to clothing or electrical current escape. These electrodes are used extensively in hospital or rehab facilities where numerous patients are seen and reusing electrodes is neither feasible nor sanitary as well as in individuals who desire or require maximum convenience.

A third option in electrode selection includes so-called “dry gel” electrodes manufactured from a conductive polysaccharide gum, called Karaya or Sterculia gum when taken from the Sterculia Urens tree native to India or a manufactured comparable material. These dry gel electrodes represent a good compromise between the disposable and reusable carbon silicone electrodes, as they are self adhesive, do not require electroconductive gel application, may be reused several times, and represent a significantly lower cost/use ratio than disposable pads.

Patients should be informed of the various pros and cons of the various electrodes as well as counseled regarding proper usage. According to Szeto, several factors should be considered when selecting the proper electrode:

1. How long will each application of the electrodes last, and therefore what is the level of adhesion needed?

2. Is the stimulation site readily accessible or will there be someone to assist? How simple must the application of the electrodes be?
3. What is the patient’s skin type (hairiness, oiliness, hyperallergic)? Will special pregelled electrodes be required?
4. Where is the painful area? This factor will help to determine the best electrode size, shape, cosmesis, and number.
5. Does the TENS user lead an active life? If so, a high performance electrode in terms of adhesiveness, pliability, and nonirritability would be needed.
6. Can the user take good care of the electrodes, and what are the financial arrangements? These issues will affect the cost-effectiveness of disposable or semireusable type of electrode (24).

Electrode size is another factor to consider in selection and depends on the location of pain, area required for stimulation, and personal preference. Numerous sizes and shapes of electrode pads are available and suitable for virtually any application.

Sample Electrodes

Electrode Placement

Electrode placement is crucial in maximizing positive outcome with TENS units. Most units employ two or more channels of current, which splits to two electrodes, and it is often advisable for multiple channels to be used to cover maximal areas, as many pain syndromes often do not exhibit pain localized to a specific point source. Numerous books on TENS or manufacturer information as well as various anatomical charts provide users with possible electrode placements. While it is impossible to describe

Figure 8. TENS electrodes.

proper electrode placement for every pain syndrome, certain electrode arrangements are frequently used.

For the purposes of this discussion, the channels will be referred to as I and II and the negative electrode as “a” and the positive as “b”. Parallel placement with one channel is utilized for relatively localized areas of pain, such as point pain or pain from a surgical incision. Electrode Ia is placed on one side of the incision, while Ib is on the other, producing a current that flows between the two with the area of pain in between the electrodes. Bilateral placement is similar, but generally defined as meaning Ia and Ib electrodes are placed on either side of the spine, symmetrically and close together, useful for localized, nonradiating neck or back pain. For radiating neck or back pain, a longitudinal arrangement is often utilized in which electrodes of one channel are on the same side of the spine and placed along the pain pathway. If the pain is bilateral, electrodes of another channel on the can be placed on the opposite side of the spine along the pain pathway (Fig. 9).

A crossed, or interferential, placement is useful for pain localized to large joints, such as shoulder, elbow, or knee. In this pattern, Ia and IIa are placed side by side with IIb below Ia and Ib below IIa, creating a square pattern with electrodes of the same channels diagonally opposite each other with the area of pain in the center of the square. Bracketed placement is generally reserved for treating the dermatomal neuralgia that frequently is associated with shingles, varicella zoster, out breaks. In this arrangement, electrodes Ia and Ib are placed along

Figure 9. Bilateral pain electrode placement.

the dermatome cranial to the neuralgia and electrodes IIa and IIb placed along the dermatome caudal to the neuralgia (Fig. 10).

Occasionally, localized pain is so severe that the user cannot tolerate electrode placement over the affected site, and in this case a contralateral placement in the nonaffected hemisphere over the same anatomical area as on the affected side is utilized. This arrangement will sometimes permit sufficient pain relief for the user to eventually tolerate direct stimulation. While the exact mechanism of analgesia is not known, it is hypothesized the analgesic effect is the result of central inhibitory pathways (24). Certain syndromes, such as Reflex Sympathetic Dystrophy, lend themselves to this placement, and reflex vasodilatory effects may explain contralateral analgesia in these syndromes (25) (Fig. 11).

Certain pain syndromes, such as phantom limb pain, glove–stocking distribution peripheral neuropathy, or acute burns, fractures, lacerations, or other injuries of the hands or feet lend themselves to a placement of the electrodes proximal to the actual source of the pain. In this placement, the electrodes of one channel are simply placed along the dermatome of the pain source, but proximal to the pain (Fig. 12).

The final placement method to be covered is a linear, unilateral, overlapping pattern useful for pain along some, as in myofascial pain, or all, as in radicular pain, of an extremity, and follows a placement procedure outlined by Wolfe (25). After the dermatomal distribution of the pain is elucidated, electrode Ia is placed at the most proximal location where the user experiences pain. Distal to this electrode, the user identifies the site of maximal pain and places IIa here. At the most distal site of pain, electrode IIb is placed, and between IIa and IIb, electrode Ib is placed, being careful to keep all electrodes in the affected dermatome (Fig. 13).

It is important to note with the above placement, the electrical current covers the entire length of the pain the

Figure 10. Dermatome maps of the peripheral distribution of spinal nerves (a and b) and trigeminal nerve (c) d. Details of dermatome maps on anterior and posterior surfaces of the hand and foot.

user experiences. If the user inadvertently places electrodes in a nonoverlapping pattern (i.e., Ia and Ib both proximal to IIa and IIb), the current will not cover the entire pain pathway; instead it will only travel between electro-

des of the same channel, leaving the area between Ib and IIa “uncovered”. The following should be generally avoided due to poor current coverage area: unilateral, linear (Fig. 14).

Figure 11. Contralateral electrode placement.

Electric Amplitude–Frequency Selection

Once the proper electrode type is chosen, as well as optimal electrode placement ascertained, the optimal electrical signal must be selected. Generally speaking, the most used currents include “classical” TENS with high intensity–low frequency currents for up to 12 h at a time, low intensity–high frequency currents for up to 45 min several times a day, and intermittent low frequency bursts are used. The varying current intensity–frequency produces analgesia via the different mechanisms as discussed above.

Classical TENS employs high frequency (60–200 pulses per second)/low intensity (15–60 mA) stimulation and produces a distinct “electrical tingling” sensation in the area of electrode pad placement that most users find pleasant. This current is not of significant intensity to produce significant muscular contraction. Pain relief from this form of stimulation is transient, occurring quickly once stimulus is applied and disappearing once current is removed, and the gate control theory likely explains the mechanism of analgesia. The high frequency pulses activate Aβ sensory afferent fibers and inhibit pain transmission in the dorsal column of the spinal cord.

Low frequency (1–5 pulses per s)/high intensity stimulation, producing sustained muscle contractions, results in slower onset pain relief that persists after the stimulus is removed. Numerous studies have demonstrated partial to near total inhibition of analgesic effect via administration of naloxone (13–15). The endorphin and enkephalin theories described previously likely largely account for the mechanism of analgesic activity, especially the endorphin

Figure 13. Unilateral, linear, and overlapping electrode placement.

theory and long-term analgesia. While effective at inducing long-term analgesic effects, the low frequency–high intensity method of stimulation is often perceived by many patients as less pleasant than high frequency stimulation.

As the long-term effects of low frequency intense stimulation are desirable, manufacturers have devised means of producing a more pleasurable sensation while at the same time stimulating muscle contraction enough for long-term analgesia via modulation of the current. To understand the modulation of current in TENS, a brief review of the current waveforms it employs is needed. Briefly, biphasic waveforms, consisting of both a positive and negative phase are used, and these may be either symmetric or

Figure 14. Unilateral, linear electrode placement.

asymmetric. If the current amplitude is equally positive and negative, the current is termed “electrically balanced,” also referred to as zero net charge (znc) or no net dc current. While both balanced and unbalanced electrical currents are employed, unbalanced current transmission can result in pH changes in the skin with long-term usage, do to ion exchange, which can result in skin irritation. Additionally, the current employed in TENS is a pulsatile current with interspaced periods of electrical activity and electrical silence. The periods of electrical silence may be either uniform or varying. The frequency of electrical pulses may be given in units of hertz (Hz), cycles per second (cps), or pulses per second (pps) (25). It is important to note that while frequency may be a constant 100 cps, the period between the pulses may be variable.

All of these variables in the current waveform may be adjusted to achieve a net effect that is both pleasant to the patient while sufficient to achieve muscular contraction. For example, the amplitude of the current may be varied over a constant time interval, the duration of the pulse may be varied, the time between pulses may be varied, or a combination of some or all of the previous may be used. As pain severity and character can frequently change, models that allow modulation of electrical current via one or more characteristic offer distinct advantages in patients’ individualizing their therapy as well as help prevent physiologic adaptation to the electrical stimulation. While numerous studies have delved into optimizing the electrical waveform (26–28), their conclusions have been varied, and it is likely, there is no optimal waveform. As such, TENS therapy is an individualized one, and patients should have frequent follow ups with their physician to ensure the patient is receiving optimal care for their specific complaint (Table 4).

TREATMENT PLANS

Treatment with TENS is an extremely variable and personalized process, and this cannot be underscored enough. It is vital for close healthcare supervision for a user to obtain the maximum therapeutic benefit from tens. TENS may only be used in an acute phase for a short period of time (e.g., incisional pain postsurgery) or for months or years (e.g., those suffering from chronic back pain). For chronic pain sufferers classical TENS may be used for several hours continuously daily. Modulated or low frequency/high intensity may be used for ~30 min three times a day for an indefinite period of time. When using TENS it is important to use as strong or nearly asstrong a current as the user can tolerate to achieve best results.

Fibromyalgia is a poorly understood chronic pain condition that presents unique management challenges not only because it is poorly understood, but also because it is often refractory to traditional treatment modalities. A recent double-blinded study by Cork et al. (29) explored cranial electrotherapy stimulation (CES) as a possible treatment for fibromyalgia. In this study, using electrodes clipped to the participants’ ear lobes, the Alpha-Stim CES device, delivered either modified square-wave stimulation at 100 μA and a 50% duty cycle at 0.5 Hz for 1 h daily for 3 weeks or sham therapy (see Fig. 15). While there were no

differences in baseline pain scores of the participants in either group prior to beginning the study, after 3 weeks of CES therapy those in the treatment group displayed significantly lower Pain Intensity Scores, Tenderpoint Scores, and POMS Scores compared to the sham group. After 3 weeks the study was unblinded, and 23 of the 35 participants in the Sham group elected to switch over to active treatment for 3 weeks. Those switching from sham therapy to active CES therapy displayed significant reductions in the aforementioned pain scores as well (29) (Fig. 16).

WARNINGS AND CONTRAINDICATIONS

TENS is contraindicated in individuals with pacemakers, especially those with demand-type pacemakers as the electrical stimulation could cause misfiring or other malfunction of the pacemaker. Electrode placement in areas of sensory or circulatory deficits should be avoided due to the potential for burns or excessive muscular contraction. Electrodes should not be placed over the carotid sinuses to prevent a vasovagal reflex reaction with resultant hypotension. Electrodes should not be placed over the anterior neck due to potential to induce laryngospasm and subsequent asphyxiation. Electrodes should not be placed over the eyes. TENS should be avoided in pregnant women due to the potential to induce contractions and premature labor. Caution should be used in patients with implanted spinal stimulators as well as intrathecal opiate pumps. The unit should not be used with other electrical medical equipment, such as ECGs, EEGs, pulse oximeters, and electrocautery devices.

PRECAUTIONS

Tens has not been proven to have curative value and should be used only under the supervision of a physician. Patient selection is crucial, and not all patients will respond to TENS. The TENS has not been shown to exhibit curative value and should not be used for pain of unknown origin. The unit itself as well as wires and electrodes should be kept out of reach of children and water.

ULTRASONIC IMAGING

OLIVER KRIPFGANS
University of Michigan
Ann Arbor, Michigan

INTRODUCTION

Medical imaging has many modalities and most of them provide clinicians with unique features of a volume of interest (VOI) resulting from a chosen modality. Ultrasonic imaging is one technique for collecting anatomical and physiological information from within the human body. It can be used for diagnosis (imaging) and for image-guided therapy, where therapeutic intervention can be applied with direct image-based feedback. Other modalities include X ray (roentgen radiation), CT (computed tomography), MRI (magnetic resonance imaging), PET or PET/CT (positron emission tomography), and SPECT (single photon emission computed tomography). In contrast to most other imaging techniques, ultrasonic imaging is very attractive to professionals because it is cheap, real time (with >100 full frame images per second, >100 Hz), and it uses nonionizing radiation. Moreover, current clinical ultrasound machines can be integrated into laptop computers with very little external hardware for maximum portability and versatility. These combined features allow the use of ultrasonic imaging in a wide variety of settings, from private physician practices, to ambulances with on-site paramedics, to battle field situations, where very robust and lightweight equipment is required. Many other uses of ultrasonic imaging are found in science and industry these include, for example, ultrasonic microscopy, nondestructive testing and touch sensitive screens.

PHYSICAL PRINCIPLES

Ultrasonic imaging is based on ultrasound, which is sound produced at frequencies beyond those detectable in human hearing, that is, >20 kHz. In the same way that ultraviolet (UV) light is invisible to the human eye, ultrasound is inaudible to the human ear. Often objects that serve as carriers for ultrasound waves need to be treated as waveguides. Nonlinear effects become apparent for ultrasound propagation when leaving the range of elastic deformation during the propagation of waves through a medium. Physical material constants form ultrasound parameters, for example the speed of sound or the attenuation of sound. Very high frequency sound waves are treated by quantum acoustic laws. Historically, ultrasound was produced by oscillating platelets (1830), or pipes (1876).

Magnetostriction (1847) and the piezoelectric effect followed (1880 by Curie), and are still very much relevant mechanisms for medical and industrial ultrasound. In 1918, it was found that the use of oscillating crystals could be used to stabilize frequencies. The upper frequency for sound in a given solid material is determined by the separation of neighboring atoms in the host medium. This upper frequency limit is met when neighboring atoms, assuming the linear chain model, oscillate with a 180° phase shift, the so-called optical branch of oscillations in a solid (1–15).

Sound Waves

Sound waves are mechanical waves by nature and a medium is needed to carry them. These spatial-temporal oscillations occur nonsynchronously throughout a medium and cause density fluctuations, which in turn cause temperature oscillations if the rate of such fluctuations is larger than the time constant for thermal equalization. Typical properties to describe sound waves are

Displacement $\mathbf{s} = \mathbf{s}(t)$ of a particle due to a traversing wave

Sound particle velocity $\frac{d}{dt}\mathbf{s} = \frac{d}{dt}\mathbf{s}(t) = \mathbf{v}(t)$

Instantaneous mass density $\rho = \rho(t)$

Instantaneous pressure $p = p(t)$

where the later most is the deviation from the ambient static pressure. Mechanical properties, such as strain tensor σ_{ij} and stress tensor s_{ij} can be used to develop relationships between the above mentioned properties of sound waves (Fig. 1).

For mostly lossless media, such as water, one can use the laws of conservation of momentum and conservation of mass to derive the wave equation for sound waves,

$$\nabla p(r) = \frac{1}{c^2} \frac{\partial^2}{\partial t^2} p(r) \quad \frac{B}{A} = \text{const} \left[\frac{\partial c}{\partial p} \right]_T + \text{const} \left[\frac{\partial c}{\partial T} \right]_p \quad (1)$$

where spatial variations in pressure ∇p are coupled to temporal variations $(\partial p)^2/(\partial t^2)$ via the speed of sound c . This simple relationship represents only a linear approximation, and is therefore valid only for waves of small displacements. The isentropic nonlinearity parameter B/A measures the amount of density change (ρ , $c = (\rho K)^{-1/2}$ (see Eq. 10) for a given pressure (p) and temperature (T) (6). Note that only second-order temporal derivatives in the pressure result in a spatial pressure change, that is, only accelerations can result in sound.

Planar and Spherical Waves. In general, mechanical waves can either travel as longitudinal waves by compressing and expanding the host medium itself or as transversal waves by exerting shear force on the host medium. Water is a very good host medium because it bears minimal

Figure 1. Ultrasonic waves travel through media by elastic deformation of matter. This deformation can be written in terms of strain σ_{ij} and stress s_{ij} tensors.

energy loss for traveling sound waves. The human body is 55–60% (8) composed of water, which ensures good acoustic accessibility. Exceptions are areas blocked by either bone or air, since bone and air provide poor ultrasound transmission characteristics. However, water mostly supports longitudinal waves. Transverse waves are attenuated at a high rate in water and can therefore be neglected. The three-dimensional (3D) wave equation in Eq. 1 reduces then to a one-dimensional (1D) equation with the general solution of an inward and outward propagating wave:

$$\left. \begin{aligned} p(x, t) &= F(x - ct) + G(x + ct) \\ p(r, t) &= \frac{1}{r}(F(r - ct) + G(r + ct)) \end{aligned} \right\} \begin{array}{l} \text{for Planar and} \\ \text{spherical waves} \end{array} \quad (2)$$

where x and r are the direction of propagation, t is time, and F and G are general, but continuously differentiable functions. The rationale for these arbitrary functions is their argument $x \pm ct$ and $r \pm ct$. This expression ensures the character of the wave as a traveling entity. Whatever the function F represents at time $t = 0$ at position $x = 0$, it will travel to position x/c after time t . In other words, by keeping the argument of the function $F = 0$, one can compute where and how fast the wave travels. Vice versa for the function G , except that it travels in the opposite direction (Fig. 2). For harmonic waves, these two functions are represented by harmonic functions, that is, sin, cos, or more general e^{ix} . Planar and spherical waves follow as:

$$\left. \begin{aligned} p(x, t) &= pe^{ik(x \pm ct)} && \text{planar waves} \\ p(r, t) &= \frac{p}{4\pi r} e^{ik(r \pm ct)} && \text{spherical waves} \end{aligned} \right\} \quad (3)$$

Here, k is the wave number, defined as $2\pi/\lambda$, which is the conversion between spatial coordinates of wavelength to

Figure 2. Illustration for the general solution of equation 1; two traveling waves F and G in opposing directions, $+r$ and $-r$, respectively.

radians in the complex exponential. Acoustic attenuation or absorption can be mathematically written as a imaginary valued wave number k_i , leading to the complex valued total wave number $k = k_r + k_i$.

Quantifying Sound

Sound intensity $I(\text{W} \cdot \text{cm}^{-2})$ and acoustical power P [W]

$$\mathbf{I} = \overline{p\mathbf{v}}, \quad P = \oint_S \overline{p\mathbf{v}_n} dS \quad (4)$$

are measures of the strength of the acoustic waves. In both equations, the temporal average of the product of pressure and particle velocity is computed. In the equation for intensity in equation 4, the temporal average value is a vector quantity, while in the equation for power it is a scalar because the velocity is taken as the normal component to the encapsulating surface element dS . In addition to acoustic intensity and power, very often one refers to a measure for the acoustic pressure. In SI units, pressure is given by Newton per square meter ($\text{N} \cdot \text{m}^{-2}$). However, sound pressures extend over a large range, and therefore a logarithmic scale, the dB scale, is commonly used to measure pressure.

$$\text{dB value} = \begin{cases} 20 \cdot \log p_{\text{rms}}/p_{\text{ref}} \\ 10 \cdot \log I_{\text{rms}}/I_{\text{ref}} \end{cases} \quad (5)$$

As can be seen from Eq. 5, a reference value must be used to compute the pressure level on a dB scale. Typically, this reference is chosen to be the peak output level of the system under test or it can be a fixed value such as when 1 mW into 50Ω is used on some oscilloscopes. Sound pressure level (SPL) and sound intensity level (SIL) reference values in underwater ultrasonics are $1 \mu\text{Pa}$ and $10^{-12} \text{W} \cdot \text{m}^{-2}$, respectively. In contrast, SPL for air bourne sound is $20 \mu\text{Pa}$, whereas SIL remains at $10^{-12} \text{W} \cdot \text{m}^{-2}$.

Acoustic Impedance

Impedance is a term commonly known from electromagnetism. However, it also applies to sound waves and relates sound pressure and particle velocity in a manner analogous to Ohm's law. One distinguishes at least four types of acoustic impedance: specific acoustic impedance (z) is used to compute the transmission of an acoustic wave from one medium into another; acoustic impedance (Z) is used to estimate the radiation of sound from vibrating surfaces; mechanical impedance (Z_m) is the ratio of a complex driving force and the resulting complex speed of the medium; and radiation impedance (Z_r), which is used to couple acoustic waves to a driving source or a load driven by a force.

$$\begin{aligned} z &= \mathbf{p}/\mathbf{v} && \text{Specific acoustic impedance} \\ Z &= \mathbf{p}/\mathbf{U} = z/S && \text{Acoustic impedance} \\ Z_m &= \mathbf{f}/\mathbf{U} && \text{Mechanical impedance} \\ Z_r &= Z/S = \int d\mathbf{f}s/\mathbf{v} && \text{Radiation impedance} \end{aligned}$$

Here, \mathbf{p} is the acoustic pressure as a function of space and time, \mathbf{v} is particle displacement velocity as a function of

space and time, \mathbf{U} is a volume velocity, \mathbf{S} is the surface that emits the sound, \mathbf{f} is a complex driving force of the sound source, such as the force of a coil that makes the membrane of a loudspeaker move, and subsequently \mathbf{u} is the complex speed at which the forced medium is moving.

Moreover, a quantity called characteristic impedance is analogous to the wave impedance $\sqrt{\mu/\epsilon}$ of a dielectric medium. Its analytical form depends on the type of wave. Equation 7 shows the closed form expression for planar and spherical waves. It should be noted that the characteristic impedance for spherical waves can be complex valued and therefore pressure (p) and velocity (v) are not required to be in phase.

characteristic impedance:

$$z = \frac{p}{v} = \rho_0 \cdot c \quad \text{For planar waves}$$

$$z = \frac{p}{v} = \rho_0 c \cdot \frac{kr}{(1 + (kr)^2)^{1/2}} e^{j\theta} \quad \text{For spherical waves} \quad (7)$$

For these two special cases one can see that planar waves have pressure (p) and particle velocity (v) in phase. The ratio of pressure to velocity is a real number and is constant ($\rho_0 c$). Spherical waves, however, behave differently. Pressure and particle velocity are out of phase when measured close to the sound source. The ratio of pressure to velocity is a complex value (due to the $e^{j\theta}$ term and $\cot \theta = kr$) and it changes with distance (r). For large r , the spherical wave solution approaches the planar wave solution, that is, when $kr \gg 1$.

The parameter Z , the acoustic impedance, is often referred to as a frequency independent constant. The importance of this property lies in the nature of ultrasound. When imaging the human body, the sound waves travel through many layers of varying impedances, such as skin, fat, connective tissues, and organs. The crossing of each tissue boundary changes the sound waves in several ways. Typically, sound both transmits and reflects from tissue layers. While sound is mostly transmitted, small reflections are recorded and displayed as gray levels in a so-called B-mode image, where larger amplitudes of reflected waves is displayed as brighter pixels. More complicated scenarios include mode conversion between longitudinal and transverse waves. Reflection and transmission coefficients for pressure are directly related to the change in acoustic impedance as given in the following equation:

$$R = \frac{Z_2 - Z_1}{Z_2 + Z_1} \quad T = \frac{2Z_2}{Z_2 + Z_1} \quad 1 + R = T \quad (8)$$

Here Z_1 and Z_2 are the impedances of the proximal and distal side of the interfacial surface. Therefore, no reflection will be seen from sound entering a layer of equal impedance, but varying density and speed of sound compared to the current medium. Reflection and transmission coefficients for intensities are derived by squaring R and T in Eq. 8 (Fig. 3).

Attenuation

Acoustic attenuation manifests itself in many ways. Sound can be attenuated by mechanisms of reflection,

Figure 3. Acoustic propagation is altered when sound waves encounter an impedance change (Z_1 to Z_2), that is, a change in the product of local speed of sound and mass density.

absorption, or scattering. Reflection is caused by impedance changes, whereas absorption and scattering occur due to the internal structure of the medium. Viscous forces cause sound absorption following Lambert–Beer–Bouguer’s law

$$dI = -\beta I dx$$

$$I(x, \beta) = I_0 e^{-\beta x} \quad (9)$$

$$p(x, t) = p(x = 0, t) \cdot e^{ikx \pm ct + ik_i x}$$

where k_i is imaginary, and therefore $p(x, t)$ decays exponentially for $x > 0$. In general, acoustic waves in medical imaging are attenuated by traveling through layers of different tissues due to reflection and also due to attenuation inside tissue. Typical acoustic attenuation in biological tissues is of the order of $0.1\text{--}1.0 \text{ dB MHz}^{-1} \cdot \text{cm}^{-1}$, that is, a acoustic wave of 1MHz center frequency, which travels 0.5 cm deep into tissue (1 cm round trip), is diminished by 0.1–1.0 dB, or its amplitude is reduced by ~1–11%. However, a 2.25 MHz wave penetrating the abdomen to a depth of 15 cm at $0.7 \text{ dB MHz}^{-1} \cdot \text{cm}^{-1}$, will be amplitude attenuated by 47.25 dB or 99.6%. Good ultrasound systems have signal to noise and amplification capabilities up to 120 dB, and therefore allow penetration to a reasonable depth at megahertz frequencies. Typical frequency selections are 7.5–15 MHz for 1–3 cm depths and 2.25–3.5 MHz for 12–15 cm depths.

Pulse–Echo

Most medical imaging via ultrasound uses a pulse–echo method to obtain images. That is, sound waves are transmitted into the body and echoes from within the body are registered, and their origin is computed using complex algorithms. Pulse–echo is somewhat unique to ultrasonic imaging. Other modalities use transmission (X ray and CT) or register preexisting radiation from within the body (PET, SPECT).

Multiple transmissions at the same physical location can reveal the motion of targets. A fundamental assumption is the speed of sound in the investigated volume. Typically, water is assumed to be $1485 \text{ m} \cdot \text{s}^{-1}$, and human tissue varies between 1450 and $4080 \text{ m} \cdot \text{s}^{-1}$ (see Table 1), with an average soft tissue value of $1540 \text{ m} \cdot \text{s}^{-1}$ (6). In general, the speed of sound is inversely related to the compressibility K ($\text{m}^2 \cdot \text{N}^{-1}$) and mass density ρ ($\text{kg} \cdot \text{m}^3$)

Table 1. Speed of Sound in Various Human Tissues^a

Tissue	Mean Velocity, m · s ⁻¹	Tissue	Mean Velocity, m · s ⁻¹

of the host medium:

$$c = \frac{1}{\sqrt{\rho K}} \quad (10)$$

Figure 4 shows the radio-frequency (rf) data for three firings at a set of moving targets. In this depiction, one can assume that the firings shown in a–c occur at a 1 ms interval. As time progresses, the scatterers move farther away from the transducer. At (a) the particles are $1/2 \cdot 26 \mu\text{s} \cdot 1485 \text{ m} \cdot \text{s}^{-1}$, that is, 19.3 mm, away from the transducer; in (b) the particles shifted to $1/2 \cdot 32.5 \mu\text{s} \cdot 1485 \text{ m} \cdot \text{s}^{-1}$, that is, 24.1 mm, away from the transducer. This shift of $6.5 \mu\text{s}$ or 4.8 mm is related to the interfiring time referred to by either pulse repetition interval or frequency (PRI or PRF). A PRI of 1 ms leads to the conclusion that the set of particles is moving at a speed of $4.8 \text{ m} \cdot \text{s}^{-1}$.

ULTRASOUND GENERATION

Physics

Sound is produced by anything that moves in an accelerated fashion. Nowadays, most practical materials are piezoelectric, such as quartz (SiO₂), polyvinylidene fluoride (PVDF), and lead zirconate titanate (PZT). Piezoelectricity is an effect that is associated with the crystalline structure of the materials. A piezoelectric crystal yields a voltage across its surface when under strain, and the reverse effect facilitates mechanical oscillations of the crystal in response to an alternating current (ac) electric field applied across its surface.

Transducer Construction

Ultrasound transducers are made from piezoelectric materials, as described above. Typically, a layer of material is

Figure 4. A set of three particles in water moves away from the ultrasound transducer during a set of three transmissions and receptions. (a) At time $t = 0 \text{ ms}$ the first backscatter signal of the set is received after $26 \mu\text{s}$. (b) For the second acquisition the first backscatter is received at 32.5 and $39 \mu\text{s}$ at (c). Signal travel time is directly related to travel distance by means of the speed of sound.

used to create a surface area for creation and transmission or reception of ultrasonic waves. The thickness of this layer is a function of the material properties and the desired acoustic frequency. As seen in Fig. 3, acoustic waves are reflected by impedance changes. An oscillating layer of piezoelectric material produces mechanical waves that propagate in the oscillation direction. These waves can be either compressional or shear waves. Here, the focus will be on compressional waves. Constructive interference of waves launched or reflected from the front surface and from the back surface of the crystal yield maximum pressure generation. High frequency transducers are made from very thin crystals due to their short wavelength and low frequency transducers are made from larger thickness crystals. For example, a 4 MHz transducer can be made from a 0.55 mm thick crystal. Table 2 lists the speed of sound in PZT_{5A} as $4400 \text{ m} \cdot \text{s}^{-1}$. The wavelength in PZT_{5A} at 4 MHz is 1.1 mm. Transducer crystals are typically machined to a thickness of $\lambda/2$, that is, 0.55 mm for 4 MHz. The rationale for this thickness is in the constructive interference of acoustic waves inside of the crystal. Figure 5 shows the bottom of the crystal moving up and down. Mechanical waves will launch from this surface and travel to either side of it. Assume that the

The reverse effect is used to produce ultrasound; applying an alternating electrical potential across a piezoelectric crystal causes the crystal to vibrate along a given direction.

bottom side of the surface is facing air and that there is no sound transmitted into it. The sound wave traveling toward the top surface will be transmitted beyond that surface into the desired medium (e.g., tissue).

Reflected waves will travel downward and interfere with upward traveling waves. Moreover, reflected waves experience a phase shift of 180° . This is the reason that $\lambda/2$ is the required thickness and not λ .

Array Design. Modern clinical ultrasound imaging arrays are composed of hundreds of individual piezoelectric elements. Mostly these elements are arranged in a linear, 1D fashion, hence their name: linear arrays. The 3D in front of an imaging array are denoted axial, lateral, and elevational. Axial and lateral axes lie in the imaging plane, with the axial distance extending away from the transducer. The lateral axis is parallel to the transducer surface, inside the imaging plane, whereas the elevational axis extends perpendicular to the imaging plane. By convention, the origin is located at the transducer surface in the middle of the active aperture (see the section Acoustic Imaging). Each element may be rectangular with a fixed curvature for focusing in the elevational direction. Curvature as well as the elevational size of each array element determine the thickness of an image plane, which can be 1 mm. Typical element widths range from $\lambda_m/2$ to $3/2 \lambda_m$. The wavelength λ_m is the wavelength within the medium where the wave is launched. Arrays with element sizes of $\lambda/2$ or smaller are referred to as fully sampled. Element sizes are typically 0.5–1 cm in the elevational direction and hundreds of micrometers in the lateral direction. The size of the space between individual elements is called the kerf (Fig. 6) and it is meant to diminish acoustic crosstalk between adjacent elements. A major design criterion for arrays is the distance between the centers of elements, called pitch. This distance determines the location and amplitude of acoustic grating lobes. Variations in the pitch, either due to changes in kerf or element width cause the grating lobes to shift. Moreover, the total extent of the aperture is directly related to the full width at half the maximum (fwhm)

Figure 6. (a) Schematic of the piezoelectric elements of an array ultrasound transducer. Elevational curvature as well as spacing (white area, called kerf) between shaded elements is exaggerated. (b) Definition of geometric parameters: kerf, pitch, and aperture.

amplitude of the main lobe and the location of the side lobes. Equation 11 gives the fwhm of the main lobe and the angular position of the side lobes as well as grating lobes. Side lobes result from a transmit and receive aperture being small relative to the wavelength of the acoustic wave (λ/a), whereas grating lobes result from a steered and undersampled aperture, that is, an aperture with too few elements per wavelength.

$$\begin{aligned}
 \text{fwhm main lobe} & \quad \Lambda = \frac{aw}{p} \\
 \text{side lobes} & \quad \theta_s = \arcsin \frac{\lambda n}{a} \quad n \in N_0 \\
 \text{grating lobes} & \quad \theta_g = \arcsin \frac{\lambda n}{p}
 \end{aligned} \quad (11)$$

The consequence of improper selection of pitch and kerf for a given frequency is illustrated in Fig. 7a. At an imaging depth of 10 cm one can see a main lobe of almost 3 mm fwhm and strong side lobes and grating lobes. In this case the ratio of λ to element pitch is 0.4. For a ratio of λ to element pitch of 1.6, the width of the main lobe is 1.2 mm and the side lobes are mostly suppressed (Fig. 7b). Moreover, the grating lobes have disappeared when the ratio of λ to element pitch is increased.

High spatial resolution imaging is achieved by a proper selection of these geometry factors. Of additional importance to the acoustic field pattern are acoustic output, field of view, and practicality. The smaller the actual radiating area, the lower the acoustic pressure in the generated field. Moreover, a large pitch and/or element width will, for a given number of elements, cause the active aperture to increase in size, which limits the possible shift of the active aperture across the physical aperture of the array (see the section Acoustic Imaging). A

Figure 7. (a) Four elements ($200\ \mu\text{m}$ kerf, $1000\ \mu\text{m}$ pitch) using 4 mm aperture, yield a main sound lobe width of 2.8 mm fwhm. (b) Forty elements ($50\ \mu\text{m}$ kerf, $250\ \mu\text{m}$ pitch) using 1 cm aperture, cause the main lobe to narrow to 1.2 mm fwhm and the sidelobes and grating lobes to diminish. Half maximum corresponds to -6dB .

large number of elements is beneficial for focusing and field geometries, but it is physically difficult to electrically wire a substantially larger number of elements. Furthermore, it directly increases costs, since each element requires cabling and multiplexing electronics. Channels with transmit and receive electronics are in general multiplexed to the physical elements. The complications involved with cabling hundreds or thousands of elements as well as the challenge of real-time data acquisition of a large number of channels are directly related to the still limited usage of two-dimensional (2D) imaging arrays. A good introduction and very detailed overview can be found in Shung and Zipparo (16), as well as Angelsen et al. (1,17).

Acoustic Fields. Acoustic fields of transducers can be analytically derived from basic principles. Logically, this derivation originates at the sound source, a moving object or surface. Its motion and surface shape/orientation define the so-called source strength Q (Eq. 12). Using this source strength one can compute the actual pressure field at a distance r from the source. In order to do so, it is necessary to derive the fact that for all simple geometries, the ratio of source pressure P_1 to its source strength Q_1 and the ratio of a second source pressure P_2 to its source strength Q_2 are equal at the same distance (assuming the same frequency). However, the derivation of this equality is beyond the scope of this text. The pressure of a circular piston can now be written as a function of its source strength, as well as the pressure and source strength of a known source, typically a small sphere. Equation 13 gives the analytical expression for the pressure field of the piston transducer, where r is the distance of the observation point from the center of the aperture, θ is the angle between the axis extending perpendicularly

from the center of the transducer and the line from the center to the observation point, t is time, ρ is the mass density of the surrounding water, c is the speed of sound in water, U_0 is the sound particle velocity on the aperture, and ω and k are angular frequency and wave number, respectively. The integral is simplified for circular geometry and taken over the entire surface of the transducer's aperture. In *real world* simulations, one could take into account that the circumference of the aperture might be clamped or for other reasons not be able to oscillate with the same amplitude as the center of the aperture. To do so, one would keep U_0 inside the integral as a function of radius or even radius and in-plane angle of the aperture.

$$Q = \int_S (\mathbf{u} \cdot \mathbf{n}) dS \quad (12)$$

$$\frac{P_1}{Q_1} = \frac{P_2}{Q_2} \Rightarrow P_p = \frac{P_s}{Q_s} Q_p$$

$$P_p = \frac{\rho c}{-i2\lambda r} \int_S (\mathbf{u} \cdot \mathbf{n}) dS \quad (13)$$

$$P_p(r, \theta, t) = \frac{i\rho c U_0}{r} e^{i\omega t} \int_S \frac{e^{-ik\sqrt{r^2+s^2}}}{\sqrt{r^2+s^2}} 2\pi s ds$$

After deriving the general pressure field, one can compute special cases that are of particular interest, such as the central axis, as well as the far-field angular distribution of the radiation pattern. Further simplification of Eq. 13 yields approximate expressions for both cases and plots are shown in Fig. 8.

$$p(r, 0, t) = \rho c U_0 \left(e^{-ikx} - e^{-ik\sqrt{x^2+a^2}} \right) e^{i\omega t} \quad (\text{central axis})$$

$$p(r \gg a, \theta, t) = \frac{i\rho_0 c U_0}{2r} a(ka) e^{i(\omega t - kr)} \frac{2J_1(ka \sin \theta)}{ka \sin \theta} \quad (\text{far field}) \quad (14)$$

From the axial dependence one can see strong interference for locations close to the transducer surface. This region is called near the field or Fresnel region and it extends approximately $r = 4$ aperture diameters a away from the transducer. Beyond that point, the pressure falls off following a $1/r$ dependence, and this region is called the far field or Fraunhofer region. As a rule of thumb, the far field starts at $a^2(2\lambda)$. Imaging is impractical or impossible in the near field. However, one should keep in mind that this result is true only for a *single* element transducer, and subdividing the aperture into an array of small elements shifts the near-field–far-field transition toward zero based on the actual dimension of the array. Moreover, this transition point is also a function of the emitted frequency as represented by angular frequency and wave number in Eq. 13 and 14. For illustration purposes, a ka value of 8π was chosen for Fig. 8a. When plotting the angular field pattern in Fig. 8b. However, $ka = 4\pi$ was chosen to reduce the number of sidelobes and make the plot more readable. Similarly to Fig. 7, a strong main lobe and additional side lobes are evident in Fig. 8b, that interfere with the main lobe in the sense that appreciable sound will be detectable in nearly all directions. In fact, for this particular example echo amplitudes

Figure 8. Acoustic field of a circular single element ultrasound source (transducer). (a) The axial transducer response can be divided into near field and far field, with an asymptotic $1/r$ dependence for large r . Phase interference is dominating in the near field. (b) Angular radiation patterns are described by the Fourier transform of the aperture function. A circular piston transducer yields a function that is defined as a Bessel function of the first type divided by its argument $[J_1(x)/x]$.

60–70° off the center axis will be only 50% lower than the main lobe. Note that this example is for educational purposes and is not at all a suitable design for imaging. Aperture sizes and frequencies as shown in Fig. 7, where a narrow and dominant main lobe can yield lateral and elevational spatial selectivity and time range gating, can yield depth information. In general, radiation patterns can be derived as Fourier transforms of the emitting aperture. Circular apertures are described by Bessel functions of the first type divided by their argument, that is, $J_1(x)/x$. For rectangular apertures the sine function $[\sin(x)/x]$ directly describes the field.

ACOUSTIC IMAGING

Ultrasonic imaging yields 2D images. Pixel columns represent the lateral extent and rows of pixels display reflections of the transmitted acoustic waves from progressively deeper tissues within the body.

The most rudimentary way of obtaining lateral image data is done by using a single element transducer and wobbling it back and forth over a chosen sector. The most elegant way is to use an electronically controlled array of very small transducers and scanning and or steering an imaging beam across the region of interest. The former

method is rarely used anymore. The latter method is the modern standard for ultrasonic imaging of single image planes and a few clinical scanners are even already available for 3D image acquisition of steered elevational image planes.

Depth information is encoded in the time that an acoustic wave takes to travel to a tissue site and back to the transducer. Transmitted sound can be received after a theoretically predictable wait time (see top section of Fig. 9). Such prediction requires the knowledge of the speed of sound along the traveled path. Unfortunately, an assumption of $1540 \text{ m} \cdot \text{s}^{-1}$ for soft tissue is not always precise. Various tissues in the human body differ from each other in terms of their specific speed of sound. When performing abdominal scans, aberration distortions can become significant due to the change in the speed of sound between connective tissues, fat layers, muscles, and abdominal organs. Other anatomical sites that provide difficulties for ultrasonic imaging include the human brain

Linear array: small parts, superficial vascular, obstetrics

Curved array: abdominal, obstetric, transabdominal, or for transvaginal or transrectal, or pediatric imaging

Phased array: heart, liver, spleen, fontanelle, temple

Figure 9. Transducer geometries include (curved) linear arrays and phased arrays. Linear arrays transmit and receive acoustic beams perpendicular to their surface area, whereas phased arrays steer the acoustic beam by a phasing scheme (Fig. 10).

and the heart. Fortunately, for newborns and infants ultrasound can be used to image the brain. Using a phased array (see bottom section of Fig. 9), pediatricians can image the brain directly through the fontanelle, which provides enough acoustical access for imaging. Premature newborns tend to have bleeding in the brain and develop larger ventricles, both of which can be imaged very easily through the fontanelle. However, when this acoustic access window closes, it is very difficult if not impossible to use ultrasound to image the brain. In adults, the temple fissure can be used to image (using a phased array Doppler system at 2.25 MHz) the germinal matrix near the foramen of Monroe. However, transcranial Doppler requires some guesswork on the orientation of vessels. Because of the limited access via the temple fissure, only small aperture and low frequency arrays with sub-optimal imaging capabilities can be employed.

The simplest imaging device is a linear array (range of transducer frequencies: 3–12 MHz). As its name suggests, this type of transducer has a linear arrangement of individual transducer elements. Images from a linear array are generally rectangular, and the image width corresponds to the width of the array. A set of adjacent elements (a subaperture) is used to fire a single image line or a portion thereof. Figure 10 shows how a subaperture can be used to steer and focus a beam. On the left side of each drawing, single sinusoids symbolize the electrical signals being used to excite the individual transducer elements (thick-lined vertical bars) of the array. After excitation an elementary spherically spreading wave launches from each element. Appropriate delay times applied to each electrical signal allow the ultrasound scanner to steer and focus the emitted wave front.

Additional wave conditioning includes amplitude shading of the subaperture. Typically, Gaussian-type functions or approximations thereof are used to weaken the transmit power for the outer most elements of a subaperture. The process is called apodization and yields lower side lobes since the side lobes are related to the Fourier transform of the aperture function. A gaussian apodization will result in a gaussian envelope for the side lobes, whereas no apodization (i.e., a constant amplitude excitation) would yield a sinc function $(\sin(x)/x)$ side lobe envelope.

Figure 10. Delaying or advancing the phase of waves emitted from neighboring elements relative to the center element can achieve focusing and steering of the acoustic wave front.

To render an image, a subaperture is formed and linearly moved through the whole physical aperture. A major drawback of this imaging scheme is the dead time of the scanner, which occurs while waiting to receive the backscatter from the maximum depth. Fifteen centimeters of penetration require a wait time of at least (two fold for the round trip time):

$$t = \left[\frac{0.15 \text{ m}}{1540 \text{ m} \cdot \text{s}^{-1}} \right] \times 2 = 200 \mu\text{s}$$

In addition to this delay, some additional wait time may be required to suppress echoes from even larger depths. Image lines might be separated by 250 μm. For a physical aperture of 5 cm, for example, one has to transmit and receive 201 scan lines, which is equal to a time of 200 μs * 201 lines, that is, 40.2 ms per one full frame or a frame rate of 25 Hz. This frame rate seems reasonable, but one has to keep in mind that no extra wait time was added nor any other imaging overhead such as occurs during blood flow imaging using Doppler.

Nonetheless, if one takes into account the finite lateral width of a transmitted wave, one can subdivide the total image width into independent image segments in which beams can be fired simultaneously, or at least with minimal delay (see Fig. 11). Therefore an aperture of 5 cm could eventually be imaged with five simultaneous beams or a five-fold higher frame rate. Such high frame rates allow real-time ultrasonic imaging of the body and additional overhead, such as is mentioned above for Doppler or multi-zone focusing. This type of focusing is used when a large depth image would cause the acoustic beam to diverge too much before and after the focal point. By firing the same image line two, three, or four times, the same number of foci can be formed for tighter acoustic beams at larger depths or for shallow regions. This scheme will work to the limit that the beams are not overlapping, that is, there is no signal coming from adjacent image lines.

Other imaging modalities, such as X ray, do not suffer from slow acquisition time due to low wave speeds. Another method to overcome the speed of sound limitation is the use

Figure 11. Interleaving scheme for image data acquisition. By minimizing the segment separation d , a maximum of L/d semisimultaneous transmit and receive zones can be achieved. The beam shape determines the smallest value of d , such that no overlap between adjacent firings will occur.

of *synthetic aperture* imaging. This method is already used in astronomy. Instead of 201 firings for 201 image lines, only one transmit is fired, and only one receive is recorded. Image reconstruction and especially spatial resolution will be computed/extracted from received data by extensive postprocessing. This scheme does not yield as much detailed backscatter data; however, it does yield very high frame rates. If only the speed of sound is limiting the data acquisition, then for the above example, the frame rate will increase by a factor of 201. Only the vast processing power of current computers makes synthetic aperture imaging possible. Typical applications for this type of image formation include full screen flow imaging, 3D, or 4D imaging (see respective subsections).

Other types of arrays include curved arrays and phased arrays which are popular for scans that require a larger image width then can be achieved by simply extending the physical aperture. Curved arrays, as seen in Fig. 9, form sector images. Because of the shape of the aperture, a relatively wide image can be achieved using a smaller footprint aperture. Scan lines are no longer parallel to each other but form a fan beam arrangement with field of view angles of up to 85° (150° for some endocavitary arrays). Typical bandwidths range from 2–8 MHz, which is a lower range than for linear arrays since this type of probe is intended for large penetration depths where frequency dependent attenuation prohibits very high frequencies. The use of nonionizing radiation to achieve real-time imaging with large fields of view makes these probes ideal for abdominal interoperative guidance of, for example, biopsy needles or radiofrequency (RF) ablation tumor treatments. These features are also ideally suited for obstetrics (see Fig. 12).

Phased arrays are also designed to form sector images. Contrary to curved arrays, where the natural shape of the

Figure 12. B-mode image of a fetus at the end of the second trimester (cross-sectional sagittal view). Low backscatter amniotic fluid is surrounding her head and upper body. The video reveals that the embryo is sucking her thumb. A curved array was used in this obstetrics exam.

physical aperture provides the basis for the sector shape, phased arrays steer the beam to form the image. As illustrated in Fig. 10, specific timing delays for the subaperture can not only focus to a specified depth, but also steer the beam in the lateral direction. Large fields of view can be achieved this way, but the development of increased side and grating lobes are a trade-off. Anatomical locations with small diameter access to larger distal regions can be imaged with this type of ultrasound array. For example, temple access can be used to image the frontal brain, and extension of the carotid artery above the jaw line is possible. Cardiac imaging typically relies on phased arrays due to acoustic shadowing from the rib cage, where one needs to image between narrowly spaced ribs in order to interrogate the much larger sized heart chambers.

B-Mode

B-mode is one of the most commonly used operation modes of a clinical ultrasound scanner. As explained earlier, ultrasound is a reflection or scattering based imaging modality, and the sophisticated generation of a sound wave allows the focusing of the sound to a specific location. Each transmission yields one scan line around the targeted focal point. If only one focal point is selected, one scan line extends over the total depth range, which is user defined in the current imaging settings. In order to record a full image frame using a linear array, the imaging software of the scanner electronically moves the active aperture of the array across the physical aperture to transmit and receive at a given line density. Typically, hundreds of scan lines are generated this way and displayed on a monitor. Figure 12 shows the cross-sectional sagittal (front to back, vertical slice) image of a fetus *in utero*. She is sucking on her thumb, as real-time video reveals. On the left of Fig. 12 one can see the head and the strong reflection of the skull bone. The very left side of the image is black, an artifact that could be due to maternal bowel gases that scatter the sound away from the transducer. The remainder of the skull is clearly visible from the forehead to the chin and from the back of the head to the neck area. Bones reflect sound waves well and result in a bright signal in the image. The black surroundings of the fetus are regions of amniotic fluid, which does not scatter sound due to the homogeneous nature of the fluid.

In front of the mouth, one can see the hand of the fetus. Once again the bones of the hand, namely, the knuckles, are pronounced since they scatter more ultrasound than the soft tissue of the hand. In the same fashion one can see the reflections of the spine.

M-Mode

M-mode (also called motion-mode imaging) does not yield full frame images per se, but rather one selected image line is rendered as a function of time. This is used for displaying motion of, for example, the periodic movement of heart valves. Any abnormalities or temporal variations can be directly seen as an image on the screen. The B-mode cross-section of a carotid artery is shown in Fig. 13a. Proximal and distal vessel wall delineates the dark vessel interior, as indicated by the arrows to the right.

Figure 13. a. Longitudinal cross-section of carotid artery. The pixels along the vertical white line in (a) are plotted in (b) as a function of time. Black arrows indicate the proximal and distal vessel wall. Such walls are in motion as blood is pumped through the vessel in a pulsatile fashion. The repetitive pulsatile wall motion can be seen in the M-mode image in (b).

In a M-mode representation in Fig. 13b, pixels along the white vertical line in (a) are repeated parallel to each other over time. Figure 13b shows 5 s of repeated scans. For each heart beat a pulsatile wave travels through the arterial blood pool locally expanding the blood vessels. This expansion can be seen in B-mode as well as in M-mode representation. However, in B-mode it is an event in time occurring over several image frames, whereas in M-mode this event is plotted as the horizontal axis and therefore easy to detect. White arrows in Fig. 13b indicate the temporal expansion of the blood vessel. Figure 13c shows a much more pronounced motion. The transducer was pointed toward the heart and is therefore either imaging the heart wall or one of the heart valves, showing the typical cardiac pattern.

Doppler Imaging

Acoustic transmission of multiple beams along the same line can reveal temporal changes in the human body. As seen in Fig. 4, pulse echo fringes in a rapid fashion can track flow, as well as flow changes in time. A more formal

Figure 14. Illustration of Doppler imaging of a blood vessel.

derivation of the mathematical framework shall follow here.

Assume a vessel that is imaged at some angle α , which has acoustic scatterers such as red blood cells flowing at speed $v(r, t)$, as is depicted in Fig. 14. A recorded acoustic echo has an amplitude, frequency, and phase ($\alpha \cdot e^{i(\omega t + \phi)}$). The measured phase is the sum of temporal and spatial phase components. The first term $\omega \Delta t$ in Eq. 15 changes in time with ω and the second term changes in time with the velocity $v(t)$ of flowing red blood cells. Flow speed $v(t)$ and direction α ($\cos \alpha$) determine the magnitude of the measurable phase shift. Due to the $\cos \alpha$ term, any displacement that occurs parallel to the aperture will not be detected.

$$\Delta\phi(\Delta t) = \omega\Delta t - 2\pi \frac{v(t)\cos\alpha\Delta t}{\lambda} = \omega\Delta t \left(1 + 2\frac{v(t)}{c} \right) \quad (15)$$

It is assumed that the time between firings Δt is small enough that the scatterer does not move out of the main lobe of the beam pattern (Fig. 7). Moreover, it is assumed that $v(t)$ is constant during Δt . The absolute and relative received Doppler shift frequency can be directly derived from the change in phase, as the temporal derivative of the phase angle (Eq. 16).

$$\begin{aligned} f_{\text{receive}} &= \frac{1}{2\pi} \frac{\partial}{\partial t} \Delta\phi(t) = \frac{\omega}{2\pi} \left(1 + 2\frac{v_i(t)}{c} \right) \\ &= f_{\text{transmit}} \left(1 + 2\frac{v_i(t)}{c} \right) \\ \Rightarrow \frac{f_{\text{receive}}}{f_{\text{transmit}}} &= \left(1 + 2\frac{v_i(t)}{c} \right) = \left(1 + 2\cos\alpha \frac{v(t)}{c} \right) \end{aligned} \quad (16)$$

In the following example, a simulated scatterer is imaged and its traveling speed is measured. In the computation, the scatterer is travelling away from the imaging array from an axial distance of 2.50–2.52 cm, that is, 200 μm . On that path, the scatterer is imaged 32 times, once every 0.36 ms. Its speed is 2 $\text{cm} \cdot \text{s}^{-1}$. Figure 15a displays the backscatter of a scatterer as shown in Fig. 4, except that only one scatterer is imaged. Thirty-two

Figure 15. Doppler processing for velocity estimation. (a) Shows stacked (slow time) backscatter signals (fast time) of a moving scatterer. Complex analysis of such signals reveals the change in phase of the backscatter signal (b), and subsequently the scatterer velocity can be computed (c).

backscatter signals are stacked vertically, and the ordinate is labeled with the time at which the signal was measured (“slow” time in ms), whereas the abscissa shows the time frame of the measured radiofrequency signal (“fast” time in μ s) same as in Fig. 4. This arrangement of backscatter data is very similar to that used in M-mode imaging. Signal amplitude is displayed as gray scale with gray for zero, black for negative amplitudes, and white for positive amplitudes. Two major steps are performed in order to estimate the velocity of the scatterer from the backscatter signal. At first the signal $f(t)$ is transformed into a complex valued signal $f^*(t)$ by performing a Hilbert transform (Eq. 17). Measured signals are always real valued quantities. However, for computational purposes it is desirable to have complex valued data $f^*(t)$. This step allows us to directly measure the phase of the backscatter signal and yield the velocity of the scatterer after basebanding, which is the second step.

$$f^*(t) = \frac{1}{\pi} P \int_{-\infty}^{\infty} \frac{f(\tau)}{t - \tau} d\tau \quad (17)$$

$$= \frac{1}{\pi} \lim_{\epsilon \rightarrow 0^+} \left(\int_{-\infty}^{t-\epsilon} \frac{f(\tau)}{t - \tau} d\tau + \int_{t+\epsilon}^{\infty} \frac{f(\tau)}{t - \tau} d\tau \right)$$

Basebanding is a mathematical procedure used to remove the carrier frequency, the main transmit frequency, from a rf-signal. For a complex valued signal, $f^*(t)$, this is done by multiplying the signal with a complex harmonic of the same, but negative frequency ($-\omega_0$) as the carrier to obtain the complex valued envelope or amplitude modulation $a(t)$ and the phase ϕ (Eq. 18).

$$f^*(t)e^{-i(-\omega_0)t} = a(t)e^{i\phi(t)} \quad (18)$$

The phase is constant for each rf line in tissue, but varies between firings as targets, such as red blood cells, move. Figure 15b shows the phase of the basebanded signal and therefore the position of the scatterer. At ~ 7.5 ms, the phase wraps from $-\pi$ to $+\pi$ and continues

to decrease. This phase wrap was detected and unwrapped before computing the velocity as proportional to the derivative of the phase. This phase unwrapping is not performed in clinical ultrasound scanners. Rather one will see flow of the opposite direction being displayed on the screen as the Doppler processing unit concludes that the sudden increase in phase from $-\pi$ to $+\pi$ must be due to flow in the opposite direction. This artifact is called aliasing and is typically avoided by increasing the pulse repetition frequency (PRF), that is, the rate at which Doppler firings are repeated along the same scan line in order to track backscatter from blood cells. Inverting Eq. 16 for $v(t)$ and using data processed via Eq. 17 yields the flow velocity as given in Eq. 19. A comprehensive description of medical Doppler and Doppler physics can be found in and McDicken and Evans (18).

$$v(\tau) = \frac{c}{2\omega_0} \frac{d}{d\tau} \phi(\tau) \quad (19)$$

Pulse Wave Doppler. Pulse wave Doppler (PW Doppler) is used for measuring blood flow. The user can position a Doppler scan line and Doppler window to any location within the B-mode image, as seen in Fig. 16. The two short horizontal lines at a depth of 6.9 cm in the top B-mode image in Fig. 16 represent the sample volume. This is where the Doppler data is acquired. Typically, the beamformer of the scanner is set to the same sample volume location for transmit and receive. The axial size of this window can be adjusted and is displayed on the screen (here 2 mm, see Size in the right side data column of Fig. 16). Changes in the window’s size will affect the duration of the transmitted tone burst cycles. Commonly scanner software adjusts the duration of the transmit pulse to be twice as long as the chosen sample volume. Additionally, an angle (α) can be selected along which a blood vessel is oriented (here 0° , for example, along the Doppler scan line). As shown in Fig. 14 and Eq. 16, the measured flow

Figure 16. Pulse wave Doppler example. See text for more description.

velocity is only the projection of the actual flow vector onto the acoustic beam, which results in a $\cos \alpha$ term. By manually choosing the correct α , the actual flow velocity can be computed and displayed from the measured flow.

The bottom part of the screen image in Fig. 16 shows the temporally resolved blood velocity, where the abscissa represents time (here, a total of 5 s), and the ordinate represents velocity (here, from -30 to $+30 \text{ cm} \cdot \text{s}^{-1}$).

Traditional processing computes the power at each frequency and subsequently the associated velocity, as outlined in Eq. 20.

Here the phase ϕ of the basebanded backscatter signal $a(t)e^{i\phi(t)}$ is digitized along the slow time scale (ms). Fourier analysis is used to determine the frequency or rate of change (ω_n) of the phase $\phi_n = \phi(t_n)$. More precisely, the so-called spectral power $P(\omega_n)$ at each frequency ω_n is computed by Fourier analysis. This quantity yields how much contribution to the power there is for a given rate of change or speed v_n . These two quantities $P(\omega_n)$ and v_n are plotted in the velocity graph in Fig. 16 (lower plot). The gray level for a given point in the graph is determined by $P(\omega_n)$, whereas v_n or ω_n and the time t determine the location of the pixel. The indicated cardiac cycle in Fig. 16 shows contributions from high velocities that yield high Doppler frequencies. At the end of this cycle the blood flow slows down and contributions to high frequencies diminish and formerly white pixels are now plotted in black. Other operations such as windowing of the phase signal ϕ_n are neglected here for simplicity.

$$\begin{aligned} f^*(t)e^{-i(-\omega_0)t} &= a(t)e^{i\phi(t)} \\ P(\omega_n) &= \left| \sum_n \phi_n T_n e^{i\omega_n n} \right|^2 \\ v_n(t) &= \left(\frac{\omega_n(t)}{\omega_0 T_{rep}} \right) \left(\frac{c}{2} \right) \cos \alpha \end{aligned} \quad (20)$$

Color Flow Doppler. Color flow Doppler allows the user to see a 2D map of flow in the current B-mode image. Instead of measuring flow only along a single scan line as in Pulse wave Doppler (PW Doppler), all lines inside a chosen region of interest (ROI) are fired repetitively (4–16 times) and analyzed for flow. Velocity resolution and frame rate are limited due to the large number of acoustic transmissions and the computational burden of analyzing the resulting received waveform data. In the same fashion as in B-mode, interleaved imaging can be used to counterbalance the reduction in frame rate caused by the necessary increase in (Doppler) scan lines (see Fig. 11).

In Fig. 17, one can see a regular B-mode image of a carotid artery, extending from the left to the right side of the image, parallel to the transducer face. The gray scale B-mode image is overlaid with Doppler information inside a user-defined color flow box, which is either a rectangle or a parallelogram slanted either to the left or right. For this specific example, a rhomboid with 20° rightward steering was used in order to measure the velocity of blood flow. One should remember that vessels parallel to the transducer do not yield a Doppler or phase shift and therefore can not be identified with Doppler methods. However, a 20° rightward steering provides enough angle deviation to measure flow

Figure 17. Color flow example showing blood flow in the carotid artery. The color data (here in gray scale) encodes magnitude and direction of flow. A color bar allows the quantitative conversion to actual speed, here a maximum of $\pm 23 \text{ cm} \cdot \text{s}^{-1}$.

and to display velocities everywhere in the chosen color flowbox. Ultrasonic waves are transmitted parallel to the slanted rhomboid.

Typically, blood flow is encoded from dark red to red to yellow when it is approaching the transducer, indicating low, moderate, or high velocities, respectively. Alternatively, it is colored in shades of blue to cyan when it is moving away at low to high speed. The maximum detectable velocity magnitude is directly related to the PRF used. A PRF of 2.4 kHz was chosen in the example shown, resulting in a maximum detectable velocity of $\pm 23 \text{ cm} \cdot \text{s}^{-1}$. Note that the PW Doppler example in Fig. 16 used a 4% greater PRF but allows a 30% greater velocity range. This is related to the greater burst length used in PW Doppler (15–20 cycles) compared to CF Doppler (2–6 cycles) and the subsequent data processing. The PW Doppler is designed for high velocity resolution and simultaneous temporal resolution, whereas CF Doppler is designed for great spatial resolution. Moreover, one should notice the very low backscatter level of blood relative to the surrounding tissue, which can be as much as 40 dB below that of soft tissue. The blood vessel in Fig. 17 appears black relative to the tissue on the proximal and distal side of it.

As mentioned above, CF Doppler demands not only more acoustic transmissions, but also more computing power to estimate the actual flow velocities from the measured acoustic backscatter. This imaging modality became practical when Kasai et al. (12) succeeded in designing a method (see Eq. 21) by which the mean Doppler frequency, that is, the mean velocity in every pixel, could be computed in real time by cross-correlations of the quadrature components, I and Q , of the analytic (complex) backscatter signal. Quadrature components I and Q are obtained by mixing the rf-signal at the hardware level with $\sin(\omega_0 t)$ and $\cos(\omega_0 t)$. This corresponds to the complex base banding given in Eq. 18, since $e^{-i\omega t} = \cos \omega t - i \sin \omega t$. It follows that I and Q are the real- and complex- valued parts of the

basebanded signal, $a(t)e^{i\phi(t)} = I + iQ$.

$$\phi = \frac{\sum_{n=1}^{N-1} Q[n]I[N+n] - I[n]Q[N+n]}{i\sum_{n=1}^{N-1} Q^2[n] + I^2[n]} \quad (21)$$

$$\bar{v} = \frac{c}{2\omega_0 T_{rep}} \arctan \phi$$

Power Doppler

The previous two methods of flow quantification suffer from a lack of good flow detection. In perfusion studies, it is often necessary to detect very small amounts of flow volume travelling through capillaries at velocities of the order of $1 \text{ mm} \cdot \text{s}^{-1}$, which is $\sim 0.1\%$ of the speed observed in the carotid artery. In order to overcome the poor sensitivity of PW and CF Doppler, power Doppler displays the integral of the power spectrum $P(w)$, shown in Eq. 20. Typically, the integration value is also averaged over a very long period of time (several heart beats). Averaging at least one cardiac cycle results in a nearly constant value for flow. Physically, this value represents the amount of blood flowing, but not the velocity, since it is the integral of all detected velocities.

First, imaging capillary flow yet remains difficult, even in power Doppler mode, partially because blood cells do not scatter much of the transmitted acoustic signal. Small blood vessels, such as the capillaries, provide small fractional blood volume, which further decreases the total backscattered signal. Second, at $1 \text{ mm} \cdot \text{s}^{-1}$, flow velocities in capillary beds are difficult to differentiate from static soft tissue background at zero frequency shift, without being suppressed by the wall filter. This filter is used to prevent tissue motion from being incorrectly ascribed as real flow. In Fig. 17 flow that causes $< 71 \text{ Hz}$ frequency shift per Doppler firing is filtered out of the Doppler data to eliminate flow speeds of $< x \text{ cm} \cdot \text{s}^{-1}$.

The ultrasound machine transmits Doppler pulses every 0.42 ms (reciprocal of 2.4 kHz). Backscatter will contain phase shifts between $-\pi$ and $+\pi$, which corresponds to $+23$ and $-23 \text{ cm} \cdot \text{s}^{-1}$ flow speed.

The acoustic wavelength of the color Doppler (CF panel on the right side in Fig. 17) transmits equals 0.385 mm in tissue ($c = 1540 \text{ m} \cdot \text{s}^{-1}$, $F_{rq} = 4 \text{ MHz}$, $\lambda = c/F_{rq}$) and each firing is separated 0.42 ms (reciprocal of $\text{PRF} = 2.4 \text{ kHz}$). The Doppler electronics measures phase shift, therefore it can not measure more than a shift of 2π or $\pm\pi$. Two-pi corresponds to λ or $\pm\pi$ to $\pm\lambda/2$, hence the maximum detectable speed of $v = s/t = 45.8 \text{ cm} \cdot \text{s}^{-1}$, with $s = \lambda/2$ and $t = 1/\text{PRF}$. However this value does not match the displayed $23 \text{ cm} \cdot \text{s}^{-1}$. Doppler pulses work in pulse-echo mode, in which any displacement dx results in a time shift of 2-times dx/c . Finally the maximum detectable flow speed is given by equation 22. For a given wallfilter (WF) the minimal detectable flow is given by the ratio of the PRF to wall filter times the maximum flow, that is, $(2.4 \text{ kHz}/71 \text{ Hz}) * 23 \text{ cm} \cdot \text{s}^{-1} = 0.68 \text{ cm} \cdot \text{s}^{-1}$.

$$v = \frac{\delta s}{\delta t} = \frac{0.5 \cdot c / (2f)}{1/\text{PRF}} = \frac{0.5 \cdot 1540 / (2 \times 3.75 \times 10^6)}{1/2.4 \times 10^3} = 23 \text{ cm} \cdot \text{s}^{-1} \quad (22)$$

3D Imaging

Current ultrasound images are naturally 2D because ultrasound imaging arrays are only 1D. One-dimensional arrays are still predominant in the market. Even so, great efforts in the ultrasound community are pushing ultrasonic imaging toward 2D arrays. The transition from 1D to 2D is especially apparent in the naming scheme of current arrays:

- 1D: Is the classic linear or focused array, which has one row of elements that allows focusing and steering in the lateral imaging plane. The elevational focus is constant due to a fixed elevational curvature of each element.
- 1.25D: Extra rows of elements on either side of the main row allow changes in the elevational aperture, but there is no electronic elevational focusing, nor steering.
- 1.5D: This class of arrays has a 2D set of elements, where the elevational elements are connected symmetrically to the center row. This array can focus in the elevational direction but not steer.
- 1.75D: A 2D set of individually driven elements is available for this type of array, but the number of elements in the elevational direction is much less than in the lateral direction. Elevational focusing is possible, but only limited elevational steering is available.
- 2D: Elevational and lateral directions should be equivalent and indistinguishable for a true 2D array. Full apodization, steering, and focusing is possible in 3D. Currently there are some commercial systems that use 2D arrays particularly in cardiac imaging.

Hardware and software implementations allow the 3D reconstruction of a scanned volume even when using 1D arrays. Sophisticated 3D hardware position sensors allow ultrasound scanners to register the position and orientation of a 1D array in 3D space. Therefore, any acquired image in a set of many can be aligned with others in the set to render a 3D volume (see Fig. 18). However, these hardware additions are costly and can be inconvenient. Moreover, they might show limitations due to interference with electromagnetic fields or nearby metallic objects. Software solutions use correlations between adjacent image frames to determine the transducer translation or rotation. Figure 18 rudimentarily illustrates how individual frames taken in freehand fashion are “stitched” together to form a 3D volume, which can be rendered in various ways. Figure 19 shows an anatomical example of the bifurcation of the ascending carotid aorta rendered as a 3D volume. Some implementations on clinical scanners, however, already use the 4D nomenclature by adding time as the fourth dimension.

CONTRAST IMAGING

As in every other clinical imaging modality, agent based imaging enhancements are available for ultrasonic

Figure 18. Illustration of 3D image reconstruction. Sets of spatial misaligned images are stacked according to their spatial position and orientation and used to fill a 3D image volume. Afterward this volume can be read out in any slice plane direction or even rendered as a 3D volume, such as shown in Fig. 19.

imaging. However, a limited number of clinical applications is approved by the Food and Drug Administration (FDA). As of 2004, the only FDA approved application for ultrasound contrast agents is for cardiac procedures, and more precisely, for outlining the border of the heart chamber. Other countries or regions such as Europe and Japan have a variety of agents approved. However, considerable research has been performed on ultrasound contrast agents, and it is likely that more FDA approvals will follow in the future. Contrast agents are used to enhance ultrasound image quality; therefore, imaging techniques implemented in current ultrasound scanners will be described.

Figure 19. Three-dimensional reconstruction of the ascending carotid artery. This imaging mode uses 3D correlations and compounding to align individual images as the imaging array is swept across the vessel.

Moreover, the physics of contrast agents as well as their optimal clinical use will be discussed.

Clinical Background. Every year 135 million (Source: Amersham Health Inc. owned by GE Healthcare.) ultrasound scans are performed in American hospitals. Only 0.5% of these procedures actually use contrast-enhancing products. For example, better diagnosis of myocardial perfusion and better visualization of fine capillary-level vasculature will be possible when ultrasound contrast agents are certified by the FDA. Ultrasound is a relatively inexpensive imaging technique, and better diagnostic information can be obtained.

New contrast-agent-based ultrasound imaging modes include: Harmonic imaging, Pulse inversion (with harmonic or power mode), Microvascular imaging, Flash contrast imaging, as well as Agent detection imaging.

Enhancing Contrast. A major duty of ultrasound contrast agents is the improvement of ultrasound based image acquisition. The definition of contrast is given in Eq. 23, where I_1 and I_2 are the echo intensities before and after contrast administration, respectively. Even though this is a very simple formula, the mechanism for contrast improvement can be rather complicated.

$$\Lambda = \frac{I_2 - I_1}{I_1} \tag{23}$$

The key for contrast improvement for ultrasonic contrast agents lies in the physical principles of sound transmission, reception, and the nonlinear characteristics of bubbles themselves. For example, an increase in backscatter *amplitude* in the presence of contrast agents relative to the average human tissue backscatter level would improve the overall image. Furthermore, the creation of acoustic *frequencies* that occur in the backscatter signal of bubbles but not in the transmit signal nor in the backscatter of tissue, would provide a mechanism by which bubbles can improve the overall image. An important fact to keep in mind is that ultrasound contrast agents do not enhance the visibility of human tissue nor of blood, but the bubbles themselves can be visualized better than tissue or blood. Nevertheless, imaging perfusion of tissue or measurement of the amount of blood flowing through a vessel can be greatly improved by the usage of ultrasound contrast agents.

Modern Agents. Modern agents are not just gas bubbles. A sophisticated shell coating is used to prevent coalescence and reduce diffusion of the interior gas into the surrounding medium. This shell can be made of serum albumin. Lipids are also used as stabilizing agents. The gases filling the interior of the shell are chosen for low diffusion rates from the bubble into the blood stream as well as because of their low solubility in blood. Table 3 lists commercially available contrast agents. Currently FDA approved contrast agents include Imavist by Alliance Pharma/ Photogen, Definity by Bristol-Myers Squibb Medical Imaging Inc., Alunex by Molecular Biosystems, and Optison by GE/Amersham.

Table 3. Modern Ultrasound Contrast Agents^a

Manufacturer	Agent Name	Interior Gas	Shell Material
Acusphere	Al-700	Perfluorocarbon	Copolymers
Alliance Pharma. / Photogen	Imavist	Perfluorohexane, air	Surfactant
Bracco	SonoVue	Sulfur hexafluoride	Phospholipid
Bristol-Myers Squibb Medical Imaging, Inc.	Definity	Perfluoropropane	Lipid bilayer
	MRX-815-stroke	Perfluoropropane	Lipid bilayer
Molecular Biosys.	Albunex	Air	Albumin
	Oralex	Air	Dextrose
GE/ Amersham	Optison	Perflutren	Albumin
Nycomed Imaging AS	Sonazoid	Perfluorobutane	Lipid
Schering AG	Echovist	Air	Galactose
	Levovist	Air	Lipid layer
Sonus Pharma.	EchoGen	Dodecafluoropentane	Albumin
	SonoGen		Charged surfactant

^aSee Refs. 3,7, and 9.

Acoustic Bubble Response. Ultrasound contrast agents can be viewed as systems known as harmonic oscillators, with a given amplitude, phase, and frequency. Min-naert has derived Eq. 24, which gives the resonance frequency of a gas bubble as a function of its size. For example, a 3 μm radius (R_0) air bubble (adiabatic coefficient κ) in water (mass density ρ_L) under atmospheric pressure P_0 has a resonance frequency f of 1.1 MHz (Table 3). This is a very fortunate relationship since capillaries of the human circulatory system are as small as 8 μm in diameter and typical clinical frequencies used are 1–10 MHz.

$$f(R_0) = \frac{1}{2\pi} \frac{1}{R_0} \sqrt{\frac{3\kappa P_0}{\rho_L}} \quad (24)$$

The amount of acoustic scattering of the bubble surface (scattering cross-section σ_S) is described by the Rayleigh equation. This equation is used for scatterers that are small (μm) relative to the acoustical wavelength used (mm). For gas bubbles in water, the Rayleigh equation can be written with a series of mathematical terms for corresponding physical oscillation modes.

$$\sigma_S = 4\pi a^2 (ka)^4 \left[\left(\frac{\kappa - \kappa_0}{3\kappa} \right)^2 + \frac{1}{3} \left(\frac{\rho - \rho_0}{2\rho + \rho_0} \right)^2 \right] \quad (25)$$

The first term represents a monopole type bubble oscillation, whereas the second term describes a dipole term. One can see that the monopole term dominates the scattering due to the large compressibility (κ) difference between water and air–gas. Density differences (ρ) between water and air/gas are large too, however, the monopole term dominates the acoustic scattering (see Table 4).

Mathematical and Physical Modeling. The equation of motion of a bubble can be readily derived from an energy balance of kinetic (T) and potential energies (U) using the Lagrange formalism ($L = T - U$). It should be mentioned that the momentary inertial mass of the bubble as an oscillator does change with time. This is a major reason why ultrasound contrast agents are nonlinear systems, as

will be shown shortly. One of the first equations describing the motion of a gas bubble excited by ultrasound was derived by Rayleigh–Plesset and is given in Eq. 26. This formula is derived under the assumption that the interior gas follows the ideal gas law, and other forces acting on the bubbles are comprised of the internal vapor pressure p_d , the external Laplace pressure caused by the surface tension σ , the viscosity η_L of the surrounding host medium (water), the mass density ρ_L of the water, as well as the static p_0 and acoustic $p_\infty(t)$ pressures.

$$R(t) = \frac{1}{R(t)} \left(-\frac{3}{2} \left(\frac{\partial}{\partial t} R(t) \right)^2 + \frac{1}{\rho_L} \left(\left(p_0 + \frac{2\sigma}{R_0} - p_d \right) \left(\frac{R_0}{R(t)} \right)^{3\kappa} + \dots + p_d - \frac{2\sigma}{R(t)} - \frac{4\eta_L \frac{\partial}{\partial t} R(t)}{R(t)} - p_0 - p_\infty(t) \right) \right) \quad (26)$$

Figure 20 shows a simulation of the bubble response to a short tone burst excitation. Transmitted acoustic pressures of 1 and 50 kPa were simulated. Graph (a) shows a 1.1 MHz and 50 kPa pressure waveform as transmitted by a simulated ultrasound transducer. Graph (c) shows the subsequent radial oscillations of the simulated bubble (resting radius of 3 μm). Graph (b) shows the spectral response of these oscillations for a sound pressure of 1 kPa. The bubble oscillates mostly at the driving frequency of 1.1 MHz. An increase in sound pressure amplitude (i.e., 50 kPa) reveals the nonlinear nature of gas bubbles. In panel (d), in addition to 1.1 MHz one can also see higher harmonics of 2.2 MHz, 3.3 MHz, and so on.

Table 4. Scattering Coefficients for Monopole and Dipole Terms in Eq. 25 of a Water or Air Filled Sphere Under Water

Material	Bulk		Monopole Magnitude	Dipole Magnitude
	Modulus κ , MPa	Density ρ , $\text{kg} \cdot \text{m}^{-3}$		
Water	2250	1000	0	0
Air	0.14	1.14	2.9×10^7	0.33

Figure 20. For higher transmit sound pressures (p_T) gas bubbles exhibit nonlinearities at similar magnitudes as the fundamental frequency [(b) vs. (d)]. Higher harmonics increase in their relative amplitude with sound pressure. Radial oscillations of the gas bubble contrast agent shows the nonlinear response during the compressional phase (arrows at small radii). Harmonic imaging takes advantage of the strong nonlinear character of contrast agent, which can be stronger than tissue depending on the number density of the bubbles.

Modern ultrasound contrast agents cannot be modeled using the free gas bubble Rayleigh–Plesset model. Elastic layer-based models presented by de Jong (5), Church (4), and Hoff (10) contain additional parameters, such as the mass density of shell material, a second surface tension term, a second viscosity term, or the elastic modulus of the shell material.

Imaging Modes

The following sections will cover imaging modes that rely on nonlinear backscatter, either originating from body tissue or due to nonlinear reflections from contrast agents. Each mode will be theoretically described and illustrated with examples.

Harmonic Imaging

Nonlinear tissue and contrast agent backscatter is the basis for harmonic imaging. Human tissue, as well as ultrasound contrast agent, can be driven in a nonlinear fashion such that the backscattered signal contains not only the original frequency f_0 , but also $2x f_0$, $3x f_0$, and so on (see Fig. 20d). Higher harmonics increase in their relative amplitude with sound pressure. Harmonic contrast imaging takes advantage of the strong nonlinear character of contrast agent, which is stronger than tissue. As a result, nonlinear backscatter from tissue will be smaller in amplitude than that of contrast agent and the vascular system will be visible over tissue. Subharmonic emissions are also characteristic for bubbles ($1/2x f_0$, $1/3x f_0$, etc.) and can be used to distinguish bubbles from tissue.

Figure 21 is comprised of a direct gas bubble simulation and an illustration of harmonic bubble behavior. As can be seen from the simulation results, harmonic scattering

Figure 21. Higher harmonics increase in their relative amplitude with sound pressure (left), P_{harmonic}/P_0 . Harmonic imaging takes advantage of the strong nonlinear character of contrast agent, stronger than tissue, depending on the number density of the bubbles. Subharmonic emissions $f_{1/2}$ are also characteristic for bubbles.

of gas bubbles increases with increasing incident sound pressure. Specifically, the normalized amplitudes of the fundamental and the second harmonic frequency are shown here ($p_{\text{fundamental}}/p_0$ and p_{harmonic}/p_0). Increasing the incident sound pressure causes a proportional increase in the fundamental response, while the contribution of the harmonics increases more strongly. At 50–100 kPa, the backscatter amplitude of the second harmonics peaks and for higher pressures more and more energy is distributed over a wide range of frequencies, from sub-harmonics f_0/n to higher harmonics $n \cdot f_0$. Because the model as described in Eq. 26 does not take into account any losses, such as those induced by radiation or viscous damping, backscatter predictions for large excitation pressures will not be accurate. However, at modest amplitudes tissue scatters in a linear fashion, gas bubbles contribute harmonic signals, and the amplitude ration between fundamental and harmonic components can approach 1 for bubbles driven at sufficiently large amplitudes (illustration in lower right panel of Fig. 21).

Figure 20 shows the oscillation of a gas bubble in a large amplitude acoustic field. Panel (a) shows the excitation sound pressure waveform of 50 kPa amplitude. Radial excursions as well as the sound pressure spectrum at a distance of 5 cm from the bubble are plotted on the bottom panels (c) and (d), respectively. Most notably are the sharp peaks for bubble radii smaller than the initial bubble radius (see arrows in Fig. 20c). At positive incident sound pressures, the bubble is compressed and exhibits a large internal pressure. At the same time, the bubble’s resonance frequency changes. This change in resonance is the reason

Figure 22. Tissue and contrast agent can yield different backscatter when exposed to an acoustic field of moderate intensity (typically of a mechanical index (MI) of less than 0.2). (a) Tissue responds in a linear fashion, that is, it yields a 0 and a 180° phase-shifted signal. The sum of both waves is zero. (b) For ultrasound contrast agent, the backscatter will include higher harmonics. A 180° phase shift in the transmit frequency f_0 will result in a 360° phase shift in the second harmonic $2f_0$. However, a 360° phase shift will result in the original signal. Therefore, the sum of a regular pulse and an inverted pulse will cancel for f_0 frequency components but not for $2f_0$ components.

for their highly nonlinear character. Panel (b) shows the scattered sound pressure spectrum for a low incident pressure of 1 kPa. No harmonic contributions can be seen within 40 dB of the pressure amplitude at the fundamental frequency.

Pulse Inversion Mode

As its name suggests, pulse inversion uses inverted pulses to gain contrast in the image. Figure 22 illustrates how this imaging mode works. As opposed to regular B-mode imaging, this mode requires *two* transmissions per image line. The first transmission does not differ from regular B-mode. However, the second transmission is 180° phase shifted, that is, inverted with respect to the first pulse transmitted. In case of tissue the backscatter for both pulses will mostly remain the same in magnitude. However, contrast agents respond with harmonic contributions which differ for 0 and 180° pulses. For very low acoustic pressures, this difference might not be distinguishable from the linear backscatter, but a mechanical index of 0.2 or less is sufficient to perform pulse inversion imaging. The mechanical index is a measure for the sound pressure amplitude and will be defined in the bioeffects section.

High sound pressure amplitude pulses can have two effects. First, they cause nonlinear tissue backscatter, thus reducing the contrast between tissue and contrast agent in the vascularity. Second, they destroy the contrast agent. One has to keep in mind that contrast agents are comprised of encapsulated gas bubbles. Therefore the bubble can shatter and the contained gas can subsequently dissolve into the blood pool. This shattering is possibly a source for bioeffects of ultrasonic imaging and will be discussed in a later section.

Theoretical modelling of the oscillatory behavior of gas bubbles using the above-introduced model directly shows the nonlinear response of gas bubbles. Figure 23a shows the two-pulse sequence required for pulse inversion ima-

Figure 23. Two transmitted pressure waveform pulses with 180° phase shift with respect to each other, are displayed at time equal 5 and $20 \mu\text{s}$ in panel (a). This concept of inverted pulses is illustrated in Fig. 22(a). For 1 kPa sound pressure amplitude the sum of the oscillations of these two pulses is near zero (b). However, for a sound pressure of 50 kPa, the radial excursions of the contrast agent bubbles is nonlinear (as shown in Fig. 20) and the sum of the 0 and 180° signal is almost as great ($3.2 \mu\text{m}$ in d) as the oscillation itself ($3.4 \mu\text{m}$ in c). This technique is used in pulse inversion contrast agent detection scheme.

ging. For transmit pressures of 1 kPa, the difference in bubble response to 0 and 180° is very small. However, on the same scale, the response to a 50 kPa excitation yields two signals whose fundamentals f_0 cancel, but whose second harmonic contributions $2f_0$ add in phase (see Figs. 22 and 23 d).

A major downside of pulse inversion imaging is its sensitivity to motion. Spatial shifts cannot be distinguished from changes in back-scatter due to changes in transmit phase. A clever work-around to this problem is illustrated in Fig. 24, where a three-pulse transmit of varying phase is shown. Situations in which motion is anticipated or intestinal peristalsis or chest wall excursions during breathing. The latter is on the order of $2 \text{ cm} \cdot \text{s}^{-1}$, or for a 1 kHz PRF, $20 \mu\text{m}$ per firing. A signal of 1 MHz center frequency will experience a phase shift of 4.8° when spatially translated $20 \mu\text{m}$. It is assumed that the time duration in which the three pulses are fired is small compared to that of the body motion. If so, then the motion can be approximated as being linear on the time scale of the firings. The first firing is transmitted with zero phase, the second one with $5 + 180^\circ$, the third one with 10° phase shift. Linear response of tissue will result in backscatter signals of 0° , $5^\circ + 180^\circ$, and 10° phase shifted signals. Averaging the first and third backscatter signal will yield an average of 5° phase shift. Adding this average signal to the second backscatter signal will yield a value of zero for linear tissue, even while it is in motion. Bubbles, however, will yield a similar, nonzero, signal whether in motion or not.

Coded Excitation and Coded Harmonic Excitation. *Coded excitation* is a way to overcome poor signal to noise ratios (SNR) in ultrasonic imaging. It was already used in radar imaging for the same purpose, before its introduction to medical ultrasound. The most simple solution for poor

Figure 24. A three pulse sequence with a linear shift in transmit phase (0° , $5^\circ + 180^\circ$, and 10°) is used to suppress tissue signal, even when the tissue is in motion. The 0 and 10° backscatter signals are averaged to yield a 5° signal from tissue (SI). The 5° phase-shifted and inverted transmit signal (S2) is then added to the averaged signal SI. For moving tissue the result will be zero. If the tissue motion is linear during the time span of the three transmit pulses (~ 1 ms), then pulse will be separated by an offset of x° . This offset is in addition to the initial 5° offset between first & second and second and third pulse. Therefore tissue will yield zero for $S1+S2$. Ultrasound contrast agents, however will yield $S1 \neq S2$ as shown in Figs. 22 and 23.

signal/noise ratios is to increase the amplitude of transmitted sound. However, the FDA regulates sound pressure amplitudes because of the likelihood of acoustic cavitation in the presence of large sound pressure amplitudes. Moreover, the number of acoustic transmissions per unit time (pulse repetition interval, PRI) as well as the length of individual pulses (burst length) are regulated by means of the overall deposited energy that will eventually result in tissue heating. Both effects will be discussed in the Bioeffects section below. In addition to regulatory and safety concerns, increasing the number of cycles in a traditional transmit pulse also reduces the axial resolution.

However, improvements in signal to noise ratios without sacrificing axial resolution can be achieved despite regulations on pressure amplitudes and burst lengths. Transmission of specially designed and unique signals can significantly improve their detectability. This concept is called Coded harmonic excitation.

Various code types shall be discussed here to illustrate how Coded excitation works. Figure 25 illustrates two codes. On the left side is the most simple code, a so-called pulse train (or uncoded tone burst), that is, a series of pulses or sinusoids. When transmitting four cycles at a certain frequency one can use a frequency filter that is sensitive at the transmit frequency, but only for signals that are four cycles long. A more complicated type of coded excitation is the code shown on the right side of Fig. 25.

Figure 25. Some signal to noise problems can be overcome by the use of coded excitation. Instead of a single pulse, a pulse train (commonly also known as a tone burst) or coded pulse train is transmitted for better backscatter detection. See Fig. 26 for temporal /spatial resolution.

This signal also transmits four cycles, but now the four cycles all differ in sign as well as in amplitude. Both features make this code more unique and therefore more detectable when ambient noise lowers SNR.

Above mentioned frequency filters are explained in Figs. 26 and 27. The first column in Fig. 26 illustrates the transmit pressure waveforms and the second column shows the receive filter used. A mathematical technique termed convolution is used to match the transmitted waveform with the anticipated receive signal by means of an appropriately designed filter. The average reader might not have adequate signal processing background to be familiar with this concept. Therefore, Fig. 27 will be used to explain Coded Excitation for the example of Golay code

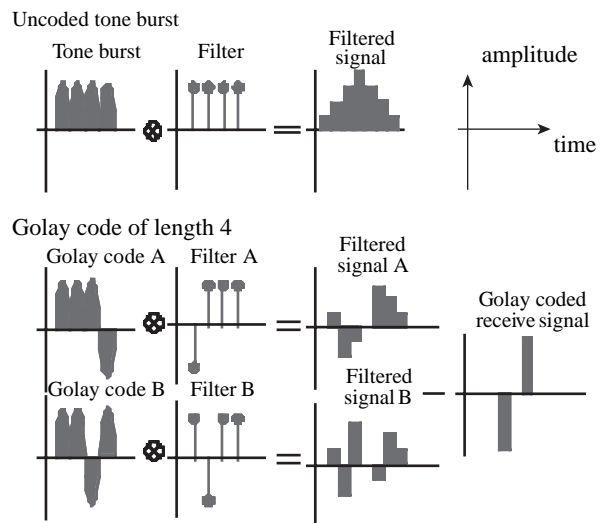

Figure 26. Coded excitation is implemented on modern ultrasound scanners to overcome signal loss and low SNR. A simple solution is the increase in burst length. However, this simultaneously results in a decrease in axial/temporal resolution. Specially coded waveforms are designed for an increase in SNR by reasonably maintaining spatial resolution. Golay codes, for example, can be designed for a 10-fold increase in SNR by losing only a factor of two in temporal resolution.

Figure 27. The mathematical process of convolution is described in this figure. For this purpose the reader should refer to the Golay code of length 4 given in Fig. 26 and to the text section on Coded excitation for a detailed description.

of length 4 (see Fig. 26). This code consists of two transmit pulse packages. The first and second packages are four pulse sequences of $[+1, +1, +1, -1]$ and $[+1, +1, -1, +1]$, respectively. Such pulses are shown on the top row of each box in Fig. 27. The pulses are transmitted into the body and the resulting echoes, which should show the same pattern, are recorded. Matching filters are shown below the pulse packages and have been replicated at a total number of 7 positions. Each filter replication has an overlap with the transmit pulse ranging from 1 to 4 digits. For a given position, numbers in the same column are multiplied and then the resulting values of the overlapping columns are added.

For clarification the highlighted case in the top system for position 5 (arrow) is explained in detail. The filter $[-1, 1, 1, 1]$ and the recorded pulse $[1, 1, 1, -1]$ overlap for three digits and the computational method of convolution is equivalent to computing the inner product of two vectors: $[1, 1, -1] \cdot [-1, 1, 1] = 1 \cdot (-1) + 1 \cdot 1 + (-1) \cdot 1$, which sum to -1 . This value is displayed in the column on the right. This convolution procedure is done for both transmits. Subtracting the two resulting 7 digit vectors $X = [1, 2, 3, 0, -1, -2, 1]$ and $Y = [1, 2, 1, 0, 3, -2, 1]$ will yield $[0, 0, 2, 0, -2, 0, 0]$, a receive vector (called Golay-coded receive signal in Fig. 26) with good temporal/spatial resolution. In the given case it is essentially three time steps long: $[-2, 0, 2]$. The uncoded tone burst is 7 time steps long (see top of Fig. 26).

Back to Fig. 26, the result of the convolution is shown in the third column. For the uncoded tone burst one can see a triangular shaped signal that peaks where the receive filter perfectly matches the incoming pressure wave. The temporal duration of the convolution increases as the duration of the tone burst increases. This unwanted effect of loss of spatial resolution is overcome by the use of more sophisticated codes. Golay transmit codes and receive filters, for example, can mostly maintain spatial resolution while improving SNR. Two differing transmit codes are used and the resulting convolutions are subtracted from each other, similar to pulse inversion imaging.

Coded excitation in the form of a Chirp-type pulse train yields a signal to noise gain of $\sqrt{\Delta F T}$; for example, a signal with a 1 MHz frequency sweep and $T = 16 \mu\text{s}$ pulse duration will yield a fourfold increase in SNR, which corresponds to 12 dB. Chirps are tone burst of continuously increasing transmit frequencies within the pulse train. Continuously in frequency decreasing pulse trains are called chirps, which almost spells chirp backward. General Barker and Golay codes perform well too. For a standard Barker sequence the side lobe amplitudes of the transmit/receive signal are -22 dB down relative to the amplitude main lobe. A Golay code with 16 pulses per burst yields a ten-fold increase in SNR. Here, only a length-4 sequence is shown for clarity (see Fig. 26).

More detailed mathematical background, as well as clinical feasibility can be found in publications by Nowicki (19) and Misaridis (20), for example.

BIOEFFECTS

Ultrasound related bioeffects are centered on two main categories: cavitation and heating. Acoustic output (and therefore to some degree acoustic cavitation) is regulated by the FDA through the implementation of the mechanical index (MI), as well as the temperature index (TI) in the so-called Output Display Standard (Standard for Real Time Display of Thermal and Mechanical Acoustic Output Indices on Diagnostic Ultrasound Equipment (1992), published by the National Electrical Manufacturers Association as UD-3). The output display standard is used to obtain approval by the FDA for medical use of ultrasound scanners.

Cavitation is a well-studied effect and manifests itself, for example, by the erosion of ship propellers and for therapeutic purposes in lithotripsy. Hydrodynamically generated microscopic gas bubbles imploding in close proximity to the metallic surface of the propellers punch small holes into the metal. This occurs due to the existence of water jets generated by asymmetrically imploding gas bubbles.

To date, there are only very limited clinical reports on the occurrence of bioeffects in diagnostic ultrasound. Nevertheless, *in vitro* cell cultures and animal models are used to study bioeffects at acoustic parameters beyond the limits for diagnostic imaging. No limits for single parameters (e.g., pressure amplitude, wave frequency, or pulse length) were identified *per se* due to the complicated biological end points (21). However, two fundamental quantities, MI and TI, were introduced as parameters by which to judge the probability of bioeffects (11,21). Both quantities gain in presence, especially with the MI being used by the FDA to limit the acoustic output of scanners.

$$\text{MI} = \frac{p[\text{MPa}]}{\sqrt{f[\text{MHz}]}} \quad \text{TI} = \frac{Wp[\text{Nm} \cdot \text{s}^{-1}]}{W_1^2[\text{Nm} \cdot \text{s}^{-1}]} \quad (27)$$

Pressure p and frequency f are quantities that can be directly measured experimentally. Power W_p , however, is a derived quantity and is related to the pressure waveform as

shown in Eq. 28 (22).

$$PII = \frac{\int_{t_1}^{t_2} v_h(V(t))^2 dt}{10^4 \rho c M_L (f_c)^2} [J \cdot cm^{-2}] \tag{28}$$

$$I_{SPTA} = PII(j, v, z_{m,jPII}) \times PRF [W \cdot cm^{-2}]$$

The pulse intensity integral *PII* is computed over a truncated duration of the acoustic wave, namely, from *t*₁ to *t*₂. These times correspond to the 10 and 90% indexes of the accumulated total energy in the tone burst and can in most circumstances be regarded as the burst length. When calibrating an acoustic transmitter, one often measures an electric waveform produced by a underwater microphone, called a hydrophone. A conversion function *v_h*, is then used to determine the actual pressure of the measured electric waveform *V(t)*. *M_L* is the hydrophone’s frequency dependence. Together, *v_h*, and *M_L* allow the complete conversion of the electrical hydrophone signal to the pressure of the measured wave. Mass density and speed of sound of the medium in which the wave travels are labeled as *ρ* and *c*. Even when the burst length is taken into account, one does not know the total transmitted power without the PRF. Spatial peak and temporal average intensities (*I_{SPTA}*) are computed with knowledge of the PRF, yielding units of watts per centimeter squared (*W · cm⁻²*). For computing the TI, however, one needs to multiply that value with the geometric cross-section of the acoustic beam. In reality, the computation of the TI is more complicated and takes into account more parameters such as the chosen exposure conditions, as well as nominal perfusion parameters. In clinical use, perfusion parameters are estimated from user selected target tissue types.

An additional step toward reducing the possibility of bioeffects is the usage of the principle of ALARA (as low as reasonably achievable), that is, the reduction of acoustic output and reduction of exposure time to the lowest reasonable minimum. Typical diagnostic acoustic procedures operate at or below the FDA limit for *I_{SPTA,3}* of 720 mW · cm⁻² (see Table 5 and (23)). Currently, the FDA regulates output limits via Tracks 1 and 3 of 510(k). Track 1 uses the *I_{SPTA}* levels shown in Table 5, whereas Track 3 allows device manufacturers to increase their output to a general 720 mW · cm⁻² if their device provides user feedback via MI and TI display standards (24).

Biological effects of ultrasound can be investigated after the acoustic output of a sound source is quantified and

qualified as described in the previous paragraphs. *In vitro* cell studies are typically the first method for research on the biological effects of ultrasound. Such studies can be performed in a highly controlled environment and are therefore repeatable. This is not necessarily the case for patient studies where many factors cause unavoidable variabilities.

It was found in a study on anesthetized rats that the interaction of the incident sound field with ultrasound contrast agent can cause pete-chial hemorrhages (punctuate sites of bleeding from blood vessels) in heart tissue. In a study by Li et al. (13,14) ultrasound contrast agents were injected in a similar fashion as is used in clinical contrast echocardiography. Heart tissue was observed in real time using a phased array ultrasound scan head (1.7MHz transmit frequency) operating in a harmonic mode native to the clinical scanner used. Postmortem heart tissue analysis showed that bleedings scaled monotonically, proportionally to the square of the peak rarefactional pressure (*P_{rare}*) amplitude of the sound field. Pressure amplitudes of 0.6–1.8 MPa *P_{rare}* were used in that study. This pressure range corresponds to MIs between 0.5 and 1.5. Real-time ultrasonic imaging showed that premature ventricular contractions (PVC) were triggered by ultrasound in the presence of contrast agents. However, no significant PVC were observed for MIs of 0.5 and 1.0, but up to 40 PVCs were observed for a 3 min exposure at a MI of 1.9, the maximum allowed by the FDA.

Currently, there are very limited clinical reports on unanticipated bioeffects of ultrasound. Intended effects exist since ultrasound can be used to treat kidney stones and during such procedures it is likely that tissue bleeding occurs. There have been reports of effects associated with diagnostics, but the review of these reports has yielded no establishment of a causal relationship with ultrasound exposure. However, a study by van der Wouw in healthy male volunteers concludes: "Imaging of contrast agents with high acoustic pressures can cause PVCs if end-systolic triggering is used. This effect is related to both the dose of contrast agent and acoustic pressure. It does not occur during end-diastolic triggered imaging. Precautionary measures would include using lower MIs or end-diastolic triggering" (25).

It has been seen that the level of bioeffects varied with the ultrasound contrast agent used. This is probably due to different shell materials and internal gases, which cause the bubbles to oscillate at different amplitudes. If agent rupture occurs, cavitation type damage is produced in the surrounding tissue (13,14). Thermal and nonthermal effects exist and they are under investigation. According to Natori (26) temperature increases of no more than 1.5°C above normal are considered clinically acceptable and nonthermal, that is, cavitation based effects can only be found where gas bodies are present, such as postnatal lung and intestines, or via ultrasound contrast agents. Therefore regular B-mode imaging is considered by many unaffected (26).

Finally, it should be mentioned that there are no bioeffects in the absence of contrast agent and also no bioeffects in the presence of contrast agents but absence of an ultrasonic field. Moreover, low doses (10–50 μL · kg⁻¹)

Table 5. Acoustical Output Limits for Clinical Ultrasound Scanners per FDA Regulation

Tissue	<i>I_{SPPA,3}</i> , mW · cm ⁻²	<i>I_{SPTA,3}</i> , W · cm ⁻²	MI
Peripheral vasculature	720	190	1.9
Cardiac	430	190	1.9
Fetal and other	94	190	1.9
Ophthalmic	17	28	0.23

^aIntensity values are derated for tissue attenuation with an acoustic attenuation of 0.3 dB · cm⁻¹ · MHz⁻¹.

^b*I_{SPTA}* and MI are defined in the text, *I_{SPPA}* is defined as the intensity of the spatial peak pulse averaged waveform.

of ultrasound contrast agent yielded little if any bioeffects. In general, radiological contrast agents, or the imaging procedure itself, may bear the risk of bioeffects. That risk has to be balanced with the medical need for the procedure.

ACKNOWLEDGMENTS

I wish to thank Katy, Kim, Mario, John, and Jessi for their invaluable efforts for proof reading and their technical comments. Also, I would like to thank the reviewers for their contributions and very helpful commentary. Most of all, I wish to thank my wife Naki for her patience during many lost hours of family time.

ULTRAVIOLET RADIATION IN MEDICINE

J. J. LLOYD

Department
Royal Victoria Infirmary
Newcastle-upon-Tyne,
United Kingdom

INTRODUCTION

It is to the philosophers and physicians of the ancient civilizations that we should attribute the earliest history of ultraviolet radiation (UVR) in medicine (1). For example, the Greek sun god, Apollo, was also the spiritual god of healing, providing the first documentation of an association between sunlight and health. In 525 BC, Herodotus observed that the strength of a human's skull was related to sunlight exposure, >2000 years before the formal discovery of the role of sunlight in vitamin D metabolism. At about the same time the Egyptians were using psoralens from plant extracts and sun exposure in the treatment of vitiligo. However, it was not until Jonathan Ritter in 1801 discovered the UV region in the solar spectrum that the science of photobiology could really begin.

The Danish physician Niels Finsen (1860–1904) is regarded by many as the father of modern UV therapy. In a series of articles published between 1893 and 1896,

Figure 1. Patients receiving sun heliotherapy for the treatment of tuberculosis. (Picture courtesy of the University of Denver.)

Finsen stressed that it was the UVR in the solar spectrum that was responsible for sunburn and not the radiant heat, as the name implies. In parallel with his scientific investigations, Finsen was also an active clinician. He is best remembered for his successful treatment of *lupus vulgaris* (tuberculosis of the skin, mainly on the face) and in 1903 was awarded the Nobel Prize for medicine in recognition of this work. The photograph shown in Fig. 1 shows patients with *lupus vulgaris* being treated with sunlight (heliotherapy). Treatment of disease using artificial sources of UVR is known as actinotherapy or phototherapy.

Following the pioneering work of Finsen, the early part of the twentieth century saw the rapid expansion of heliotherapy and actinotherapy throughout Europe and the United States. The practice of actinotherapy continued to expand through the middle part of the twentieth century and was accompanied by an enormous literature on the subject during the 1920s and 1930s. This rapid growth is reflected by the many revisions of the handbook *Actinotherapy Technique* first published by the Sollux Publishing Company in 1933 and reprinted for the ninth time (7th ed.) in 1949 (2). (A copy of this can be seen on-line at <http://www.meridianinstitute.com/eaem/hanovia/hanocont.html>) Most of the irradiation protocols for the countless number of diseases, such as diabetes and angina, described in this book are now of historical interest only. The advent of effective antibiotics and the realization that the successes claimed in many of these diseases were little more than anecdotal have resulted in a more limited role of UVR in clinical medicine. However, today there is considerable interest in photobiology, both in treatment of diseases such as psoriasis, and in research into the photobiological basis of skin aging, carcinogenesis, and photodermatoses. Greater leisure time and ease of travel has led to potential for greater exposure to solar UV and greater potential for short- and long-term deleterious effects. This article presents a review of photobiology with particular emphasis on sources and measurement of UV relevant to medical diagnosis and treatment, but also encompassing

biological effects of UV, natural UV exposure, medical applications, and hazard assessment.

THE ULTRAVIOLET SPECTRUM

Ultraviolet radiation is part of the electromagnetic spectrum and lies between the visible and the X-ray regions. Different wavelengths in the UV spectrum show enormous variations in ability to cause biological damage, and for this reason the UV spectrum is divided into three spectral regions: UVA, UVB, and UVC. The notion to divide the UV spectrum into different spectral regions was first put forward at the Copenhagen meeting of the Second International Congress on Light held during August 1932. It was recommended that three spectral regions be defined as follows:

UVA 400–315 nm

UVB 315–280 nm

UVC 280–100 nm

The subdivisions are arbitrary and differ somewhat depending on the disciplines involved (3). The boundary between UVA and UVB is sometimes set at 320 nm and that between UVB and UVC is sometimes regarded as 290 nm. The short wavelength limit for UV is sometimes quoted as 100 nm and sometimes as 200 nm. The UVA region has recently been divided into UVAI (340–400 nm) and UVAII (320–340 nm).

Due to potential confusion with this terminology and because of rapidly changing biological effects as a function of wavelength, it is recommended that, in publications in photobiology, bandwidths are quoted explicitly and ideally the full spectrum of UV sources is described.

BIOLOGICAL EFFECTS OF ULTRAVIOLET RADIATION

An understanding of biological effects of UV is vital in appreciating the requirements for sources and detectors in medical applications. As UV does not penetrate tissue readily, it is the eyes and skin that are organs of particular interest. Comprehensive reviews of the health effects of UV are given in a recent book from the National Radiation Protection Board in the United Kingdom (4). Briefer reviews can be found elsewhere (5,6). In this section, the effects of UV in normal subjects is briefly described; effects in disease are discussed in later sections.

In order to cause a biological effect, UVR must be absorbed and initiate a photochemical process. The biological molecule that absorbs the radiation is known as a chromophore. A plot of the effectiveness of a chromophore at absorbing radiation as a function of wavelength is the absorption spectrum. A plot of the effectiveness of the UVR of different wavelengths in causing a given biological effect is called an action spectrum. The shape of the action spectrum will depend both on the absorption spectrum for the chromophores initiating the effect and also the optical properties of the skin that influences the radiation reaching the chromophores. The transmission of UVR

Figure 2. Fractional UVR penetration through the epidermis as a function of wavelength (B.6 L. Diffey, personal communication).

through the epidermis is shown in Fig. 2; UVA has much higher transmission than UVB or UVC, and therefore penetrates deeper into the skin.

Effect of UV Exposure on the Eyes

Both UVC and UVB radiation is predominately absorbed by the conjunctiva and cornea. The lens absorbs radiation in the range 300–370 nm, whereas radiation in the range 400–1400 [visible blue light to near-infrared (IR) radiation] is absorbed on the retina. Acute effects of UVR overexposure are photokeratitis (corneal injury) and photoconjunctivitis. Photokeratitis may occur in mountaineers as a result of high solar UV at altitude and high UV reflection from snow; this is referred to as “snow-blindness”. Many epidemiological studies suggest a link between chronic ocular UV exposure and ocular disorders such as cataracts and the appearance of yellow/brown deposits in the cornea. Absorption in the UVC range is of little interest in epidemiological studies since there is no natural exposure at these wavelengths. However, corneal absorption is very high between 190 and 220 nm and radiation in this range is used therapeutically in laser photorefractive surgery. Also certain artificial sources, such as germicidal lamps, emit significant UVC, and therefore care is required in their use.

Effect of UV Exposure on the Skin

The acute effects of UVR on the skin include erythema (sunburn), skin thickening, tanning, and vitamin D production. Long-term effects include induction of skin cancer and premature skin aging. Individual response to UVR varies greatly. Fair skinned people burn more easily in the sun, find it difficult to obtain a tan, and have a higher risk of skin cancer compared to darker skinned individuals. In photobiology it is usual to categorize skin into six types, as shown in Table 1.

Acute Effects. Erythema is skin redness caused by inflammation and dilation of small blood vessels. Despite being extensively studied the underlying cause of UV induced erythema is poorly understood (7). The erythema response of the skin in an individual can be defined by the minimum dose required to produce a just perceptible redness. This is referred to as the Minimal Erythema Dose

Table 1. Characteristics of Different Skin Phototypes^a

Skin Type	Skin Color	Sensitivity to Sunburn	Ability to Tan	Skin Cancer Risk
I	White	Very high	Virtually nil	High
II	White	High	Poor	High
III	White	Medium	Good	Medium
IV	Olive	Low	Very good	Low
V	Brown	Very low	Very good	Very low
VI	Black	Very low	Very good	Very low

^aFrom Ref. 65.

(MED). A standard erythema action spectrum has been defined taking into account many published studies (8) (see Fig. 3). Skin sensitivity is maximum to radiation in the UVC and UVB range up to 298 nm. At longer wavelengths, the sensitivity drops rapidly reducing to be about 10,000 times less at 400 nm. The MED is a threshold measurement made by visual assessment. For quantitative studies a device measuring reflectance (11) can be employed to quantify erythema. This device works by measuring the decreased green reflectance, relative to red, from haemoglobin in the dermal blood vessels.

Within an individual the sensitivity to erythema can vary considerable from site to site (12,13). Minimal erythema dose measured on the forearm may be twice that on the back, and the buttock skin is more sensitive than the back.

Chronic Effects. There are three types of skin cancer associated with UVR: squamous cell carcinoma (SCC), basal cell carcinoma (BCC), and malignant melanoma (MM). The SCCs appear as persistent red crusted lesions on exposed sites and have an incidence about a quarter of BCC. The BCCs appear as raised translucent nodules, normally on the face. Basal cell carcinoma appears to be related to cumulative UVR exposure, whereas SCC and MM may be related to intermittent exposure to UVR. In support of this idea is that fact that BCC and SCC tend to occur on habitually sun-exposed sites whereas MM occurs more commonly on intermittently exposed sites. Although MM has a much lower incidence than non-melanoma skin cancer, it accounts for ~80% of all skin cancer deaths.

Figure 3. Standard action spectra for erythema (9), non-melanoma skin cancer (10), and UV hazard (6).

Melanoma incidence is increasing rapidly, probably due to increased recreational sun exposure, although other non-UV factors also play a part. Since the 1970s melanoma has seen the largest increase in incidence compared to all other major cancers in the United Kingdom and now stands at 8/100,000 person-years. It is predicted that the incidence will continue to rise, perhaps doubling over the next 30 years in the United Kingdom (14).

Photoageing is the term used to describe features of chronically sun exposed skin. These features include: wrinkles, “age spots”, and thick leathery skin.

Effects on the Immune System

There is some evidence that exposure to UVR may have a systemic immunosuppressive effect. It is possible that UV exposure may increase the incidence of infectious diseases and play a role in the promotion as well as initiation of skin cancers.

ULTRAVIOLET SOURCES

Ultraviolet radiation is emitted during transition of a molecular electron from an excited, high energy, to a less energetic state. As the possible energy levels are fixed for a given molecule, radiation is emitted with distinct photon energies. When excitation is by heating, the release of radiation is termed incandescence. Alternatively, excitation can be generated by passage of an electrical discharge through a gas. This is the basis for most artificial UV sources used in medicine, for example, mercury arc lamps and fluorescent UV lamps. The UV emitting LEDs (light emitting diodes) are available, although these tend to have low output and be restricted to long wavelength UV. A further recent development has been the production of UV emitting lasers.

Solar Ultraviolet Radiation

Although direct use of solar radiation as a medical therapy (heliotherapy) is no longer employed, an understanding of solar UV can be helpful clinically, particularly in the investigation of abnormal reactions to sunlight. In clinical phototesting solar simulating sources may be used. A brief summary is therefore given here, for more information the reader is directed to various recent reviews (15–18).

The spectrum of extraterrestrial solar radiation approximates that of a black body at ~5800 K. At the earth's surface, this spectrum is modified by atmospheric attenuation. The stratospheric ozone layer prevents almost all radiation with wavelengths <290 nm and a substantial proportion of UVB (70–90%) reaching the earth. When the sun is lower in the sky, the path length through the atmosphere is greater. The UV intensity is therefore reduced at all wavelengths, but more so for UVB than UVA. The relative intensity of UVA compared to UVB is therefore greater in the winter than summer in the United Kingdom. At mid-day in the summer in the United Kingdom the ambient total UV is ~4 mW/cm², of which UVB contributes ~5%. However, due to its greater deleterious effect, UVB contributes to ~80% of the harmful effects of solar UV.

Incandescent Sources

Incandescent sources emit a smooth broad spectrum of radiation with the peak wavelength inversely related to the absolute temperature. Conventional tungsten bulbs used for domestic lighting have peak emission in the infrared (IR) region and emit very little UVR. Tungsten halogen bulbs operate at higher temperatures and may produce rather more UVR. These sources are not used for medical applications due to the low UV output, although, they may be used as reference sources for UV meter calibration.

Mercury and Metal Halide Arc Lamps

The radiation emitted from a mercury-vapor arc lamp arises from two mechanisms. Line or characteristic radiation is produced as a result of excitation of the constituent atoms, together with a spectral continuum that is chiefly due to ion and electron recombination. Lamps can be produced that operate at different pressures. A low pressure mercury arc lamp consists of a fused silica tube filled with argon at ~1 Pa and containing a drop of mercury. A discharge occurs between the electrodes sealed into the ends of the tube. More than 90% of the radiant energy produced by the discharge is at 253.7 nm. Various other characteristic mercury spectral lines occur, for example, at 313 and 365 nm, and these sources are useful for wavelength calibration of spectroradiometers.

If the pressure in the lamp tube is increased, then the spectral lines broaden and also more radiation occurs in the continuum (see Fig. 4). The “alpine sunlamp” is a type of medium pressure arc lamp that was widely used for phototherapy, but has since been superseded by fluorescent lamps. The addition of metal halides to a high pressure mercury discharge lamp greatly enhances the UV output. These lamps were common in phototherapy departments at one time, but have now been mostly replaced by fluorescent UVB lamps. These lamps are still occasionally used for cosmetic tanning. By incorporating optical filters between the lamps and the irradiated subject, absorption of the UVC or UVC and UVB components can be achieved (see Fig. 5).

Figure 4. Ultraviolet emission spectra from low and medium pressure mercury lamps.

Figure 5. Ultraviolet emission spectra from metal halide lamp with and without filters.

The medium pressure mercury lamp is also the source in the “Wood’s lamp”, although in this case optical filtration is incorporated into the lamp housing to limit the short-wavelength UV and visible light emissions. This results in an approximate monochromatic source of 365 nm. The Wood’s lamp is used in diagnostic fluorescence techniques in dermatology.

Fluorescent Lamps

A fluorescent lamp is a low pressure mercury discharge lamp that has a phosphor coating applied to the inside of the envelope. Fluorescence radiation is produced by the excitation of the phosphor by the 253.7 nm radiation. The spectral power distribution of the fluorescence radiation is a property of the chemical nature of the phosphor material. In addition to a continuum due to the phosphor, the mercury characteristic lines are superimposed. These lines are present in all mercury fluorescent lamps irrespective of the phosphor material. However, it is possible to suppress the emission of certain lines either by using a lamp envelope material that absorbs unwanted short-wavelength radiation or by incorporating a suitable filter in the lamp housing. Because fluorescent lamps are relatively cheap, stable, and efficient and can produce a large high intensity irradiation field, they are now very widely used in phototherapy and cosmetic tanning.

The spectral power distribution of UVA lamps used in cosmetic tanning and PUVA phototherapy are shown in Fig. 6. Broad-band UVB fluorescent lamps (e.g., TL12, Phillips, Eindhoven, the Netherlands) incorporate a phosphor that results in a continuous spectrum from 270 to 380 nm, with a peak at 313 nm. This lamp is used in phototherapy, however, it is being replaced by the narrow-band lamp (Phillips TL01), which has ~80% of its output within 2 nm of the peak at 311 nm (Fig. 7).

The black light fluorescent lamp emits a similar spectral power distribution to the UVA fluorescent lamp in the region 315–400 nm, but with suppression of the mercury lines in the visible spectrum. This results from using a visible-absorbing, UVA transmitting, glass envelope. When switched off, the lamp envelope appears almost black. A purplish light is perceived when the lamp is operating.

Figure 6. Ultraviolet emission spectra from fluorescent UVA lamps used in PUVA therapy and commercial tanning studios (Cleo Performance and TL09). Also shown are the Phillips TL10 fluorescent lamps emitting longer wave UVA, that were popular for tanning at one time and the Phillips natural fluorescent lamp that have been promoted by the manufacturers as “a more natural way to tan”.

Xenon Arc Lamps

In the xenon arc the radiation is emitted primarily as a continuum, unlike the mercury arc, which essentially emits a line spectrum. The production of the continuum is optimum under conditions of high specific power, high current density, and high internal pressure, leading to compact, bright sources. Because of high operating temperatures the lamp envelope is normally constructed from fused silica. Unlike arc lamps containing mercury that has to vaporize, xenon lamps contain a permanent gas filling and the full radiation output is available immediately after switching on so that no run-up period is necessary.

Solar Simulators

Because of the similarity of the spectrum to that of the solar spectrum, the xenon lamp has been employed as a laboratory source of sunlight, the so-called solar simulator. In order to improve the match to sunlight, a WG320 filter

Figure 7. Ultraviolet emission spectra from fluorescent UVB lamps.

Figure 8. Ultraviolet emission spectra from solar simulator sources together with the solar spectrum obtained at mid-day on a sunny summer's day in Newcastle-upon-Tyne (UK). The relative irradiance has been displayed on a logarithmic scale to allow comparison of small differences in the UVB range.

(Schott AG, Mainz, Germany) should be used and often a visible light absorbing filter (e.g., Schott UG5 or UG11) is also employed. A drawback of the arc lamp solar simulator is that it is difficult to irradiate a large area. Fluorescent lamps can be used for this purpose and the best match to sunlight is probably given by the Arimed B lamp. The suitability of a lamp as a solar simulator can be assessed by comparing the percentage relative cumulative erythral effectiveness (%RCEE) for a number of wavebands and compare this with the %RCEE values for a "standard sun" (17). Various solar simulator sources are shown in Fig. 8.

Monochromatic Radiation

A radiation monochromator consists of a xenon arc lamp together with a double diffraction grating monochromator. By adjusting the angle of the diffraction grating, and by adjusting the input and output slit widths a narrow range of UV wavelengths can be obtained. These instruments are widely used in photobiology studies, both *in vivo* and *in vitro*. They are also routinely used for testing the erythral sensitivity of patients in phototesting clinics. Although the radiation is referred to as monochromatic, in fact bandwidths of between 30 and 5 nm are typically employed. Narrowing the bandwidth <5 nm may lead to unacceptably low irradiance.

Lasers

Lasers produce truly monochromatic radiation. There are a number of lasers that produce UV radiation with emissions possible in the UVA, UVB, and UVC range. Argon Fluoride lasers produce 193-nm radiation (UVC) and are used for corneal refractive surgery (19). Dye lasers have been used to investigate the action spectrum for erythema in human skin (20).

THE MEASUREMENT OF ULTRAVIOLET RADIATION

Techniques for the measurement of UVR may be divided into three classes; biological, chemical, and physical. In

Table 2. Radiometric Terms

Term	Unit
Wavelength	Nanometer, nm
Radiant energy	Joule, J
Radiant flux	Watt, W
Radiant intensity	Watt per steradian, W/sr
Radiance	Watt per square meter per steradian, W/m ² /sr
Irradiance	Watt per square meter, W/m ²
Radiant exposure (often referred to as "dose")	Joule per square meter, J/m ²

general, physical devices measure power, while chemical and biological systems measure energy.

Quantities and Units

In clinical and photobiological UVR dosimetry, it is customary to use the terminology of radiometry rather than that of photometry. Photometry is based on visible light measurements weighted by the human eye's response curve, and therefore not relevant as the eye does not respond to radiation at wavelengths <380 nm. The common radiometric terminology is listed in Table 2. These radiometric quantities can also be expressed in terms of wavelength by adding the prefix "spectral". In clinical photobiology, the derived unit of milliwatt per square centimeter is commonly used and radiant exposure tends to be referred to as dose. Note that dose in this context differs from the term used in radiobiology where dose indicates energy absorbed per unit mass of tissue.

The most frequent radiometric calculation is to determine the time for which a patient who is prescribed a certain dose (in J/cm²) should be exposed when a radiometer indicates the irradiance in mW/cm². The relationship between these quantities is

$$\text{exposure time (min)} = \frac{1000 \times \text{dose (J/cm}^2\text{)}}{60 \times \text{irradiance (mW/cm}^2\text{)}}$$

Weighted Irradiance

It is useful to derive quantities by weighting the spectral irradiance by an appropriate action spectrum. The erythemally effective irradiance E_{eff} is defined as

$$E_{\text{eff}} = \sum s(\lambda)E(\lambda)\Delta\lambda$$

Where $s(\lambda)$ is the CIE erythemal action spectrum (8), $E(\lambda)$ is the measured spectral irradiance, and $\Delta\lambda$ is the bandwidth of measurement. The "Global UV index" (21) can be used as a standard way of expressing the erythemally weighted solar irradiance. A measure of the integrated effective irradiance received is given by the Standard Erythemal Dose (SED) (9). One SED is equal to an effective dose of 100 J/m². In the past, some have used the MED as a standard measure of erythemal dose. However, this is not correct, MED should be reserved to describe an individual's erythemal response and not a standard measure of dose received. The number of SED required to cause just

perceptible erythema ranges from ~ 1.5 to 6 for skin types I to IV. It can be demonstrated that erythematous responses to UV sources with different spectra are similar if the doses expressed are SED (7).

Physical UV Detectors

Physical UV detectors utilize either thermal or photon mechanisms (22).

In thermal detectors, the absorption of radiation increases the temperature in the detector element and this rise in temperature is measured by some means. Thermopile UV detectors are the simplest and commonest thermal device used to measure UV irradiance. A multijunction thermopile is formed from a number of thermocouples in series, which generate a voltage that is proportional to incident energy in the form of heat. Thermopiles intended for use with UV radiation are fitted with quartz windows, which transmit well in the UV range. The advantage of thermal detectors is that they have a relatively flat spectral response over a wide wavelength range.

Photon detectors operate by absorbing discrete quanta of photon energy, and therefore have a threshold wavelength above which no radiation is detected. The lower wavelength limit is related to optical properties of the detector or associated filters. The response of photon devices are therefore inherently wavelength dependent and thus have to be calibrated for each source of interest.

Photoemissive detectors have a photocathode from which electrons are ejected when photons are absorbed. These electrons are then collected by an anode and a current is produced. The simplest of this type of detector is the vacuum phototube consisting of an evacuated tube with a potential difference applied between the cathode and the anode. This device has a gain of unity and a low responsivity (~ 0.05 A/W). A gas-filled phototube has a gain of ~ 10 due to secondary ionization of the gas in the tube that has the effect of producing a greater anode current. Photomultiplier tubes have a series of electrodes (called dynodes) having successively greater potential differences applied between them. As electrons hit each dynode they release further electrons that in turn release more electrons at the next dynode, and so on, leading to a high overall gain (typically 10^6). The responsivity of photomultiplier detectors tends to be high ($\sim 5 \times 10^4$ A/W).

Photodiodes, or junction photodetectors, have a depletion region formed by the junction of n and p doped semiconductor material. On absorption of a photon in this region, electron hole pairs are formed that are then swept out of the region and cause a current to flow in an external circuit. These devices can either be operated in a zero bias or reverse bias mode. For UV detection, GaAsP, GaP, or Si photodiodes are used. These photodiodes are small, cheap, and rugged with good responsivity (~ 0.1 A/W), and are therefore ideal UV detectors.

UV Radiometers

A radiometer is a complete UV measurement device, consisting of a detector and a meter to amplify and display the detector output. Narrow-band UV radiometers are used to measure the irradiance of a source in the different UV

bands. The detector consists of a diffuser to collect the UVR, a filter, and the sensor (e.g., a photodiode) itself. Lambert's law states that the irradiance falling on a surface varies with the cosine of the incident angle. A good diffuser should possess an angular response close to the ideal cosine response—of particular importance in phototherapy, where arrays of tubes are used leading to a large source area irradiation.

A good example of a hand-held radiometer for phototherapy is the IL1400A UV radiometer system (International Light, Newburyport, MA) used with the following probes (see Fig. 9):

- SEL 240 solar blind vacuum phototube, fitted with a SCS280 filter.
- SEL 033 Silicon photodiode detector, fitted with a UVA filter.

Both of these detectors are fitted with domed Teflon diffusers that have a good angular response. The SEL 240 responds over the 185–320 nm range, and the SCS280 filter is a sharp-cut filter, removing all wavelengths < 280 nm. The combination of the two gives a system that responds to wavelengths in the 265–332 nm range, which is well matched to the UVB band. The SEL 033 detector responds

Figure 9. A hand-held UV radiometer suitable for routine monitoring of phototherapy equipment. Model shown in an International Light IL1400A radiometer with UVA detector (see text for further details).

over the 200–1100 nm range, therefore the UVA filter used is a wide-band filter that restricts this response to the UVA range (325–388 nm). It is important to note that narrow-band radiometers have a response that varies with wavelength, and therefore they must be calibrated for each type of source they will be used to measure.

A broad-band radiometer possesses no filter, and therefore measurement of the total irradiance from a source is obtained. Typically these incorporate a thermopile detector connected to an amplifier and display electronics.

Spectroradiometry

Spectroradiometry is concerned with the measurement of the spectrum of a source of optical radiation. In many cases, spectral measurements are not required as ends in themselves, but for application to the calculation of biologically weighted radiometric quantities.

The three basic requirements of a spectroradiometer system are (1) the input optics, designed to conduct the radiation from the source into (2), the monochromator, which usually incorporates one or two diffraction gratings as the wavelength dispersion elements, and (3) an optical radiation detector, either a photomultiplier tube or a solid-state photodiode. The UVR is collected by a diffuser, which should have good angular response, and transmitted to the monochromator by a light guide. A quartz optical fiber is required as quartz has a very high UV transmission, unlike ordinary glass. The monochromator allows the separation of polychromatic radiation into very narrow bandwidths (typically 1 nm) thereby allowing the spectral irradiance of a source to be measured. This is achieved by using a diffraction grating, which disperses the incident radiation. Scanning spectroradiometer systems operate by measuring at a given wavelength, then changing the angle of the diffraction grating, making another measurement, and so on. For photobiology applications it is recommended that a double diffraction grating system is used. The second diffraction grating achieves a reduction in the radiation transmitted outside the waveband of measurement (so-called "stray radiation"). Very small amounts of stray radiation may have large implications in the measurement of erythemally weighted irradiance if it occurs at biologically highly effective wavelengths. The spectroradiometer system requires a high responsivity detector as narrow bandwidths are selected. All of the spectral examples in this article were obtained with this type of spectroradiometer system (the majority using a model DMc150 monochromator from Bentham Instruments, Reading, U.K.). Spectroradiometers need to be calibrated with reference to a standard lamp, which in turn has a output calibrated by a national standards laboratory. The disadvantage of double-diffraction grating scanning spectroradiometers systems are the high cost, large size, and relatively long time required to obtain a complete spectrum.

Recently small, rugged, and relatively cheap spectroradiometers systems have become available (e.g., Sola-Scope 2000, 4D controls Ltd, Redruth, U.K.). These devices consist of an input optic, single diffraction grating, and solid-state multidetector array. In this device, there are no moving parts and a complete spectrum is rapidly obtained.

A major disadvantage for photobiology application is that the stray light level is high (>10%), although this can be subtracted from the measured spectrum to give a reasonable level of compensation (23).

Calibration of Meters for Phototherapy. It is recommended that radiometers are routinely used in phototherapy practice and regularly calibrated in a manner traceable to a national standards laboratory (24). This can be done in one of two ways: either by reference to a calibrated spectroradiometer (25) or by reference to a calibrated meter (26). Surveys of radiometer accuracy have shown very disappointing results, particularly for the measurement of narrow-band UVB radiation (26,27). This is of particular concern since narrow-band UVB phototherapy is becoming increasingly popular, surpassing traditional PUVA therapy. Also, the increase in erythema with dose is greater with narrow-band UVB than PUVA, and therefore the need for accurate dosimetry is greater.

Chemical and Biological Methods

Detailed description of chemical and biological methods is beyond the scope of this article, but they are mentioned briefly as they may be used in a few medical applications. Polysulphone film (28) changes its optical properties with the absorption of UVR. It is possible to measure this change and relate it to the exposure dose received by the film. These devices are useful for measuring human UV exposure as they are unobtrusive for individuals to wear. Biological dosimeters (29) make use of the inactivation of bacteria or viruses as a function of UVR dose. There are certain applications, such as measuring UV doses in water flowing in a disinfection plant, where biological dosimeters are the only reliable way to measure UV dose.

DIAGNOSTIC USES OF ULTRAVIOLET RADIATION

Fluorescence Techniques in Diagnosis

The principle of fluorescence diagnosis is based on the absorption of radiation by a fluorophore in tissue and the subsequent emission of photons of light at a longer wavelength. Typically, the exciting radiation is short wavelength visible light or UVR and the fluorescence is longer wavelength visible light. Certain tissue types may be distinguished (e.g., neoplastic tissue) from surrounding tissue due to differences in endogenous fluorophore. Other techniques use exogenous photosensitisers that may be selectively accumulated in neoplastic tissues. The most common of these photosensitisers is 5-aminolevulinic acid (5-ALA). Originally, applications were limited to visual observation of fluorescence at easily accessible sites, such as the skin and mouth. However, technological advances in fiber optics, light sources, digital video cameras, and computer enhanced imaging has led to considerable interest in endoscopic fluorescence imaging (30). There is a wide range of excitation and emission wavelengths that can be used in these applications, often these are both in the visible range, but techniques using a Wood's lamp have been used for many years by dermatologists.

Tinea capitis (ringworm) is a fungal infection of the scalp. Hairs that are infected with the fungi *Microsporum audouini* or *Microsporum canis* will fluoresce with a bright blue-green color under Wood's light. The diagnosis can be confirmed by removing the fluorescent hairs for direct microscopic examination and culture. Erythrasma is a superficial bacterial infection of the skin, usually between two surfaces of skin that rub together, such as the groin or toe webs. Erythrasma produces scaling and cracking and may be accompanied by itching. The responsible organism (*Corynebacterium minutissimum*) produces a porphyrin that fluoresces a bright coral-red color on irradiation with a Wood's lamp. Irradiation of the oral cavity with a Wood's lamp will produce fluorescence that may prove useful in the diagnosis of various dental disorders such as early dental caries (tooth decay). Normal teeth fluoresce with a light blue color. The presence of calculus on the teeth will result in a yellow-orange fluorescence under UVA illumination.

Photosensitivity Investigations

Sunlight is capable of inducing or aggravating skin diseases. This group of diseases is collectively known as the photodermatoses (31,32). The classical appearance of a photodermatosis is a rash confined to regions exposed to sunlight; the face, neck, arms, and hands. The appearance may be an exaggerated sunburn, or there may be eczematous changes with polymorphic lesions that can include papules, vesicles, and bullous eruptions. The principal photodermatoses are shown in Table 3.

The accurate diagnosis of a suspected photosensitive patient demands, above all, a clear and detailed history. For example, the season of the year in which the symptoms occur may give some guide to the wavelengths in the sun's spectrum that are responsible. The time between exposure and the appearance of the lesion may also be a helpful guide. However, in equivocal cases, phototesting investigations are desirable (33). The object is twofold: to reproduce the disease so as to confirm the diagnosis, and to ascertain those wavelengths of sunlight that are responsible for the

photosensitivity, so that suitable preventative measures can be taken.

Provocation Testing. The aim of provocation testing is to expose a relatively large area of skin (say 10–20 cm²) to UVR and attempt to reproduce the rash of which the patient complains. The methodology used and the success of the technique is variable. The provocation source used in the past has been a medium pressure mercury arc lamp in combination with optical filters to isolate broad spectral regions (e.g., UVB or UVA). Recently, the use of a filtered xenon arc solar simulator source has been recommended as optimal (34). However, others have had good success with narrow-band UVB and UVA fluorescent lamps (35).

Minimal Erythmal Dose Determination. The MED is usually determined using a radiation monochromator. This enables the patient to be irradiated in narrow wavelength intervals. The patient's back is normally chosen for irradiation since it has a large surface area with reasonably uniform sensitivity to UV radiation. A geometric series of doses at each of several different wavelengths is used (33,36) and the results of irradiation are observed 24 h later. In most centers visual inspection is used, although for quantitative research studies an erythema meter may be used (11). Comparing the response in the UVA and UVB range may be helpful in diagnosis (37). For example, in drug induced photosensitivity the UVA MED may be low, and the UVB MED may be normal, whereas in chronic actinic dermatitis, both UVA and UVB MEDs are low (see Fig. 10).

Photopatch Testing. Certain chemicals when activated by UVR in contact with the skin may cause a photocontact allergic reaction in sensitive individuals. This is not to be confused with a phototoxic reaction that occurs in all subjects when exposed to a photosensitizer such as psoralen. The most common photocontact allergens are sunscreens. When UVR is absorbed by a chemical sunscreen it becomes altered and the patient may have an allergic

Table 3. The Principal Photodermatoses, Main Clinical Features, and Typical Phototest Responses

Condition	Typical Clinical Features	Typical Erythmal Response	Provocation Test Response	Photopatch Test Response
Polymorphic light eruption	Itchy, papular rash occurring after a few days sun exposure. Persists a few weeks	Usually normal MEDs, occasionally low MEDs	Positive response (50–80% sensitivity) at suberythmal doses	n/a
Chronic actinic dermatitis	Eczematous rash on sun exposed site in summer months	Low or very low MEDs within UVA and UVB waveband, sometimes sensitivity to blue light also	n/a	n/a
Solar urticaria	Urticarial reaction a few minutes after sun exposure. Fades rapidly	Rapid reaction (within minutes) that may include UVB, UVA and blue/green light sensitivity	n/a	n/a
Drug induced photosensitivity	Rash on sun exposed sites: features vary with responsible drug	Low MEDs in UVA, normal MEDs in UVB range	n/a	n/a
Photocontact allergy	Confluent rash on exposed sites: may be severe	Normal	n/a	Positive when chemical is exposed to UV

Figure 10. Abnormal erythematous sensitivity test obtained at 24 h after exposure in a patient with chronic actinic dermatitis. Dose increments of 40% were used at the 300, 320, and 350 nm. The \gg marks indicate the direction of decreasing dose. In a normal subject, only a few exposed areas would become red.

reaction to this altered chemical. Photopatch testing (33,38) consists of placing several small patches of chemicals on the back in two duplicate sets. After 24 h, one set is exposed to UVR (usually 5 J/cm^2 UVA from a fluorescent lamp or radiation monochromator). Reactions are examined after a further 48 h. If a chemical causes a reaction at exposed and unexposed sites this is a contact allergic reaction. If the reaction occurs at the UVR exposed site, only then this is a photocontact reaction.

THERAPY OF SKIN DISEASE WITH ULTRAVIOLET RADIATION

The principal application of UVR for therapy is to treat a variety of skin diseases. The UVR may be administered on its own (phototherapy) or in conjunction with adjunctive agents applied topically or photoactive drugs taken systemically (photochemotherapy).

Ultraviolet Phototherapy

In 1994, a survey of UVB phototherapy in the United Kingdom (39) found that an appreciable number of centers were using equipment that was old and was suboptimal in producing a therapeutic effect. A similar survey in 2002 (24) showed that improvements in equipment were being made. Mercury discharge lamps had mostly been replaced by fluorescent tube irradiators and broad-band UVB lamps

had mostly been replaced by narrow-band UVB lamps. The use of narrow-band UVB therapy has increased recently and now surpasses the use of psoralen plus UVA photochemotherapy (PUVA) (40). A recent review and guidance on the use of narrow-band UVB therapy by the British Photodermatology Group (40) concluded that there was good evidence to support its use in the treatment of psoriasis, chronic atopic eczema, vitiligo, and polymorphic light eruption. A range of other diseases have been treated with varying success.

Action Spectrum for Clearance of Psoriasis Using UVR Alone. Psoriasis is a common genetically determined skin disease with a 2% incidence worldwide (41). It is characterized by disfiguring, often distressing, red scaly plaques that may become confluent. The severity varies in any individual at any given time, but it often persists indefinitely. Parrish and Jaenicke (42) studied psoriasis response at different UV wavelengths to derive an action spectrum for psoriasis clearance. Figure 11 shows the clearance action spectrum together with the action spectrum for erythema for one subject in that study; similar results were found for other subjects. It can be seen that radiation with wavelengths $<290 \text{ nm}$ is ineffective at clearing psoriasis, but effective at producing erythema. Broad-band UVB sources (such as the Phillips TL12 lamp) that have traditionally been used for phototherapy tend to have relatively high emissions at wavelengths $<290 \text{ nm}$. The narrow-band UVB lamp (Phillips TL01) has only 2.3% erythemally effective radiation at wavelength $<290 \text{ nm}$. It is therefore not surprising that clinical studies comparing traditional broad- and narrow-band (TL01) UVB lamps for psoriasis treatment (40) have usually shown that narrow band is more effective. There are fluorescent broad-band UVB lamps available (e.g., UV6; Sylvania, Brussels, Belgium) with little or no emission $<290 \text{ nm}$ and the efficacy of these for psoriasis clearance has not yet been established. Spectra of various UVB fluorescent sources are shown in Fig. 7.

Figure 11. Psoriasis clearance action spectrum and erythema action spectrum in an individual subject. (From Ref. 42). The triangles indicate the reciprocal of the lowest daily dose to clear psoriasis and the circles are the reciprocal of the minimal erythemal dose. Similar responses were seen for the other three subjects in this study.

Psoralen Photochemotherapy

This form of treatment, known as PUVA, involves the combination of the photoactive drug psoralen and UVA irradiation to produce a beneficial effect. Psoralen photochemotherapy has been used to treat many skin diseases (43), although its principal success has been in the management of psoriasis. The psoralen may be applied to the skin either topically (44) or systemically (45); the latter route is generally preferred. The psoralen is usually administered as 8-methoxypsoralen (8-MOP). The patient ingests the 8-MOP tablets and is then exposed to UVA radiation 1 or 2 h later when the photosensitivity of the skin is at a maximum. The mechanism of the treatment is thought to be that psoralen binds to DNA in the presence of UVA, resulting in a subsequent transient inhibition of DNA synthesis and cell division. The UVA lamps used for PUVA therapy (such as the Phillips TL09 or Phillips Cleo Performance lamps) (Fig. 6), typically have a broad spectrum from ~315–400 nm peaking at ~352 nm. Within the UVA range, the action spectrum for psoriasis clearance is thought to be similar to the erythema action spectrum in psoralen sensitised skin and these peak near 320 nm (46). A study using narrow-band UVB and psoralen found no significant difference in response compared to conventional PUVA treatment (47). It is possible that UVA lamps conventionally used for PUVA treatment do not have the optimum spectral characteristics. However, narrow-band UVB phototherapy is now more widely used than PUVA and there is less interest in pursuing optimisation of PUVA treatment.

Treatment Regimes for UV Therapy

It is the custom in phototherapy and photochemotherapy to use the patient as their own biological monitor. The exposure of UVR at a given wavelength required to produce a given degree of erythema in normal Caucasian skin can vary by a factor of 5 or more (48), depending on an individual's susceptibility to sunburn. For photochemotherapy the degree of variability in erythema in sensitized skin may be greater due to variations in psoralen metabolism. Therefore, before embarking upon a course of irradiation, the minimum dose to cause just perceptible erythema should be determined. For phototherapy, this is termed the MED, whereas for photochemotherapy it is termed the minimal phototoxic dose (MPD). Either MED or MPD measurement is made by exposing the skin to increasing doses of UV using a lamp with the same spectral output as the treatment lamp. Devices using a series of filters have been designed to facilitate this (49) (see Figs. 12 and 13). For phototherapy, the MED is usually determined at 24 h. However, erythema in psoralen sensitized skin does not reach a maximum until ~72–96 h, so the MPD is determined at this time. Starting doses for treatment are usually set at ~50–70% of the MED or MPD. Treatment is typically given two or three times weekly until the psoriasis clears. At each treatment, the dose is increased to allow for acclimatisation of the skin. If erythema occurs then the dose may be reduced. The total time until clearance varies considerably from one patient to another, and in some cases complete clearing of the lesions is never

Figure 12. An erythema skin testing device for use prior to phototherapy, consisting of a TL01 fluorescent lamp and a number of apertures covered by metal grid filters [based on design by Diffey et al. (49)].

achieved. However, typically ~25 treatments are required for clearing of the psoriatic lesion in many patients over a period of ~10 weeks. Various different treatment regimes are used with varying starting doses and number of treatments per week. Examples are given in British Photodermatology Group guidelines (40,44,45) and by Diffey and Hart (50).

UVA1 Therapy

There have been several studies into the use on UVA1 (340–400 nm) therapy (51). As yet this treatment is only available in a few centers and insufficient work has been done to reach a firm conclusion on its efficacy.

Risks of Phototherapy

The major acute risk in phototherapy is that of erythema. In phototherapy, it is the erythema response in the unaffected skin that limits the treatment dose and frequency. Therefore, it is important to have an understanding of how erythema increases over time and with increasing dose for different therapy sources. Erythema peaks at ~8–12 h after exposure for solar simulated radiation, UVC and UVB (7,52). The degree of erythema varies rapidly with the dose of UVR. When the log of dose is plotted against erythema index, a sigmoid shaped curve is seen with a relatively linear portion above the MED. The steepness of this curve will show variation from individual to individual.

Figure 13. Normal erythema response at 24 h obtained using the device shown in Fig. 12 in a subject with skin type 2. The MED is seen at site 6 or possibly 7.

Figure 14. A common type of whole body phototherapy therapy supplied by Waldmann (Herbert Waldmann GmbH & Co., Villingen-Schwenningen, Germany.) This illustrates the direct method of measuring UV irradiance; after the door is closed lamps are lit and measurements are made in a number of positions.

However, on average, for UVB sources doubling the dose will cause a change from mild to moderate erythema (53), whereas for psoralen sensitized skin a quadrupling of the dose is required to cause a similar change (54). It is now firmly established that long-term PUVA treatment leads to a rise in SCC incidence (50). A cumulative dose of $<500 \text{ J/cm}^2$ is unlikely to result in significant risk, whereas for a cumulative dose of 2000 J/cm^2 the risk of SCC is $\sim 50\%$. Phototherapy with UVB alone is thought to carry a lower risk of skin cancer than PUVA (40).

Equipment for Ultraviolet Therapy of Skin Diseases

Ultraviolet therapy is usually delivered using large cabins housing $\sim 24\text{--}48$, 6 ft vertical fluorescent lamps Fig. 14. Compact units for treating just the hands and feet or smaller areas are also available (Fig. 15). All treatment devices usually incorporate timers to terminate treatments and most now have in-built UV meters. This enables treatment to be entered in dose units; the machine then terminates the treatment when the dose reaches the preset level. The benefits of using in-built meters are that changes in lamp output over time are compensated for and there is less opportunity for human error in calculating the

Figure 15. A small PUVA therapy unit suitable for treatment of the hands and feet.

required treatment time for a given dose. The disadvantage is that if the meter sensitivity changes (maybe due to dirt covering the detector) or the sensor becomes covered or shadowed by a large patient, then the patient will receive an overexposure. This problem has been partly overcome in some cabin designs that have 2 m and treatment is terminated if the two readings differ by a set amount. Most systems have safety features to limit the maximum time or dose that can be delivered. An external backup alarm (55) can also help to prevent overexposure.

Equipment Quality Control in Phototherapy

It is recommended that a quality control regime is implemented for phototherapy equipment (24). The approach used is different for cabins with in-built meters to those without. If in-built meters are not used then measurement of irradiance is required for calculation of exposure time for a given prescribed dose. The frequency of measurement required will depend on usage, but typically monthly readings are desirable due to lamp ageing. Daily checks are required to identify any tube failures. If in-built meters are used, compensation is automatically made for changes in cabin irradiance. However, the accuracy and reproducibility of the meter needs to be assessed. It is important to note that the irradiance at the patient surface during treatment is less than that

measured in the same position with the cabin unoccupied, because some of the energy received at the patient surface has been reflected from other parts of the cabin by mirrors behind the fluorescent tubes (56). Without the patient present this reflected fraction is greater. The ratio between “direct” (i.e., with patient in cabin) and “indirect” measurements ranges from ~ 0.65 to 0.90 (57,58), varying with cabin geometry, lamp spectrum, and patient size. The irradiance within a cabin will vary with position, so it is usual to determine the mean irradiance over several positions for an average sized patient; this is termed the Designated Patient Irradiance (DPI). In order to avoid undue staff hazard, the DPI may be measured using the direct method initially (Fig. 14) and subsequently using the indirect method with a correction for the direct–indirect ratio. Automated systems may be employed to move the detector to a number of predetermined positions within the cabin (59,60). The in-built meter reading should agree with the DPI measured using an independent meter to within 20%. Measurement of irradiance from all equipment should be regularly recorded in a standard manner so that trends over time can be assessed. It is important that there is consistency between calibration of equipment used for MED or MPD testing and that used for treatment. The meter used should be correctly calibrated for the lamp being measured and be recalibrated with reference to national standards annually.

SUNBEDS AND TANNING

One could argue that a sunbed is not a medical device, since its primary purpose is cosmetic tanning. However, information on sunbeds is included here for a number of reasons:

- Certain sunbeds could be classed as medical devices according to British Standards.
- There are concerns and considerable media interest regarding the safety of long-term sunbed use that may impact on health services.
- Many people with skin diseases try using sun beds to treat themselves.

Sunbed Lamps

Prior to the mid-1970s, the only artificial way to achieve a tan was using a “sunlamp” at home. These lamps were unfiltered medium or high pressure mercury arc lamps that emitted a wide spectrum including significant UVC and UVB components. Because of the significant short wavelength contribution, exposure times were short (a few minutes) and the incidence of burning was high. In the early 1980s tanning using UVA fluorescent lamps became popular, largely because the tanning industry promoted the idea that UVA tanning was safe (61). Typical UVA lamps used were similar to those used for PUVA therapy (e.g., Philips TL09 lamp) with $\sim 0.7\%$ of the total UVR in the UVB range. In the mid-1980s, a new lamp was introduced for tanning (Philips TL10) that had a spectrum

extending from 340 to 400 nm with a UVB component of only 0.05%, but these lamps are not often used today (62). It has been proposed that the “least bad” way to acquire an artificial tan may be to use a lamp that emits UVB in a similar proportion to natural sunlight (63). Philips have recently introduced the Cleo Natural lamp with this in mind (64). A survey of commercial tanning establishments in Scotland (62) found 13 different models from 7 manufacturers. However, the lamps fell into three categories; 81% were type 1 UVA lamps (e.g., Philips Cleo Performance, emitting $\sim 0.7\%$ UVB); 8% were type 2 UVA lamps (e.g., Philips Cleo Professional, emitting $\sim 1.4\%$ UVB); and 11% were filtered high pressure metal halide lamps. Other new higher UVB emitting lamps are now available such as the Philips Cleo Advantage and Swift (64), but surveys to assess the popularity of these lamps have not been reported. Spectra of UVA lamps used for tanning are shown in Fig. 6.

McGinley et al. (62) found that the UVB irradiance from an average sunbed was similar to that of Glasgow, UK, on a sunny summer day, whereas mean UVA irradiances were three or four times higher. They estimated that the total UVR received during 20 sunbed sessions was similar to that received during a week sunbathing in the Mediterranean.

Tanning

In the tanning process, melanocytes are stimulated to produce melanin that is transferred to keratinocytes. It is widely believed that obtaining a tan protects against sunburn. However, the degree of protection may only be equivalent to a sunscreen with a sun protection factor (SPF) of 3 (65) and there is evidence to suggest that a UVA tan provides even less protection than that due to natural sunlight. The action spectra for tanning and erythema are very similar for people who do not tan easily (42). For those who tan easily it is possible to obtain a UVA tan without burning.

Risks of Sunbed Use

Short-term risks of sunbeds include sunburn, itching, skin rashes, nausea conjunctivitis, and photokeratitis (66). Sunbeds can also provoke the common photodermatoses, polymorphic light eruption. A serious concern over long term sunbed use is that of developing skin cancer (65). The erythema, tanning and squamous cell carcinoma action spectra (see Fig. 3) are all similar, and therefore tanning by any part of the UV spectrum carries an approximately equal risk for SCC. There is also now increasing evidence that sunbed use is associated with increased melanoma risk (65).

Legislation

Sunbeds are used by a significant minority of the population and recently they have become popular with young people. British and European standards (67) classify sunbeds according to the erythemally weighted irradiance in the UVA and UVB range. According to this classification, the typical UVA sunbed is a type 3 device and a sunbed

with Philips Natural lamps is a type 4 device (68). Type 4 devices should be marked with the following warning: "to be used following medical advice only". There is, however, no statutory regulation of sunbed use in the United Kingdom. Some countries or U.S.A. states have regulated access to sunbeds to a certain extent (65). Autier (61) proposes strict controls to minimize and regulate sunbed use. However, Diffey (69) believes that outright prohibition is unnecessary since the excess deaths from sunbed use in the United Kingdom is relatively small compared to that from natural UV exposure and other voluntary risks (e.g., smoking and alcohol).

Sunbeds and Home Phototherapy

A survey has shown that many patients use sunbeds at home to treat psoriasis and believe it to be effective (70). However, a randomized placebo controlled trial of UVA sunbed therapy for psoriasis (71) found only a small degree of improvement. A consensus report of the British Photodermatology Group (72) concluded that home phototherapy represented suboptimal treatment with greater risks compared to hospital based treatment. Das et al. (68) carried out a randomized comparison between conventional UVA sunbed lamps and lamps with higher UVB component (Philips Natural). They found no difference in response for equal erythemal doses. However, when equal exposure times were used (similar to that used in a conventional tanning session) significant improvement in psoriasis were seen. The authors conclude that this home sunbed treatment is likely to be less effective compared to conventional hospital treatment, but may be appropriate for some patients who cannot access hospital therapy. Several groups have investigated installing conventional phototherapy systems in patient's homes. A recent project in Scotland (73) installed narrow-band UVB in patients home and provided them with treatment schedules and training. They concluded that the treatment was effective, safe and cost effective. Overall, home phototherapy probably is worth considering for certain patients and centers with a very rural catchment area.

OTHER USES OF UV IN MEDICINE

Laser Eye Correction

Energy from an ArF₁ (argon fluoride) excimer laser at 193 nm is very well absorbed by proteins within the cornea. Molecular bonds are broken as the photon energy is greater than the bond strength within these proteins. The process of tissue removal is not like that of a scalpel, or other lasers. Rather, a broad beam is used that removes tissue by a process called "ablative photodecomposition". Since the laser energy is absorbed very near the surface, little tissue damage beyond this region occurs. The degree of tissue removal is computer controlled so that the cornea is reshaped to give the appropriate degree of refractive correction for the patient. Several different effective techniques are used (74,75), Photorefractive Keratectomy (PRK) uses the laser alone to reshape the cornea, whereas Laser-Assisted *In Situ* Keratomileusis (LASIK) is a combined

surgical and laser technique. During LASIK surgery, a thin flap on the cornea is cut and folded back and the laser is then used to remove a precise amount of corneal tissue. The LASIK method is currently the dominant procedure and has the advantage of maintaining the central corneal epithelium (76). Current evidence on LASIK suggests that it is efficacious in selected patients with mild or moderate myopia. Evidence is weaker for its efficacy in patients with severe myopia or hyperopia, and there are concerns about the safety of its use in the long term (77). The U.K. National Institute of Clinical Excellence is due to issue guidance on the use of PRK during 2005.

Photopheresis

Photopheresis (also known as extra-corporal photochemotherapy or ECP) was first described by Edelson et al. in 1987 (78) and its use has recently been reviewed by McKenna et al. (79) The technique involves the following process: venous blood is removed from the patient, the white cells are separated and mixed with 8-methoxypsoralen, these cells are then irradiated using UVA lamps and then returned to the patient. A treatment session takes ~4 h and this is repeated every few weeks for several months. Currently, the technique is expensive and only used on a relatively small number of patients in a limited number of centers. It has been investigated in a wide range of diseases with varying degrees of success. The most promising results have been in the treatment of cutaneous T-cell lymphoma and graft versus host disease. There is some debate about the mechanism of action; it is not likely to be a direct effect on circulating lymphocytes since only a few percent are treated during each session. It is thought that it may work by stimulating the patient's immune response to the malignant lymphocytes.

Blue Light Phototherapy

Blue light phototherapy (50) is used in the treatment of neonatal jaundice. The condition is caused by the inability to clear bilirubin. Bilirubin is formed as the body scavenges iron from heme molecules released during the destruction of red blood cells. Irradiation of bilirubin by blue light causes its conversion to forms that are less toxic and more easily removed from the body. As the liver matures it becomes more able to excrete bilirubin so that phototherapy is only required for a short time. There is uncertainty about the optimum spectral output for lamps used in phototherapy, although it is thought that the most effective wavelength is ~450 nm. Either fluorescent lamps or metal halide lamps are used for blue light phototherapy. The hazards of blue light are almost entirely to the retina. Note, however, that many blue light phototherapy lamps emit radiation in the UV range. Normally, this is removed using an acrylic sheet. However, it has been shown that lamps may emit ~0.2 mW/cm² UVR with the shield in place and ~10 times this with the shield absent.

Disinfection and Hygiene

Ultraviolet radiation of wounds and ulcers has been used in the past (80). The success of the treatment relies on the

bactericidal properties of UVR and for this reason it is important that lamps that emit UVC are used. Advances in antibiotic therapy meant that the technique became less common. There is, however, renewed interest in this treatment for methicillin resistant *Staphylococcus aureus* (MRSA) infected wounds (81,82).

UVC irradiation is also used to kill bacteria in the air in operating theaters and there has recently been increased interest in this technique as a method of dealing with deliberate terrorist release of pathogens in buildings (83).

Many flying insects are attracted for UVA radiation (~350 nm). Certain insect killing devices attract insects with UVA, and then electrocute them as they fly toward the source. This method of dealing with flying insects is the technique of choice in many hospital kitchens (84).

Stimulation of Vitamin D Production

Production of vitamin D is the only definite beneficial effect of human UVR exposure. Low level UVR has been used to stimulate vitamin D production in residents of an old people’s home (85).

HAZARD ASSESSMENT AND PROTECTION

Exposure Limits and Hazard Assessment of UV Sources

The International Commission on Non-ionizing Radiation Protection has published guidelines on MPE limits for UV sources. The latest revision of the guidelines (6) contains updated information on hazards, but does not change the value of the limits published in 1989 (86). For most individuals, if exposure is below the limits, then they will not experience acute effects and the risks from long-term effects will be at an acceptable level. The limits are based on an envelope action spectra for all acute and chronic deleterious effects on the eye and skin. Certain individuals with disease or sensitized by chemicals or drugs may experience effects at exposure levels below the limits. To be below the MPE there are two criteria that must be satisfied:

1. Total effective spectrally weighted UV radiation (180–400-nm range) incident on the unprotected skin or eye should not exceed 30 J/m² over an 8 h period
2. Total unweighted UV radiant exposure in the spectral region 315–400 nm on the unprotected eye should not exceed 10⁴ J/m² over an 8 h period

The effective spectrally weighted exposure is calculated using the following expression:

$$E_{\text{eff}} = \sum E_{\lambda} \cdot S_{\lambda} \cdot \Delta_{\lambda}$$

Where E_{λ} is the measured irradiance of the source (W/m²), S_{λ} is the relative spectral effectiveness (unitless), and Δ_{λ} is the wavelength measurement interval. The weighting factors used form a “hazard action spectrum” (6), similar to that used when calculating erythema effective irradiance. Figure 3 shows a comparison of the two spectra.

The hazard weighted effective irradiance can be measured in two ways: A spectroradiometer can be used to measure the absolute spectral irradiance of the source in question, and the relevant weighting factors can be applied accordingly. A less accurate (but simpler) method is to use a radiometer fitted with an appropriately weighted filter. However, attempts to develop filters that have a good match to the hazard action spectrum have not been particularly successful. Measurements of various UV sources in the author’s laboratory with a spectroradiometer and narrow-band meter with hazard weighted filter (International Light, IL1730A UV Actinic radiometer, fitted with an ACT270 filter) are shown in Table 4. While the broad-band meter provides a reasonable approximation for some sources, there are very large errors for others due to the poor matching of the filter characteristics and the hazard action spectrum. It is important to consider both the weighted exposure to the skin and eye and the separate limit for UVA exposure to the eye. As can be seen from the examples in Table 4, the former limit usually dominates, but for the source with high UVA output it is the latter that is more restrictive.

Table 4. UV Hazards Measured in the Author’s Laboratory (all at 10 cm)^a

UV Source	Weighted Irradiance, W/m ² Measured with Spectroradiometer	Weighted Irradiance, W/m ² Measured with Radiometer	UVA Unweighted Irradiance, W/m ² Measured with Spectroradiometer	Time min to Exceed 30 J/m ² Weighted Irradiance, Skin Hazard	Time min to exceed 10 ⁴ J/m ² Unweighted UVA Irradiance, Eye Hazard
Bank of six 4 ft TL01 tubes	0.43	0.40	4	1	45
Bank of eight 2 ft TL09 tubes	0.02	0.14	67	30	2
Single 2 ft TL12 tube	0.73	1.1	2	1	80
Single 6 ft UV6 tube	0.22	0.26	4	2	40
Xe Arc lamp	0.20	0.24	2	3	70

^aThe weighted irradiance was obtained either by using a radiometer with a hazard weighted filter (International Light IL1730 with ACTS filter) or by spectroradiometer measurements combined with INIRPC hazard spectrum (6). The times given in the final two columns are those required to exceed to the maximum permissible exposure for eye and skin calculated from the spectroradiometer measurements.

Protection Measures

The National Radiological Protection Board (NRPB) in the United Kingdom has issued advice on protection against UVR (5). For workers exposed to artificial sources, administrative, engineering, and protective measures should be in place to ensure limits are not exceeded. For other situations, such as members of the public exposed to the sun, strict observance of limits is not practicable. If possible, exposure to artificial sources should be limited by engineering controls. For example, phototherapy cabins are usually fitted with interlocks so that the lamps go out when the door is opened. It is essential that staff working with UV sources are well trained and understand the nature of UV hazards. Access to suitable trained Medical Physics staff for advice on UV hazards is also important. Warning signs and access restrictions should be used where exposure above the MPE level is possible. Personal protective equipment (such as face shield and gloves) should be used if exposure to UVR above the MPE cannot be avoided.

The British Standards Institute provide information on the performance specifications of UV filters for personal eye protection (87). Percentage UV transmission should be <0.0003% at 313 nm and <7% at 365 nm and luminous transmission should be between 43 and 58%.

Patient Safety

Good staff training is vital to minimize risks of patient UV overexposure during phototherapy. There must be adequate protection against electrical hazards. Patients should not come into contact with bare lamps. There is a risk of injury if the patient falls against the lamps and it is now common practice to place a UV transmitting sheet between the lamps and the patient.

Because psoralen is deposited in the lens of the eye, there is a risk of cataract induction if the eye is exposed to UVA in the 12 h following psoralen ingestion. Consequently, the patient should avoid unnecessary sunlight exposure for the remainder of the day following PUVA treatment and they should wear appropriate eye protection. These may either be sunglasses, prescription lenses, or clear safety spectacles. Contact lenses even if marked as UV protective may not afford sufficient protection (88). The suitability of UV protective eyewear may be assessed using a spectrophotometer to fully characterise the transmission and comparison with limits suggested by Moseley et al. (89). Alternatively, a simpler approach (50) is to measure the lens transmission of radiation from PUVA therapy lamps using a hand-held narrow-band meter.

Hazards from Ozone

Ozone is a colorless, toxic irritant gas formed by a photochemical reaction between short wavelength UVR and oxygen in the air. It is possible to find ozone near UV lamps, especially where radiation <250 nm is transmitted through the envelope of the lamp. If ozone production is suspected, then adequate ventilation should be provided to remove the hazard.

ACKNOWLEDGMENTS

This article is based on that in the first edition by Prof. Brian Diffey and certain sections (e.g., the historical introduction) are taken directly from that source. Brian Diffey provided spectra for some lamps and the skin cancer action spectrum. Brian Diffey and Peter Farr were both very helpful in discussing certain parts of the text and providing useful references. Some of the practical measurements were made by John Frame. Steve Burnet and Muzz Hanliffa provided some of the pictures.

INTRODUCTION

The system of blood vessels in the body is crucial to transport cells, oxygen, and nutrients to the vital organs. When injured by diseases, such as atherosclerosis, the blood vessels may become occluded, leading to decreased blood flow and organ damage, or may be weakened and rupture due to aneurysmal dilatation. One method of treatment is to use surgery to bypass diseased blood vessels by using an artificial blood vessel substitute, or vascular graft prosthesis. Materials currently used in vascular graft prostheses include polyethylene terephthalate (Dacron) and expanded polytetrafluoroethylene (ePTFE). These devices successfully function as vascular grafts in larger diameter applications, but suitable materials for small diameter prostheses (<5 mm) are still being developed. Current trends in the development of small diameter prostheses include surface modification to prevent thrombosis, incorporation of endothelial cells, and a tissue engineering approach with the development of a biological blood vessel based upon a biodegradable material scaffold.

THE CLINICAL NEED FOR VASCULAR GRAFT PROSTHESES

Normal Blood Vessel Anatomy

The largest artery leaving the left ventricle of the heart is the aorta, which is ~20 mm in diameter. The aorta branches into progressively smaller arteries (<5 mm internal diameter) that feed blood and nutrients to organs, such as the brain (carotid arteries), liver (hepatic artery) and kidneys (renal arteries), and to the extremities of the arms (cephalic arteries) and legs (iliac and femoral arteries). The smaller arteries branch further to become smaller arterioles (<1 mm), which branch even further to become the smallest capillaries (<100 μ m), through which only single cells can pass. The capillaries are the site of most oxygen and nutrient exchange into the tissues. Capillaries then join together to form venules, small veins, and then larger veins that carry deoxygenated blood back to the lungs and heart. The design of replacement blood vessels should take

into account both the structure and function of native vessels for optimal function.

Normal arteries have three different layers: the internal intima, the middle media, and the external adventitia (1). (see Fig. 1). The intima is composed of a layer of endothelial cells, with underlying extracellular matrix proteins delimited by the internal elastic lamina. Endothelial cells are responsible for preventing blood vessel thrombosis under normal physiologic conditions by preventing platelet adhesion, coagulation, and thrombus formation (2,3). (see Fig. 2). This is accomplished by the expression and secretion of antiplatelet agents, such as ecto-ADPase, prostacyclin (PGI₂) and nitric oxide (NO) (2). Endothelial cells express thrombomodulin (TM) and release tissue factor pathway inhibitor (TFPI) to prevent activation of the coagulation cascade. Endothelial cells also express heparan sulfate to bind circulating antithrombin and rapidly inhibit local thrombin formation (2). If a fibrin clot is formed, endothelial cells can release factors that stimulate the fibrinolytic system to degrade the thrombus, such as tissue plasminogen activator (tPA) (2). Upon cytokine or thrombin stimulation, endothelial cells can develop a procoagulant phenotype with expression of tissue factor (TF) and release of vWf, PAI-1, and coagulation factors (6). The intima is present in all vessels, with the smallest capillaries composed of only a single layer of endothelial cells resting upon a thin basement membrane of extracellular matrix proteins.

The media varies in composition from large elastic arteries, such as the aorta, where it is composed of layers of elastic tissue and glycosaminoglycans to the smaller muscular arteries, such as the coronary arteries in the heart, where it is composed predominantly of vascular smooth muscle cells (1). The elastic and mechanical properties of the media allow vessels to contract or relax to maintain the luminal pressure and volumetric flow rate. Arterioles may have only a single layer of smooth muscle cells and capillaries have no media at all.

The external blood vessel layer, or adventitia, serves to supply nutrients to the cells in the blood vessel itself. It consists of a loose layer of connective tissue, with small arterioles and capillaries (vasa vasorum or "vessels of the vessel") feeding the blood vessel. It also contains a network of nerves that can stimulate medial smooth muscle cell contraction or relaxation. The adventitia is prominent in larger vessels, becoming progressively smaller as the vessel diameter decreases. Arterioles and capillaries lack an adventitia completely.

Coronary Atherosclerosis

Atherosclerotic cardiovascular disease, in its many guises, is the leading cause of mortality in the United States, resulting in coronary artery disease, myocardial infarction, stroke, aneurysms, and peripheral vascular disease. Atherosclerosis is a multifactorial disorder of the arterial vascular tree where lipid dysregulation and vascular

Blood Vessel Structure

Figure 1. Arteries are composed of three layers: the intima, media, and adventitia. The intima is lined by endothelial cells and bounded by an internal elastic lamina. The media maintains vascular tone and is composed of smooth muscle cells or layers of elastic tissue. The adventitia supports the vessel and provides nutritional and neural stimulation.

inflammation leads to endothelial injury, vascular lipid accumulation, and calcification with the development of lipid-laden deposits, or “plaques” in the vessel wall that eventually lead to stenosis of the vascular lumen (7). The resulting stenosis or narrowing of the blood vessels compromises blood flow through the artery. Rupture of the atherosclerotic plaque with subsequent thrombosis may lead to complete occlusion of the blood vessels. Depending on the location of the artery, this stenosis or occlusion leads to decreased distal blood flow and end-organ dysfunction. Examples include infarction of cardiac muscle with complete coronary artery occlusion or stroke with occlusion of carotid or cerebral arteries.

Despite advances in prevention and early diagnosis, cardiovascular disease claims more lives than the next five leading causes of death, combined (8,9). Coronary atherosclerosis alone, leading to stenosis and occlusion of the small coronary arteries that nourish the cardiac muscle, is the single leading cause of death in American today, responsible for 494,000 deaths in 2002 (8,9). The current modalities for treating coronary artery disease include intravascular angioplasty, stenting, and bypass of the stenotic lesions using saphenous vein or internal mammary artery grafts. Coronary bypass surgery was performed in over one-half million individuals in the United States alone in 2002 (10,11), with the majority of

individuals requiring bypass of three or more vessels. Unfortunately, in a significant number of individuals, autologous veins and arteries are not available, and there is a need for readily accessible, functional, alternative small diameter vascular graft prostheses.

Cerebrovascular Disease

Atherosclerotic vascular disease also affects the cerebral vessels and peripheral arterial tree, leading to stroke, renal failure, and arterial claudication. Stroke is the third leading cause of death, with ~275,000 Americans dying of stroke in 2002 (9). One of the leading causes of stroke is atherosclerotic stenosis of the carotid arteries in the neck, leading to thromboembolic stroke (11). Due to the danger of any further thrombosis or embolism, vascular prostheses have not been used to treat carotid artery disease, and therapy is currently limited largely to carotid endarterectomy, with removal of vascular plaque, and limited use of carotid stents (12). Use of vascular prostheses for cerebrovascular disease will not be feasible until prostheses are developed that pose no risk for distal thromboembolism.

Peripheral Vascular Disease

Peripheral arterial disease, with atherosclerotic occlusion of peripheral arteries predominantly in the lower extremities, leads to claudication and leg pain in ~8–12 million Americans (13,14); while it is not a major cause of mortality, it is associated with significant morbidity (9,13). Current therapies for treating peripheral arterial disease include angioplasty and vascular bypass. Prosthetic grafts have been successfully employed to treat atherosclerosis of the aorto-iliac bifurcation, but saphenous vein bypass is still the most widely used therapy for femoral-popliteal and below-the-knee bypass surgery (15–17). Suitable saphenous veins may not be available in ~15% of patients (17), often due to prior use for coronary artery bypass surgery. There is a clinical need to develop small diameter vascular prostheses that remain patent for long periods to more effectively treat peripheral arterial disease, and provide a viable alternative to saphenous veins.

Aneurysms

An aneurysm is a dilatation of a blood vessel wall that may be circumferential (fusiform aneurysm) or may involve only a portion of the vessel circumference (saccular aneurysm). Aneurysms most frequently affect the abdominal aortic wall and are a significant cause of mortality due to aneurysm rupture, resulting in 1.3% of all deaths (18). Aneurysms can affect other arteries, such as the cerebral arteries, renal arteries, and splenic arteries. Aneurysms usually do not occlude blood flow, but the dilated vessel wall is weakened mechanically and can rupture, leading to extravasation of blood into the surrounding tissues. Infra-renal aortic aneurysms 5.5 and 6.5 cm have annual rupture rates of 11 and 26%, respectively (19). Abdominal aortic aneurysms are usually observed in older patients in association with atherosclerosis, but other factors, such as proteolytic degradation of elastin and collagen by matrix metalloproteinases and plasmin is thought to be contrib-

utory (20–22). Therapy has generally been surgical, with the placement of an intraluminal vascular graft (23,24) or an endoluminal stent-graft (25).

Trauma

Vascular trauma from gun shot wounds, knife wounds, motor vehicle accidents or accidental dismemberment may result in laceration or transection of blood vessels. This injury may necessitate replacement with a vascular graft, if the vessel wall cannot be surgically repaired or an autologous saphenous vein is not available (26). Traumatic injury of large diameter vessels, such as the pulmonary artery or aorta usually requires a synthetic vascular graft or patch, as autologous tissue of large diameter is not available. One unique consideration with vascular trauma is bacterial contamination due to open wounds or colon injury, and remote bypass grafts through clean subcutaneous tissues may be desirable. In cases of dismemberment, the blood vessels usually retract into the severed tissue, and microvascular repair methods are usually required to reestablish blood flow (27). This is also a scenario where an off-the-shelf small diameter vascular prosthesis would be desirable.

THE HISTORY OF VASCULAR REPLACEMENTS

Arterial aneurysms have been noted back to antiquity, when the Roman historian Antyllus first reported their tendency to rupture in the second century AD (28). Treatment dates back to 1684, when Moore attempted to induce thrombosis of an aneurysm by introducing large masses of intraluminal wires (23,29). The first reported surgical therapy was ligation of the abdominal aorta proximal to a leaking iliac artery aneurysm by Sir Astley Cooper in 1817 (28). Aneurysmectomy, with excision of the aneurysm and vascular repair was reported by Cooley and DeBakey in 1952 (4). Early vascular grafts employed aortic wrapping or the use of preserved or freeze-dried homograft replacement (30,31). Use of an intraluminal graft replacement was instituted by Creech in 1966, and this remains the standard treatment today (23). In 1991, Parodi introduced a new technique of treating abdominal aortic aneurysms with a stent-graft that could be inserted endolumenally through an incision in the femoral artery (25).

The use of synthetic materials as vascular substitutes for aneurysms and other vascular bypass grafts was initiated in 1952 with the use of Vinyon-N cloth as an arterial conduit (5). This was followed by the use of polyethylene terephthalate (Dacron) as a vascular conduit in 1957 (32,33). In 1969, Gore patented a microexpanded ePTFE, which was first used as an arterial conduit in 1973 (34,35). Umbilical veins were further developed with use of glutaraldehyde cross-linking and an external wrapping of polyester mesh (36). These synthetic prostheses showed some success in large diameter vascular applications, but were plagued by thrombosis and occlusion due to intimal hyperplasia in small diameter (<5 mm) applications. Lining of synthetic vascular prostheses with endothelial cells to improve thromboresistance was first described by Herring in 1978 (37). Development of a blood

vessel by in vitro culture of biologic tissues (i.e. tissue engineering) was first described in 1986, with a multilayer structure of collagen and vascular cells (38).

CURRENT VASCULAR GRAFT PROSTHESES

Vein Grafts

The saphenous vein is a long vein arising in the calf and thigh with extensive collateral circulation. It has been utilized extensively as a vascular graft due to its long size and diameter that is similar to coronary arteries and smaller arteries in the leg, such as the femoral or popliteal arteries. The use of veins as bypass conduits to surgically treat coronary atherosclerosis was first described by Kunlin in 1949 (39), and this procedure remains the standard method of coronary artery bypass surgery to this day. For coronary bypass, saphenous veins are harvested surgically or endoscopically and the quality of the veins assessed by inflation, with valves stripped prior to use, if necessary (40). Current coronary artery bypass techniques using saphenous veins have an occlusion rate of 10–15% at 1 year after surgery, increasing to 30–40% at 10 years after surgery (41). Improved patency has been observed using arterial conduits, such as the internal mammary artery and radial artery grafts (42).

When used as peripheral vascular bypass grafts for the femoral or popliteal arteries in the leg, saphenous veins can be dissected and the direction reversed to allow flow through the valves, but they can also be utilized *In situ* and the valves stripped to allow retrograde flow (43). It is thought that the *In situ* graft should have lesser disruption to the vein endothelium and adventitia compared to the reversed vein conduit (44), but 2 year clinical patency rates for femoropopliteal bypass are similar at ~82% for both procedures (45). Not all patients have an appropriate saphenous vein for either cardiac or peripheral bypass surgery. This is most frequently due to prior surgical harvest, but also may be from poor vein quality due to insufficiently small diameter or increased branching. In these patients, suitable synthetic vascular conduits are desirable.

Dacron

Dacron is a polyester fabric, polyethylene terephthalate. Clinically utilized Dacron vascular prostheses are manufactured as textiles, either knitted or woven (34) (Fig. 3). The original design of a Dacron vascular graft as a textile versus a solid tube was an attempt to allow tissue healing of the prosthesis through the pores of the material. The knitted prostheses have higher porosity than the more densely fabricated woven prostheses and require preclotting or use of a surface coating, such as gelatin, collagen, fibrin glue, or albumin, to prevent transluminal leaking after implantation (34,46,47) (Fig. 4). The woven grafts are most commonly used in the thoracic aorta and for ruptured abdominal aortic aneurysms to minimize blood loss (43). Most Dacron graft prostheses are crimped like a soda straw to improve graft flexibility and decrease lateral compressibility (Fig. 4). An alternative to crimping that results in a thinner prosthesis wall is the use of an external spiral winding of a stiff polymer, such as poly(propylene). In a

Figure 3. Scanning electron micrograph (SEM) of knitted Dacron vascular graft prostheses. The knitted prostheses are of lower porosity than the woven Dacron prostheses and must be sealed by preclotting prior to implantation. SEM, Original Magnification 1000 \times .

Figure 4. (top) A typical Dacron vascular graft prosthesis. Notice the crimped appearance of the prosthesis, which is utilized for flexibility and lateral compression-resistance. The blue line is to facilitate implantation without twisting, that would lead to kinking (bottom). An albumin-coated Dacron prosthesis. The albumin coating is used to seal the graft interstices and eliminate the need to preclot the graft prior to implantation. This type of coating often fails due to flaking and removal from the surface.

further attempt to foster tissue incorporation and vascular graft healing, some prostheses employ a velour surface, where thousands of individual fiber loops are pulled almost perpendicularly from the material, resulting in a surface that has a markedly increased surface area (48,49). Luminal velours are employed to trap fibrin and platelets, while external velours are used to increase adventitial healing and cellular incorporation (50).

Dacron vascular grafts have most successfully been employed in the surgical treatment of thoraco-abdominal and abdominal aortic aneurysms, where they are manufactured in a both a tubular and bifurcated aorto-bifemoral configuration. They have also been utilized for longer bypass applications, such as axillary-femoral or femoral-femoral surgery. In these longer length applications, the reinforced, eternally wound prostheses are typically utilized to prevent kinking when transversing joints. The successful treatment of abdominal aortic aneurysms with Dacron vascular grafts is proportional to the size of the aneurysm; for smaller aneurysms, the survival rates for surgical and nonsurgical populations is similar (51). The 5 year patency rates are 93% for aortic bifurcation grafts (52), with similar patency for knitted and woven grafts (53).

Dacron has not been widely used for lower extremity bypass, especially when the bypass entails vessels below the knee, due to poor patency rates. However, a recent study utilizing heparin-bonded Dacron showed favorable patency rates for femoro-popliteal bypass grafting for modified Dacron versus ePTFE (55% vs. 42%; $p < 0.044$) at 3 years, with similar patency rates at 5 years (45% vs. 35%; $p < 0.055$) (54).

Expanded Polytetrafluoroethylene

Polytetrafluoroethylene (PTFE-Teflon) is a chemically inert, hydrophobic polymer that resists long-term *In vivo* degradation. As mentioned above, PTFE has been manufactured in a microporous fabric for vascular grafts (ePTFE). The ePTFE is manufactured by a heating, stretching, and extruding process to form solid nodes of PTFE separated by many thin fibrils, with an internodal distance of $\sim 30 \mu\text{m}$ (34) (see Fig. 5). This same material, known as Goretex, is also popular for waterproof sporting applications, such as jackets and shoes, as the material hydrophobicity prevents gross water flux while allowing air transport. The same material properties that make ePTFE attractive for sporting materials make it attractive as a vascular graft. The hydrophobicity is designed to prevent surface thrombosis, while the microporous texture prevents transluminal graft leaking, while encouraging cell incorporation and healing. In applications where increased structural stability is required, an external winding or wrap of polypropylene is often employed.

Patency rates of ePTFE for aorto-bifemoral bifurcation grafts are 95% at 5 years, similar to Dacron (52,55). In extraanatomic bypass, ePTFE has shown a cumulative patency of 83% for femoro-femoral bypass and 75% for axillo-femoral bypass at 5 years (56). In lower extremity revascularization, saphenous vein bypass remains the

Figure 5. An SEM of expanded ePTFE vascular graft. Note the solid nodes of ePTFE separated by thin fibrils. The typical internodal distance of most clinical prostheses is $30 \mu\text{m}$. Due to the hydrophobic nature of ePTFE, this structure makes the material microporous, allowing limited cell migration, but limiting bulk water leakage. Original magnification $1000\times$.

graft of choice for below-knee applications. However, there is still controversy regarding the optimal material for above-knee femoro-popliteal bypass. Many studies report five year patency rates $< 50\%$ for ePTFE in femoro-popliteal bypass (54,57), with 5 and 10 year saphenous vein patency rates at 77 and 50% (58,59). However, in a retrospective study, the primary patency rate at 4 years was not significantly better for vein bypass (82.2%) versus ePTFE (80.6%) (60).

A somewhat unique use for ePTFE grafts is the arteriovenous graft used to provide vascular access to patients with renal failure undergoing hemodialysis. These grafts are interposed between the radial artery and cephalic vein in the wrist (61). Other options are the creation of a direct arterio-venous fistula without the use of a graft, and a central venous catheter. Primary patency of arteriovenous grafts is inferior to that of fistulas, irrespective of graft material or postoperative treatment with anticoagulants (62-64).

Endovascular Stent-Grafts

Historically, surgical repair of abdominal aortic aneurysms required major abdominal surgery with its attendant morbidity. For this reason, a procedure to repair aneurysms endolumenally from within the vasculature was attractive. In 1991, Parodi (25) reported the first successful use of a combined stent-graft that could be placed into the aortic aneurysm endolumenally through a femoral artery catheter without open surgery. During the past decade, many different stentgrafts have been developed for this application. They typically are composed of a fabric graft (Dacron or ePTFE) and an expandable metallic skeleton (23,65). They are usually inserted in a closed configuration and then opened via a balloon catheter. The stent is typically held in place with proximal and distal hooks. The metallic

skeletons employed are stainless steel, Elgiloy (nickel, cobalt, and chromium alloy) and Nitinol (nickel titanium alloy).

The stent-grafts may have a lower operative mortality and less frequent complications than open repair (18). However, two large European registries indicate a 3% yearly failure rate for endovascular repair versus 0.3% for open repair (66,67). Failure mechanisms unique to endovascular stent-grafts include endoleak, with blood flow between the exterior of the graft and the lumen of the aneurysm. There are also difficulties with stent-graft migration due to movement of the anchoring hooks (65). Some devices have problems with durability, due to repeated rubbing of the graft material against stent metal, with either fabric degradation or corrosion or stress cracking of the metal (68). In other patients, the aneurysm may continue to expand despite the presence of the stent-graft, termed endotension, due to transmission of lateral wall pressure through the graft.

Vascular Graft Healing

Implantation of synthetic vascular grafts that are not preclotted is associated with rapid protein adsorption, followed by platelet adhesion, inflammatory cell adhesion and variable degrees of fibrin formation (69,70). The fibrin formation is usually limited to a thin layer on the luminal surface, but this is variable depending on the diameter of the graft. The fibrin layer also includes entrapped macrophages and neutrophils, and reaches a maximal thickness ~2 weeks postimplantation (43). In preclotted Dacron grafts, there is already a fibrin-platelet layer in the graft interstices created by the preclotting process. This may be associated with increased platelet adhesion upon implantation (71). Later cellular healing may come from blood-borne cells, migration of cells from the anastomosis,

or in-growth of cells from the adventitia. This may or may not be accompanied by endothelial growth and development of a neo-intima, either due to migration from the anastomoses or implantation of circulating endothelial progenitor cells from the blood stream (72). In the absence of an endothelial layer, the fibrin matrix and inflammatory cells forms a pseudointima. There also may be an in-growth of smooth muscle cells and fibroblasts from the adventitia of the graft, depending on the porosity of the graft material. The adventitia is often associated with fibrosis and a foreign body giant cell response (see Fig. 6).

Most ePTFE grafts implanted in humans do not develop an endothelialized lumen spontaneously (73), and endothelialized pannus in-growth from the anastomosis is usually limited to only a few centimeters. Similarly, Dacron grafts usually do not re-endothelialize, but typically maintain a compact fibrin layer at the lumen. In lower porosity grafts, the graft interstices usually remain acellular. In ePTFE grafts and higher porosity Dacron prostheses, the interstices become populated with fibroblasts, macrophages, and less frequently, smooth muscle cells. Neovascularization, with new capillary in-growth, is rare.

Failure Mechanisms

The healing of implanted vascular grafts is not optimal due to lack of endothelialization or neovascularization. This may lead to clinical complications, such as thrombosis, intimal hyperplasia, and infection. Failure may be acute, midterm, or late (74). Early or acute failure is usually due to technical surgical problems or acute thrombosis. Early infection may be tied to contamination during surgery. Midterm failure (3 months to 2 years) may be due to cellular proliferation and intimal hyperplasia or infection. Late failure may be due to development of atherosclerotic lesions in the graft (75).

Figure 6. Healing of an ePTFE vascular graft. Note the cellular pseudointima without an obvious endothelial lining. The graft itself is sparsely populated with cells. The adventitial layer is dense compact fibrous tissue with a lining of multinucleated giant cells. Hematoxylin and eosin. Original magnification, 10 \times . Inset, 20 \times .

Thrombosis of Vascular Grafts

Figure 7. Thrombosis of a Dacron vascular graft in the aorta. In such a large diameter prosthesis, this degree of luminal thrombosis was of little clinical consequence. A similar degree of thrombosis in a small diameter vessel could result in complete occlusion.

The rapid adhesion of platelets and development of a luminal fibrin layer can lead to thrombosis (Fig. 7). Thrombosis is a leading cause of vascular graft failure, especially in smaller diameter prostheses, where it leads to decreased flow or occlusion. It is usually an acute or subacute failure mechanism, but may be a cause of late failure due to thrombosis super-imposed upon stenosis due to other causes of vessel narrowing, such as atherosclerosis or intimal hyperplasia. Antithrombotic therapy, particularly antiplatelet therapy, has been shown to be beneficial in decreasing graft occlusion up to 2 years after surgery (76–78).

The majority of stenotic vascular graft failures are due to hyperplasia of the tissues near the anastomosis, particularly the distal anastomosis (79,80), termed anastomotic intimal hyperplasia (81,82). This is particularly a problem with arteriovenous grafts used for dialysis access where the distal intimal hyperplasia may lead to significant stenosis of the lumen (83). The development of intimal hyperplasia is multifactorial, and its etiology is not completely known. It evolves from the tissue healing response at the anastomosis, but inciting factors include chronic inflammation, platelet adhesion with release of platelet derived growth factor (PDGF), vessel wall injury and mechanical factors, such as disturbed hemodynamic flow and compliance mismatch between the native vessel and the more rigid prosthesis (43,83–85). Alteration in cell phenotype due to interaction with the prosthesis or due to disturbed flow may lead to smooth muscle cell prolifera-

tion from altered production of basic fibroblast growth factor (bFGF) or PDGF by endothelial cells (86,87) or tumor necrosis factor-alpha (TNF α) by inflammatory cells (88). Indeed, antibodies to bFGF have been shown to decrease smooth muscle cell proliferation in ePTFE grafts experimentally (89). Recent gene-transfer experiments have suggested that increased expression of tPA and increased fibrinolysis may be associated with increased intimal hyperplasia, while increased expression of nitrous oxide synthase (eNOS) and increased expression of the platelet inhibiting molecule nitrous oxide may decrease the hyperplastic response (90).

Infection occurs in 1–6% of arterial vascular graft prostheses (43,91). The sources of infections may be contamination of the prosthesis during implantation or hematogenous seeding from bacteremia. The earlier infections are often due to *Staphylococcus aureus*, while the later infections are often due to a lower virulence organism, such as *Staphylococcus epidermidis* (92). Clinical symptoms of graft infections include fever, leukocytosis, and bacteremia; newer imaging techniques that are able to detect acute inflammation may be useful in diagnosis of graft infections (93). These infections may be resistant to antibiotics due to the lack of vascularity in the graft interstices. Complete or partial graft excision is often necessary for treatment (94). Graft modifications to decrease the risk of infection have included bonding antibiotics to graft surfaces or including antibiotics in the blood used to preclot the graft.

Figure 8. Gross photograph of a pseudoaneurysm at a graft anastomosis. This is not a true aneurysm as there is no failure of the graft material, but a defect between the graft and the native vessel, leading to blood leaking in the interstitial tissues. This type of pseudoaneurysm may cause graft occlusion due to external pressure from the leaking blood.

Material failure of Dacron or ePTFE grafts has been quite uncommon. Neither are substantially susceptible to *In vivo* degradation, although Dacron grafts may expand slightly *In vivo* due to flattening of the crimps or relaxation of the knitted or woven structures. Suture failure and blood leakage at the anastomosis with pseudoaneurysm formation has also been described (Fig. 8).

NEW DEVELOPMENTS IN VASCULAR GRAFT PROSTHESES

Surface Modification

Attachment of an anticoagulant, such as heparin or dipyridamole, to the graft lumen has been investigated as a method to improve small-diameter graft patency (76,95). As an example, Lin et al. (96) modified the luminal surface of a standard ePTFE with an aldehyde-modified heparin bound to layers of crosslinked polyethyleneimine (PEI), Carmeda bioactive surface (CBAS), and dextran sulfate. This graft (4 mm ID), as an exteriorized baboon femoral arteriovenous shunt, showed an 80% reduction in 1–4 h platelet deposition. When compared to contralateral uncoated grafts in a 4 week baboon aortoiliac bypass model, there was significant reduction in neointimal cell proliferation and area at both proximal (0.26 vs. 0.56 mm²) and distal (0.29 vs. 0.63 mm²) anastomoses for the heparin-coated grafts (96). One major concern with this strategy is the duration of heparin function. Delamination of portions of the layered coating or the presence of physical barriers deposited on the graft surface in the form of blood components would lead to failure for this type of approach. A heparin-bonded Dacron graft is currently available on the European market, with the heparin attached using a tridodecyl-methyl-ammonium chloride (TMAC) and the outer portion of the graft coated with collagen to decrease porosity (97). This heparin-bonded Dacron had similar 5 year patency rates to ePTFE for femoral-popliteal bypass grafting. Other surface modifications for ePTFE grafts have included carbon coating to decrease thrombogenicity (98,99), or incorporation of

growth factors to facilitate the healing process (100,101) and coating with polyurethane to enhance endothelialization (102).

Newer Biomaterials

There has been some interest in polyurethane elastomers as vascular graft materials, in an effort to develop radially compliant vascular grafts (34,85). Initial vascular grafts with polyester and polyether-based polyurethanes resulted in failure due to material degradation (103). Vectra, a polyetherurethaneurea vascular access graft, showed 12 month patency similar to ePTFE (104), and received U.S. Food and Drug Administration (FDA) clearance in 2000. More recently developed polyurethanes for vascular grafts utilize polycarbonate-based polyurethanes to impart hydrolytic and oxidative stability (85,105). One of these prostheses, Myolink, is available commercially for hemodialysis access. Some experimental hybrid polyurethane grafts have been developed in which the polyurethane is coupled with a gelatin–heparin matrix and reinforced with Dacron mesh (106). Other hybrid polyurethane grafts include a polyurethane with a biodegradable poly(ethylene glycol)–poly(lactic acid) copolymer coating (107). Polyurethanes have recently been modified to incorporate a diazeniumdiolate-modified nitric oxide (NO)-producing peptide, which can release NO, a potent platelet-inhibiting compound (108). A similar NO-producing polyurethane has recently been shown to decrease thrombus formation in a sheep model (109).

Endothelial Incorporation

Current clinically used large-diameter vascular graft materials, such as polyethylene terephthalate (PET) and ePTFE, suffer from early occlusion and thrombosis or late intimal hyperplasia. When employed in small-diameter applications, these failure modes are more prominent and have largely prevented the use of these materials in applications where the diameter is <5 mm. Since these prostheses characteristically do not develop a luminal

endothelial layer spontaneously, there has been considerable effort expended to develop surface modifications of ePTFE in particular, in order to encourage growth of a confluent endothelial layer, subsequent to the initial report by Herring in 1978 (37).

Two different procedures have been described, endothelial seeding, and sodding. Endothelial seeding involves treating the graft with a low concentration of endothelial cells prior to implantation with *In vivo* expansion of the cells. A two-stage endothelial seeding technique involves treating the graft with a low concentration of cells, followed by extended *In vitro* culture time to expand the cells to a confluent monolayer (110,111). Conversely, endothelial sodding entails coating the graft with a high concentration of endothelial cells to quickly form a confluent endothelial layer. The ePTFE is a very hydrophobic material and few, if any, endothelial cells attach directly to the ePTFE with either direct seeding or sodding techniques. Without modification, hydrophobic ePTFE grafts show attachment of only $10 \pm 7\%$ of applied cells, with EC retention only $4 \pm 3\%$ (112,113). Surface modification of the ePTFE is necessary to encourage endothelial attachment and growth. The source of autologous human endothelial cells can range from harvested veins, adipose tissue capillaries, and endothelial progenitors (75,114,115).

Many different surface modifications of ePTFE to promote endothelialization have been studied, such as attaching cell-binding peptides (116) or fibrin glue (117). A few of these have reached human clinical trials. One such modification involved the application of fibrin glue to the luminal surface of a small-diameter ePTFE graft to which autologous endothelial cells can attach (110,118). These coated grafts were seeded with autologous endothelial cells, harvested 4–6 weeks prior to graft implantation and expanded *In vitro*. The seeded graft constructs were allowed to mature for 8–10 days before implantation as either one of 21 coronary artery bypass grafts (110) or 153 infrainguinal grafts (118). After a mean postoperative follow-up of 27.7 months, the 4 mm diameter coronary artery graft patency was 90.5%. Angiograms of all 19 patent aortocoronary bypass grafts showed smooth luminal borders without stenotic regions. Percutaneous transluminal angioscopic evaluation showed a glossy white and smooth endoluminal graft surface without any fibrin, platelet, or erythrocyte deposits. The EC seeded grafts showed an improvement in patency versus unseeded ePTFE aortocoronary bypass grafts (110). For the 6–7 mm diameter infrainguinal reconstructions, Kaplan–Meier analyses revealed a primary patency rate of 84% after 4 years and 63% after 7 years, comparable to primary patency rates for vein grafts (118).

These clinically applied ePTFE modifications were not without incident. In one trial, *In vitro* flow experiments revealed a washout of ECs between 10–15% in the first minute after the application of a physiologic pulsatile flow. Additionally, one patient had a perioperative MI caused by the immediate occlusion of the EC-seeded ePTFE graft because of poor runoff and possible culture contamination with fibroblasts (110). In the other trial, 5% of patients had EC that failed to grow in culture despite rescue serum treatment. At implantation, 5% of seeded grafts were sub-

confluent and 5% had patches devoid of EC (118). These clinical trials highlight common difficulties faced in many ePTFE endothelialization attempts. Subconfluent EC coatings allow for possible thrombus formation. Extended and technically demanding *In vitro* EC culture is required to generate enough cells for confluent seeding. An additional surgery is required for vessel harvest to isolate primary EC.

To circumvent these difficulties, a potential way to encourage autologous cellular healing *In vivo* is to alter ePTFE pore size. The ePTFE is a hydrophobic material that is microporous due to thin fibrils of material stretched between nodes of solid PTFE; the internodal distance controls the porosity of the ePTFE material. In standard grafts with an internodal distance of 30 μm , endothelialization typically proceeds slowly, if at all, due to EC migration from the anastomoses. Animal studies employing larger pore sizes have shown improved cell in-growth and tissue healing for prostheses with larger internodal distances (119–121). Some (122,123) have suggested that an internodal distance of 60 μm allows optimal cell in-growth from the adventitia while not being as macroporous as prostheses with internodal distances greater than 90 μm (119).

Neovascularization has been demonstrated in animal models with vessels penetrating the larger graft pores (124), however, similar neovascularization and endothelialization is not observed in humans (125). Pore size alone, due to the hydrophobic nature of ePTFE, may be insufficient to influence cell in-growth into ePTFE prostheses.

A significant improvement in ePTFE graft design would be the development of *In vivo* endothelialization without the need for EC preseeding, due to capture of circulating endothelial progenitor cells *In vivo* or facilitating rapid neovascularization from the adventitia, also termed transmural endothelialization. A confluent luminal monolayer of endothelial cells would serve to eliminate the primary thrombotic mechanism of vascular graft failure. In this regard, the important consideration with ePTFE is how to facilitate endothelial cell attachment. Methods to improve endothelial cell retention include fibronectin preadsorption, covalent fibronectin attachment or glow discharge modification to facilitate protein adsorption. In a study of amide–amine glow-discharge modification, endothelial cell surface adhesion was four-fold higher in treated versus untreated ePTFE grafts (113). Additionally, the endothelial population on treated grafts remained shear stable, whereas untreated grafts showed a >90% decrease in endothelial cell population after application of shear stress (113). An animal implantation model showed improved graft healing after covalent binding of fibronectin to the graft materials (126). In a different approach, Kidd et al. attempted to promote *In vivo* endothelialization in a 1 mm ID ePTFE rat abdominal aortic implant model by facilitating transmural endothelialization (127). Squamous epithelial cell lines were allowed to attach and elaborate extracellular matrix (ECM) on the abluminal surface of the ePTFE graft for 8 days prior to implantation. The cells were removed, leaving an ePTFE graft with incorporated ECM for

implantation. Upon removal at 5 week, all samples were patent with ECM-modified grafts exhibiting extensive abluminal vascularization and tissue incorporation compared to nonmodified samples. Additionally, ECM modified grafts possessed a luminal cellular lining, while nonmodified grafts were void of a cellular lining except for limited pannus in-growth. These results indicate that luminal EC coverage can be derived from in-growth of capillaries through porous grafts (127).

Tissue Engineering

The recent thrust in developing a successful small-diameter vascular graft has been the use of a tissue engineering approach, instead of starting with an established vascular graft material (128,129). Strategies have included developing degradable polymeric biomaterials (130), utilizing decellularized biological conduits (131), and fabrication of a totally tissue-engineered vessel (38). Typically, a tissue engineering approach utilizes some type of degradable scaffold in which layers of endothelial and smooth muscle cells are grown to recapitulate an arterial architecture. These approaches have unique advantages and limitations. Ideally, tissue engineered vascular constructs should be nonthrombogenic, vasoreactive, and biostable, but should also be biocompatible and not prone to excessive inflammation, immune response, or infection. The cells should also be able to regenerate and angiogenesis should be supported. One challenge for tissue engineered vascular grafts is to combine degradability of the scaffold with sufficient mechanical strength to withstand pulsatile arterial pressures without developing aneurysmal dilatation. From an operative standpoint, tissue engineered grafts should be stored in a readily implantable form, be individualized to particular implant requirements of size and length and not prone to leaking.

Scaffolds. Synthetic polymer scaffolds for tissue engineering applications have utilized bioresorbable polymers, such as polyglycolic acid, polylactic acid, and polydioxanone (34). Polylactic acid is semicrystalline with high mechanical strength, with a naturally occurring degradation product, L-lactic acid (34). In one example, Niklason et al. (132) utilized polyglycolic acid (PGA) scaffolds chemically modified with sodium hydroxide. These were seeded with bovine smooth muscle cells and allowed to incubate under conditions of pulsatile radial stress for 8 weeks. Bovine aortic endothelial cells were seeded onto the lumen of the constructs and continuous perfusion was applied for the final 3 days of culture. These vessels cultured under pulsed conditions with appropriate supplements had average rupture strengths of 2150 ± 708 mmHg (286.6 ± 94.3 kPa) after 8 weeks with 50% dry weight collagen content. These values were very similar to native vessel rupture strength [1680 ± 307 mmHg (223.9 ± 40.9 kPa)] and collagen content (45% dry weight). The engineered vessels also displayed measurable contractions in response to vasoactive substances, such as serotonin, endothelin-1, and prostaglandin F_{2a}.

Another approach is to use two or more bioresorbable polymers with different degradation rates to optimize mechanical properties. Matsumura et al. (133) fabricated two types of bioresorbable polymer for use in a tissue engineering vascular autograft for pediatric patients. One polymer system was comprised of a 50:50 copolymer of lactide and ϵ -caprolactone [P(CL/LA)] that was reinforced by a nonwoven fabric made with PGA. Endothelial cells were harvested from saphenous vein 1–2 months prior to surgery, expanded *In vitro* and seeded onto the scaffold 10 days prior to surgery. This graft construct was used in a limited clinical study in the pulmonary artery, a low pressure application, with some success. Another hybrid scaffold was similar, but the reinforcing material was changed to a woven fabric made from poly-L-lactic acid (PLLA) to increase durability and the polymer scaffolds were seeded with bone marrow cells aspirated at the time of cardiac surgery and allowed to incubate with the scaffold in culture medium for 2–4 h before implantation. This BMC seeded polymer scaffold was used in 22 patients without thrombogenic complications, stenosis, or obstruction of tissue-engineered autografts. The benefits of this type of tissue engineered vascular autograft is that it has growth potential, reduced incidence of calcifications, and no risk of rejection due to use of autologous cells, but long term *In vitro* cell culture may increase the risk of infection and changes in cell phenotype could lead to thromboembolic complications.

The degradable polymer scaffolds have also been modified to include cell-binding peptides to further encourage cell growth and incorporation, such as arginine-glycine-aspartic acid (RGD), a well-characterized amino acid peptide that is a ligand to several cell surface integrin receptors (134–136). In one study, a biotinylated PLA–polyethylene glycol copolymer was reacted with streptavidin–RGD to facilitate endothelial cell attachment (137). Controlling the density of RGD groups on the polymer surface has been shown to modulate endothelial cell migration rate and shear stability (138,139).

A different approach to synthetic materials is the use of deoxyribonucleic acid (DNA) technology to engineer synthetic proteins. These have been used with some success to incorporate both RGD functionality and elastin-based peptides to facilitate endothelial cell growth and function, while allowing cross-linking and control of mechanical properties (140). Degradation can be controlled by incorporating sequences susceptible to degradation by enzymes, such as collagenase. Incorporation of cell binding amino acid sequences into these matrices has been shown to control cell functionality (141).

Biological materials have also been used as scaffolds, including fibrinbased or collagenous matrices and decellularized materials, such as extracellular matrix, arteries, small intestinal submucosa, and peritoneum–fascia (75,142–145). Cross-linked collagen is an attractive scaffold material, as it can have significant mechanical strength, depending on cross-link density, and contains several cell-binding peptides to encourage cell incorporation. A collagen scaffold was used in the first tissue engineered prosthesis (38), but this failed due to suboptimal mechanical properties. A fibrin gel-based graft has recently

shown some success, albeit in a low pressure jugular vein model (142). Methods to improve the scaffold mechanical properties have included mechanical preconditioning and use of fabricating techniques, such as electrospinning (146,147). Matsuda and co-workers used a rodlike mandrel around which a solution of collagen and smooth muscle cells was formed (148). The mandrel was then removed and the lumen seeded with endothelial cells. This was unsuccessful due to low burst pressures, and external reinforcement was needed to impart suitable mechanical properties (149,150). A collagen microsp sponge has been combined with a biodegradable polymeric scaffold to produce an implantable graft material for *In vivo* cell repopulation (151). Recently, a hyaluronan-based material (Hyaff-11) has been tested as a scaffold for endothelial cells (152).

Use of biological tissues with a preexisting extracellular matrix, such as arteries (153) or ureters (154), would be attractive, but antigenic differences between xenogenic species and humans preclude their use due to immunoreactivity and rejection. For this reason, there have been attempts to remove the cells from these scaffolds by enzymatic and detergent treatment and repopulate the decellularized scaffolds with autologous human cells (155). The xenogenic matrix still is potentially immunogenic (156), which may be alleviated by cross-linking (157) or population with autologous cells. Decellularized porcine carotid arteries treated with heparin and repopulated with canine cells have been shown to function for up to 18 weeks in a canine aortic graft model (153). Decellularized porcine small intestinal submucosa has also been studied as a tissue engineering scaffold. These constructs have been tested in animal models with some success, but intimal hyperplasia and incomplete endothelial coverage have been observed (158).

Source of Cells. In most tissue engineering constructs, the endothelial and smooth muscle cells are isolated from autologous human tissue, such as abdominal fat aspirates or veins, then cultured *In vitro* together with the construct for up to several weeks prior to implantation. There has been some recent interest in the use of bone marrow-derived endothelial progenitor cells as a novel source of endothelial cells (154). Cho et al. (159) examined tissue engineering of small diameter vascular grafts using bone marrow cells (BMCs) and decellularized arteries. Bone marrow mononuclear cells (BMMNCs) were isolated and two distinct fractions, one containing smooth muscle (SM) α -actin/SM myosin heavy-chain (SMMHC) positive cells and one containing vWF/CD31 positive cells, were cultured for 3 weeks using different culture media and supplements. Other studies have shown that when using BMCs, sufficient cells for seeding can be obtained on the day of surgery, thus obviating the need for extra vein harvesting surgery and prolonged cell culture.

SUMMARY

Vascular prostheses are vital in the treatment of many vascular diseases, from coronary artery disease and aortic

aneurysms to peripheral arterial disease. Several synthetic vascular graft materials, particularly Dacron and ePTFE, have been successful as arterial substitutes in large diameter applications. However, these devices can fail due to thrombotic occlusion, intimal hyperplasia, and infection. There is a need to develop novel vascular prostheses that function well in small diameter applications. Progress has been made on methods to facilitate the incorporation of endothelial cells into vascular grafts. The tissue engineering approach, with advances in new materials that can control graft mechanical properties plus cell attachment and proliferation, holds promise for the next generation of these crucial medical devices.

VENTILATOR USE

Introduction

A ventilator, like most critical care devices, is simply a machine. However, it is not a “simple machine.” Over the past five decades, the means of delivering gases to patients have become more complex. This has led to an evolution of more than 30 critical care ventilators being used in the United States. The numerous modes of ventilation and our unfortunate attempt to reach a consensus on the terminology used when referring to mechanical ventilation presents a challenge to even the most skilled clinician. Mushin’s description of ventilators in his archetypal text (1) is appreciated by many and addresses the classification scheme that can be adopted to the less-sophisticated mechanical ventilator. An innumerable count of authors has used this classification method when writing about mechanical ventilator support (2–4). Today’s mechanical ventilators are designed to provide life support using an array of computerized logic systems, software utilities, and even artificial intelligence models to deliver gas to patients. This evolution of ventilators has led to a modernistic classification system (5) to describe today’s microprocessor-controlled mechanical ventilator. A classification system that is specific and well defined is intended to enhance communications between clinicians (6). However, some respected organizations (7) and clinicians (8) have been reluctant to accept this new system for understanding mechanical ventilation despite its acceptance by leading members in the pulmonary and critical care medicine community (9–11).

Basic Concepts

A mechanical ventilator is a system designed to alter, transmit, and direct applied energy in a predetermined manner to perform useful work (12). This work was generally accomplished with some pneumatic component in earlier (first-generation) ventilators. Current systems employ electronic circuitry that is microprocessor controlled.

The energy we put into ventilators is in the form of electricity or compressed gas. Mechanically speaking, a

ventilator will take the power input and convert or transmit that energy using the control scheme circuit to arrive at a desired output. Put more plainly, that energy is transmitted or transfigured by the ventilator in a predetermined manner to provide partial or full support to the patient's respiratory muscles.

Input Power

The input power or power source is the energy needed to perform the work required to ventilate the patient.

Generally, two forms of input energy are used to operate mechanical ventilators:

Electric

AC (alternating current)

DC (direct current)

Pneumatic. Many critical care ventilators in use today incorporate electric and pneumatic power sources to function properly because they employ advanced mechanical systems in combination with microprocessor control.

Electric

Critical care ventilators for use in the United States use common electrical voltage (110–115 V) to power them. Some manufacturers have adapted their machines with rechargeable batteries as an alternative in case of transport from one location to another or in case a power failure erupts. Some disadvantages to the type of batteries (lead-acid) used is that they supply limited power, lasting approximately 1 h and generally require a 12–24 h recharging time.

Pneumatic

The availability of compressed gases of oxygen and air in many hospital intensive care units (ICUs) makes it an ideal energy source (energy = pressure × volume) to power today's mechanical ventilator. Although the standard regulated source gas pressure is 50 pounds per square inch (psi), periodic fluctuations in gas pressure may occur (13). Ordinarily, ventilators have internal regulators that work at a lesser pressure (30–45 psi) than the source pressure. This will inherently maintain normal function despite inconsistent source gas pressure. Aside from unpredictable gas pressures, a pneumatically powered ventilator is useful in environments using magnetic resonance imaging (MRI) or when the need for transport arises. To date, only a few machines are capable of functioning on pneumatics only. Most ICU ventilators that are pneumatically powered still require electricity to support their control functions.

Power Conversion and Transmission

Power conversion and transmission refer to the mechanism(s) used to provide gas delivery. Sometimes this is referred to as the drive mechanism. This is only *partially*

true. The drive mechanism generates the actual force (force = pressure/area) to deliver gas under pressure. This is usually done with a compressor (internal or external) and/or motor linkage. Power transmission and conversion systems also consist of an output control mechanism. This is usually in the form of one or a series of valves that is used to regulate gas flow to the patient. In more complex machinery, a computerized, closed-loop feedback system is established or provides consistent gas delivery in the event of system disturbances. More recent developments of power transmission and conversion mechanisms are described here. A more detailed list can be found elsewhere (14,15).

Drive Mechanisms. This section will investigate the various drive mechanisms required to accomplish lung inflation. The post-polio epidemic introduced an upsurge in the development of many types of drive mechanisms. Although a pressure gradient (required for lung inflation) can be accomplished by one method, many forms of drive mechanisms were developed and used. Whereas each drive mechanism had a unique way of generating a particular pressure and flow pattern during a positive pressure breath, the ideal mechanism should mimic the physiologic breath and restrain adverse effects. Unfortunately, that is still not accomplished today.

There are two categories of drive mechanisms: (1) direct application of compressed gas via a pressure reducing valve and (2) indirect application via an electric motor or compressor.

Compressed Gas and Pressure Reducing Valve. When compressed gas is used for the drive mechanism, its force is adjusted via a pressure-reducing valve. A pressure-reducing valve (PRV) reduces high input pressure to a lower constant output pressure. This pressure may be set as high as 50 psi or be adjusted to a few cmH₂O. The functioning principle of an adjustable PRV can be described by

$$P_L = \frac{(F_{S1} - F_{S2}) - (P_H \times a)}{A}$$

where

P_L = Low or reduced pressure (generated pressure)

F_{S1} = Force of the large spring (adjusting spring)

F_{S2} = Force of the small spring (sealing spring)

P_H = High input pressure (source pressure)

a = Area of the small seat

A = Area of the large diaphragm

After gas is reduced from the PRV, it is delivered to the patient by one of the following approaches:

1. Directly inflate the lung, as the Puritan-Bennett 7200.
2. Prime a spring weighted bellows as in the Servo 900C.

Electric Motor and Compressor. The drive system in electrically powered ventilators consists of an electrical motor that drives a compressor. The compressor may use either a rotating crank and piston, rotary vane, or linear drive motor. Of particular interest is the type of motor and linkage system employed, because this determines the waveform the ventilator will produce.

Electric Motor/Rotating Vane

Referred to as nonlinear pistons (16), eccentric wheel (17), and rotary pistons (18), these units have a constant speed-rotating wheel with a piston rod connecting a piston to the outer edge of the wheel. As the wheel turns, the piston's actual movement is not constant. Consequently, the pressure and flow developed by this mechanism varies with the motion of the piston.

Electric Motor/Rotating Vane

A rotary vane compressor consists of an electric motor with vanes (blades) attached to the motor's shaft, which rapidly spin inside a cylinder. This action generates a constant level of pressure to serve as a drive mechanism. A series of electrically controlled switches (solenoids) serves to assure that the patient is connected to the breathing circuit only during inspiration. During exhalation, the pressure generated by the blower is vented to the atmosphere.

Electric Motor/Linear Piston

Linear piston drive systems may be a rack-and-pinion gear system, a high-tension spring driven system, or a high-pressure pneumatic drive system. This system may be constructed as a single-circuit or double-circuit scheme. In a single circuit, gas is sent directly to the patient from the device's power circuit. The piston's movement is constant throughout its stroke. Therefore, the flow of air being delivered to the patient is also constant, resulting in a square flow wave and linearly increasing pressure curve. A double-circuit design is constructed so that gases from a power circuit are used only to compress a bag-type apparatus (bellows) containing separate gases, which are sent to the patient through a patient circuit. This results in a progressively increasing flow pattern and initially an accelerating pressure pattern. Once the pressures start to equilibrate, a drop in circuit pressure occurs producing a notch in the pressure curve.

Output Control Systems. An output control system is designed to control the flow of gas to a patient. Most ventilators used in intensive care units employ a series of valves to accomplish this. In earlier models (Puritan Bennett MA-1), it was a simple ON/OFF exhalation valve. Current technology enables a valved component to be controlled with microcomputer intelligence. This allows for precise control over gas flow delivery that was not feasible with the compressor-bag delivery system used in earlier generations of mechanical ventilators. For example, the Puritan Bennett 7200 ventilators can precisely manage the movement of its output control system allowing for 3095 movements within 0.003 of an inch (19). The most common valves are discussed below.

Pneumatic Poppet Valve. Sometimes referred to as electromagnetic valves, Plunger valves, and Poppet valves (20,21). This type of device uses a magnetic force to control gas pressure in an ON/OFF fashion. A given valve regulates flow by opening or closing a particular opening. By digitally controlling the open/close sequence of the valve, flow output can be varied.

Proportional Solenoid Valves. Proportional solenoid valves can control flow incrementally instead of turning flow "ON and OFF." This allows for shaping of the inspiratory gas flow being delivered to the patient. Most current generation ICU ventilators use some type of proportional solenoid technology.

Control Scheme

Mechanical ventilators coordinate the delivery of gases based on four variables: flow, volume, time, and pressure. Therefore, the control variable becomes the variable that the ventilator manipulates to create inspiration. A single breath does not reflect significant changes in compliances and resistance. However, flow, volume, time, and pressure can shift and are regulated by the ventilator. In general, if flow, volume, time, or pressure are individually preprogrammed, the others must respond. The control variable will remain constant in the presence of changes in impedance (resistance and compliance). For example, a ventilator is a volume controller if the volume is measured and used to control the volume signal. Many of today's volume ventilators are truly *flow controllers*. They derive a volume measurement from a flow signal. The signal is measured and calculated and displayed as a volume unit of measure on the ventilator display window.

Now that we have discussed *what* is controlled, let us examine *how* it is controlled. In the open-loop system, the user selects the variable (volume, pressure, and flow), for input and observes the output variable (volume, pressure, and flow), which mirrors the actual valve. The operator handles any needed adjustments. The closed-loop system analyzes the data using a feedback signal and automatically modifies the input in an attempt to match the reference value.

Phase Variables. Control of the breath requires the ventilator to perform four phases during a breathing cycle (22):

1. End of expiratory phase (beginning of inspiration)
2. Inspiration
3. End of inspiration (beginning of expiratory phase)
4. Expiration

During these phases, the mechanical ventilator assumes all or part of the work of breathing. During each stage, a certain variable is used to start (trigger), sustain (limit), and end (cycle) the breath.

Trigger. Inspiration is initiated when one of these variables reaches a preset value. This describes

the “trigger” phase of the ventilator. With patient triggering, the ventilator senses the patient effort to initiate gas delivery. The breath is flow, volume, or pressure triggered if the patient initiates the breath. Most modern adult ventilators have a frequency, breathing rate, or respiratory rate control knob that serves as the time trigger. Manual trigger is available on most ventilator control panels as well.

Limit Variable. A limit variable is a parameter that can reach a preset level before inspiration ends, but it does not terminate the inspiration phase (23). This is often confused with a cycle variable. A limit variable does not terminate inspiration; it sets the upper boundaries for pressure, volume, or flow. An example present in many critical care ventilators is the ability for an operator to perform an “inflation hold” of plateau maneuver. The ventilator is allowed to deliver a preset volume, but inspiration does not end until a preset time interval has elapsed. The volume is limited (held and maintained) until the preset pause time is reached.

Cycle. Inspiration will end when either time, pressure, flow, or volume reaches its preselected value. Unlike the “limit” variable, the inspiration phase will end (cycle off).

Baseline Variable. The variable controlled during the expiratory phase is the baseline variable (24). Although flow or volume can serve as the baseline variable, pressure is the most commonly used. Expiratory pressure can be set to atmospheric—Zero. This is called ZEEP (zero end expiratory pressure). ZEEP is obtained when the ventilator’s exhalation valve opens to the atmosphere, exposes the patient’s airway to the atmosphere, and exposes the patient’s airway to a relative pressure of zero. Pressures exceeding atmospheric are referred to as PEEP (positive end expiratory pressure) or CPAP (continuous positive airway pressure). Two well-documented phenomena applicable to PEEP/CPAP therapy are reduced functional residual capacity (FRC) and extravascular lung water (25–27).

Conditional Variables. Specific patterns of breath delivery are examined by the microprocessors control logic system. The ventilator may be set to keep the breath constant or perform more complex maneuvers. The ventilator algorithm for a particular set of breath delivery patterns makes this determination.

Modes of Ventilation. A mode of ventilation represents a combination of control, phase, and conditional variables that establish a set pattern of mandatory and/or spontaneous breaths (28).

Output. Most ventilator waveforms can be classified as one of the following:

1. Exponential
2. Ramp
3. Rectangular
4. Sinusoidal

No ventilator is an ideal controller, and ventilators are designed to only approximate a particular waveform (29,30).

Alarm Systems. Ventilator alarm systems have increased in number and complexity (31) and have recently begun to draw national attention on its proper use in and out of the critical care area (32).

VENTILATOR OPERATION

Introduction

The scope of medical practice expanding to accommodate the needs of those with respiratory diseases is immense. The field of respiratory therapy alone encompasses over 35,000 persons in the United States (33). As one may glean from the previous section of this article, not unlike other areas of medicine, when the need for new technology and therapeutic interventions is required, along with it will come a vast array of specialists, technical support, ancillary staff, and commercial entrepreneurs. The use of ventilators is expensive and represents approximately 10% incidence and contributes significantly to hospital costs (34). Although these costs are impressive, so are the diseases from which the patients suffer, and the true cost is patient mortality, which is invariably high (35). To that end, we have experienced increased understanding of the pathophysiology of their diseases as well as have enjoyed a significant increase in the technologic advances to support them.

The initial aim of ventilatory support has been justified to aid those persons suffering from neuromuscular disorders such as poliomyelitis or tetanus. The practice of medicine precludes one from solely defining a disease and indicating an intervention. But, rather, it identifies a derangement from normal and determines whether it causes harm. Should this be the case, then one should implement a therapeutic change. In the case of mechanical ventilatory support, we refer to the concept of work of breathing (WOB) (36).

$$\text{Work} = \text{Force} \times \text{Distance}$$

$$\text{Force} = \text{Pressure} \times \text{Area}$$

$$\text{Distance} = \text{Volume}/\text{Area}$$

$$\text{Work} = (\text{Pressure} \times \text{area})(\text{Volume}/\text{Area})$$

$$\text{Work} = \text{Pressure} \times \text{Volume}$$

$$\text{WOB} = \text{Tidal Volume} \times \text{Transpulmonary Pressure}$$

The tidal volume that is normally generated results from a relatively small pressure gradient from the intrapleural space to the atmosphere drawing gas inward. Exhalation is then passive when the pressure gradient is reversed, and the pressure then exceeds atmospheric. The relationship between pressure and volume is known as compliance. Pulmonary parenchymal (C_p) compliance is one component of total lung compliance (C_T) that would

also include the chest wall and rib cage (36).

$$C_T(\text{L}/\text{cm H}_2\text{O}) = \Delta V(\text{L})/\Delta P(\text{cm H}_2\text{O})$$

$$1/C_T = 1/C_L + 1/C_{CW}$$

Suffice it to say that most disease processes that impart ictus on patients and require ventilatory support alter pulmonary compliance, usually decreasing it. For example, a patient with pneumonia will generally have areas of alveoli, which are normally air-filled, collapsed, and filled with a pus-like edema matter. This fluid decreases lung compliance in the patient and increases the work (WOB) one must do to generate the same tidal volume to breathe. When this tidal volume is sacrificed, minute ventilation is diminished unless respiratory rate (RR) is increased.

$$\text{Minute ventilation} = \text{RR} \times \text{tidal volume}$$

Minute ventilation is a universal measure of the amount of gas that moves in and out of the lungs and sometimes indicates their global ability to remove carbon dioxide. Blood is delivered to the alveoli, and over a tremendous surface area, CO₂ diffuses freely and expires. As CO₂ diffusion is efficient, this process is uncommonly compromised. However, ventilatory failure is common. When a disease process, either of pulmonary etiology or otherwise, overcomes the normal compensatory mechanisms of the body, such that the patient can no longer maintain a normal pH and a normal PaCO₂, acute ventilatory failure is present. In this circumstance, the blood pH falls below a normal level and the PaCO₂ of arterial blood rises. The imposed, detrimental, WOB requires that the lungs and muscles of ventilation (i.e., chest wall, intercostals, sternocleidomastoid, and diaphragm) consume the oxygen that is delivered to them, hence, complicating matters because this oxygen is intended for the rest of the patient.

The remaining physiologic systems will begin to falter and malfunction as the acidemia worsens due to the fact that many proteins in the body operate within a narrow pH range (heart, brain, kidneys). This process typically will reveal a patient who is breathing rapidly and shallowly. The associated signs often include diaphoresis and the use of accessory muscles. However, of most concern, patients will describe a feeling of breathlessness, even that they are about to die. These are the patients with a clinical diagnosis of impending ventilatory failure.

Respiration Versus Ventilation

The terms “respiration” and “ventilation” are often incorrectly used interchangeably. It is imperative to offer a brief discussion depicting their differences. Respiration refers to the to and fro movement of a gas across a membrane. In the specific instance of breathing, we will consider the gases oxygen and carbon dioxide. Whereas oxygen is inhaled and taken up by the capillary endothelium and removed by the pulmonary venous system, carbon dioxide is delivered to the lungs by the pulmonary artery where it is eliminated by freely diffusing across the alveolar membrane. Typically, diffusion of carbon dioxide is very rapid, in contrast to oxygen, which requires approximately one third of the course of the capillary (37). The cardiopulmonary system maintains oxygen and carbon dioxide tensions within

the normal range (and a normal pH) despite changing metabolism. Any derangement from the normal compensatory homeostatic mechanisms (i.e., disease) may be life-threatening (38).

Ventilation simply defines the movement of a gas in and out of the pulmonary system (38). Clinical medicine makes a distinction and refers to carbon dioxide as a marker for ventilation. This is essentially because the tension of CO₂ inspired is usually zero, and is therefore a better indicator for the cardiopulmonary system’s ability to excrete it (38). Modern ventilators, although complex, are designed simply to improve oxygenation, ventilation, or both. Germane to the following, they are not always mutually exclusive.

Mechanical Ventilatory Support: Indications

Many have classified respiratory distress and the need for mechanical ventilatory support into categories that are useful. In addition, a thorough understanding of the physiologic derangement allows selection of the most optimal mode of support. However, simple definitions that are clear allow straightforward clinical judgment so that an intervention can be made and later fine tuned, (Table 1).

If one was to obtain an arterial blood gas and find a pH of less than 7.30 and a PaCO₂ greater than 60 mm Hg, they would meet criteria for acute ventilatory failure. This is because, at both this pH and PaCO₂, the CSF hydrogen ion concentration creates a maximal stimulus to breathe and represents an acute process. Impending ventilatory failure refers to the patient who is clearly in respiratory distress and frequently is found to be diaphoretic, tachypneic, using accessory muscles, and claims to be short of breath as described above. Apnea is intuitive, and the clearest example is a patient suffering from cardiac arrest. Although intermittently controversial, yet clinically important, hyperventilation for those patients with intractable intracranial hypertension will benefit from lowering carbon dioxide tensions with mechanical ventilatory support. Lastly, the concept of total ventilatory support is reserved for those persons with acute lung injury or adult respiratory distress syndrome at risk for ventilator-associated injury and severely decreased pulmonary compliance.

Mechanical Ventilatory Support: Goals

It seems appropriate to ascertain salient endpoints once a therapeutic intervention has been implemented such as mechanical ventilatory support. In this circumstance, if the ventilator can assume some or all of the patient’s WOB and alleviate the detrimental component, it would be helpful to classify the level of support provided to the patient

Table 1. Indications for Mechanical Ventilatory Support

Indication	Comments
Acute ventilatory failure	ABG diagnosis
Impending ventilatory failure	Physical diagnosis
Apnea	Cardiac arrest
Therapeutic hyperventilation	Neurosurgery
Total ventilatory support	Lung protective strategy

Table 2. Levels of Ventilatory Support

Support Level	Work of Breathing	Eucapnia and Normal pH
Partial ventilatory support	Significant	Yes
Full ventilatory support	Not required	Yes
Total ventilatory support ^a	Not required	No

^aFor use in patients with abnormal lung compliance. Reprinted with permission from Reference 39.

based on the amount of work the *patient is required* to provide to achieve a normal pH and a normal carbon dioxide tension in arterial blood (Table 2).

Full ventilatory support is likely the most common mode of ventilatory support employed in the postoperative period or immediately after intubation for one of the above indications for institution of mechanical ventilatory support. The aim of this intervention is to alleviate all of the patient's WOB until whatever medical or surgical disease has begun to resolve. Once a patient's respiratory status has stabilized, it seems prudent to allow one to resume spontaneous ventilatory effort and a significant amount of WOB.

It seems intuitive that once a breathing tube has been placed and ventilatory support has been instituted, it would be wise to work toward retuning the patient to a state free from those devices. Interestingly, there is evidence to support the concept that patients may not demonstrate the hypotensive effects of positive pressure ventilation in the presence of hypovolemia or decreased pulmonary compliance (40). In most circumstances, it is commonplace to transition to partial ventilatory support using various volume- or pressure-limiting modes (see below). As one is "weaned" from support, it is imperative that several items are taken into consideration. It has been suggested that some protocol be followed to standardize the routine and enhance safety. One such protocol, involves a daily screen and a spontaneous breathing trial (41).

Advantages that have been suggested include shorter days on mechanical ventilation, shorter intensive care unit stays and days in the hospital, and lower cost. To that end, safety still seems to be an appropriate concern. Patients must be monitored appropriately for any sudden deterioration in clinical status. Aside from standard intensive care unit monitoring, recommended additional parameters would include evidence of adequate ventilation by arterial

blood gas analysis. Should this not be available, continuous end-tidal carbon dioxide capnometry is an alternative. However, intermittent arterial pH and PaCO₂ should be obtained to correlate with the EtCO₂ values. The best monitor for the adequacy of oxygenation and ventilation remains the patient. Even while ventilated, it is imperative to engage in frequent assessments.

Modes of Support: Volume Versus Pressure

Despite all best efforts, at times there is a need for postoperative mechanical ventilation for a period of time. This may be due to residual anesthetic effects or the effects of surgery, especially abdominal or thoracic, on an already compromised respiratory status. When providing this support, several different modes of mechanical ventilation can be used, depending on the clinical situation at hand. Generally, during a period of acute stabilization, it is best to use a volume preset–pressure variable mode of ventilation (i.e., synchronized intermittent mechanical ventilation) and then to change to a volume variable–pressure preset mode (i.e., pressure support) when the patient is ready for withdrawal of mechanical ventilation (42). However, in postoperative patients, even in those with severe lung disease, the mode of ventilation is not as important as the endpoints of ventilation that are chosen (42).

The flexibility of modern mechanical ventilators has allowed for other considerations such as the degree of patient triggering, whether the breath is limited by pressure or flow, and the degree to which these pressures and volumes support the patient (Table 3).

An understanding of the limitations of the various modes is essential to success. For example, if one was to place a patient on assist/control mode and subsequently decrease the respiratory rate in an effort to wean the patient from support, the patient would continue to receive the preset tidal volume at his or her intrinsic respiratory rate and would not gain any intrinsic WOB. To the contrary, this method of weaning is perfectly acceptable in the synchronized intermittent mandatory ventilation mode (SIMV). In such a case, decreasing the SIMV rate would leave the patient to generate whatever tidal volume he or she could as determined by their transpulmonary pressure and pulmonary compliance (Fig. 1).

An alternative approach would be to change a patient from a volume-targeted mode of ventilation (i.e., SIMV or A/C) and convert to pressure support ventilation (PSV) for weaning purposes, perhaps. Having some discrete

Table 3. Characteristics of Volume-Targeted Ventilation (VTV) and Pressure-Targeted Ventilation (PTV)

Variable	Volume TV	Pressure TV
Trigger	Patient or time	Patient or time
Limit	Flow	Pressure
Cycle	Volume	Time or flow
Tidal volume	Constant	Variable
Peak pressure	Variable	Constant
Modes	Assist/control (synchronized) intermittent Mandatory ventilation	Assist/control (synchronized) intermittent Mandatory ventilation Pressure support

Figure 1. Airway pressure tracings of the four standard volume-preset modes. *Thick solid lines* represent ventilator breaths; *thick dotted lines* represent spontaneous breaths; and *thin dotted lines* refer to what the spontaneous pattern would have been without the ventilator breaths. IMV, intermittent mandatory ventilation; SIMV, synchronized IMV. Reprinted with Permission from Reference (36).

knowledge of the patient's arterial blood gas and a minute ventilation set on the ventilator commensurate with adequate oxygenation and ventilation, alternating between either, mode can mode be done easily. For example, if one has a ventilator set to deliver an SIMV respiratory rate of 10 by 700 mL, this then equates to about a 7 L minute volume. If the plateau pressure (point B in Fig. 2) generated is roughly 20 cm H₂O, a reasonable pressure support setting would then be 20 cm H₂O. Provided the patient respire about 10 times a minute, the same degree of oxygenation and ventilation should be anticipated. The minute volume would roughly be similar, and the volume-pressure relationship remains in tact provided there is no abrupt change in the patient's clinical condition.

As a patient's pulmonary disease regresses, lung compliance should improve. Using the ventilator monitor, the tidal volume that is generated from a pressure support breath should increase or the plateau pressure generated from a volume cycled breath should decrease (point B in Fig. 2). This can be a valuable piece of information often overlooked in the daily management of critically ill

Figure 2. Schematic illustration of inspiratory cycle for volume-preset (1000 mL) tidal volume delivered by square-wave generator in 1 s, followed by 1-s inflation-hold maneuver. Note that the inspiratory cycle is 2 s, although tidal volume is delivered by the ventilator in 1 s. Normal compliance and resistance are assumed. Proximal airway pressure is shown as a *solid line*, alveolar pressure as a *dashed line*, and gas flow in airways as a *dotted line*. Peak airway pressure (A) is achieved near the end of tidal volume delivery, at which point there is considerable gradient between peak airway pressure and alveolar pressure that results in continued flow to the lung. Airway pressure rapidly diminishes as flow continues toward alveoli. Note that measurable flow in the system has essentially ceased 0.5 s after the ventilator has delivered tidal volume (B); however, a gradient remains between airway and alveolar pressures. An elevated peak pressure (A) in the presence of normal plateau pressures indicates increased airway resistance, which may include bronchospasm. To attain true plateau pressure, in which the airway pressure reflects the average peak alveolar pressure, an additional 0.5 s of inflation hold is required after the absence of measurable flow in the system. Reprinted with permission from Reference 42.

patients. Any difference between the peak and plateau pressures (points A and B in Fig. 2) would indicate an increase in airway resistance from bronchospasm, inspissated secretions, kinking of the tracheal tube, or some other form of incomplete obstruction.

PEEP/CPAP

Many patients suffer from a deficit in arterial oxygenation. The use of CPAP or PEEP is an effective means to remedy the malady. To clarify, the physiologic effect of CPAP/PEEP is identical; however, the nomenclature will vary depending on whether the patient is receiving positive pressure ventilation. One should use the term CPAP if the patient is not receiving positive pressure ventilation and is spontaneously ventilating and PEEP if the patient is receiving positive pressure.

Increasing the fraction of inspired oxygen, although simple and seemingly effective, to treat arterial hypoxemia may not be entirely benign. There is evidence that exposure of alveolar membranes to prolonged periods of high concentrations of oxygen will induce an oxygen-free radical species and subsequently lung injury (38). In addition,

Figure 3. Multiple pressure/volume (P/V) curves of the respiratory system recorded from different levels of PEEP (---: PEEP 5; =: PEEP10; —: PEEP15) and from zero end-expiratory pressure (ZEEP; -.-), and related to the elastic equilibrium volume of the respiratory system at ZEEP ($EELV_{ZEEP}$). The curves are aligned on the same P/V diagram after correcting the starting points of each PEEP P/V curve for the volumes measured during passive expired spiroms performed at each PEEP level. The upward shift of PEEP P/V curves indicates alveolar recruitment. The recruited volume with 15 cm H_2O PEEP (double-headed arrow), compared with ZEEP, is quantified by the volume difference between the curves, for the same level of airway pressure (20 cm H_2O in this example). In other terms, when PEEP is applied, for the same level of airway pressure, lung volume is greater than without PEEP, suggesting the reopening of some alveolar units previously collapsed at ZEEP. Note that recruitment continues far above the value of pressure at the lower inflection point (LIP) and above to the upper inflection point. The different P/V curves tend to join at higher lung volumes, suggesting that the maximal lung volume is approached. Reprinted with Permission from Reference 43.

even shorter periods of high levels of inspired oxygen fractions limit the amount of nitrogen that may “stent” open; an alveolar unit can contribute to alveolar collapse, a phenomenon termed *denitrogenation absorption atelectasis* (38). The Law of LaPlace states that the pressure that tends to keep an alveolus open is twice the wall tension (T) divided by the radius and is represented by

$$P = 2T/r$$

To that end, many employ CPAP/PEEP therapy to improve arterial oxygenation and decrease WOB. WOB may be decreased by shifting a patient to a more favorable portion of the pulmonary compliance curve (Fig. 3).

On the flatter part of the curve, less tidal volume is generated with a substantial change in pressure. According to Fig. 3, on the steeper portion of the curve, less pressure is needed to generate a larger volume, which results in less work. By definition, the alveolar units would remain open at end-expiration, continually participating in gas exchange. It is this very concept of “open lung” ventilation that is thought to be the mainstay of avoiding ventilator-induced injury and ARDS (44,45).

CPAP/PEEP in most instances will have a significant impact on arterial oxygenation. Bringing alveoli into closer contact with the pulmonary capillaries will provide a

greater surface area for gas exchange, and as such, the pulmonary venous blood leaving the lungs will have a higher oxygen content. If one could make existing alveoli larger, opening previously closed alveoli, arterial oxygen tension would improve. At CPAP/PEEP levels less than 10 cm H_2O , existing open alveoli are made larger. When CPAP/PEEP levels exceed 15–50 cm H_2O , the collapsed alveoli are then opened and can participate in gas exchange, and thus they are recruited.

This fluid typically does not move out of the lung to some other area of the body. Rather, it shifts within the small spaces of the alveolar unit to the loose connective tissue-filled peri-bronchiolar areas that do not affect gas exchange. Perfusion will better match ventilation, thus increasing the oxygen content of arterial blood.

Mechanical Ventilatory Support: Adverse Reactions

Just as with any drug or medication that is prescribed, ventilators are not without iatrogenic potential. Typical side effects may include inadvertent hyperventilation or patient dysynchrony. These issues can be avoided with careful monitoring of the patient. Meticulous attention to artificial airway maintenance is mandatory. Relative to mechanical ventilatory support, the usual culprit of iatrogenic injury is excessive positive pressure termed *barotrauma* and large tidal volume in specific patients at risk for acute lung injury or ARDS referred to as *volu-trauma*.

Barotrauma is simply the disruption of the large conduction airways when exposed to very high pressures. When this occurs, gas leaks into the tissues of the neck

Figure 4. Changes in the capillary filtration coefficient ($K_{f,c}$) of isolated blood-perfused lobes of dog lungs given 20 min of intermittent positive pressure ventilation. Moderate (up to 30 cm H_2O) increases in peak airway pressure did not affect $K_{f,c}$, whereas higher peak pressure produced a steep increase in $K_{f,c}$. Reprinted with Permission from Reference 47.

and chest such as the mediastinum (pneumomediastinum) or the pleural space (pneumothorax). The most life-threatening of these is the tension pneumothorax, which allows gas to fill and accumulate in the pleural space. If there is no mechanism to remove it, the accumulated gas compressed the mediastinum and cardiac chambers compromising cardiac output to the point where venous return ceases and left ventricular output approaches zero.

ARDS, also referred to as acute lung injury, has been studied at great length. It has been noted that more patients survive in certain circumstances if lower tidal volumes are used to ventilate their lungs. In addition, it has been proven in several instances that chemical mediators of inflammation as released and adversely affect the body of large tidal volumes that are used (46) (Fig. 4). Recently, much has been learned about ARDS, and patient populations at risk for ventilator-induced injury have been identified.

Medicine

INTRODUCTION

One of the most important aspects of the clinical care of patients with known or suspected cardiopulmonary disease is monitoring the adequacy or status of their ventilatory function. However, in order to understand why various parameters of lung function are monitored, a few aspects of basic respiratory physiology require review. Although the lungs perform important metabolic and endocrine functions, their primary function is gas exchange. They provide the vehicle by which oxygen (O₂) in inspired air moves into venous blood and carbon dioxide (CO₂) in venous blood is released into expired gas. The mechanisms by which these processes occur are complex, but can be subdivided into four phases. The first phase involves the movement of gas into and out of the lungs themselves. This aspect of respiratory physiology is termed lung mechanics. During spontaneous breathing, contraction of the diaphragm and intercostal muscles increases negative pressure within the intrapleural space, leading to lung expansion. This results in a pressure gradient along the airways causing gas to flow into the lungs and to eventually reach the alveoli. With relaxation of the inspiratory muscles, the elastic recoil of the lungs reverses the pressure gradient resulting in gas being expired through the mouth into the atmosphere. In the second phase, gas exchange occurs in the alveoli. By the process of diffusion across the alveolar capillary membrane, O₂ enters and CO₂ exits the vascular system. The third phase involves the transport of O₂ and CO₂ in the blood, and is intimately related to adequate cardiovascular and hematologic functioning. Oxygen is carried in the blood primarily in a complex with hemoglobin in the red blood cells. A small amount of O₂ is also dissolved in plasma. The total amount of O₂ delivered throughout the body is a function of the volume of O₂ in the blood, and the rate of delivery or cardiac output. Transport of CO₂ in the body is more complex, but also is related to the properties

of hemoglobin and cardiac function. The fourth phase is cellular respiration (defined as the metabolic consumption of O₂ and production of CO₂ and H₂O), and involves the mechanisms by which cells in the body utilize O₂ and excrete CO₂. All of these phases are related to each other, and are essential for normal respiration to occur. Ventilatory monitoring encompasses methods by which the functional status of the aforementioned aspects of lung function can be determined. This article reviews the indications, principles, and techniques used in clinical ventilatory monitoring. A detailed discussion of pulmonary function testing is not included, and is reviewed elsewhere (1).

INDICATIONS FOR VENTILATORY MONITORING

Ventilatory monitoring usually is performed for four general clinical indications: (1) diagnostic, (2) therapeutic, (3) prophylactic, and (4) safety considerations. With respect to diagnostic use, the goal of monitoring is to obtain information pertinent to making a specific etiologic diagnosis of a disease entity or process. For example, in myasthenia gravis patients who are having an acute deterioration in ventilatory function, vital capacity (VC) measurements (the maximum volume excursion of which the lungs are capable by voluntary effort) are obtained after injection of a short-acting cholinesterase inhibitor (edrophonium, Tensilon). Documentation of an increase in VC suggests the need for an increase in anticholinesterase medication, whereas a deterioration is evidence for excessive effect from medication. Another frequently encountered situation where ventilatory monitoring is used diagnostically is the continuous monitoring of airflow and ventilatory effort in sleep disorders laboratories to detect evidence of sleep disordered breathing (2).

A number of ventilatory parameters are useful in monitoring the therapeutic effect of specific treatment modalities. The most frequently encountered situation is where arterial O₂ and CO₂ gas tensions are sampled following institution of supplemental O₂ or mechanical ventilation. Measurement of respiratory system compliance following application of positive end-expiratory pressure (PEEP) in mechanically ventilated patients with acute respiratory failure is another example of where ventilatory monitoring is used to determine the effects of a treatment modality (3). In both the aforementioned examples, therapy frequently is adjusted using results obtained from the ventilatory parameters monitored.

Ventilatory monitoring commonly is performed prophylactically with the goal of detecting a perturbation in normal or baseline respiratory function so that treatment can be instituted early. For example, apnea monitors are employed in infants suspected to be at risk for sudden infant death syndrome. In this clinical situation, alarms are activated if life-threatening apnea or bradycardia occurs so that the infant can be resuscitated before a full cardiorespiratory arrest ensues.

Finally, safety considerations require ventilatory monitoring when certain categories of biomedical life support devices are used. In patients with pulmonary disease, a

Computerized analysis with treatment algorithms

commonly encountered example is the use of mechanical ventilators. With mechanical ventilation, a number of ventilatory parameters with appropriate alarms are monitored so as to avoid inadvertent disconnection and dangerously high airway pressures. Another example is patients undergoing general anesthesia. Inspired gas concentrations delivered by anesthesia machines frequently may be monitored to insure that the concentrations of anesthetic gases and O_2 are appropriate (4).

LEVELS OF VENTILATORY MONITORING

As emphasized elsewhere (5), there are several levels of intensity with respect to ventilatory monitoring (Table 1). On the most basic level is visual observation and examination by experienced personnel. Although inherently simple, examination of patients is an attribute of clinical medicine that is irreplaceable. The clinical "gestalt" obtained by an experienced healthcare practitioner from observing the work of breathing and the breathing frequency of a patient in respiratory distress has not yet been duplicated by any automated monitoring device. Furthermore, physical examination of the respiratory system is an "art" that should not be lost on future physicians, physician's assistants, nurses, and respiratory care practitioners. In many patients with pulmonary disease, little monitoring other than periodic observation and examination is required.

In some patients with pulmonary disease, more objective data than can be obtained with visual observation and examination are needed. Therefore, the next level of monitoring intensity is the use of intermittent objective measurements of ventilatory function. Probably the most common ventilatory parameter obtained at this level of monitoring are arterial blood gases. Periodic sampling of arterial blood to determine pO_2 , pCO_2 , and pH is used in almost all patients with the presence or suspicion of significant ventilatory dysfunction. Arterial blood gases are invaluable in following the clinical course and the effect of ventilatory therapy rendered in these patients. Arterial blood gas tensions currently are considered the "gold standard" against which any other measurement of gas exchange is compared. Abnormalities in pO_2 and pCO_2 now are used as definitions of the degree of respiratory impairment. Other frequently used intermittent monitors of ventilatory function are measurements of the VC, the volume of gas exhaled in the first second during a forced expiration (FEV_1), the peak expiratory flow rate during a forced expiration (PF), and the maximum negative airway pressure generated during inspiration against an occluded airway (maximum inspiratory force, MIF). All of these parameters may be useful in following the clinical progress of patients with certain types of pulmonary disease.

Patients who are critically ill may require the third level of monitoring intensity, which is continuous measurement of various ventilatory parameters over time. In most intensive care units, devices are available to continuously track breathing frequency. Patients receiving mechanical ventilation have continuous monitoring of their airway pressures and exhaled tidal volumes for safety considerations. Recent technological advances now allow for continuous monitoring of arterial and venous oxygen saturations. In the most sophisticated intensive care units, on-line monitoring of exhaled gases from ventilated patients and complex measurements of lung mechanics, such as resistance and compliance, can be performed.

Finally, the highest level of monitoring is the use of computer algorithms to not only monitor various ventilatory parameters, but to also adjust therapy according to the values obtained without human intervention. The technology required for such monitoring is undergoing continuous development, and there is increasing use in patient care applications. This is particularly evident on newer microprocessor ventilators where some ventilator modes allow for automatic adjustments to the level of ventilator support according changes in patient lung mechanics.

PARAMETERS USED IN MONITORING LUNG MECHANICS

Breathing Frequency

The most common measurement of ventilatory function is an assessment of the patient's breathing frequency. Usually, this is performed by visually counting the breathing frequency over a 30–60 s period of time, although biomedical devices also can be used for this purpose. Normal individuals breathe at a frequency of ~ 12 min. However, this rate is markedly altered in patients with lung disease. Reductions in spontaneous respiratory rate are diagnostic of ventilatory dysfunction and suggest central depression of ventilatory control centers in the brain stem. Examples of clinical situations in which this might occur are narcotic overdose, incomplete recovery from a general anesthetic, and primary central alveolar hypoventilation. Whereas reductions in breathing frequency indicate ventilatory dysfunction, an increase in spontaneous breathing frequency (tachypnea) is more nonspecific since individuals can voluntarily increase their breathing frequency in response to physical or psychological stress, or an increase in metabolic demands. However, if a nonpulmonary basis for an increase in breathing frequency can be excluded, tachypnea generally indicates the presence of lung disease. Common examples are pneumonia, congestive heart failure with pulmonary edema, and asthma.

Lung Volume and Airflow. An assessment of the volume of air inspired and expired with each breath (tidal volume, V_T) is an important ventilatory parameter since adequacy of ventilation is determined not only by the breathing frequency, but also by the V_T . The spontaneous V_T in normal individuals varies according to their size, but in an average adult is ~ 500 mL. Ventilatory dysfunction, whether from processes such as parenchymal pulmonary disease or a reduction in central respiratory drive, generally results in a

decrease in V_T . In mechanically ventilated patients, exhaled V_T is often measured to monitor for inadvertent disconnection or leaks in the ventilator circuit. Sudden declines in exhaled V_T herald disconnection or large ventilator circuit leaks, and on most ventilators trigger audible alarms.

The VC and FEV₁ are frequently monitored intermittently in ambulatory patients with diseases characterized by airflow limitation such as asthma, asthmatic bronchitis, and emphysema. In these diseases, a reduction in comparison to predicted norms (6) is observed in both these parameters. In addition, the ratio of the FEV₁ to the forced VC (FVC), which is normally >0.7, is decreased. The VC by itself is a useful parameter to follow in patients with acute respiratory failure. In spontaneously breathing patients, one criterion for intubation and mechanical ventilation is a VC <10 mL/kg body weight. Conversely, in mechanically ventilated patients, a VC <10 mL/kg body weight is used as a criterion to wean mechanical ventilatory support. Obviously, many other factors are involved in a decision to remove or supply mechanical ventilation, but VC definitely is one key determinant.

The rate of inspiratory air flow is an important ventilatory parameter during mechanical ventilation. It determines the duration of inspiration, and influences airway pressures and the distribution of ventilation in the lungs. Higher peak inspiratory flow rates result in a shortening of the duration of inspiration, higher peak airway pressures, and less uniform intrapulmonary distribution of inspired gas. However, if inspiratory flow rates are too low, inspiration becomes longer than expiration. This may lead to incomplete exhalation, gas trapping in the lung, and an increase in the functional residual capacity (volume of the lung at end-expiration, FRC). These physiologic effects may have deleterious consequences with respect to a decline in cardiac output and an increase in the incidence of pulmonary barotrauma (i.e., pneumothorax, pneumomediastinum, and subcutaneous emphysema).

Monitoring of expiratory flow rates is useful in following the clinical course of patients with airflow limitation. Measurement of flow rates during the middle of a FVC maneuver is a frequently performed pulmonary function test and will not be discussed further. However, periodic determination of PF is a useful monitoring technique to follow the progress of patients with acute and chronic asthma, and also is used to monitor pulmonary function in outpatient studies of patients with suspected bronchospasm resulting from occupational or environmental exposures. Normal values are <500 L/min, but measurements <120 L/min frequently are observed during acute exacerbations of asthma.

Airway and Esophageal Pressures. In patients receiving mechanical ventilation, perhaps one of the most important ventilatory parameters that can be monitored is airway pressures. With volume constant ventilators, a feedback loop is present so that the peak airway pressure cannot exceed a manually preset level. When such a situation occurs (e.g., a patient coughing while inspiratory flow is being delivered from the ventilator), inspiration is terminated when the preset pressure is reached, and an alarm is activated. In this case, peak airway pressure monitoring

acts as a safety feature to prevent overpressurization of the airway and the possibility of barotrauma. In contrast, when pressure limited ventilators are used, peak airway pressure is set as a ventilator control parameter and is one of the factors that determines the V_T . Airway pressures are also important in monitoring for inadvertent disconnection or unrecognized leaks in the ventilator circuit during mechanical ventilation. A sudden marked reduction in airway pressure is indicative of a leak in the ventilator circuit, whereas a reduction in the airway pressure to atmospheric pressure would signal a disconnection. On most ventilators, auditory alarms are activated when such events occur. Inspection of the airway pressure curve during mechanical ventilation also can yield important information. As examples, a marked downward concavity at the onset of inspiration is a sign of an insufficient inspiratory flow rate to meet patient demand. During expiration, the failure of the airway pressure curve to return to baseline with an end-expiratory occlusion is indicative of auto-PEEP or air trapping. Finally, airway pressure measurements are an important component of derived ventilatory parameters such as airway resistance and lung compliance.

Monitoring of the maximum inspiratory force (MIF) in patients who are receiving mechanical ventilation is an important ventilatory parameter in determining whether they can be weaned from mechanical ventilation. The MIF can be considered an indicator of the underlying strength of the inspiratory muscles. Values more negative than -25 cm H₂O usually indicate that a patient will be able to maintain adequate ventilation without mechanical ventilatory support, although other factors obviously must also be taken into account.

Measurement of esophageal pressure is used as a reflection of intrapleural pressure (7). It is therefore a component of calculated ventilatory parameters such as lung compliance and the work of breathing. Esophageal pressure catheters also are used to quantify ventilatory effort during sleep studies (polysomnography). However, although there are commercially available devices that incorporate esophageal pressure monitoring to measure lung mechanics, they have not found common acceptance, because placement of an esophageal catheter is invasive and technical factors make accurate determinations difficult (7).

Resistance, Compliance, Volume-Pressure Curves. The total pulmonary resistance to the flow of gas into the lungs is comprised of two factors: (1) friction between the molecules of flowing gas and the airways (airways resistance, R_{aw}), and (2) resistance of the tissues (lungs, rib cage, diaphragm, abdominal contents) as a result of their own displacement (tissue resistance) (8). Elevations of airways resistance are observed in patients with diseases characterized by airflow limitation such as asthma and emphysema. In addition, superimposition of external devices such as narrow endotracheal or tracheostomy tubes can increase airways resistance. Tissue resistance can be increased in patients with such disorders as kyphoscoliosis or pulmonary fibrosis. Total pulmonary resistance is not a frequently used clinical measurement since it requires the simultaneous measurement of lung volume, airway, and esophageal (as a reflection of pleural) pressures (8). Similarly,

airways resistance is also not performed on most patients since it is necessary to use a body plethysmograph (8). No direct measurement of tissue resistance is available, but it is generally calculated as the difference between total pulmonary resistance and airways resistance. Normally, the pulmonary tissue resistance represents ~20% of the total pulmonary resistance. In spite of the difficulty in obtaining a precise measurement of pulmonary resistance in mechanically ventilated patients, an estimate of the pressure needed to overcome airways resistance can be obtained by measuring the difference between the peak airway pressure (p_{\max}) and the airway pressure observed after a 1 s inspiratory hold (p_{st}). If airflow measurements (V) at the point of peak airway pressure are available, the equation:

$$R_{\text{aw}} = (p_{\max} - p_{\text{st}})/(\dot{V})$$

is an estimate of airways resistance. In general, however, estimates of resistance have not been shown to provide important information relating to the care of patients.

Measurement of compliance or elasticity of the lung is of more importance to the care of patients than resistance. The compliance of a biological system can be defined as the change in volume occurring in response to a change in distending pressure. In addition, compliance measurements can be obtained during static conditions (no flow), or during dynamic conditions (continuous flow). With respect to the respiratory system, static respiratory system compliance (C_{st}) is defined as the change in lung volume occurring with a change in airway pressure over the tidal volume range. Similarly lung compliance (C_{L}) is defined as the change in lung volume with respect to the change in pleural pressure over the tidal volume range. The relationship between C_{st} and C_{L} is defined by the following equation:

$$\frac{1}{C_{\text{st}}} = \frac{1}{C_{\text{L}}} + \frac{1}{C_{\text{t}}}$$

where C_{t} is the compliance of the thorax.

Dynamic lung compliance (C_{dyn}) is the change in lung volume occurring with a change in pleural pressure between two points of instantaneous zero flow during breathing (9).

In the respiratory system, changes in compliance are a function of two factors: the elasticity of the tissues and lung volumes. In the upright position, the normal value for C_{st} in adults is ~100 mL/cm H₂O, and the normal value for C_{L} is 2.0 L/kPa. However, many types of lung pathology such as pulmonary edema and pneumonia result in a reduction of both C_{st} and C_{L} . In addition, normal values decline with decreasing lung volume. Thus, the normal C_{st} of a small animal or infant is less than an adult human. Dynamic lung compliance and C_{L} are virtually identical in the absence of significant parenchymal lung disease. However, with airways disease, all alveoli do not ventilate evenly during dynamic conditions, with some gas exchanging areas ventilating slower than others. This phenomenon also has been described as time constant disparity. Because of this disparity in time constants, these slow ventilating areas do not participate fully in gas exchange, and in effect a smaller lung volume is ventilated with each breath. In

contrast, during static conditions, a disparity in time constants does not influence the distribution of ventilation. Therefore, C_{dyn} is $<C_{\text{L}}$ in the presence of significant airways disease. Another measure of lung elasticity called the "dynamic characteristic" (C_{dch}) (10) also has been described. It is calculated in patients receiving mechanical ventilation as V_{T} divided by the difference between P_{\max} and PEEP. However, C_{dch} is not just a reflection of lung compliance, but also is influenced by changes in airways resistance.

Measurements of both C_{dyn} and C_{L} require an estimate of intrapleural pressure that, in most cases, is obtained using an esophageal balloon. Because accurate esophageal pressures are difficult to obtain, especially in critically ill patients, clinical measurement of these ventilatory parameters are uncommon. However, C_{st} only requires measurement of V_{T} and airway pressure, and thus is easily obtained in most patients receiving mechanical ventilation. Since, in most patients, changes in C_{st} are primarily a result of changes in C_{L} , serial measurements of C_{st} frequently are used to follow changes in lung elasticity. For example, maximizing C_{st} during application of PEEP has been shown to correspond to the best levels of oxygen transport (product of the cardiac output and the arterial oxygen content) (3). Serial measurements of both C_{st} and C_{dch} are useful in many patients with acute respiratory failure who are receiving mechanical ventilation. A change in both these parameters usually signifies an alteration in the properties of the lung parenchyma such as increasing pulmonary edema or pneumonia. However, a change in C_{dch} without a change in C_{st} is indicative of an increase in airways resistance such as might occur with the onset of bronchospasm or mucous plugging of the airways (10).

Measurements of compliance and resistance summarize pressure–volume relationships in the lung. These can be depicted graphically with two-dimensional (2D) plots of volume versus pressure. A decrease in compliance will be represented by a decrease in slope of this relationship, whereas bowing of the volume–pressure relationship is observed when airways resistance is increased. Analysis of the inspiratory volume–pressure curve may aid in determining the optimum level of PEEP for patients with the acute respiratory distress syndrome who require mechanical ventilation. The optimum level of PEEP is suggested by the inspiratory airway pressure at which the slope of the volume–pressure curve appears to increase (11). In some intensive care units, on-line plots of volume versus pressure can be obtained, but their value in the care of patients has not been proved.

Work of Breathing. In physics, linear work is defined as the product of force times distance. The analogous situation when applied to the movement of air into the lungs is described by the product of pressure times volume. Therefore, the work of breathing is equivalent to the cumulative product of the transpulmonary pressure and the volume of air moved at each instant in time (12). Work of breathing measurements have been proposed as a method of determining whether mechanically ventilated patients are able to breathe spontaneously (13). Unfortunately, accurate determinations require simultaneous measurements of

pleural pressure (usually estimated from esophageal pressure), and airflow. Therefore, work of breathing measurements have not found great utility in the clinical management of patients.

Other Parameters. The rapid shallow breathing index (RSBI) is frequently used to assess the ability of a patient to breath without ventilator support (14). It is calculated by measuring the breathing frequency and dividing it by the V_T in liters. High values (>105) indicative of low V_T and a high breathing frequency suggest that a patient cannot be removed from the mechanical ventilator. However, there has been some controversy concerning the predictive value of this parameter in all clinical situations.

Ventilatory drive is another parameter that can be monitored. Although measurement of the minute ventilation in response to hypoxia or hypercapnia are indexes of central drive in the absence of impairment of neuromuscular or mechanical pulmonary disease, measurement of the airway pressure generated within the first 100 ms after airway occlusion ($p_{0.1}$) is generally recognized as the best indicator of the central drive (15). Unfortunately, this is difficult to accomplish without specialized equipment.

PARAMETERS USED IN THE ASSESSMENT OF GAS EXCHANGE

Oxygenation

The amount of oxygen contained in arterial blood (oxygen content, CaO_2) is determined by the arterial oxygen tension (PaO_2), the percent saturation of hemoglobin (Hgb) with oxygen (S_aO_2), and the Hgb concentration in arterial blood:

$$CaO_2 = 1.34 \times (\text{Hgb}) \times (S_aO_2) + 0.003 \times (PaO_2)$$

where $CaO_2 = \text{mL } O_2/100 \text{ mL blood}$, $1.34 = \text{mL } O_2/\text{g Hgb}$, $\text{Hgb} = \text{g}/100 \text{ mL blood}$, $S_aO_2 = \% \text{ saturation}$, $0.003 = \text{mL } O_2 \text{ dissolved in blood}/\text{mmHg}$, $PaO_2 = \text{mmHg}$.

In most circumstances, adequacy of oxygenation is monitored by measurement of the PaO_2 or the S_aO_2 . Although the PaO_2 and S_aO_2 are intimately related to each other, their relationship is not linear (Fig. 1), but rather is described by a sigmoid curve. At levels of oxygen tension greater than $\sim 60 \text{ mmHg}$, there is little increase in S_aO_2 with increasing values of PaO_2 . In contrast, when the PaO_2 falls $<60 \text{ mmHg}$, S_aO_2 declines rapidly with decreases in PaO_2 . Therefore, monitoring of S_aO_2 as an estimate of PaO_2 is of little value when the PaO_2 is $>70\text{--}80 \text{ mmHg}$, since significant alterations in PaO_2 will not be reflected by corresponding changes in S_aO_2 . At sea level, the normal PaO_2 is $\sim 100 \text{ mmHg}$ and the S_aO_2 is 97%. However, normal values may vary according to alterations in barometric pressure and increasing age (16). Occasionally, arterial oxygen content (normal value = $9.5 \text{ mL } O_2/100 \text{ mL blood}$) is monitored as an indicator of oxygenation. Because most of the oxygen in blood is carried in combination with Hgb, this may be of value when Hgb levels are severely abnormal or fluctuating rapidly.

Figure 1. Oxyhemoglobin dissociation curve. The graph shows the relationship between hemoglobin saturation and oxygen tension. Above 60 mmHg, the curve becomes progressively flatter so that little additional saturation occurs when the PO_2 is $<60\text{--}70 \text{ mmHg}$.

Mixed venous oxygen tension ($P_{\bar{v}}O_2$) or saturation ($S_{\bar{v}}O_2$) generally is regarded as an indicator of cardiac output or metabolic consumption of oxygen in the tissues. However, during continuous monitoring of $S_{\bar{v}}O_2$ in critically ill patients, an abrupt fall in $S_{\bar{v}}O_2$ may herald a sudden deterioration in arterial oxygenation.

There are several parameters derived from measurements of P_aO_2 , S_aO_2 , $P_{\bar{v}}O_2$, and $S_{\bar{v}}O_2$ that are occasionally used in monitoring the status of oxygen gas exchange. Higher inspired oxygen concentrations (FIO_2) result in higher P_aO_2 values. In order to compare P_aO_2 values obtained at differing FIO_2 values, the P_aO_2/FIO_2 ratio or its reciprocal, the FIO_2/P_aO_2 ratio, can be computed. It is assumed, however, that these ratios remain constant with changing FIO_2 in the presence of lung disease, and that the P_aCO_2 is constant. Since changes in P_aCO_2 result in approximately reciprocal changes in P_aO_2 , the status of oxygen gas exchange is sometimes determined by calculating the alveolar–arterial oxygen tension difference ($AaDO_2$; A-a gradient), which controls for changes in oxygenation resulting from changes in the P_aCO_2 . This is performed by calculating the alveolar oxygen tension (P_AO_2) using the alveolar air equation:

$$P_AO_2 = (P_B - PH_2O) \times FIO_2 - P_ACO_2/R + [P_ACO_2 \times FIO_2 \times (1 - R)/R]$$

where P_B is barometric pressure, PH_2O is water vapor pressure, P_ACO_2 is alveolar PCO_2 tension, and R is the respiratory gas exchange ratio. It is generally assumed that the $P_ACO_2 = P_aCO_2$ and that R is ~ 0.8 . After the P_AO_2 is computed using the alveolar air equation, the $AaDO_2$ is

Figure 2. Two-compartment lung model and shunt equation. Conceptually, mixed venous blood either perfuses normal lung and is completely oxygenated or is shunted past the lungs and receives no oxygen. Both oxygenated blood and shunt blood combine to form arterial blood.

the difference between the $P_{A}O_2$ and the $P_{a}O_2$. $AaDO_2$ changes with age, $F_{I}O_2$, and position. In a young, healthy person breathing air at sea level, this value is usually 10 mmHg, and 100 mmHg on 100% $F_{I}O_2$.

The principal disadvantage to the aforementioned indicators of oxygen gas exchange is that they all fail to account for changes in cardiac output, confounding the interpretation of changes in these indicators in the presence of lung disease. In general, impairments in oxygen gas exchange can be quantified using a two-compartment model. As shown in Fig. 2, mixed venous blood can be thought of as either becoming fully oxygenated by the lungs or “shunted” through the lungs without receiving any oxygen. The percentage of the total cardiac output (Q_t) that is “shunted” (Q_s) is termed the shunt fraction (Q_s/Q_t). Since changes in Q_t may result in changes in the oxygen content of mixed venous blood ($C_{\bar{v}}O_2$), arterial oxygenation may be altered without any change in Q_s/Q_t (Fig. 3). Therefore, a change in arterial oxygenation may be misconstrued as resulting from an alteration in gas exchange in the lungs when a change in cardiac output is actually responsible. To

circumvent this problem, Q_s/Q_t occasionally is calculated:

$$Q_s/Q_t = C'_cO_2 - C_aO_2 / C'_cO_2 - C_vO_2$$

where C'_cO_2 is the pulmonary capillary oxygen content. Usually C'_cO_2 is calculated by assuming that the hemoglobin in pulmonary capillary blood is fully saturated with oxygen and that the $p_{A}O_2$ reflects the amount of dissolved oxygen in pulmonary capillary blood. Unfortunately, computation of Q_s/Q_t requires the presence of a pulmonary artery catheter for sampling of mixed venous blood, which makes it unfeasible as a ventilatory parameter in many patients. In the vast majority of patients, however, measurement of the $p_{a}O_2$ and, in some situations, the S_aO_2 , will provide satisfactory indicators of oxygen gas exchange. Calculation of the aforementioned derived parameters should be reserved for selected critically ill patients in whom such information is necessary for their care.

Ventilation. Adequacy of ventilation is defined by the levels of arterial pCO_2 (p_aCO_2) and pH. These parameters are usually obtained from arterial blood gas samples, and are normally 40 and 7.40 mmHg, respectively. Although hypoventilation is defined as a p_aCO_2 significantly >40 mmHg and hyperventilation is present when the p_aCO_2 is <40 mmHg, the appropriateness of the lung’s ventilatory response is determined by the arterial pH. For example, in the presence of a metabolic acidosis, hyperventilation is appropriate if the pH approaches 7.40. However, the hyperventilatory response would be considered inadequate if the pH remained significantly <7.40.

Precise determination of the p_aCO_2 and arterial pH can only be obtained by sampling of arterial blood. Venous pCO_2 and pH occasionally can be used as indirect indicators of arterial values, but this is not recommended since these parameters also reflect cellular metabolism. Of more use as a reflection of p_aCO_2 are measurements of end tidal pCO_2 ($p_{et}CO_2$). In normal individuals, the composition of the gas at the end of a normal exhalation primarily represents gas originating from alveolar areas of the lung. Therefore, the pCO_2 of the gas at the end of a normal tidal breath should approximate the alveolar pCO_2 ($p_{A}CO_2$). Since the alveolar–arterial pCO_2 gradient across the alveolar capillary membrane is only 1–2 mmHg, $p_{et}CO_2$ is a good estimate of the p_aCO_2 in normal individuals. In the presence of lung disease, however, the distribution of

Figure 3. Effect of changes in mixed venous oxygen content on arterial oxygen content in a two-compartment lung model. (1) Assuming that shunted blood flow equals 50% of the cardiac output, mixture of shunted blood with an oxygen content equal to 15 vol% with oxygenated pulmonary capillary blood equal to 20 vol% yields arterial blood with an oxygen content of 17.5 vol%. (b) If the shunt fraction remains 50% and the mixed venous oxygen content decreases 10 vol%, the arterial oxygen content decreases to 15 vol%.

ventilation becomes more uneven. In such situations, the gas composition at the end of an exhalation is composed not only of alveolar gas, but also of gas from poorly perfused or nonperfused areas of the lung (dead space). Therefore, in this situation the $p_{\text{et}}\text{CO}_2$ will be lower than the $p_{\text{a}}\text{CO}_2$. However, even in situations where lung disease has caused the $p_{\text{et}}\text{CO}_2$ to be lower than the $p_{\text{a}}\text{CO}_2$, observation of trends in $p_{\text{et}}\text{CO}_2$ may be useful for suggesting similar changes in $p_{\text{a}}\text{CO}_2$. For example, a slow increase in $p_{\text{et}}\text{CO}_2$ in a patient with an acute pulmonary illness who is breathing spontaneously would suggest that the patient was beginning to hypoventilate. In addition, an acute increase in the $p_{\text{a}}\text{CO}_2 - p_{\text{et}}\text{CO}_2$ difference is indicative of an increase in dead space ventilation such as what would be observed with a pulmonary embolism. However, the most common use of measuring the $p_{\text{et}}\text{CO}_2$ is to assist in the recognition of an esophageal intubation. In contrast to intubation of the tracheal, inadvertent esophageal intubations are associated with negligible amounts of CO_2 .

Estimates of the efficiency of CO_2 gas exchange can be obtained by measurements of expired minute ventilation (V_{E}) and dead space ventilation to tidal volume ratio ($V_{\text{D}}/V_{\text{T}}$). In individuals without lung disease, a normal $p_{\text{a}}\text{CO}_2$ can be maintained with a minute ventilation of $\sim 5\text{--}6$ L/min. Situations where a higher minute ventilation is required to maintain a normal $p_{\text{a}}\text{CO}_2$, suggests either that there is increased ventilation to nonperfused areas of the lung (dead space) or that the production of CO_2 (V_{CO_2}) by the body has increased. The latter can often be excluded on clinical grounds (i.e., absence of fever, sepsis, hyperthyroidism), but both the $V_{\text{D}}/V_{\text{T}}$ and the V_{CO_2} can be measured. The $V_{\text{D}}/V_{\text{T}}$ can be measured using the Enghoff modification of the Bohr equation:

$$V_{\text{D}}/V_{\text{T}} = p_{\text{a}}\text{CO}_2 - p_{\text{E}}\text{CO}_2 / p_{\text{a}}\text{CO}_2$$

where $p_{\text{E}}\text{CO}_2$ represents the $p\text{CO}_2$ in a sample of mixed expired gas. The V_{CO_2} is determined by measuring the fraction of CO_2 contained in a timed collection of expired gas. Monitoring of V_{E} , $V_{\text{D}}/V_{\text{T}}$, and V_{CO_2} occasionally are helpful in determining the efficiency of CO_2 gas exchange in patients where the etiology of their high minute ventilation requirements is unclear.

METHODS AND DEVICES USED IN VENTILATORY MONITORING

Measurement of Breathing Frequency, Airflow, and Lung Volumes

Aside from visual observation, there are several automated methods of continuously monitoring breathing frequency and effort (Table 2). Since patients in the intensive care unit are universally monitored for cardiac rhythm, one of the most conveniently employed techniques is impedance pneumography. This method is based on the principle that electrical impedance across the chest wall varies with inspiration and expiration (17). Chest wall impedance is measured by passing a constant, sinusoidal, low intensity current between two electrodes affixed to the chest wall. Usually, impedance devices are incorporated into electrocardiogram electrodes, thus permitting the simultaneous

monitoring of cardiac rhythm and respiratory effort. Since the relationship between changes in impedance and lung volume are linear, it is possible to obtain measurements of lung volume. However, because the relationship between impedance and volume varies between patients (2.8–4.6 Ω/L), a different calibration must be obtained for each patient. While accurate measurement of lung volumes has been obtained by some investigators (18), others have observed poor reproducibility (17), which may be a result of variability induced by the changing contribution of intercostal and diaphragmatic contraction with alterations in body position. Therefore, most impedance devices are used only qualitatively to assess the frequency and depth of respiratory effort. In addition to their use in an intensive care setting, impedance pneumograms are used as monitors for sleep apnea studies (polysomnograms), and sudden infant death syndrome diagnosis and monitoring (pneumocardiograms and apnea monitors). Since impedance pneumography only measures respiratory effort, however, a major drawback is its inability to distinguish between normal respiratory effort and respiratory effort associated with airway obstruction.

A quantitative indicator of respiratory effort can be obtained from measurements of pleural pressure. Usually, this is performed indirectly by measurement of esophageal pressure with an esophageal balloon and a pressure transducer. However, esophageal pressure measurements also have been obtained using fluid filled catheters (19). With the use of a properly sized and inflated esophageal balloon or fluid catheter placed in the lower third of the esophagus and with the patient in the sitting or lateral decubitus position, esophageal pressures are accurate reflections of pleural pressure. Measurements recorded in the supine position are inaccurate because of artifacts produced by the weight of the mediastinum. Although a commercial esophageal balloon incorporated into a standard nasogastric tube is available (20), recording of accurate pressures is technically difficult in a research environment (7), and even more so in a clinical setting. Nevertheless, esophageal pressure measurements are continuously recorded as an

index of respiratory effort in some sleep disorders laboratories. Otherwise, however, they are not frequently used clinically for continuous monitoring. Direct measurement of pleural pressure using a small catheter placed into the pleural space has also been reported (21), but is not commonly performed.

Respiratory effort also can be monitored using strain gauges (2) and magnetometers (22) placed around the chest and abdomen. Magnetometers measure the change in magnetic fields, produced by electrical coils placed on opposite sides of the body. If expansion of the lungs can be considered as a volume change with only 2° of freedom, the rib cage being 1° of freedom, and the abdomen the other, then lung volume changes are nearly linearly related to changes in the anteroposterior diameters of the chest wall and abdomen. Although the accuracy of magnetometers is limited for the same reasons mentioned for impedance devices, their reliability may be increased if additional magnetometers are used to measure lateral chest wall movement. However, for clinical purposes, both strain gauges and magnetometers are not usually used for quantification of tidal volume. Rather, these methods are used primarily in sleep disorders laboratories for a qualitative estimate of respiratory effort.

Intercostal EMG measurements can be obtained by placement of surface electrodes in the intercostal spaces in the anterior axillary line, and can be employed as an indicator of respiratory effort (2). However, when used in diagnostic studies for sleep disordered breathing, intercostal EMG activity may not be representative of respiratory effort during rapid eye movement sleep because of the inhibition of skeletal muscle tone during this stage of sleep. Frequency analysis of the intercostals and diaphragm EMG has been used by some investigators to study fatigue of the respiratory muscles (23). Although EMG evidence of respiratory muscle fatigue can be detected before clinical findings of acute respiratory failure, routine application of processed respiratory muscle EMG data to patient care has not occurred.

A more reliable method of quantifying breathing frequency and airflow is inductance pneumography. Similar to magnetometers, this technique considers lung volume to be a result of alterations in two compartments: the rib cage and the abdomen. Therefore, the volume of each tidal breath is theoretically attributable to the independent movement of both these compartments. Hence, an inspired volume will be equal to the sum of the volume changes from both compartments. To measure the volume changes in each compartment, bands of insulated wire coils are placed around the chest and abdomen and held in place with a mesh vest. With appropriate calibration, changes in inductance of the coils are accurate reflections of both alterations in lung volume, and the relative contributions of the chest and abdomen to the volume changes (24). Clinical usage of inductance pneumography has been limited primarily to ventilatory monitoring for polysomnography.

There are several categories of devices available that primarily measure airflow (Table 2). With many of these devices, flow rate can be integrated over time to derive a measurement of V_t or VC. Thermistor flow meters are commonly used in sleep disorders laboratories, and in

portable ventilation monitors. These devices are based on the principle that the resistance of a thermistor varies with temperature (25). Using a Wheatstone bridge, changes in resistance can be easily measured. The determinants of heat transfer between the thermistor and a gas are gas density and flow rate, and the temperature difference between the thermistor and the gas. In general, an increase in gas flow cools the thermistor and increases thermistor resistance, whereas a decrease in gas flow has the opposite effect. By calibrating the resistance changes to flow rate, quantitative measurements of flow and volume can be obtained. Unfortunately, the changes in resistance with airflow are nonlinear, and correlation with directly measured airflow is relatively poor. Nevertheless, less complex devices are frequently used in sleep disorders laboratories to qualitatively assess airflow during polysomnography.

Flow rate can be calculated by measuring the pressure difference between two sequential points. The most commonly used device employing this principle is the Fleish pneumotachograph (25). With this device, airflow is directed through a mesh screen having little resistance. The pressure drop across the screen is measured using a sensitive differential pressure transducer. Over the flow range for which the device has been designed, flow rate varies with the pressure changes. Inaccuracies result from condensation of water vapor in the device, but can be prevented by heating the pneumotachograph. The Fleish pneumotachograph is primarily used in research applications although some mobile pulmonary function units measure airflow using this device. The pressure difference across a variable orifice also can be used to measure airflow (25). With this device, flow is directed past an elastic flap that acts as a variable orifice. As flow rate increases, the flap opens larger. Similar to the Fleish pneumotachograph, the pressure drop across the orifice is proportional to airflow.

Ultrasonic principles can be employed to monitor ventilation in several ways (26). One method utilizes the principle of vortex shedding. Devices using this principle direct airflow past precisely sized struts creating vortices within the gas stream. An ultrasonic transducer directs sound waves through the air stream to a receiver. These sound waves are interrupted by the formation of vortices within the gas stream. The rate of vortex formation is proportional to airflow. Another method is based on the transit time of an ultrasonic burst between two crystals placed at an angle to the direction of gas flow. Frequencies between 3 and 10 MHz are transmitted, and the transit time can be related to airflow. Advantages of ultrasonic flowmeters are that no moving parts are present, and that there are no problems with condensation in the system.

Ionization of gases by a radioisotope (americium 241) has been proposed as a method of measuring airflow (27). With this technique, gases are ionized by alpha particles emitted by the radioisotope. The alpha particles displace electrons from some of the gas molecules, leaving them positively charged. A downstream electrode measures the amount of ionized particles reaching it. Since the ionized gas particles quickly neutralize themselves by recombination, the number of ionized gas particles reaching the

downstream collector is proportional to the gas flow rate. Similar to ultrasonic devices, potential advantages of this technique are the absence of moving parts, and the lack of interference from condensation in the system.

Interruption of a light beam by a small flapping vane in the gas stream has been used to measure airflow. With this device gas flow oscillates a flapping vane in the gas stream (25). Oscillation of the vane interrupts a light beam from a photoelectric cell. As air flow increases, the frequency of oscillation of the vane and, consequently, the frequency of interruption of the light beam increase. A disadvantage of this type of device is that high flow rates and condensation can cause malfunction.

Airflow can be measured by a variety of mechanical type devices (25,26). The most common example of this category used at the bedside is the Wright Respirometer. This device, and others that are quite similar, direct gas flow through rotating vanes. The vanes, which spin with the flow of gas, are connected through a series of gears to a calibrated dial. The dials on these devices usually are calibrated to measure V_t , VC, and V, but not flow rate. An exception is the Wright Peak Flow Meter, which also uses the principle of gas hitting a rotating vane. However, this device is calibrated to measure flow rate and has a brake that keeps the needle indicator on the highest flow rate obtained until the device is reset. The main disadvantage of these devices is that undermeasurement of airflow occurs at flow rates $<3\text{--}4$ L/min and that the units can be damaged if flow rates are >300 L/min. Nevertheless, their compact size makes them attractive to use.

An indirect estimate of airflow through the nose can be obtained by measuring changes in nasal pressure using a simple oxygen cannula and a pressure transducer. Changes in nasal pressure correlate well with airflow. In addition, flattening of the peak of the nasal pressure tracing during inspiration is indicative of elevations in upper airway resistance. However, it is susceptible to artifact due to mouth opening that results in signal loss. This technique is increasingly used during polysomnography.

A qualitative estimate of breathing frequency and airflow can be obtained by monitoring expired CO_2 . Since inspiratory gas has negligible amounts of CO_2 , the expiratory phase of breathing is marked by the appearance of measurable amounts of CO_2 in the exhalate. Periods during the ventilatory cycle where no CO_2 is detected indicate the presence of apnea. Carbon dioxide in respiratory gases is usually monitored with an infrared (IR) absorption system or a mass spectrometer (see below). The most common application of the qualitative monitoring of expired CO_2 is in sleep disorders laboratories where the absence of expired CO_2 is a marker for apneic episodes.

Measurement of Oxygen in Blood

Development of the polarographic $p\text{O}_2$ electrode by Dr. Leland Clark in 1953 revolutionized the diagnosis and treatment of patients with impairments in oxygen gas exchange. Today, measurement of arterial oxygen tension is nearly as common place as determination of the hematocrit and can be performed using a modern blood gas analyzer within a minute. The standard $p\text{O}_2$ electrode

consists of a platinum cathode sealed in a glass tip and a silver or silver-silver chloride anode. Electrical contact between the anode and the cathode is made by placing them both in a potassium chloride and hydrogen phosphate buffer solution. The blood sample to be analyzed is separated from the electrodes by a gas permeable membrane (polypropylene, Teflon, or Mylar). A constant polarizing voltage is applied between the anode and cathode. Oxygen in the blood sample diffuses across the membrane and combines at the cathode with water and electrons in the electrolyte to form hydroxide ions. The hydroxide ions then are attracted to the anode where electrons are transferred to form silver oxide and water. The current represented by the transfer of electrons at the anode is proportional to the oxygen tension in blood (28).

Blood samples for measurement of oxygen tension usually are obtained from indwelling intravascular catheters or percutaneous needle puncture of a vessel. However, an estimate of $p_a\text{O}_2$ sometimes can be obtained from capillary samples. Warming the skin to induce vasodilation in skin capillaries will cause the $p\text{O}_2$ in these capillaries to approach arterial levels, so-called arterialization. A small amount of this arterialized blood can be obtained by performing a skin prick in the area that was heated, and collecting the blood with a capillary tube. The sample then can be analyzed in a blood gas analyzer designed to accommodate small samples. In infants, such samples frequently are obtained from the heel ('heel stick blood gases'). However, blood gas tensions obtained in this manner are less accurate than direct arterial sampling, and may be inaccurate in situations where skin perfusion is poor (29).

Although the intermittent sampling of arterial and mixed venous blood for oxygen tension is now considered an essential element in the care of critically ill patients in intensive care units, continuous monitoring may be more desirable in very unstable patients. In the late 1970s, a device incorporating a sampling catheter attached to a portable gas chromatograph was introduced into clinical use (30). With this device, a 0.7 mm external diameter probe was inserted through a standard 18-gauge arterial pressure monitoring catheter. The probe consisted of a chamber made from heparin-bonded gas-permeable rubber that was connected through tubing to the gas chromatograph. Oxygen and carbon dioxide were allowed to diffuse from the blood into the probe, and then were carried by helium in the tubing to the chromatograph for analysis. Both $p\text{O}_2$ and $p\text{CO}_2$, which represented the average values of the previous 3.5 min, were displayed every 4 min. Although reasonably accurate, the device was not a commercial success in part because of the requirement that the probe be inserted into an 18-gauge catheter in comparison to the smaller and more commonly used 20-gauge catheter. Continuous $p\text{O}_2$ monitoring also can be performed using miniature Clark-type electrodes inserted intravascularly. One such device has an external diameter of 0.65 mm, making it suitable for insertion into a peripheral artery in adults (31). In addition, these devices have been used to continuously monitor $p\text{O}_2$ circulating externally in heart-lung oxygenators during cardiac bypass surgery. Although potentially attractive for monitoring patients with a very unstable respiratory status, continuous intravascular $p\text{O}_2$

monitoring has yet to find any substantial clinical acceptance.

A continuous approximation of oxygen tension in arterial blood also can be obtained by measuring transcutaneous oxygen tensions ($T_c pO_2$). Using a small polarographic oxygen electrode operating on a principle similar to that employed in a standard blood gas analyzer, the tension of oxygen diffusing through the skin can be measured. In infants, when the skin is heated to 40°C, the $T_c pO_2$ approximates the $p_a O_2$, and can be used as an indicator of arterial oxygenation. However, the response time of the electrode is relatively slow (95% response time 50–100 s). In adults, skin thickness is greater, and the amount of O_2 able to diffuse to the skin surface is less. Therefore, the $T_c pO_2$ in adults is significantly less than the $p_a O_2$ (32). In addition, $T_c pO_2$ measurements are affected by skin perfusion. When perfusion of the skin falls, as would occur with any condition producing a decrease in cardiac output, $T_c pO_2$ becomes perfusion dependent. In this situation, a decrease in cardiac output results in a decrease in $T_c pO_2$ that may not be related to a change in $p_a O_2$.

Oxygen tension measured from the conjunctiva using a small polarographic electrode has been shown to reflect the $p_a O_2$ in the absence of hemodynamic impairment. Conjunctival pO_2 values generally range from 50 to 75% of simultaneously measured $p_a O_2$ values. However, when blood flow to the eyelid is diminished, conjunctival pO_2 measurements are more accurate indicators of changes in peripheral perfusion than approximations of oxygen gas exchange (33). Although measurements of pO_2 in the conjunctiva and the skin appear to monitor similar physiological changes, there are several advantages of measuring the pO_2 of the conjunctiva instead of the skin. First, since the conjunctiva lacks a keratinized surface and has its capillary bed lying just below its surface, it is not necessary to supply extrinsic heating. Second, the capillaries supplying the conjunctiva are branches of the ophthalmic artery, which in turn is a branch of the internal carotid artery. Therefore, measurements of the conjunctival pO_2 may represent a method of indirectly monitoring cerebral perfusion and oxygenation. Last, variability in values resulting from using different skin sites is not a factor in conjunctival pO_2 measurements.

The oxygen saturation of hemoglobin in blood can be calculated from the pO_2 , pH, and pCO_2 of the blood sample and the body temperature using a standard nomogram (34), or directly measured using an oximeter. However, use of calculated values is strongly discouraged since they do not account for such factors as the level of carboxyhemoglobin or shifts in the oxyhemoglobin dissociation curve resulting from changes in 2,3-diphosphoglycerate. The latter is a phosphate compound that can shift the oxyhemoglobin dissociation curve independently of pH, pCO_2 , and temperature. Oximeters measure oxygen saturation by applying observations made by both Lavoisier and Priestly in 1774 that the color of blood and atmospheric oxygen were related. Subsequently, techniques were developed that allowed determination of the concentrations of different species of hemoglobin by measuring differences in their absorption or reflection of light to

different wavelengths. Current blood oximeters pass at least two wavelengths of light through the blood sample to a photodetector whose output is used to calculate absorbances. The oxygen saturation can then be determined by the relative absorbances of each wavelength. Usually, when measuring the relative amounts of saturated or oxyhemoglobin and unsaturated or deoxyhemoglobin, wavelengths of light are chosen so that, with at least one wavelength, the absorbance difference between the two is maximum, and with the other wavelength, the difference approaches zero.

In addition to performing oximetry directly on blood samples, indwelling fiberoptic probes are now available that permit continuous monitoring of the oxygen saturation in mixed venous and umbilical artery blood. In the case of continuous monitoring of mixed venous oxygen saturation, the fiberoptic probe is incorporated into a flow-directed pulmonary artery catheter. Therefore, pulmonary artery pressures and cardiac outputs can be obtained simultaneously with mixed venous oxygen saturation. When compared to oxygen saturation measurements obtained with intermittent blood sampling, these devices have been shown to measure oxygen saturation quite accurately (35). Although continuous monitoring of arterial saturation with such devices is possible, there has not been a large demand for this clinical application since noninvasive methods of measuring arterial oxygen saturation are available (see below), and because there does not appear to be notable clinical utility for measuring mixed venous oxygen saturations continuously. The principle involved with continuous monitoring of oxygen saturation using fiberoptic probes is reflection oximetry. A fiberoptic bundle transmits light of several different wavelengths down the bundle to the blood where light reflected by hemoglobin is transmitted back to a photodetector through a separate fiberoptic bundle. The amount of light reflected by the different wavelengths then can be converted into hemoglobin saturation.

Oxygen saturation can be continuously monitored noninvasively *in vivo* using principles similar to that employed with blood oximeters. The earliest of these devices (Hewlett Packard Ear Oximeter) measures the oxygen saturation of blood flowing through the ear lobe. The technique involves heating the ear to arterialize the blood flow and measuring the optical transmittance of light passed through the ear at 8 wavelengths in the 650–1050 nm range. Oxygen saturation can be computed using a model based on the Beer-Lambert law (36), which states that the absorbance for any wavelength of light is a function of the layers, concentration, and thickness of absorbers. Using the model and converting absorbance to transmittance allows for calculation of the oxygen saturation. The major clinical disadvantage of this device was its bulkiness, and the requirement that it be placed on an ear lobe. More recently, a variety of pulse oximeters have been introduced into clinical use (37). With pulse oximeters, any pulsating arterial vascular bed such as a fingertip, is placed between a light source transmitting different wavelengths and a detector. Expansion and relaxation of the vascular bed by the arterial pulsations alter the length of the light path. The amount of the light detected therefore varies, and this results in the

production of a plethysmographic waveform. The amplitude of the waveform is a function of the wavelengths of light used, the hemoglobin saturation, and the size of the pulse changes. Since the wavelengths of light used are known, beat-to-beat arterial oxygen saturation can be calculated using the magnitude of the pulse changes and a mathematical model based on the Beer–Lambert law. Current pulse oximeters are quite compact, and can be used for ambulatory and home monitoring. In comparison to ear oximeters, they also provide continuous monitoring of the arterial pulse rate. Their use in clinical medicine has proliferated exponentially. The major disadvantage to both ear and pulse oximeters is the inability to measure arterial saturation in low cardiac output states when tissue perfusion is impaired.

The oxygen content of blood can be calculated from the hemoglobin concentration, the saturation of hemoglobin with oxygen, and the pO_2 in the blood sample, as previously described for the arterial oxygen content. In most situations, calculated oxygen contents are used when determination of oxygen contents is required. However, devices and approaches have been developed to directly measure oxygen content. In one approach that is used commercially, the hemoglobin is lysed to release all of the oxygen in the sample into solution. The amount of oxygen is then analyzed using one of a variety of techniques (see below) More cumbersome and difficult is to measure oxygen content by carbon monoxide displacement, or by volume extraction and manometric measurement. The first technique involves displacement of oxygen in the sample to be analyzed by addition of carbon monoxide, and subsequently measuring the increase in pO_2 in the resultant mixture (38). The second technique, described by Van Slyke and Neill (39), involves extraction of the gas from solution with various reagents over mercury, creating a Torricellian vacuum, and measuring pressure changes with a manometer. Both of these techniques are seldomly used today and are primarily of historical interest.

Measurement of Oxygen in Gas

Several techniques are available to measure the concentration of oxygen in gas:

- Paramagnetic analyzers
- Electrical analyzers
- Galvanic fuel cell
- Polarographic gas analyzers
- Ionized oxygen electrode
- Scholander volumetric technique
- Gas chromatography
- Mass spectrometry

Paramagnetic analyzers use the principle that oxygen alters a magnetic field when introduced into it (40). With one such device, oxygen introduced into the magnetic field causes a glass dumbbell, filled with nitrogen and suspended in the field, to rotate. The amount of rotation of the dumbbell is proportional to the percentage of oxygen concentration. Since the alteration in the magnetic field is

a response to the amount of oxygen present in the sample gas, a paramagnetic analyzer more accurately reflects the partial pressure of oxygen rather than the oxygen percentage.

Electrical oxygen analyzers compare the resistance of a wire in a reference gas to that of a wire in contact with the sample gas using an electrical current that is proportional to the number of oxygen molecules in the Wheatstone bridge apparatus (40). As the oxygen concentration in the sample gas increases, the resistance of the wire decreases, allowing more current to flow through the wire in contact with the sample gas in the Wheatstone bridge. This phenomenon occurs because oxygen, having a greater mass than nitrogen, cools the wire and decreases its resistance. These devices are sensitive to the presence of gases, other than oxygen and nitrogen, that have a high mass. For example, significant concentrations of carbon dioxide will result in a falsely high oxygen percentage. Since it is the resistances between a sample gas and a reference gas that are being compared, electrical analyzers more accurately reflect oxygen percentage rather than oxygen partial pressure.

Another commonly used type of oxygen analyzer is the galvanic fuel cell (26,40). With this type of device, a semipermeable membrane separates the gas sample from an hydroxide bath. The bath consists of a lead anode and a gold cathode. Oxygen diffuses across the membrane where electrons from the gold electrode and water in the bath combine with the oxygen to form hydroxyl ions. The hydroxyl ions are then attracted to the anode where another chemical reaction occurs that yields lead oxide, water, and electrons. The released electrons produce an electric current that is proportional to the concentration of oxygen in the sample gas. Fuel cell devices sense the amount of oxygen molecules in a sample gas, and therefore most accurately sense oxygen partial pressure. Their readings are adversely affected by excessive moisture, gas under high pressure such as with PEEP, and altitude.

The polarographic principle used in the pO_2 electrode of a blood gas analyzer also can be applied to measurement of oxygen in a gas (40). In fact, many blood gas analyzers will allow processing of gas samples, thus providing an alternative method of measuring the pO_2 in a small gas sample. Factors adversely affecting polarographic units are the same as those for fuel cell devices. In addition, polarographic units most accurately reflect partial pressure. Although both fuel cell and polarographic-type devices utilize positive and negative electrodes and measure the current generated by an electrochemical reaction with oxygen, a faster response time is observed with polarographic units because their electrodes are polarized with a battery. However, the electrodes with galvanic units may have greater longevity.

Another method of measuring the concentration of oxygen in a gas is the use of an ionized oxygen electrode. With this technique, a thin coating of platinum is layered on both sides of a zirconium oxide ceramic tube that is permeable to oxygen. When the tube is heated to a high temperature, O_2 is ionized to O_2^- . The zirconium oxide tube becomes selectively permeable to these ions, and an electrical potential is

Figure 4. The pO_2 electrode. Sealed platinum cathode and silver-silver chloride anode are bathed in a potassium chloride and hydrogen phosphate electrolyte buffer solution.

generated between the two platinum surfaces that is proportional to the oxygen concentration outside the tube (4).

The most cumbersome method of measuring oxygen concentration in a gas is the Scholander volumetric technique (41). With this technique, volume changes in the sample gas are measured as the various gaseous components are absorbed from the sample. This method is of little clinical utility for continuous monitoring of oxygen concentrations, but is an important reference technique against which more portable units can be compared.

Another, uncommonly used, gas analytical technique in clinical medicine is gas chromatography. With this method, the gas sample to be analyzed is added to the flow of a carrier gas. The carrier gas (usually helium) transports the sample through a column that contains material having a differential affinity for the components of the sample. The column impedes the passage of components with higher affinities, and therefore separation of the components occurs. After passage through the column, the components of the gas sample can be measured using a nonspecific sensor. Usually, this is done by detecting changes in thermal conductivity induced by the components of the gas sample, but other types of sensors also can be employed (42). Gas chromatography is an accurate method for analyzing O_2 , CO_2 , and anesthetic gas concentrations. However, the slow response time (minutes) is a major drawback. Nevertheless, it has been used for *in vivo* measurements of arterial pO_2 (see the section Measurement of Oxygen in Blood).

The most expensive, but also most versatile technique to analyze oxygen and other gases is mass spectrometry (MS) (4,26). With MS, the sample gas is passed through an electron gun that ionizes the gas particles. The ionized gas particles are then drawn into a magnetic field, where the particles are deflected toward a collection plate. The larger the mass of the gas particle, the farther it will travel down the collection plate. The collection plates count the number of particles of each molecular mass impacting on the plate over time. From this information, the relative composition of the sample gas can be computed. Mass spectrometers are quite accurate, but very expensive. However, one unit can be used to sample gas from multiple sources in a similar way to the method a mainframe computer uses to perform multiple tasks. Such arrangements are used in some operating rooms and intensive care units.

Figure 5. Schematic of the pH electrode. The pH electrode consists of a measurement (silver-silver chloride) electrode and a reference (calomel) electrode.

Measurement of pH and Carbon Dioxide in Blood

Measurement of the pH of blood or another body fluid such as pleural fluid is performed using a pH electrode (Fig. 5). With all pH electrodes, a sample of unknown pH, such as one containing arterial blood, is placed on one side of a pH sensitive glass membrane and a reference pH solution is in contact with the other side. A potential difference develops that is proportional to the pH difference of the two solutions. Since the pH of the reference solution is known, the pH of the sample can be calculated. The actual pH electrode consists of two separate electrodes—a pH-sensitive glass electrode and a reference electrode. Components of the pH sensitive electrode are a silver-silver chloride wire connected to a voltmeter surrounded by a chloride ion buffer with a pH of ~ 6.8 , and a pH-sensitive glass membrane. The reference electrode is constructed so that a platinum wire attached to a voltmeter is in contact with a mercury chloride paste. A 20% potassium chloride solution is used as a wetting agent to insure that the platinum wire maintains contact with the paste. The pH and the reference electrodes are placed in proximity so that the sample is introduced on one side of the pH-sensitive membrane with the buffer of known pH on the other side.

The pCO_2 electrode is actually a modification of the pH electrode. With the pCO_2 electrode, a pH-sensitive glass electrode and a reference electrode are in contact with an electrolyte solution behind a gas-permeable membrane. When a sample is placed on the opposite side of this membrane, CO_2 diffuses across the membrane in both directions and equilibrates with the electrolyte solution. Hydration of the CO_2 results in the production of carbonic acid and a consequent increase in hydrogen ion activity. The pH electrode detects the change in hydrogen ion concentration and develops a voltage change that is proportional to the pCO_2 in the sample.

Whereas reliable methods are available to continuously monitor oxygenation in blood, there are few techniques that are currently used to measure pCO_2 .

Intravascular $p\text{CO}_2$ has been measured using a portable gas chromatograph as previously described (30). However, an intravascular sensor using optode technology (see below) to measure $p\text{CO}_2$ and pH, and a miniaturized intravascular Clark $p\text{O}_2$ has been successfully used in humans (43). Devices to measure transcutaneous $p\text{CO}_2$ ($T_c p\text{CO}_2$) are commercially available, and employ a small $p\text{CO}_2$ electrode similar to that used in a standard blood gas analyzer (44). In general, $T_c p\text{CO}_2$ values are higher than corresponding $p_a\text{CO}_2$ values. Similar to $T_c p\text{O}_2$ measurements, the $T_c p\text{CO}_2$ is adversely affected by changes in skin perfusion, and the response time of the electrode is slow (63% response time: 2 min) (31).

Measurement of Carbon Dioxide in Gas

For monitoring purposes, determination of the concentration of CO_2 in a gas is necessary for calculations of V_D/V_T , $V\text{CO}_2$, and measurement of $p_{\text{et}}\text{CO}_2$. In addition, it is required in pulmonary function laboratories for performance of CO_2 and O_2 response testing. Mass spectrometry (see the section Measurement of Oxygen in Gas) is a rapid and accurate method of measuring the concentration of CO_2 in a gas, and also is adaptable to measuring gas samples from multiple sources at a central location. However, mass spectrometers are very expensive and not generally portable. The major alternative method of measuring the concentration of CO_2 in a gas is by IR absorption. This technique is based on the principle that all gases whose molecules contain either more than two atoms (e.g., CO_2 or SO_2) or two atoms of different elements (e.g., CO) will absorb IR radiation. With an IR CO_2 analyzer, IR radiation is directed through the gas sample to be analyzed where the sample absorbs a small amount of energy. After passing through the sample, the remainder of the IR radiation is directed into another chamber containing pure CO_2 where the rest of the energy is absorbed. Absorption of IR energy generates heat that can be easily quantified. As the concentration of CO_2 in the gas sample increases, less IR radiation will reach the second chamber that contains pure CO_2 . Therefore, the heating effect measured in this chamber will be inversely proportional to the concentration of CO_2 in the gas sample (45). Unfortunately, if a gas sample contains two different gases that can absorb IR energy, the analyzer will be unable to distinguish between the concentrations of the two gases. This problem occasionally arises during monitoring of $p_{\text{et}}\text{CO}_2$ during nitrous oxide anesthesia. However, placing a chamber filled with nitrous oxide between the IR radiation source and the gas sample to be analyzed will filter out any IR absorption secondary to nitrous oxide.

Practical and Technical Considerations in Blood Gas Analysis

Currently manufactured blood gas analyzers incorporate $p\text{O}_2$, $p\text{CO}_2$, and pH electrodes into a single blood gas analyzer unit so that a blood sample can be analyzed simultaneously for all three parameters. There are several practical considerations in the collection of blood samples for blood gas analysis. First, care should be exercised in the collection of the sample to eliminate air bubbles and not use excessive amounts of anticoagulant. Heparin, a com-

monly used anticoagulant, is acidic. Excessive amounts therefore will decrease the pH and increase the $p\text{CO}_2$ artifactually. Large air bubbles will produce a decrease in $p\text{CO}_2$ as CO_2 diffuses into the bubble. Oxygen tension will either increase or decrease depending on whether the $p\text{O}_2$ of the sample is higher or lower than the $p\text{O}_2$ of the air bubble. Second, plastic syringes have been observed to perform equally as well as glass syringes provided that the analysis is undertaken within an hour of obtaining the sample. Third, samples should be placed in ice for transport immediately after being obtained to minimize metabolic consumption of oxygen by white blood cells. This may be a cause of spurious hypoxemia in patients with leukemia, who may have pathologically elevated white blood cell counts. Fourth, the patient's temperature should be noted so that correction for the effect of temperature on the relative solubility of oxygen in blood can be made. Several technical factors may introduce error into blood gas analysis. Since oxygen electrodes generally are calibrated using a gas with a $p\text{O}_2$ between 130 and 150 mmHg, measurement of a sample with a higher $p\text{O}_2$ may be in error. In such cases, the electrode should be recalibrated with tonometered blood containing a high $p\text{O}_2$ prior to analysis. In addition, the sample chamber should be flushed with 100% oxygen to leach out any residual wash fluid containing a low oxygen tension. Most blood gas analyzers perform their measurements at a temperature of 37°C . Variation of the temperature in the sample chamber will alter pH by 0.015 units, $p\text{O}_2$ by 7%, and $p\text{CO}_2$ by 4.5% for each degree of temperature change.

Alarms. Alarms are used during ventilatory monitoring to either signal the occurrence of life-threatening conditions, or indicate the presence of conditions that may not be immediately life-threatening, but are abnormal. Apnea and ventilator disconnection are the most common clinical situations where life-threatening alarms are used. Apnea is detected by monitoring parameters that indicate either absence of ventilatory effort or airflow. However, devices that only detect ventilatory effort such as impedance pneumographs may not be able to distinguish normal respiratory effort from respiratory effort during an obstructive apneic event. Therefore, detection of apnea by monitoring airflow is more sensitive. Ventilator disconnection can be monitored by either a low inspiratory-airway-pressure alarm or a low exhaled-volume alarm. On many current model ventilators, both parameters are monitored. In situations where alarms are used to signal life-threatening events, alarms should be designed such that it is not possible to silence them except for very short periods of time. Otherwise, alarms may be inadvertently left off, and the patient placed at risk.

Inspired oxygen concentration and high airway pressure are two other important parameters that are frequently monitored on a continuous basis. With respect to inspired oxygen concentration, it is important to differentiate between alarms that monitor the gas pressure delivered to a device and alarms that actually sense oxygen concentration. In the first situation, true oxygen concentration is not being measured and in the unlikely situation where an oxygen source becomes contaminated with

another gas, such an alarm would not sound. High pressure alarms on mechanical ventilators not only detect when airway pressure exceeds a certain level, but they also provide a feedback signal to terminate inspiration so that the alarm pressure is not exceeded. Alarms can be used on almost any device used for continuous ventilatory monitoring. However, too many alarms can be ill-advised. If alarms are constantly sounding, all alarms, including life-threatening ones, tend to be ignored.

Evolving Technology in Ventilatory Monitoring. *In vivo* continuous measurement of O₂, CO₂, pH, and other substances in the future may be clinically useful using optode technology (46,47). An optode is a fiberoptic light bundle coupled to a microcuvette where a chemical reaction can occur. For example, the substance to be analyzed diffuses through a semipermeable membrane into the cuvette whereupon a chemical reaction would be initiated. The chemical reaction would produce a change in the optical properties of the reagent in the cuvette that would be detected by light directed along the fiberoptic light bundle. Wavelength specific absorbance can be used to quantify p_aCO₂ and pH, and fluorescence is useful for p_aO₂, as well as p_aCO₂ and pH. Imprecision of the p_aO₂ sensor has led to a hybrid probe, with a miniaturized Clark pO₂ electrode combined with absorbance p_aCO₂ and pH sensors, as well as a thermocouple for temperature measurement (43). Clinical challenges for continuous on line measurement, utilizing an *in vivo* placement, primarily deal with inaccuracies of p_aO₂ measurement secondary to arterial wall contamination or limited blood flow because of thrombus formation and vasospasm. In addition, probe longevity and cost, as well as pulse pressure dampening over time, have been issues. Because of these problems, an on demand *ex vivo* placement in the arterial line has been tested and has sufficient accuracy, but does not have the advantage of continuous measurement (48).

The ion selective electrode (ISE) or the field effect transistor-based chemical sensor (ISFET) are other new methods of continuously monitoring pH and pCO₂ that may become feasible in the future (47,49). With both these devices, the ion to be analyzed is isolated from the blood using an ion selective membrane. An ISE consists of an electrode surrounded by a buffer solution that is separated from a biological fluid or tissue by an ion-selective membrane. The electrical potential at the measurement electrode is compared to that of a reference electrode, and the potential difference is proportional to the concentration of the ion being measured. The ISFET is an insulated gate field-effect transistor without a metal electrode at the gate. Measurement of the concentration of a specific ion is a function of modulation of current flow within the semiconductor induced by the ion in the surrounding biological tissue or fluid. However, similar to optodes, both the ISE and the ISFET are still in the early developmental stages. Current problems include long-term stability, ambient light and temperature sensitivity, and interference from extraneous ions. With both the ISE and ISFET, control thrombus formation on the probe remains a problem. In addition, an adequate O₂ sensor has not been developed.

Although novel methods of ventilatory monitoring are being developed or are currently under investigation, perhaps the greater challenge will not be to simply prove efficacy. Rather, given the economics of healthcare delivery, the cost-effectiveness of any new device or technique on patient care will need to be unequivocally demonstrated for it to be clinically adopted.

VISUAL FIELD TESTING

AMOL D. KULKARNI
University of Wisconsin Madison
Madison, Wisconsin

INTRODUCTION

The visual field is the total area where objects can be seen in the peripheral vision while the eye is focused on a central point. Visual field testing is a critical part of the eye examination and is mandatory for the detailed evaluation of unexplained visual loss. Of the various reasons for conducting a visual field examination, the most common disorder is glaucoma. In glaucoma, field testing is essential not only to establish the diagnosis, but also to follow-up and determine the effectiveness of treatment. There are various modalities available for visual field testing customized to particular eye disorders. This article provides a concise review of the various methods of visual field testing and their applications for clinical and research purposes.

METHODS OF VISUAL FIELDS TESTING

There are various ways of testing the visual field (1). It can be done in a simple manner in the clinic or may involve sophisticated equipments. The commonly used modalities are described below.

1. **Confrontation visual field exam:** It is a quick evaluation of the visual field done by a physician sitting directly in front of you. With one eye covered,

Figure 1. Amsler grid.

the patient is asked to look at the examiner's eye. The patient has to alert the examiner when they can see the examiner's hand in the various zones on the nasal, temporal, superior, and inferior aspect while still looking at the examiner's eye. This is a simple method of testing in the clinic and can detect gross visual field loss, such as hemifield loss.

2. **Amsler grid:** It is a quick method of self-assessment of the central 10° of the visual field. It consists of small squares of 1×1 mm with a central dot as shown in Fig. 1. After wearing the necessary correction, the Amsler grid is held at 14 in. (35.56 cm) from the eye and the central dot is focused. If any changes in the patterns of adjacent lines or squares are disrupted, a visual defect is suspected. It can detect small central or para-central visual defects called as scotoma especially in disorders of macula.
3. **Tangent screen exam:** The patient is asked to sit 3 ft. (91.44 cm) from a screen with a target in the center. While staring at the target, the patient alerts the examiner on visualizing an object brought into their peripheral vision. This helps in mapping the extent of peripheral vision.
4. **Perimetry:** It is a systematic measurement of the total area where objects can be seen in the peripheral vision while the eye is focused on a central point. The two most commonly used modalities of perimetry are Goldmann kinetic perimetry and threshold static automated perimetry.

Perimetry

There are two types of perimetry based on the stimulus characteristics (1). In kinetic perimetry, a stimulus is moved from a nonseeing area of the visual field to a seeing area along a set meridian. The procedure is repeated with

Figure 2. Normal hill of vision.

the use of the same stimulus along other meridians spaced at every 15° . In static perimetry, the size and location of the stimulus remain constant. The retinal sensitivity at a specific location is determined by varying the brightness of the stimulus. Based on the measurements from perimetry the normal visual field is defined as the area perceived by a fixating eye extending $\sim 60^\circ$ into the superior field, 75° into the inferior field, 110° temporally, and 60° nasally. This creates an island of vision with a steep central peak that corresponds to the fovea, the area of greatest retinal sensitivity. The shape of the island is defined by conducting measurement at various locations in the field of vision (Fig. 2).

Goldmann Perimetry

The Goldmann perimeter (1) is the most commonly used instrument for manual perimetry. It is a calibrated bowl projection instrument with a background intensity of 3 1.5 apostilbs (asb). The size and intensity of targets can be varied to plot the visual field kinetically and to determine local static thresholds. The stimuli used to plot a visual field are identified by a Roman numeral, a number, and a letter. The Roman numeral represents the size of the object, from Goldmann size 0 ($1/16$ mm²) to Goldmann size V (64 mm²). Each size increment equals a twofold increase in diameter and a fourfold increase in area. The visual field corresponding to each stimulus size is called as isopter. The Goldmann visual field testing is primarily used for determining field defects caused by disorders of the brain (neuroophthalmology). However, the reliability of field mapping depends on the expertise of the operator (perimetrist).

Automated Perimetry

The introduction of computers and automation lead to the development of a new generation of perimeters (1). These enabled static testing in an objective and standardized fashion with minimal perimetrist bias. A quantitative representation of the visual field can be obtained more easily than with manual testing. The computer allows stimuli to be presented in a pseudorandom, unpredictable fashion.

Patients do not know where the next stimulus will appear, so fixation is improved, thereby increasing the

reliability of the test. Random presentations also increase the speed with which perimetry can be performed, and thereby bypass the problem of local retinal adaptation. Static computerized perimetry measures retinal sensitivity at predetermined locations in the visual field. These perimeters measure the ability of the eye to detect a difference in contrast between a test target and the background luminance. The differential light threshold is designated as the dimmest target seen 50% of the time. Suprathreshold stimuli are brighter than threshold stimuli, and they will be seen > 50% of the time. Infrathreshold stimuli are dimmer than threshold stimuli, and they will be seen < 50% of the time. The various perimeters used in clinical practice include Humphrey's visual field analyzer, and Octopus perimeter.

Comparison of static and kinetic perimetry (2,3) reveals that kinetic evaluation can clearly outline the normal visual field. However, kinetic perimetry may miss shallow scotomas and poorly define the flat slope seen nasally. Static perimetry readily detects shallow scotomas and can define the slope of both shallow and steep scotomas.

GLAUCOMATOUS FIELD DEFECTS

Perimetry is of paramount significance in the management of glaucoma. In glaucoma, there is damage of the nerve fiber layer that causes loss of visual field. Automated perimetry is widely used and the commonly used programs for glaucoma are the Octopus program 32 and the Humphrey program 30-2. These programs are tests of the central 30° with 6° of separation between locations. The various field defects in glaucoma include diffuse depression, localized nerve fibre bundle defects, paracentral defects, arcuate scotomas, nasal step defects, temporal wedge-shaped defects, early visual field defects, and blind spot changes.

NEWER MODALITIES OF FIELD TESTING

Blue–yellow perimetry, also known as short wavelength automated perimetry (SWAP), represents a recent advance in the early identification of glaucomatous visual field loss. It differs from standard automated perimetry only in that blue light is used as the stimulus, and yellow light is used for the background illumination. Moreover new algorithm, such as SITA, which stands for Swedish Interactive Thresholding Algorithm (4) have been introduced to reduce the length of a visual field test while enhancing sensitivity and specificity.

Frequency doubling technology (FDT) is used to isolate a particular pathway of visual stimulus. It involves use of alternate bars of white and black and helps in early detection of glaucoma.

FUTURE DIRECTIONS

There have been considerable developments in visual field testing in the past decade, and it has opened up areas for the development of new testing and analysis programs. A

larger database for patients with glaucoma will improve the accuracy and detection of glaucomatous visual field defects. Additional clinical studies are needed to determine the role of these and other modalities in the future.

VISUAL PROSTHESES

JEAN DELBEKE
 CLAUDE VERAART
 Catholic University of Louvain
 Brussels, Belgium

INTRODUCTION

Minute electrical stimuli delivered to the retina, the optic nerve, or the occipital cortex can induce light perceptions called phosphenes. The visual prosthesis aims at exploiting these phosphenes to restore a form of vision in some cases of blindness. Very schematically, a camera or a picture capturing device transforms images into electrical signals that are then adapted and passed on to some still functional part of the visual pathways, thus bridging the defective structures. The system has at least some parts implanted, including electrodes and their stimulator circuits. A photo-sensitive array in the eye could provide the necessary image input, but most approaches use an external miniature camera. Typically, the visual data handling requires an external processor and the power supply as well as the data are provided to the implant by a transcutaneous transmission system.

Despite a first pioneering attempt by Brindley and Lewin as early as 1968 (1) only very few experimental visual prostheses have been implanted in humans so far. The limited accessibility of the involved anatomical structures, the poorly understood neural encoding, and the huge amount of information handled by the visual nervous system have clearly hampered a development that can not yet be compared with the far more advanced evolution of cochlear implants (see article on Cochlear Implants in this encyclopedia). The visual prosthesis is still at a very

early stage, exploring different methodological directions, and seeking minimal performances that would justify clinical applications in the most severe cases of blindness. The first fully fledged clinical study has yet to begin and the experimental character of existing systems limits all trials to a restricted number of well-informed adult volunteers.

Vision Basics and Retinotopy

A basic knowledge of the anatomy and physiology of the visual system is necessary for a proper understanding of the visual prosthesis in its various forms.

The eye can be compared to a camera with an adjustable optics including the cornea and the lens, focusing inverted images of the external world onto the retina. The retina is in fact a thin slice of brain that has expanded into the eye during the embryo development. It is made up of several cell layers. Among these, the photosensitive cells called cones and rods form the external layer with, as a result that light entering the eye has to cross the complete retina before to reach them (see Fig. 1c).

The 120 million or so photosensitive cells are not uniformly distributed. Their density is highest at the fovea, a region that corresponds to the fixation point, near the center of the visual field. Cones outnumber the rods in the central retina and are the only kind of photosensitive cells at the fovea. They discriminate colors. Rods predomi-

nate at the periphery. These very sensitive sensors play a major role in night vision, but do not contribute to high resolution nor color perception. The cellular hyperpolarization generated by light impinging on the photoreceptors is carried over to other the neuronal cell layers ultimately connected to output layer represented by the ganglion cells. With the exception of the fovea (most central part) and especially in the periphery of the retina (i.e., of the visual field), there is a great deal of convergence and encoding of the visual signal that must be squeezed from the analog modulation of ~ 130 million photoreceptor potentials into the discharge bursts of little more than 1 million ganglion cells. Roughly, the bipolar cells represent the main converging vertical link between the photoreceptors and the ganglion cells. The horizontal cells at the junction between photoreceptors and bipolar cells and the amacrine cells at the junction between bipolar cells and the ganglion cells provide sideways connections. Functionally, the retinal network can be subdivided in a number of parallel channels each focusing on the transmission of one aspect of images. These include a color coding system and movement detecting circuits. Bipolar cells and ganglion cells also subdivide in ON OFF types. The ON cells increase their activity on exposure of the center of their receptive field to light while their ongoing firing slows down when light strikes in the periphery of that region. The OFF cells react in the opposite way. Ganglion cells also respond more or less

Figure 1. (a) Schematic representation of the visual pathways from the eye to the visual cortex with an indication of the hemifield segregation at the level of the chiasma. (b) Retinotopy mapping all along the visual pathways. Note also the cortical amplification, that is, disproportional cortical representation of the central visual field. (c) Enlarged view of a cut through the retina showing the various layers and their position in relation to light entering the eye.

transiently. The result is a spatiotemporal retinal filter providing the optic nerve with a complex and still not well understood neural code. Ganglion cell axons first run over the inner surface of the retina to join the optic nerve head located slightly nasally from the center of the retina. There, all ganglion cell axons join before to leave the eye and form the optic nerve.

In the orbit, the optic nerve is relatively slack, laying between extraocular muscles, fat tissue and various blood vessels and nerves. It is protected by a strong sleeve of dura mater as well as a very thin pia mater with cerebrospinal fluid in between. When the optic nerve enters the skull, it loses its dura mater sleeve, which now lines the inner surface of the skull. After a little >1 cm, the two intracranial optic nerves meet and exchange fibers at the level of the chiasma (see Fig. 1a). Ganglion cell axons of the nasal hemiretina or temporal visual field cross the midline and join the temporal axons of the other eye to form the optic tract. Foveal axons split into one branch toward each side. Some fibers (not represented) corresponding to accessory functions leave the mainstream visual pathway to reach the hypothalamus, pretectum and superior colliculus. The axons directly involved in vision end in the lateral geniculate nucleus. This structure performs further signal processing and receives control signals from various parts of the brain. From the lateral geniculate nucleus, the visual information reaches the occipital lobe of the brain through the optic radiation. Interestingly, corresponding inputs from both eyes are arranged in close proximity, but remain segregated up to the level of the primary visual cortex. From there, signals corresponding to various aspects of the visual stimulus are dispatched to different brain locations for further processing.

Consequently, of the fiber exchanges at the level of the chiasma, except for the representation of the fovea, one visual cortex receives only information about the contralateral visual field. In addition, albeit with much distortion, cells of the visual cortex tend to retain the topological relationship of the retinal location from which they receive their input. The resulting point-to-point correspondence with the retinal locations, and hence the visual field is called retinotopy. Some form of retinotopy is found at most levels of the visual pathways up to the cortex (see Fig. 1b). Despite an obvious need for corrective remapping, retinotopy of the structure to be stimulated will be an essential consideration for the development of a visual prosthesis. Right from the level of the retinal ganglion cells on, retinotopy nevertheless remains an approximation that does not take into account other significant aspects of the neural signal encoding.

Blindness

Under ideal conditions, the human minimum angle of resolution (MAR) is ~ 0.5 arc min (20/10 vision). However, the standard definition of normal visual acuity (20/20 vision) is the ability to resolve a spatial pattern separated by a visual angle of one minute of arc ($\sim 4 \mu\text{m}$ on the retina). The Snellen visual acuity measures the pattern recognition acuity as the ratio d/D , where D is the distance at which a sign subtends 5 min of arc, and d is the distance at which

they can be recognized. Reference patterns subtend 5 min of arc at a distance of 60 m and have features of 1 min of arc, corresponding to the standard normal acuity. A visual acuity of 3/60 means that such a sign can only be recognized at a distance of 3 m. For practical purposes, the Snellen chart is made up of different sized letters such that the examination can be performed at a single distance. Because the normal acuity corresponds to 1 min of arc, the MAR value in arc minutes has the same numeric value as the reciprocal of the Snellen fraction.

However, sight is a multidimensional ability that cannot be measured by acuity alone. The effect of a visual field defect or a reduced sensitivity to light cannot be compared directly to acuity.

The International Statistical Classification of Diseases and Related Health Problems of the World Health Organization (ICD-10) uses codes 1–5 to describe moderate, severe, profound, near total, and total visual impairments, respectively. Within that range, the label low vision (categories 1 and 2) designates a visual acuity $>6/18$ (0.3), but $<3/60$ (0.05) in the better eye with optimal correction or a visual field between 10 and 30° . The label blindness encompasses categories 3–5. Code 3 corresponds to a visual acuity <0.05 on the Snellen scale for the best eye using appropriate correction, or a central visual field diameter of $<10^\circ$ in its largest diameter. An acuity of <0.02 or a visual field $<5^\circ$ is coded 4 (near total) while total visual impairment means deprived of light perception.

To measure a visual acuity in near total visual impairment, alternative methods are used including close range on the Snellen chart reading, finger counting, the detection of hand motion, or the perception of light.

Blindness can result from any cause potentially affecting the visual pathways: genetic abnormalities, infections, metabolic diseases, trauma, vascular deficiency, or cancer for example. In one subgroup, mainly represented by retinitis pigmentosa (RP), age related macular degeneration, and stargardt's disease, it has been shown that blindness can result from a total destruction of the photosensitive cell layer while a proportion of other cells of the retina and the remaining of the visual pathways survive. The hereditary disease retinitis pigmentosa in particular, is a relatively frequent cause of severe and incurable blindness in developed countries with a prevalence of 1 in 5000 (2).

An essential distinction must also be made between early and late blindness. Indeed, several years of normal behavioral experience are required after birth for the human visual system to fully organize and suitably weight its synaptic connections (3). Those years are referred to as the critical period. The visual brain of people who are born blind is functionally different from that of those who lost sight later in life (4). Early blindness indicates a loss of vision before the end of the critical period. There is no sharp separation between early and late blindness and different visual functions each having their own critical period. Motion detection would probably mature before spatial localization, followed by object recognition, color vision, and stereopsis. According to ophthalmologic observations in diplopia, the critical development period for binocular vision ends around the age of 6. In addition, the visual impairment might result from a progressive

Figure 2. General layout of a visual prosthesis, with the external components on the left and the implanted components (shaded) on the right.

disease. Early blindness type increased metabolic activity has been reported in cases where progressive total blindness occurred around the age of 10 (4). By contrast, late blindness features are observed when the first visual defect appears before the age of 8–12, but only evolve toward total blindness thereafter, or when vision is accidentally lost at the age of 12 or later.

A prosthesis implanted after the critical period is doomed to failure. Age of blindness onset, however, is not the only factor resulting in a deviant visual system. In diseases such as retinitis pigmentosa, the loss of photoreceptors itself results in important remodeling of the remaining retinal network (5), resulting in aberrant neural connections and shielding by scar tissue, all potentially limiting more or less severely the efficiency of a visual prosthesis.

History

The idea of an electrical treatment for blindness is perhaps as old as the discovery of electricity itself. The first real attempt to implant a visual prosthesis, however, dates back from 1968 (1). A set of 80 electrodes were implanted over the occipital pole of the cortex of a blind person. Each electrode could be activated transcutaneously by an equal number of implanted radio receivers. Small precisely located phosphenes were obtained, suggesting that a useful prosthesis could indeed become possible, but the subdural cortex surface electrodes had very high thresholds and did

not provide an adequate resolution. While intracortical electrode arrays were being developed using technologies derived from the semiconductor industry (6), it became clear that in terminal retinitis pigmentosa, a significant fraction of the ganglion cell population remains functional despite total blindness (7,8). In such cases, a visual prosthesis interfacing with the surviving layers of the retina or with the optic nerve, all referred to as the anterior type could be as useful as the more complex cortical implant. As a result, starting around 1990, perhaps partially dragged by the success of the cochlear prosthesis, a renewed and still growing interest in visual prosthesis rapidly expanded worldwide.

Basic Theory of Operation of the Visual Prosthesis

In all published visual prosthesis approaches, the visual system is very schematically seen as a transmission chain in which retinal image pixels are encoded into series of electrical pulses ultimately activating the visual cortex. The visual prosthesis is meant to replace or by-pass the defective link in the neural chain. At the cost of not using still functional body parts (eye optics, e.g.), most visual prosthesis designs replace the whole front end of the sensory chain, requiring only the prosthesis output to be connected to the nervous system (see Fig. 2). A picture of the external and implanted components of a prototype of the optic nerve visual prosthesis is given in Fig. 3 as an example.

Figure 3. Implementation example: picture of the optic nerve visual prosthesis prototype. On the left, the external processor linked to glasses on which a camera and the external antenna are attached. To the right, the implanted components with the internal antenna, the neurostimulator and the spiral cuff electrode with their leads and connectors.

Depending on the approach, the prosthesis sensors can be any imaging device from an implanted photoarrays (9) to a miniature cameras worn on a pair of glasses. In this last case, a small-size camera is also an asset for esthetical reasons.

A processor is necessary to transform the video images in properly encoded and modulated commands to the implanted stimulator (10). The prosthesis must allow real time object localization and identification. Visual information quickly represents a huge amount of data imposing high demands on the computational performances while the processor including its power supply, must remain easy to carry around. This portability often represents a technological challenge by itself. Adaptability to new and rapidly emerging developments is also an essential requirement in this quite young technology. Transcutaneous electromagnetic transmission of data and power using magnet fixated antennas is now standard for cochlear implants. This principle was already applied in a more primitive way by Brindley back in 1968 (1). He then solved the problems of parallel transmission through the implantation of an array of transmitters. Recent projects use combined power and data electromagnetic telemetry systems similar to those of the cochlear implant systems but with improved power and data performances.

Different Approaches

The neural interface typically represents the most critical and challenging component involved. In keeping with this, the different approaches to develop a visual prosthesis are often classified according to their connection point along the visual pathways: subretinal, epiretinal, transretinal, hybrid, optic nerve, cortex surface, or intracortical. The interface can be chemical or electrical. Until now, the chemical approach has been limited to some work on retinal devices. Many more projects use electrical stimulation through specifically designed electrodes.

Chemical Stimulation. The basic idea of this approach is to use neurotransmitters (L-glutamate, e.g.) or other specific chemicals that are known to activate neural or retinal cells. Directly over the retina, photochemical reactions (typically requiring ultraviolet, UV light) liberate active components from an inactive parent molecule or from 'caging' molecules (C₆₀, fullerene) (11). The result is a direct translation of retinal images into a corresponding neural activation pattern. Alternatively, an electronically activated multichannel microfluidic device could deliver the needed chemicals locally and be used in a visual prosthesis as a substitute to electrodes (12). At present, most research efforts are still devoted to basic problems such as to reduce the required light energy level, biocompatibility, transport of the chemicals and reservoir refill (13). In the future, however, chemical stimulation could have several advantages. There is no electrode corrosion. Stimulation selectivity can bear on the subgroups of retinal cells, and so mimic the physiological activation achieved by synaptic transmission. In addition, the proposed stimulating electrodes can be made on soft materials supposed to be less damaging for the retina than electrode arrays (12).

Subretinal Implants. The most appealing aspect of the subretinal implants is that it exploits the supposedly healthy eye optics and interfaces to the visual pathways before any neural processing has blurred the neural code. The aim is indeed to replace the damaged photosensors by an array of passive miniature photosensitive devices transforming the retinal light image into local electrical stimulating currents. These currents would in turn activate the surviving neuronal circuits of the retina in keeping with the light intensity they receive, much in the same way as photosensitive cells do. The idea is straightforward and logical. Natural accommodation and physiological eye movements would remain functional. Very thin (100 μm) flexible electrode construction and perforations allowing nutrient and other metabolic exchanges between the retina and the choroid could insure biocompatibility (14). The use of glycoprotein coating has been suggested to improve the biocompatibility of the components. Small implants can be quickly and securely trapped between the neural elements and the pigmentary epithelium, which seems to pump out this space (15). The light wavelength sensitivity of the microphotodiodes is in the 500–1100 nm range, which corresponds reasonably well with the visible spectrum of 400–700 nm.

Chow's group developed a 25 μm thick subretinal implant of ~ 5000 subunits on a 2 mm diameter chip, enough to provide a tunnel vision of a little > 8°. Such devices have been implanted in a number of retinitis pigmentosa patients. After 6–18 months, no significant side effect has been noticed and some patients reported a transient improvement not related to the implant position in the visual field. All the implants were electrically functional, but no visual response of the implant themselves was demonstrated (9). These devices are only powered by incident light but, as shown by Zrenner's team, currents generated by microphotodiodes are by far too low to activate bipolar cells. Available devices, would require 12 klx (16) to do so while normal ambient light typically reaches ~ 8 lx. An active amplification is therefore necessary, finally sharing with other approaches the need for an external power supply raising again the problems of bulkiness, heat dissipation, energy and data transmission.

Epiretinal Implants. In the epiretinal approach, micro-electrode arrays are attached on the vitreal side of the retina, just over the inner layer that contains the ganglion cells and their axons. The stimulation contacts are supposed to activate local ganglion and/or the bipolar cells. Acute stimulation of the retina in human volunteers has gone very far in demonstrating the feasibility of a prosthesis with a resolution of ~ 1.75° (17). Concerns have been raised about the possibility to activate passing-by optic nerve fibers as well, which would result in aberrant perceptions (18). Also, because of the retinal preprocessing, activity in the ganglion cells can no longer be seen as a point-to-point representation of the retinal image and the encoding at that level already exploits the time dimension as well. Humayun's team developed a prosthetic device with an array of 16 electrodes connected to an implanted stimulator located outside the eye. An external system for

image acquisition and processing sends data and power to the implanted electronics by telemetry. This device was implanted in several blind RP patient. Initial results seem encouraging (19).

The basic principle in most visual prosthesis approaches is that stimulation through a small electrode will result in the perception of a point-like phosphene of corresponding retinotopic localization. An array of such electrode contacts would produce a number of phosphenes that can be distinguished by their location in the visual field. After correction for any nonconformal localization, an image perception could then be obtained by activation of the corresponding pixel electrodes. It will be seen that this pixel phosphene method to selectively activate a subset of fibers or ganglion cells does not hold in the case of the optic nerve stimulation.

The Transretinal Approach. A transretinal approach (20) has also been suggested whereby a needle placed in the vitreous is used as a single cathode facing a miniature array of anodes slit under (or in the sclera), thus yielding a transretinal stimulation. Evoked potentials have been obtained in animals using eight contact on a $2 \times 4 \times 0.18$ mm electrode with polyimide substrate. There is no indication yet as to which cells form the primary target.

The Hybrid Approach. The team of Yagi and Tano has started research to grow transplanted neural cells from a subretinal implant to the central nervous system using axon-guiding substrates. This approach could also be applied when ganglion cells are destroyed. This work remains very much preliminary and no results are available yet.

The Optic Nerve Approach. A direct stimulation of the ganglion cell axons with an optic nerve electrode can be seen as an alternative to the epiretinal stimulation. The basic idea here is that the simultaneous activation of a number of contacts can focus the stimulation on a chosen subset of the axon bundle by controlling the applied electric field. As a result, electrode contacts around the nerve can yield a selective activation (21). The number of different fiber subsets that can be stimulated independently and thus the number of phosphene perceptions that can be obtained is much larger than the number of electrode contacts available. This principle could be applied to all electrodes carrying contacts at some distance from the target cells. Focal stimuli are thus generated serially by each multicontact activation instead of in parallel through individual contacts.

This concept has been validated in a human implantation (22). The results confirm a retinotopic organization of the intracranial optic nerve and phosphenes are obtained with safe electric charges. Interestingly, due to the signal encoding in the optic nerve, phosphenes do not reproduce the distribution of the fiber activation and are much smaller than expected. Their position in the visual field can be controlled, which is of course essential in the prospect of the visual prosthesis development, making it possible to convey image information, even without resorting to more

complex selective stimulation schemes (e.g., superficial fiber blocking).

It has been suggested (23) that a penetrating electrode could increase the number of available independent responses, but the damage inflicted to the nerve has not yet allowed to validate such an alternative.

The first optic nerve electrode was implanted behind the orbit just in front of the chiasma. A new surgical technique has been developed to implant an eight contact electrode in the orbit. Avoiding intracranial surgery is certainly reassuring for the patient, but the intraorbital approach is technically difficult and has several drawbacks. At that location, the optic nerve is indeed covered by the dura mater, which shields off the fibers from the stimulation and therefore results in higher thresholds. Also, somatic sensory nerve fibers as well as blood vessels are present in the dura mater, and eye movements could limit the stability of the electrode contacts. Nevertheless, the feasibility of this approach has been demonstrated recently.

The Cortical Approach. The very first implanted human visual prosthesis prototype (1) included an array of 80 electrode contacts placed over the occipital cortex of a blind person and linked to an equal number of miniature transmitters placed under the scalp. High thresholds and poor selectivity have led to the conclusion that intracortical rather than cortex surface electrodes were necessary (24). Subsequently, a two-dimensional (2D) device known as the Huntington electrode (25) and a three-dimensionally (3D) structured, single plane, Utah electrode (26) were proposed for intracortical implantation. Resolutions of $\sim 400 \mu\text{m}$ can be obtained (27) where the surface electrodes of Brindley could only resolve minimal distances of 2–3 mm. In an acute experiment, 38 intracortical microelectrodes have been implanted, for a period of 4 months in the right visual cortex of a human volunteer (6). Two-point resolution was about five times better than had typically been achieved with surface stimulation. All phosphenes were located in the left hemi-field with the majority above the horizontal meridian. There was a clustering of most of the phosphenes within a relatively small area of the visual space (6). As opposed to subdural electrodes, intracortical devices have the potential advantage to reach the hidden parts of the cortex in the depth of the calcarine fold corresponding to the big gap in the region of the horizontal meridian of the visual field as observed by Brindley.

Brindley himself stressed the important variability of the cortical maps among individuals. Individual mapping of each cortical implant is thus expected to be necessary. Biocompatibility is still a major point of concern, owing to the large number of electrode contacts and stimulator connections, especially for chronic human implantation. However, compared with the prechiasmatic approaches, the intracortical alternative would in the long run have the advantage of being applicable to many more conditions, not just diseases of the retinal photosensors.

A consortium led by Troyk has undertaken the development of an intracortical prosthesis based on a 256-channel stimulator module and a 1024-contact array. Recently, 152 intracortical microelectrodes have been chronically implanted in area V1 of a male macaque.

Figure 4. Detailed representation of the external components of Figs. 2 and 3.

Receptive field mapping was done using a memory saccade task (28). It is expected that such new animal psychophysical tests will compensate for the lack of a linguistic report and allow further developments in animals before finally turning to human trials.

ENGINEERING ASPECTS

The Hardware

Typically, the hardware of a visual prosthesis is composed of an external system and an implanted part. The external system (see Fig. 4) includes some image capturing device, an external processor and the external part of a transmission unit. Implanted (see Fig. 5) are the other one-half of the transmission system, stimulators, and an electrode.

Depending on the approach, there are important variations on this basic scheme. In subretinal projects, a photosensor array implanted directly in the eye could replace the external camera. Some specifications of the example of the optic nerve prosthesis are given as an example in Table 1.

External Components

The Image Grabber. A miniature video camera typically mounted on glasses provides the image capturing device of the visual prosthesis. A low weight camera with good esthetical appearance is of importance to the blind person and can be improved by miniaturization. It could further be stated that the most trivial imaging devices largely outperforms the needs of all present day visual prostheses (29). Nevertheless, a good image quality including some

Table 1. Example: Main Specifications of the Optic Nerve Prosthesis

Image processing	
Pixel size	$1 \times 1^\circ$
Processed visual field	$32 \times 64^\circ$
Telemetry	
Forward carrier frequency	12 MHz
Forward data rate (Frequency Shift Keying modulation)	$3 \text{ Mbit} \cdot \text{s}^{-1}$
Data frames length (including 6 bit CRC)	64 bit
Return carrier frequency	24 MHz
Return data rate	$1.5 \text{ Mbit} \cdot \text{s}^{-1}$
Maximal power transmission (class E)	120 mW
Maximal antennae separation distance	5.5 mm
Implant	
Power consumption	80 mW
No. of independent current sources	8
Current sources	
Time resolution	21 μs
Output voltage range	-9 to +9 V
Maximum output current	3.2 mA
Current resolution (exponential)	8 bit + sign
Electrodes	
Number of contacts	8
Contact recess depth	80 μm
Contact area (platinum)	0.2 mm^2

standard correction features for luminosity compensation, autofocus, and avoidance of glare (e.g., could greatly simplify the later required image analysis). Later, when the usefulness of some image analysis procedures, such as edge enhancement or nonuniform resolution will have been demonstrated, it might become worthwhile to consider implementing such features in the front end hardware. The video camera would then be replaced by a specific imaging device that could evolve into a real artificial retina.

In conditions, such as blindness, due to retinitis pigmentosa, the main target group for all prechiasmatic types of visual prosthesis, the optics of the eye can still be functional. In the subretinal approach, a photosensor array attached to the retina would transform the eye in an artificial video camera, preserving an essential functionality of the natural eye, namely, gaze orientation. However, in addition to biocompatibility requirements, mounting such a device as well as the necessary control electronics will not be easy (15). Provision must also be made to power the device and send its output signal to an external processor, all with an acceptable level of power dissipation (30).

The external processor. The bottleneck of all visual prosthetic systems is the rather limited quantity of information that can be handled by the neural interface. The amount of data to be transmitted must therefore be reduced by all possible means including image analysis. This topic is likely to become very important in the near future. Limiting images to black and white, thresholding, and edge detection are just preliminary steps. More sophisticated image processing techniques will have to be implemented. Therefore, powerful belt wearable processors will

be necessary to translate visual data to neural stimulation (see Fig. 4). Quite unlike the situation with cochlear implants, however, little is known about the precise encoding of visual information in the visual pathways and the first human implants will contribute to such knowledge (31) allowing more efficient algorithms to be developed.

Image processing can be subdivided in several steps including: analysis, selection, mapping, and encoding. The purpose of the image analysis is essentially to reduce the amount of visual data to be transmitted through the prosthesis. After an image data reduction step, a selection procedure should allow only the most important features to be sent through. Mapping refers to the method used to establish a correspondence between selected image pixels or features and the phosphenes that can be generated. Finally, a control signals must be generated such that the implanted current sources will issue the intended stimulus. This last encoding step is entirely defined by the characteristics of the implanted device. Mapping on the other hand is linked to the neural code in the neural interface. Much of it is unknown and still requires experimental work with implanted volunteers. Later on, because of the anatomical variability, at least some individual remapping will be required before revalidation itself can be started with a visual prosthesis. Finally, except for the most basic and empirical aspects, image analysis and item selection will have to resort to further psychological studies on perception. Some of these studies could be done with healthy volunteers using virtual reality simulations.

A detailed description of one example of stimulation algorithm is given below. It should be stressed that a communication interface with the processor (see Fig. 4) is an important tool in the development and adaptation of the translation algorithm. Using monitoring equipment, the perceptions of volunteers can be explored and the system can be customized or adapted according to the findings.

Typically attached to the external processor, and probably the major weight to carry along, are the power supply batteries. Note that all published visual prosthesis designs use externally powered implants. Therefore, current is also drawn from this main battery to provide power to the implant. The main specifications to be taken into account are the user friendliness of wearing and reloading the rechargeable batteries. Their size will be defined by a trade-off between weight and autonomy.

The Transmission Unit. Electromagnetic telemetry is based on the classical cochlear implant design. It typically uses two similar antennas holding a small biocompatible (stainless steel encapsulated) magnet in their center. One of these is implanted under the scalp just above the mastoid, behind the ear. The magnets maintain the external antenna over its internal counterpart. This turns out to be the most popular transcutaneous transmission system. The normal skin thickness separating the antenna coils is from 3.5 to 5 mm. However, just after surgery, swelling up to ~ 7 mm can be observed that can take >3 months to recede. During this period, the increased distance might cause malfunction of the antennas.

A telemetry return channel from the implant to the external system is an important feature, providing acknowledgment signals as well as technical diagnostic and monitoring information. For example the output voltage of the implanted controlled current sources gives an indication about the proper operation of the system as well as an estimation of the electrode contact impedance. Also, a measurement of the supply voltage indirectly proves that the power transmission is working adequately.

Alternative antenna arrangements have been considered. For example, as proposed by the Boston group (see Fig. 6), an external primary antenna or coil could be mounted on spectacles and the secondary coil could be implanted on the eye surface or in the anterior segment of the eye. Other transmission techniques exist. A transcutaneous socket on the head (32) has been used but it exposes the patient to severe infectious complications (33) and it is not really acceptable on esthetical grounds.

An all-in-the-eye alternative has been suggested whereby an infrared (IR) (820 nm) laser would transmit power and signal to an intraocular prosthesis through the transparent media of the eye. Data can be transmitted efficiently but heat dissipation in the implanted components is still not compatible with the power requirements of practical devices. Eye movements would also represent a tremendous challenge.

Implanted Components

The Stimulator Case. The following description pertains to the intra-orbital optic nerve visual implant. The purpose of choosing one example is to provide a set of realistic numbers, but the principles apply to most visual prosthesis approaches. The antenna is connected to an 8 mm thick titanium case half engraved in the parietal skull. This neurostimulator hybrid circuit (see Fig. 5) contains the transmission electronics as well as control logic circuits and the

Figure 6. Picture of a number of different electrodes characterising the various approaches to the visual prosthesis. current sources. This circuit occupies the major part of a titanium encasing is closed by a laser welded plate carrying 10 feedthrough connections. This number of feedthroughs is a main factor in determining the minimal size of the stimulator case. The metal encasing is internally connected as the common output reference electrode. A biocompatible polymer cap carries two connectors (a two-contact one for the antenna and an eight-contact connector to the electrode) and protects their junction to the feedthrough wires.

Each stimulator connection receive has two current sources, one for each polarity, as required for the application of biphasic charge balanced pulses. As a rule, implanted current sources are coupled to the stimulation electrode through large output capacitors for safety reasons. These capacitors (470 nF), significantly contribute to the size of the implant.

In an attempt to reduce the chip size while providing a large number of channels, alternative designs (34) do multiplex the output of a single stimulator to a number of electrode contacts instead of having one dedicated stimulator circuit for each contact. Also, the telemetry data rate could be reduced if less degrees of freedom were given in the stimulus definition. The possibility to modify the shape of each pulse individually does indeed require a high rate data transfer.

The Neural Interface or Electrode Assembly. Electrodes (see Fig. 6) are the most characterizing component of the different visual prosthesis approaches. They represent a rather critical and important component in electrophysiology applications (see the chapter on Bioelectrodes). In a nutshell, electrodes form the interface between the electric current carried by electrons along metallic conductors and the ionic conduction found in aqueous solutions, such as the body tissues. This potentially harmful transformation is chemical in nature, called a reduction reaction at the cathode and an oxidation process at the anode. A local pH change is induced, becoming more acid at the anode and more alkaline at the cathode. Of course, the exact nature of the chemical reactions taking place will be influenced by the electrode metal as well as the chemicals present in the solution, their concentrations and the applied potential among other factors. Irreversible chemical reactions cause corrosion and might severely limit the electrode lifetime. However, electric charge limits can be defined within which the chemical changes remain mostly reversible. Maximal values of $0.4 \text{ mC} \cdot \text{cm}^{-2}$ (35) are given in the literature for platinum and $4 \text{ mC} \cdot \text{cm}^{-2}$ for iridium oxide (36). These metals are most often used in implantable electrode contacts. The reversible charge limits will preserve the electrode contacts, but they have no direct bearing on the potential damage to the living tissues being stimulated.

As a rule, biphasic stimulation pulses are used in implants in order to reduce the risk of deleterious effect. The cathodic phase is meant to activate the neural tissue while the anodic phase, often of smaller amplitude, but with a correspondingly longer duration, is supposed to compensate for the injected electric charge and thereby revert the local chemical changes. Because the currents are not uniformly distributed over a contact area, the electrode

Table 2. End Pulse Voltage–Current Ratio^a

Pulse Duration	42 μs	342 μs
	<i>Cathodic Current</i>	
0.4 mA	2.4 k Ω	5.0 k Ω
1.6 mA	2.3 k Ω	3.2 k Ω

^aPlatinum contacts of 0.2 mm^2 referred to titanium case as anode

geometry should also be taken into account in estimating the allowable charge limit.

The contact impedance or voltage–currents is an important characteristic of the electrodes. Dependent on a large number of factors, it is nonlinear and decreases with the current strength while increasing with the pulse duration. Table 2 gives average values as measured in the example of the optic nerve prosthesis. With epiretinal stimulation (37), using 1 kHz $10 \mu\text{A}$ sine waves, impedance values are found to be distributed from $<1 \text{ k}\Omega$ to $40 \text{ k}\Omega$ for the same contact area 0.2 mm^2 and larger values for 0.05 mm^2 contacts. The higher values correspond to lower thresholds and are found when the contacts are closer to the retina.

The Prosthesis at Work

Phosphene Generation

Phosphene Description. A first step in the rehabilitation process with a visual prosthesis is to explore the available tools, that is, the identifiable phosphenes that can be generated by the system. A large number of stimulus variable (selected contact, pulse amplitude, pulse duration, train duration and frequency) vectors are systematically tested. The resulting perceptions must be carefully recorded for later use. A more straightforward relationship between the stimulation parameters and especially the contact being activated and the perceived phosphene localization can be expected with the retinal approaches. Still, however, the thresholds will have to be determined and data will be required to correct for the expected (18) mapping distortions.

With the optic nerve prosthesis, the phosphene diameters are variable from a point-like perception to $>10^\circ$. The distribution of these values has modal peaks $\sim 2, 4,$ and 7° depending on the stimulus parameters. The luminosity is most often reported as weak. Some phosphenes, especially at the periphery of the visual field have the appearance of solid patches while others have variable textures, such as orderly arranged rows or columns of points or small lines. Phosphenes are colored sometimes with contrasting colors between texture elements and the local background. The global background of the visual field is usually described as black, but can sometimes be perceived as gray or slightly colored. Fluctuations of the diffuse background or spontaneous phosphenes occasionally hinder the perception of induced phosphenes.

In the optic nerve example, phosphenes remain located in a quadrant of the visual field that reflects the retinotopical position of the contact used. The center of the phosphenes is located peripherally if near threshold, high frequency and prolonged train stimuli are used and their position in the visual field takes on a more central position for stronger

stimuli, the strength being expressed as a stimulation to threshold current ratio. The most eccentric position that can be accessed by a given train stimulus is located nearer the center for short and/or low frequency trains (31). Phosphenes generated by single pulses are systematically located in the center of the visual field. It is thus possible to model and control the average phosphene center position in the visual field. Unfortunately, in the first implanted volunteer, phosphenes could only be induced in a small region of the visual field (from 8.5° on the left, to 11.5° on the right, and from 6° up to 47° down). This limitation is likely to be linked to the retinitis pigmentosa itself as it is known that only a fraction of the ganglion cells survive this disease (8) and the periphery is more affected than the central retina (38).

With retinal stimulation as well, it has been found that the form of the percept did not always match the stimulation pattern (18) despite the fact that small phosphenes could be obtained at visual field positions corresponding to the point of the retina being stimulated (18).

For all approaches, the phosphene position is clearly referred to retinal coordinates and therefore to the eye orientation at the time of stimulation. Any change in gaze direction or head movement preceding the stimulation will accordingly shift the perceived phosphene location. Thus, for every visual prosthesis with an image capturing device that is not attached to the eye, the users must learn to keep their eyes fixed in the orbit.

Phosphene perceptions are described as short-lived, flash-like. With repeated stimuli, flicker fusion has been found to occur ~ 8 – 10 Hz and is associated with a perception threshold decrease. At very low repetition frequencies (1–2 Hz) flashing phosphenes remain of stable brightness as long as the stimulation is maintained. By contrast, at higher frequencies, successive phosphenes are perceived with decreasing brightness and disappear after 1–3 s.

Brindley (cortex, subdural stimulation) did not obtain a flicker fusion of cortical stimuli. Flicker fusion frequency was found to be similar for normal vision and for electrically generated perceptions using epiretinal electrodes (39). In this last approach, the perceived stimulus brightness increased with increasing stimulus rate as well as with increasing the stimulus current, which is not the case with optic nerve stimulation whereby the perceived phosphenes become larger with stronger stimuli. This difference might be related to the fact that the epiretinal stimulus can activate bipolar cells in addition to ganglion cells.

Simulation on Mathematical Models. Computational models play an important role in this kind of work. Numerical evaluation of the electric potential distribution in inhomogeneous and anisotropic media (volume conduction model), and of the resulting neural activation (neural membrane model), can provide a better understanding of the observed responses and provide a predictive design tool. As later confirmed experimentally (40), modeling the epiretinal stimulation has shown that cells or the initial segments have lower threshold than the passing axons (41). For pulses longer than 500 μ s, however, the bipolar cells become activated first. Confronting modeling results with experimental data has been useful in the interpreta-

tion of the results of optic nerve stimulation studies as well, showing that the retinotopic extension of the perceived phosphenes is quite unlike the corresponding topologic distribution of the activated axons in the optic nerve.

Other techniques including an hybrid association between an adaptive neural network model and analytical expressions of physiological laws can describe the expected localization of phosphenes generated by optic nerve stimulation. These tools will in the future efficiently help to develop individual lookup tables derived from preliminary open loop testing sessions so that these can be kept as short as possible. Such tables or mapping systems are of primary importance for the development of a visual prosthesis, no matter the approach.

Stimulation Thresholds. Despite the functional importance of the activation threshold, values applicable to a given situation are hard to find in the literature. A first reason for this is the lack of standardization. Current-controlled stimulators being used in most approaches, threshold current intensity could seem to be the logical variable to describe. However, as shown by the strength–duration relationship, the electric charge required for activation approaches a minimum asymptotically for short pulses, but increases very fast for pulses longer than the above the chronaxy value (see the article on Functional Electrical Stimulation). A threshold electric charge for realistically (in terms of the electronic circuits and tissue or stray capacitance) short stimuli can thus be seen as an appropriate expression, with the advantage that it directly relates to potential electrochemical damage to the electrode and surrounding tissue. The charge per unit area of electrode contact would be an even better characteristic value including the size factor as a minimal geometric parameter.

In an homogeneous medium, and at a distance much larger than the electrode contact diameter, the thresholds current is proportional to the square of the distance to target ($I_{th} = k r^a$), where $a = 2$. This power law can be seriously distorted in real tissues. For example in the retina (ganglion cell stimulation) exponent a can vary between 0.84 and 3.19 depending on electrode geometry and anatomical factors (29). Threshold values can further be expected to depend on factors such as the pulse shape, the nature of the primary target and the animal species.

The nerve membrane activation is not necessarily linked to the production of a cortical evoked potential neither the perception of a phosphene. For example, with optic nerve stimulation, long high frequency train stimuli have been found to yield much lower perception threshold than identical single pulses while in both cases expected to activate the axons at the same level (30).

Another aspect to be considered is that a disease, such as retinitis pigmentosa itself, can be responsible for an important increase in the stimulation threshold (42). The design of a prosthesis must therefore take this fact into account as well.

With a subretinal array, 1 nC or 10 μ C \cdot cm $^{-2}$ is reported to be sufficient to excite surviving retinal neurons (43). Phosphenes are generated by epiretinal stimuli of 350 μ C \cdot cm $^{-2}$ through an electrode contact with a diameter

of 520 μm (19). However, this threshold can vary between 24 and 702 μA depending on the proximity to the retina (37). The same authors indicate that there is no simple relationship between the threshold and the electrode contact area. For the transretinal stimulation, a threshold value of 56 $\mu\text{C}\cdot\text{cm}^{-2}$ is given, corresponding to a total charge of 28 nC (20). In the case of the optic nerve prosthesis, an estimation for trains of 25 pulse (200 μs duration) at 200 Hz would yield a threshold of 60 μA with the intracranial cuff (without dura mater) and 700 μA with the intracortical cuff. The respective threshold charges are 6 and 70 $\mu\text{C}\cdot\text{cm}^{-2}$. The corresponding chronaxy values are 130 and 192 μs . Brindley (1) gives a value of 13 V on an impedance of 3 k Ω , yielding 4.3 mA to reach threshold with a good electrode driven at 30 Hz with 200 μs pulses. This represents a charge of 860 nC. Thresholds down to 0.4 nC were obtained with 200 μm^2 intracortical electrodes, which corresponds to 1.9 μA for 200 μs pulses at 200 Hz (24).

Stimulation Upper Limits. The upper limit of the stimulation range (44) is even more important to the designer than the threshold. The maximal current will indeed define the required minimal supply voltage as calculated from the expected load impedance. Any stimulus strength above a full activation of the target would represent a waste of the stimulator range and lead to unwanted physiologic response. However, despite the fact that they require higher current values, short stimulation pulses in fact activate the structures with lower charges, and therefore with a lower risk for local tissue and electrode damage. Unfortunately, the maximal current available is directly related to the size of the stimulator ASIC, which should be minimized, especially in a multichannel implant.

Increasing the electrode area to reduce the current density might seem to be an alternative. However, much of the gain in safe stimulus strength could easily be lost in the higher threshold characteristics of larger contacts that cannot be placed close to the target. Every approach will thus lead to a trade off between the stimulus strength required for proper activation, the safety limits and the size of the implant. In the example of the intracranial stimulation of the optic nerve, stable threshold levels have been observed for >6 years of compliance with an upper limit of 150 $\mu\text{C}\cdot(\text{cm}^2\cdot\text{phase})^{-1}$ for charge compensated biphasic pulses up to 50 Hz and <50 $\mu\text{C}\cdot(\text{cm}^2\cdot\text{phase})^{-1}$ at higher frequencies.

From Phosphene to Visual Perception (Stimulation Algorithm). Once phosphene perceptions can be elicited in a controlled way, one is left with the question as how to use them in order to convey visual information to the visual system of the blind person. In the optic nerve visual prosthesis example, a look-up table is first established using a phosphene position model as a mean to average and interpolate limited experimental data. From the collection of theoretically elicitable phosphenes, only those obtained with a charge density <300 nC/phase (0.2 mm² contact area) are considered. Train stimuli longer than 40 ms total duration are excluded as well. The phosphene center has to be at least 1° of visual angle apart and, in

cases of choice, the phosphene produced with the lowest stimulus strength is selected. These criteria resulted in a set of 109 individually addressable phosphene with defined position. The portion of the visual field covered is limited to 14° horizontally and 41° vertically. Even within that region, there are holes where no phosphene can be obtained. In addition, the phosphene area is usually >1° and there is thus a clear overlap in the patches of visual field covered by neighbors. The usable look-up table is thus far from representing a complete set of nicely tiled point sized light perceptions covering the entire visual field.

Therefore, black and white images from a 108° head-mounted camera are cropped and digitized to an array of 32° × 64° field of view with one square degree pixels and 8 bit resolution. Next, thresholding is applied in order to further reduce the amount of visual information. In some tasks, image processing also includes edge detection. In real time, the processed image is then superimposed on the position coordinates of the phosphenes of the look-up table. If there is a coincidence between a phosphene position and any part of the image, the corresponding stimulation variable values are selected and send to the optic nerve stimulator. A list of the last 10 occurrences is continuously updated in order to avoid repeatedly inducing the same visual sensation when there are several coincident phosphenes. The least frequently used coincident phosphene is always chosen as the next stimulus. When a single phosphene is generated for each frame captured by the camera, 25 phosphenes can be induced per second.

The processor software and data can be accessed through a communication port (see Fig. 4) allowing to modify parameters, data tables, or the applied algorithms. For example, the random selection above could be replaced by a nearest neighbor selection or reference tables and parameters could be adapted to the perceptions reported by the volunteer. Some authors (45) have proposed a fitting optimization algorithm comparing the input images with the generated perception. This could work as an automatic processor training method. A major problem, however, is to make the subjectively perceived image available for comparison with the input counterpart. It is likely that much *a priori* knowledge will always have to be included in any system. A large share of that knowledge is still not available and will come, among others, from the contribution of first blind volunteers to the preliminary experiments.

From Image to Phosphene Production (Image Processing).

No matter what encoding algorithm is used, it is obvious that the amount of information that can be transferred on by present day visual prosthesis prototypes remains extremely poor compared to real world images. Although some improvement can be expected from further interface developments, severe image reductions will be unavoidable for quite some time.

Using some form of virtual reality in healthy volunteers, a few teams have explored the minimum requirements to obtain a useful pixelized vision according to the behavioral task involved. An array of ~600 dots is found to be a minimum for useful reading performance (46). Face recognition could be obtained with 10 × 10–32 × 32 grids (47). By contrast, some subjects can recognize simple objects and

symbols using a 4×4 pixel simulated prosthetic vision (48). Subject's performances clearly increase with training.

It should be stressed, however, that quite unlike the image pixels used in simulations phosphenes are not identical point-like ordered spots that neatly tile a surface. Also, these laboratory experiments only deal with experimental objects presented in an otherwise empty environment. In the real world, subjects will first have to localize and segregate target objects by some preprocessing. However, little has been achieved along these lines hitherto.

Vision Rehabilitation. The ultimate goal of a visual prosthesis is to rehabilitate a visually handicapped person. Results must therefore be evaluated from the blind person's performances point of view and not in terms of device features. Issues, such as the number of available phosphenes or their density, although contributing to the overall performance, cannot be considered as representative of the value of a prosthetic system. Furthermore, isolated analytic characteristics, such as the visual acuity, often mean very little because they can be adjusted by accessories, such as a straightforward optical compensation.

A measurement of the performances will most reliably be obtained in laboratory conditions, but it is the usefulness in real-life that will decide of the success of a prosthesis. For mobility, the prosthesis will be judged against available alternative obstacle detectors and rehabilitation means, such as the long cane or the guide dog in mobility tasks. Stationary visual tasks, such as object localization, identification, and grasping as well as character reading, face recognition, and scene identification are less likely to be available through alternative means. In such tasks, the error rate and the time to task completion will probably be major criteria for acceptance.

Some evaluations of visual prosthesis implant prototypes have been published (19), showing that light and movement can be detected and simple shapes recognized. With the optic nerve implant, basic patterns formed by bars of 22×320 mm and backprojected on a screen as black shapes against a white background can be recognized with the optic nerve prosthesis. The volunteer, sitting at a distance of ~ 0.5 m from the screen, uses scanning head (and hence camera) movements to explore the pattern, then draws the perceived figure using aluminum rods. A learning effect can be demonstrated as well as an improvement of the results with the number of elicitable phosphenes used in this test (49). A score of 87% of correct recognition is obtained with 109 phosphenes after training. Simultaneously, the task time decreased from >2 min to ~ 53 s (49). With the same system and after substantial training, the volunteer was able to localize, discriminate, and grasp objects on a table in front of them. Three among six familiar objects lay each in one of the nine subdivisions defined on a table surface. Grasping a specified object among the three was systematically successful in ~ 60 s. In both experiments, the scanning strategy probably explains the prolonged task completion times.

The emergence of multiple alternative designs and improvements for the prosthesis now call for evaluation standards. As suggested by these early results, these should include stationary tests (pattern identification,

figure orientation, object localization, object discrimination, and grasping) as well as mobility trials (obstacle localization and avoidance, landmark localization, and identification). Evaluation of the usefulness of the visual prosthesis in a natural environment will be essential. Further down the road to improvement, face recognition, scene identification, and finally reading tests will perhaps also be considered but much better resolutions are still required (29).

HUMAN AND MEDICAL ASPECTS

Candidates for a Visual Prosthesis

No matter what approach is chosen, all visual prosthesis system require a functional visual brain to ultimately interpret their output. This means that, with today's limited performances, only people losing sight after the critical period of development can be considered as suitable candidates.

Another selection criterion is the severity of blindness. As long as the performances of the systems are questionable, only totally blind persons should be considered as candidates. The risk of interfering with residual vision can indeed only be taken if the expected results are significantly better than the remaining visual abilities. In addition, the evaluation of the rather limited performances of an implant could be obscured by any surviving visual functionality.

Other selection criteria are dependent on the chosen approach. All the prechiasmatic approaches (subretinal, epiretinal, optic nerve) require the survival of retinal ganglion cells and their axons in the optic nerve. Terminal retinitis pigmentosa emerges as the condition most typically fulfilling all the selection criteria. Except in cases of brain lesions, the cortical approach would be more generally applicable, including in many cases of acute blindness where the psychological distress is usually more important. Finally, the individual's general health should also be considered because satisfactory candidates are usually terminal cases of RP and therefore rather old while the implantation surgery requires a prolonged anesthesia.

A complete assessment procedure must precede implantation.

A standard ophthalmologic examination is a good starting point. Because of the chronic nature of the condition, the diagnosis should be checked according to up-to-date knowledge. Some candidates have not had an ophthalmologic investigation for many years and only know that they have an incurable eye disease. The blind patient could be unaware of some additional eye problem or other interfering condition. A proper evaluation of the total degree of blindness is necessary and objective tests, such as absent VEP and ERG, are very useful for comparison with the postimplantation evaluation.

Taking into account the heterogeneous nature of retinitis pigmentosa, this diagnostic label is not enough to warrant the survival of ganglion cells in a given patient. Eyelid surface stimulation is the technique of choice here. A cathode is placed on the closed eyelid while an anode is stuck on the heterolateral mastoid (50). Small current

pulses allow to generate a phosphene perception. In healthy subjects, for pulses >2 ms duration, phosphene perception occurs well before the stimulus can be felt. A threshold strength–duration curve (rheobase of 0.28 mA, chronaxy of 3.07 ms in sighted subjects) can show the perceptions to be genuine. Electrically evoked potentials (51) is an alternative technique that would not have to rely on the patient's subjective perceptions. However, much of this added confidence is lost in important stimulation artifacts and the possible confusion with somatosensory potentials, especially in RP patients in whom thresholds are much higher. Some patients describe relatively abundant spontaneous phosphenes and these can be enhanced by the surface electrical stimulation. The same phenomenon could completely jeopardize the working of a visual prosthesis and perhaps induce permanent unpleasant symptoms.

A psychological evaluation is essential as long as the procedure remains experimental. People do accept the idea of pioneering research, but quite rightly want to make sure they will not be misused as guinea pigs for the sake of science alone. The motivation put forward is to help in the development of treatments or simply for the satisfaction of an active contribution or to give their grandchildren a better chance in the frame of their hereditary disease. Esthetic aspects are questioned right from the first contacts. Visibility of a camera is a point of concern.

When the visual prosthesis will have become a clinical treatment, expectations will still have to be confronted with the systems limitations. Also, much attention should be paid to human factors, such as the impact of an implant on a person's social integration.

Magnetic resonance imaging (MRI) is necessary for some visual prosthesis approaches. For example, the optic nerve size and diameter must be estimated on MRI images for an appropriate nerve cuff electrode to be selected for the optic nerve stimulation. The cortical approach might also benefit from a detailed anatomical image before surgery. An MRI examination could be dangerous and will yield very distorted images after implantation of a prosthesis. If for any reason, it is felt that such images will later be useful, then they should be acquired before implantation.

Classical presurgical investigations including thorax X rays and an electrocardiogram (ECG) are standard presurgical procedures.

Surgical Methods

The surgical method is very specific to each of the approaches. The cortical approach can obviously start with a standard craniotomy. Implantation of intracortical electrodes, however, can require a more specific method including specifically designed instruments such as the pneumatic insertion device (52).

The optic nerve approach has resorted to two kinds of surgical methods, one to place the electrode intracranially just in front of the chiasma and the other to implant the electrode in the orbit. Basically, the intracranial method uses a standard pterional transsylvian approach. That is, after right temporo-fronto-parietal cutaneous incision and preparation of the temporal muscle, a craniotomy is

performed at the meeting line between the great wing of the sphenoid with the frontal, parietal and temporal bone (pterion). Opening the dura gives access to the sylvian fissure. From there, surgery further proceeds under a microscope to carefully dissect the arachnoid, opening the sylvian fissure until, in the depth, the optic nerve can be separated from its surroundings. Only minimal retraction of the basal posterior aspect of the frontal lobe is required. The electrode is then wrapped around the optic nerve and the lead suture to the dura.

The second surgical method involves the implantation of the spiral cuff electrode around the intracortical optic nerve. A medial orbital approach is used. After detaching the internal rectus to allow careful retraction of the eye, a thread can be inserted behind the optic nerve and be used to pull the cuff in place.

The electrode leads exit temporally from the skull (intracranial implant) or from the orbit (intraorbital implant) and run backward under the scalp toward the neurostimulator half buried in a recessed well made in the parietal bone. The neurostimulator is also connected to the antenna inserted under the scalp above the mastoid.

The epiretinal system involves the implantation of a similar neurostimulator and wireless link unit as described above. The placement of the electrode is of course completely different and works (19) as follows (19): The periorcular space is reached through a lateral canthotomy. The cable and electrode are passed subconjunctivally all around the eye behind each of the four recti muscle insertions and then introduced into the eye through a 5 mm circumferential scleral incision placed 3 mm posterior to the limbus. Prior to the introduction of the implant, the majority of the vitreous gel is removed. The electrode array is the positioned just temporal to the fovea and a single retinal tack is inserted through the electrode array and into the sclera. The attachment of the electrode to the retina is a main issue here. Several solutions have been proposed including biocompatible glues, but recently developed types of miniature nail-like devices called retinal tacks appear to work well.

At least two different subretinal electrode implantation methods have been developed (15). The *ab interno* technique, follows established vitreoretinal and submacular surgery procedures. Surgical instruments are inserted into the eye. The vitreous body is then removed while the intraocular pressure is maintained with infusion. Finally, the retina is locally incised and the electrode array is inserted in the subretinal space using a special forceps. The *ab externo* implantation is designed to avoid damage to the internal structures of the eye. In this procedure, a flexible foil is inserted into the subretinal space through an incision in the sclera and choroid. The implant is then slit into a macular position along the guiding support foil. The path opened by this implantation can also be used for any required external energy supply leads.

Risks of Active Implants

A complete risk evaluation can only be performed on the basis of a review of a significant number of cases after a long postoperative period. Unfortunately, only a limited number

of human trials have been described so far and most of them using methods too different to allow any globalization. A risk analysis will thus have to consider the various aspects of the implantation in the light of similar procedures. The required anesthesia is in itself a well known, low but finite life threatening factor linked to the duration of the procedure as well as the age and general condition of the volunteer. The surgery as such is often mentioned as the most feared aspect by patients. For most of the prechiasmatic approaches, only structures of a nonfunctional organ exposed and the worst failure would thus result in the loss of the possibility to implant a new prosthesis. Risks linked to the visual prosthesis itself can probably be considered to be similar to those for cochlear implants where they are reported to be negligible (53). In some approaches (intracranial optic nerve and cortical), a craniotomy is performed and electrodes are placed in the direct vicinity or in the brain. In such cases, the possibility of an infection or of an abnormal inflammatory reaction or even direct damage to the brain are potential hazards of major consequences.

The possibility of an infectious metastasis around the foreign material must be borne in mind and is well known from passive implant applications. Similarly, experience with other active implants can help to evaluate the burden represented by possible electromagnetic interference, including airport or other safety systems, mobile telephone, interference between multiple implants and the fact that magnetic resonance imaging is no longer available to these patients.

The possibility of a total or partial failure of the implanted system must be considered. Again, however, useful figures, such as the typical lifetime of an implanted system and the percentage of failure in the initial period, cannot be estimated from the present heterogeneous and limited trials.

Heat production by implanted components and electrochemical changes at the level of the electrode contacts are potential hazards insofar that they are not easy to predict because many factors are involved. Safety limits for functional electrical stimulation are difficult to establish. Electrode failure or tissue damage are real risk factors. Also, unwanted stimulation of neighboring structures can lead, for example, to pain or abnormal muscular contractions.

Living tissues can suffer from the activation itself. Axonal potentials are propagated at the cost of cellular metabolic energy. Too strong a functional demand on some structures could create a state of imbalance between the energy demand and supply, leading to cell death. This type of limit will vary very much in different tissues. For example, peripheral motor axons typically discharge at frequencies ~ 20 Hz and could be damaged by chronic stimulation at 50 Hz while 100 Hz is a typical frequency for afferent activities in the optic and cochlear nerves.

The electrical stimulation could also induce more subtle changes. For example, with cortical stimulation, there is a possibility to trigger repetitive firing and even epileptic fits. For high stimulation currents, Brindley has indeed described phosphenes lasting minutes after the stimulation has ended (1). Such after-discharges could be minimized by reducing the stimulus charge and avoiding prolonged regular stimuli (24).

Psychological complications represent another possible issue that should be monitored. Blindness is indeed a severe disability to which most of the implantation candidates as well as their surroundings have adapted over time. An effective prosthesis will shake this equilibrium as well as the person's social insertion with consequences that could look paradoxical if only the technical success of the prosthesis was to be considered.

Ethical Aspects

With the project to fight one of the most basic human fears using high tech methods supposed to carry out miracles, the visual prosthesis is likely to enjoy a high profile to the layman and to trigger suspiciousness to scientists. This is thus a very emotional and sensitive subject that could be driven by many political and psychological forces alien to the interest of patients. That is why ethical questions should be dealt with most cautiously, especially in the early stages of development.

Basic ethical rules still derive from the Nuremberg code of 1947. As a consequence of the Second World War, it appeared that compliance with national laws could sometimes lead to unacceptable human behaviors. Some more fundamental ethical principles were raised above the law. This gave ethics a very special status. It is not a set of rules dictated by any form of power but pertains to every human being alike, above national or cultural differences (54). Ethics has neither organized a hierarchical structure nor an absolute reference. Progressively, from conferences to declarations, sets of principles gain universal acceptance.

The World Medical Association Declaration of Helsinki, now at its fifth revision since 1964 (55), is most often considered as the main reference. Laws in democratic countries as well as many organizations including scientific publishers enforce these basic principles. The European governments have extended these rules in the Convention on Human Rights and Biomedicine (56).

It is generally admitted that the implementation of ethical principles is very dependent on cultural factors. As a result, compliance of research projects with ethical principles is considered to be ideally insured by submission to an independent local ethical committee. National laws and institutional rules tend to organize the working of such committees. Typical questions investigated by these committees are the quality of the information to the volunteer, signature of an informed consent, the risk/benefit ratio to the volunteer, the evaluation of motivations and free decision as well as a specific insurance coverage including for removal of the implanted material if requested. An absolute preservation of the volunteers' private life is a must usually requiring anonymity.

The initial development of a visual prosthesis requires a prolonged collaboration with volunteers. In that frame, it was found that the organization in collaboration with the Ethics Committee in charge, of within project meetings between members of the experimental team and representatives of the volunteers could often be a very useful place to solve communication issues and take some consensus decisions with a volunteer.

A more general ethical question in human research is at what stage to move experiments from animals to humans

(57). Because human applications are the final goal, there is always a point where one will have to decide on the involvement of human volunteers. The prosthesis implantation is not trivial. Although blindness is a severe burden, the expected benefits are not life saving and for the time being, at best limited. The balance between risks and benefits is therefore not established. As a result, the informed consent and the volunteer's motivation become central issues. The adequate information to be provided to a lay candidate pertains to a very technical field and the many scientific uncertainties are even more difficult to explain. As long as the proposed visual implants are rather experimental devices, candidates for an implantation must be explicitly informed and accept that preliminary status. They should also be aware of the fact that the postimplantation fine tuning and rehabilitation might take much more time than what would be expected from a well-established treatment.

The volunteer's motivation on the other hand can be biased by difficulties to cope with a heavy handicap and the possible hereditary character of the disease involved. Time spent with a candidate volunteer can certainly solve many of the information and decision criteria issues, avoiding above all to misuse volunteers as mere study objects.

MAIN ISSUES

Evaluation

The systems presently implanted in human volunteers have the capacity of producing either 16 differently located phosphenes simultaneously (19) either >100 phosphenes send to the optic nerve at a pace of 25 phosphenes per second (49). At first sight, it might seem that the serial phosphene generation used in the optic nerve approach will end up in less information per unit of time than in the parallel scheme. The difference might perhaps not be as important as initially thought considering the power required to drive each stimulator output and the size of each stimulation circuit. In a stimulator with a large number of outputs, some multiplexing scheme is required that makes the system serial as well. The tradeoffs between the distance to target, the electrode contact area, the required stimulation charge, the power dissipation, the size of the current sources and the biologic tolerance might represent the real bottleneck. In 2005, despite measurable results, the performances of the visual prosthesis prototypes remain limited and achieved through an unpractical systematic scanning movement. No global image perception has been obtained so far. Learning effects have been demonstrated however and much can still be done on the side of image analysis to obtain an appropriately reduced amount of visual data. A more optimistic view can perhaps be derived from the past experiences with the now well established and accepted cochlear implants. Based on the number of papers published, the visual prosthesis seems to lag ~20 years behind its auditory counterpart.

Hurdles and Limitations

The number of pixels is not the only issue in the evaluation of the quantity of visual data that can be transferred. In an

image, each pixel also carries luminance and color information. Although the phosphene perceptions generated can be colored, no approach has hitherto developed means to control it and this dimension can therefore not be exploited. The brightness of phosphene perceptions is modulated by the stimulus intensity, but intensity also modulates the spatial recruitment and therefore, localization and brightness are not independent. In the optic nerve approach, strong stimuli will yield only large phosphenes centrally located in the visual field. With the retinal approaches a stronger stimulus increases the perceived luminosity but is likely to stimulate different structures and interfere with the neural code. In the case of stronger stimuli on the visual cortex surface, Brindley reported the appearance of additional phosphenes and their persistence up to 2 min after the stimulus ceased. Until now, epiretinal or optic nerve approaches do not explicitly take into account matters, such as the existence of ON as well as OFF ganglion cells. Stimulating more than a single cell or axon perhaps leads to some cancellation of their perceptive effect. In addition, the electrical stimulation may interfere with ongoing spontaneous firing of the ganglion cells. The link between stimulus and light perception can thus be expected to be rather complex.

The number of phosphenes that can be generated is still by far not large enough to come to a realistic pixelization. On the other hand, the central visual network does not build an internal projection of the outside world images as implied by such principles. The photosensors in the eye capture images as pixels, but that is also where the pixel structure stops. All other layers of the retina analyze and encode the image according to many characteristics other than a mere pixel position. Beyond a rough retinotopy, edge enhancement, movement detection, and a few other known features, the spatiotemporal encoding appears to be very complex. Except for the subretinal approach, recreating a natural image perception will require to interface a prosthesis with this complex and largely unknown code. This hurdle is likely to be even more challenging for cortical implants than for epiretinal or optic nerve approaches.

Another difficulty is that as long as a near perfect perception will not be achievable, bilateral implantation will not be able to convey distance information. Other distance clues are also linked to a relatively high quality vision. This means that before visual prosthesis reach a very high degree of performance, indirect systems will be required to provide the important distance information.

Another direction for future developments is set by the need for image stabilization. The subretinal approach uses the eye optics with the result that eye movements are included in the normal physiological network of vision. In all other approaches, an external camera is used. This camera is attached to spectacles and follows head movements instead of eye movements. For a correct localization of the surroundings, the prosthesis user must learn to inhibit eye movements as far as possible and only use slow head movement to scan the environment. This is of course a severe limitation. Eye and head movement tracking methods will at some point be necessary to stabilize images. The most advanced solution would be to implant or integrate a miniature camera in the eye as well. A feedback system taking into account eye movements in the image analysis

might be an intermediary step in the near future, before the intraocular camera becomes a reality.

Further progress in electrode design, stimulation algorithms, and electronic miniaturization will perhaps create the prospect of a system capable to generate a high density of phosphenes issued at cinematic rate. However, only that part of the visual field that is still matched by surviving ganglion cells will be available for rehabilitation, at least in all prechiasmatic approaches. As a result, although it is supposed to access the entire visual field, the optic nerve approach appears to reactivate only a restricted field of view. On the other hand, retinal approaches will have to match the electrode location with the remaining retinal cells in order to avoid an useless stimulation of death tissue. Clearly, terminal cases of retinitis pigmentosa will never regain a complete field using these methods. Better results can of course be expected in less affected patients where the prosthesis could be combined to some method to prevent further degradation.

Future Perspectives, Advanced Applications

The visual prosthesis in no way represents a treatment of the cause of blindness. The degenerative processes of retinitis pigmentosa can thus evolve further. The effect of chronic stimulation on sick ganglion cells is not known. The stimulation could either speed up the degeneration, have no influence on the natural course of the disease or, to the contrary, prevent further cell losses (58). The cause of retinitis pigmentosa lays in the biochemistry of the photosensor cells and the degeneration of the other cell layers of the retina could be considered as the result of disuse as well as the consequence of abnormal chemical intercellular exchanges. Keeping ganglion cells active might help them to survive. If this is true, as has been demonstrated in animals equipped with a cochlear implant (59), then the implantation should be done as early as possible, when a minimal number of bipolar and ganglion cells have degenerated. Recovery of a broader visual field can surely be expected in incomplete blindness stages but interference with existing remnants of vision might create new problems to be solved.

Again in keeping with the evolution of the clinical use of cochlear implants, there might be a good reason to foresee a visual prosthesis implantation in blind children. An efficient prosthesis implanted before the end of the critical period might perhaps induce the development of a functional visual cortex and preserve the individual's chances to later benefit from similar devices in adulthood. The limited efficacy of present day visual prosthetic devices does, however, clearly not yet justify such an undertaking.

X-RAY EQUIPMENT DESIGN

MARTIN TORNAI
Duke University
Durham, North Carolina

INTRODUCTION

Radiography is a form of physical diagnosis in which X rays are used to obtain medically useful information about a patient. X rays are generated in a controlled way, and a beam of X rays is passed through the patient. The differential absorption of ionizing X-ray radiation by different tissues modulates this beam. The transmitted beam is detected, and its information content is recorded. In addition, radiological imaging methods are used to control, guide, and monitor both diagnostic and therapeutic manipulations such as needle biopsy, percutaneous transluminal angioplasty (see CORONARY ANGIOPLASTY), and radiation therapy.

X-ray equipment is composed of many subsystems and components, each of which presents unique choices and tradeoffs for the equipment designer. These components include means for X-ray production, spatial and spectral shaping of the X-ray beam, patient handling, as well as means for image detection and capture, intermediate image handling, image processing, image display, and data storage. Auxiliary equipment and logic are customarily included in the design and construction of X-ray apparatus for the control, synchronization, and automation of the examination process. The X-ray equipment designer must balance different and often conflicting requirements to obtain an optimum solution for each examination category or application. For example, fine spatial detail requires minimization of both geometric blur (implying a fine focal spot along with low power and low magnification) and motion blur (implying short exposure time with high power and a large focal spot). This leads to specialization of the equipment for different medical applications. In addition to clinical requirements, the apparatus must also be designed to meet a wide variety of industrial and professional standards as well as comply with governmental regulations.

The functional organization of an X-ray imaging system is shown in Fig. 1. In one form or another, these elements are present in all X-ray imaging systems. This article will follow the logical flow shown in Fig. 1, with emphasis given to the material contained in the double-sided boxes. Other articles in this Encyclopedia discuss the remaining topics.

Power Components

The primary purpose of the power components in the generator is to control the X-ray tube voltage, current, and exposure time. The contrast and signal-to-noise ratio (SNR) of a radiographic image, as well as dose delivered to the patient, are partially controlled by adjustments of the

X-ray tube voltage. Other influencing factors include the X-ray beam filtration, the X-ray attenuation characteristics of the object (e.g., patient), and the nature of the image receptor. The voltage applied to the tube has a major influence on the shape of the X-ray spectrum emitted from the tube (Fig. 2). This change in spectral shape as voltage is varied produces changes in image quality, including the common image metrics of contrast and SNR (see X RAYS, PRODUCTION OF). An increase in voltage leads to decreased image contrast (see X-RAY ATTENUATION IN MATTER) and increased SNR. In addition, the total quantity of radiation emitted from the tube is a power function of the voltage applied across the tube (approximately a cubic function, depending on the voltage range and beam filtration), resulting in increasing dose to the patient. In the United States, it is common to use voltage as the primary control element for regulating the amount of X rays exiting from the patient (termed penetration).

The amount of radiation emitted from a tube is also controlled by the product of the current flowing through the tube and the time during which the current flows (expressed in units of milli-ampere-seconds, or mAs). Use of exposure time is somewhat limited in an attempt to minimize patient motion. Applied current can greatly increase tube heating and reduce tube life, causing tube cooling techniques to be a major design consideration, especially in applications such as tomography, where high rates of tube exposures are experienced due to the requirement for multiple sequential images to be produced and detected. Tube current is controlled by adjustment of the X-ray tube's filament temperature. In most generators, time is controlled by switches in the primary circuits. Some generators use switching tubes in the high-tension circuit of the generator, or a control element in the X-ray tube. Figure 3 is a simplified schematic diagram of conventional single-phase, line-operated generator. Such a system draws its power directly from the main electrical distribution system. Conventional generators may be designed to operate using either single- or three-phase power. When one considers power-line impedance and generator self-loading, single-phase equipment is usually limited to lower peak power devices, whereas three-phase equipment may be found at any power level. The consequences of power-line loading are discussed briefly at the end of this section.

The need for high-power mobile X-ray generators in hospitals has led to the construction of equipment incorporating energy storage devices, either capacitors or batteries. These generators accumulate energy from a low-capacity power line at appropriately low-power levels, and then they discharge the stored energy through the X-ray tube at a much higher power level. The currently preferred design is the battery-operated mobile generator with a high-frequency inverter.

Line-operated X-ray generators place unusual loads on the hospital's electrical distribution system. Most generators draw X-ray tube power directly from the lines during

Figure 1. Functional diagram of an X-ray imaging system. Any system used for medical imaging must provide the minimum facilities for delivering a controlled X-ray beam to the patient, positioning the patient relative to the beam, detecting the modulated X-ray beam passing through the patient, and delivering the image to the radiologist.

the time of X-ray exposure. Classic X-ray circuits (Fig. 3) set the X-ray tube voltage by means of measurement of the primary voltage before exposure. The combination of these two effects requires that the power lines be well conditioned and protected from extraneous loads. In addition, other equipment in the hospital must be protected from the effects of the brief high-power demands placed on the line by the X-ray equipment. Also, in this era of ubiquitous digital control, two-way isolation is required to protect both the X-ray equipment and the remainder of the hospital from the broadcast of digital noise, or real digital control signals along the power lines. Power for X-ray generators should be obtained from separate low-impedance supplies, which include dedicated distribution transformers and appropriate size conductors. To minimize conductor size, high-power equipment is usually connected using a higher line voltage. Line-operated X-ray equipment, with the exception of low-power mobile units, is seldom operated

from 110 V supplies. Single-phase and low-power three-phase equipment typically operates using a 220 V line. Higher power equipment may require 440/480 V.

An undesirable characteristic of some X-ray generators is ripple, defined as the percent variation of voltage during an X-ray exposure. A high ripple factor can result in undesirable X-ray flux and spectral variations leading to unpredictability in image quality and patient dose. Single-phase, full-wave rectified generators suffered from very large ripple factors, and therefore they have been virtually replaced by the constant potential generator for the most demanding imaging applications, medical imaging being one of them. Although these types of generators are generally larger, more complex, and expensive, they provide extremely low (<5%) ripple factors, and they are essentially constant in their voltage output. These generators typically use single- or three-phase 50/60 Hz line voltages of 220 V or higher. One common type of constant potential

X-ray Spectra at Various Tube Potentials

Figure 2. Sample spectra, generated via validated computer simulation, using various tube potentials, 1 mAs exposure, and with 0.5 cm thick Al extrinsic filtration, illustrate the effect on beam shape.

generator is the three-phase generator, using a three-phase transformer with three sets of primary and secondary windings. The newest type of constant potential generator is the medium or high-frequency generator (also called the inverter generator), where the constant potential voltage is controlled by the frequency of the current provided by the chopper/inverter. This generator type is popular both in battery-powered and in mobile units, as well as in the higher power applications of modern equipment. Starter speed is also a consideration available to designers. The starter controls the boost and operation of the rotating anode. Typical low-speed anodes boost in approximately 3 seconds and reach a rotation speed of 3000 rotations per minute (rpm). High-speed starters are often available as add-ons that allow faster boost as well as rotation speeds in excess of 10,000 rpm. Most generators also include a thermal switch that will automatically stop the X-ray exposure

when an overheat signal is received from the tube. Additional tube details are provided in the following section.

X-Ray Tubes

The normal X-ray tube is a vacuum diode. Figure 4 is a photograph of a typical X-ray tube housing as well as a cutaway diagram of the typical interior tube components. Electrons are generated by thermionic emission from the filament of the tube. The electron stream is electrostatically focused onto a small target on the anode by means of a carefully designed, shaped, and sometimes charged, highly polished nickel cathode focusing cup.

X rays are produced by interactions between the electrons and the target (see X RAYS, PRODUCTION OF). Most electrons emitted by the hot filament become current carriers across the tube. One can, therefore, set tube current

Figure 3. Schematic diagram of a single-phase, full-wave rectified generator. Feedback and stabilization elements are not shown. X-ray tube voltage is adjusted by setting the autotransformer before exposure. Tube current is adjusted by setting the filament voltage and hence its temperature. A, Autotransformer; H, high-voltage transformer; F, filament transformer; S, exposure switch; T, radiographic timer; V, prereading voltmeter used for kV indication.

Figure 4. Diagram of a generic X-ray tube and photograph of tube enclosed in its protective housing. The useful X-ray beam emerges from the beam port at the bottom center. The anode is rotated by coupling magnetic fields through the glass envelope of the tube. The stator coils that are used for this purpose surround the tube on the left.

(by adjusting the filament temperature) and tube voltage (by adjusting primary voltage) as independent parameters. Some X-ray tubes function as a triode with a bias voltage applied between the filament and the cathode cup. At low voltage, this bias can be used to modify the size and shape of the focal spot by focusing the electron beam in the tube. A further increase of the bias voltage can serve as a switching device by gating the electron beam ON or OFF.

The X-ray tube converts a very small fraction of the electrical energy delivered to it into useful X rays. In the voltage region corresponding to diagnostic radiology (~20–150 kVp), the physical processes involved in X-ray production (primarily collisional deceleration of electrons in the target) result in an X-ray production efficiency of <1%. The remaining electrical energy is converted into heat. Tungsten is used as the target material for most general-purpose diagnostic X-ray tubes. Its high atomic number ($Z = 74$) maximizes X-ray production efficiency. Tungsten's high melting point (3400 °C) and reasonable specific heat

capacity ($C_p = 130 \text{ J/kg-K}$) help with the thermal problems associated with the waste heat. As special cases, molybdenum (Mo), rhodium (Rh), or Mo/Rh alloy targets are used to produce the specific X-ray spectra needed for mammography. The use of these lower atomic number metals as targets and filters isolates the K-characteristic X rays produced by the target, resulting in a narrow spectral beam at relatively low energy, useful for improving subject contrast in screen-film imaging of the compressed breast. The lower efficiency of X-ray production and lower melting point makes these metals unacceptable for general radiography. Other materials, including silver, cerium, and other exotic materials, continue to be proposed for target materials for specialized applications ranging from small animal imaging to computed tomography and additional industrial applications.

A major task in X-ray tube design is the provision of means for dissipating waste heat before tube structures are damaged. Different tube structures place different thermal

limitations on radiographic techniques and ultimately limit the speed of performing examinations. Tube rating charts that account for these different thermal restrictions are available from all X-ray tube manufacturers. The first consideration is the melting of the tungsten target at the focal spot, the target area bombarded by the electron beam. For sharp projection imaging, the geometry of the X-ray "optics" requires that the focal spot be as small as possible. Design elements such as high-speed rotating anodes (3,000–10,000 rpm) and shallow target angles (5° – 15°) are used to limit the power density incident on the physical target location while creating a small effective focal spot, yielding improved resolution. Effective short-term loading in excess of 50 kW/mm^2 of effective focal spot is realized using these techniques. Some tubes even provide user-selectable dual-anode angles or dual-position focal spots for increased flexibility.

Once heat has entered the target region of the anode, it is conducted away from the focal track into the bulk material of the anode. This bulk material usually consists of molybdenum or prolytic graphite. Massive anodes (several kilograms) are used to temporarily store the thermal energy before radiating it to the tube housing and eventually into the environment. The large anode mass, needed for significant thermal energy storage (e.g., for applications in computed tomography and cinefluorography), places limitations on the starting time of the tube, due to the moment of inertia of the anode, and on the length of life of the anode's bearings. The technical requirement of high anode heat storage capacity is optimally met with a heavy smaller diameter disk. The clinical requirement for short radiographic exposure time demands high instantaneous power levels. This requirement is optimally met with a light large-diameter rotating anode disk. These conflicts result in the design and use of many types of X-ray tubes mechanically specialized to meet specific examination requirements.

The tube housing serves several technical purposes. Figure 4 (top) is a diagram of such a tube in its protective housing. The housing is part of the electrical isolation between the high-voltage circuits and the environment. It also provides radiation protection for both patient and operator. Tube housings are lead lined to keep the amount of leakage radiation below legal limits (this requirement assures that the major source of irradiation outside of the beam comes from scatter and the useful beam in the patient). The tube housing illustrated is a variety commonly used, whereby the low atomic number (usually Beryllium) exit window for the X rays is located in the center of the tube between the two poles (cathode and anode) of the power supply from the generator. It is also possible to obtain unipolar X-ray tubes for special applications. With only one single pole for the power supply, it becomes possible to locate the exit window nearer the edge of the tube to allow closer proximity imaging in special-purpose applications, such as in computed mammatomography. Also, these tubes are smaller and lighter than standard dual pole tubes. Drawbacks of such tubes include much lower maximum power (i.e., on the order of $\sim 100 \text{ W}$ to 6 kW , compared with the $100+$ kW available on other tubes), static anode and, consequently, the need for a larger

focal spot to reduce concentration of heat on the anode. These tubes are usually liquid cooled.

Finally, the tube housing is a key portion in the waste-heat handling system. Housings for tubes used at low mean power levels ($<100 \text{ W}$ or so) can be adequately air cooled, with or without a fan. As the mean load increases (i.e., for applications such as angiography and computed tomography), air cooling becomes inadequate. Additional cooling may be obtained by circulating liquid through a heat exchanger contained in the tube housing or by circulating insulating oil through an external radiator.

Collimation and X-Ray Beam Definition

The geometry of projection X-ray imaging requires that the produced X-ray photons be directly projected from the focal spot onto a detector system. Radiation produced elsewhere in the X-ray tube (off-focal radiation) and scattered radiation from the vicinity of the tube contribute to geometric blur in images. Scattered radiation emanating from the vicinity of the patient, patient supports, and image receptor may not cause observable blur but will still degrade image SNR and contrast. Patient integral radiation dose is minimized, and image quality is maximized by confining the beam of radiation to the smallest possible area. Patient dose and radiological contrast are also influenced by the X-ray spectrum. This section will discuss means for controlling the spatial extent and spectral shape of the X-ray beam.

The production of scatter is reduced by limiting the spatial extent of the X-ray beam by means of a device called a collimator on the source side. The conventional radiograph is produced using a two-dimensional, four-sided cone of radiation. Minimizing the projected beam size by restricting it to the area of interest reduces both patient dose and image degradation due to scatter. Most systems are equipped with adjustable source collimators. Specialized equipment may be found that uses fixed collimation. Modern collimators, both fixed and adjustable, use several sets of apertures to minimize off-focal radiation. X-ray photons emerging from the tube whose real or virtual source is not the focal spot are termed off-focal radiation. Off-focal radiation is produced by electrons scattering from the focal spot with sufficient energy to produce X rays when they collide with some other portion of the anode structure. The use of metallic or partially metallic tubes, in place of all-glass tubes, reduces the production of off-focal radiation by providing alternative return conduction paths for scattered electrons. X-ray photons produced in the focal spot or elsewhere in the tube may be internally scattered and seem to be produced anywhere in the tube. Simple, single-plane diaphragms limit the size of the X-ray beam emerging from the beam port, but they are not very efficient in minimizing the emission of off-focal radiation and internal scatter. Some tubes also include a hood around the anode to absorb off-focal radiation and prevent it from exiting the tube.

In the United States, the law requires that the collimator and the image receptor must be linked so that the maximum settable beam size does not exceed the dimensions of the receptor. The influence of scatter can be further reduced by collimating to and using a one-dimensional fan

of radiation or a pencil beam of radiation, provided that the scatter geometrically misses the image receptor or is attenuated before it reaches the receptor. The former method is accomplished by having a small scanning detector aligned with the useful beam (e.g., in slot scanning). The latter technique involves the use of a secondary collimator between the patient and image receptor that scans synchronously with the X-ray beam. Slot scanning systems have recently become commercially available. These systems use an X-ray fan beam synchronized with a moving collimated slot of detectors to perform a planar patient scan. The effect is to provide a digital radiograph with significantly reduced scatter fractions (relative to grid systems) compared with conventional commercial cone beam systems. One drawback is a slightly longer scan with potentially increased patient motion artifacts, as well as other possible electrical or mechanical artifacts due to the use of moving parts.

The energy spectrum of the X-ray beam emerging from the target is modified (filtered) by its passage through extrinsic filtration before it enters the patient. The X-ray spectrum is further modified as it passes through the patient. These spectral modulations are due to the inherent energy dependence of the X-ray attenuation coefficients, which are intrinsic characteristics of an elemental or compound material.

An improper selection of the target material or filter, relative to the examination being performed, can result either in diminished image quality or excessive patient dose. A certain amount of filtration is beneficial to the patient. Low-energy photons that enter and are absorbed by the patient's tissues contribute to dose without contributing to the image. These photons may be removed from the X-ray beam by inserting additional filters between the tube and the patient. High-purity aluminum is the filter material that is commonly used for general radiography. Because the attenuation coefficient of aluminum decreases across the radiographic energy range, aluminum preferentially absorbs the low-energy photons emitted from the target and is therefore said to "harden" the X-ray beam.

Beam quality is usually described in terms of its half-value layer (HVL) of aluminum. This is the amount of aluminum needed to reduce the beam intensity by 50%. The U.S. Public Health Service has placed minimum HVL requirements on diagnostic X-ray beams. Too high an HVL is also undesirable as it leads to poor SNR in screen-film imaging systems. Alternatively, the molybdenum filter used for mammography functions in a different manner. As pure metals are relatively transparent to their own characteristic radiations, a molybdenum filter passes most of the K-characteristic radiation from a molybdenum target. At an appropriate tube voltage, the filter preferentially removes both low- and high-energy photons. Such a matched filter-target combination results in the transmission of a narrow energy band of X rays.

Several other methods are available for generation of narrow X-ray spectra with an inherent improved dose efficiency when the mean energy is matched to the object and imaging task. Use of heavy (i.e., 7–10 HVLs) K-edge filtration (Fig. 5) can provide a practical, low-complexity, and relatively inexpensive means of using heavy attenua-

Figure 5. Sample spectra generated via simulation using 60 kVp tube potential, 1 mAs exposure with various extrinsic filters to illustrate effect on beam shape. Illustrated are spectra for no filtration, 0.5 cm thick aluminum, and 0.09 cm thick cerium extrinsic filtration. These represent unfiltered, minimally filtered (similar to standard filtration in commercial systems), and heavily K-edge filtered beams. Note that the cerium filtered beam is quasi-monochromatic (i.e., 7% full width at half the maximum height), which can, by design, provide maximal dose efficiency in a uniformly attenuating, homogeneous object.

tion for beam hardening and near-complete elimination of lower energy photons and using the K-edge to nearly completely eliminate higher energy photons, thereby producing a narrow, quasi-monochromatic beam. Higher tube exposures are necessary, accompanied by increased object heating and reduced tube life, although the actual object exposure may be similar to that with regular filtration. Bragg diffraction can also be used to produce quasi-monochromatic beams. Although Bragg diffraction can produce a very narrow beam, devices using Bragg diffraction suffer from longer scan times because only narrow fan beams can be obtained; indeed, the object needs to be moved relative to the beam because sweeping the beam would compromise beam quality. Synchrotron light sources have also been proposed for monochromatic radiation but so far have proved far too expensive and impractical for routine medical imaging applications.

Bowtie filters can be employed within the collimator attached to X-ray tubes (Fig. 6, top). These filters conform to the general contour of the patient in that they are thinnest (i.e., allow maximum flux) at the center where the patient is thickest and become thicker near the edge (i.e., allow minimum flux) where the patient contour gets thinner. This allows reduction of dose to the patient while providing a more uniform optical density (in the case of screen-film) or SNR (in the case of digital detection) across the image.

The interactions of X rays with the patient's tissues and other structures in the beam path result in the production, by the Compton process, of copious quantities of scattered radiation. A portion of this scattered radiation is directed

Figure 6. Schematic of the radiation trajectories and various components of interaction in the X-ray generation and detection system. Near the source is the source collimation apparatus. Distal to the source, the radiographic grid consists of thin lead strips, usually aligned with the focal length of the X-ray tube. Useful imaging photons “see” narrow grid strips and wide interspaces. Scattered photons see wider lead strips; hence, they are more likely to be absorbed by the grid.

toward the image receptor. The scattering process destroys the imaging geometry, which consists of straight lines from the focal spot to the image receptor. Scatter does not contribute to the useful imaging process, but because of its diffuse nature, scatter produces a generally uniform background intensity, reducing radiologic contrast, and decreasing the SNR of the image. In chest, for example, surprisingly most (80–90%) X rays on film are scattered radiation, although the image quality of a chest radiograph is still good and full of fine detail.

The use of a grid (Fig. 6) exploits the lack of geometrical coherence of scatter and helps to remove it. The lead strips of the grid are geometrically aligned toward the focal spot of the X-ray tube. Unscattered photons “see” only narrow grid strips and relatively wide grid interstitial spaces. Only a small fraction of these photons (the photons useful in the imaging process) are absorbed by the grid. Scattered photons produced in the patient have a wider angular distribution. On average these scattered photons see much wider grid strips and much narrower interstitial spaces. Thus, a grid selectively removes scattered radiation.

When a grid is used, however, a comparatively higher skin dose is required for the same SNR. The improvement in image quality achieved with a grid usually justifies the increased patient dose. Grids are constructed with thin lead or tungsten strips, and interstitial spaces are composed of a variety of uniformly thick materials including

aluminum, organic material (solid or foam), or air. Grids are available in many different aspect ratios (the height of the strips divided by the space between adjacent strips). A higher ratio grid will reject more scattered radiation (necessitating higher incident flux to maintain SNR) but requires more precise positioning than a lower ratio device. Grids, especially coarser ones, can also be moved during the exposure so that the grid lines are blurred, and essentially eliminated by the motion. The combination of a grid and its movement mechanism is referred to as a Potter-Bucky diaphragm. Grids are now available with varying focal lengths and material compositions and can be constructed by extrusion, layering, or chemical etching.

One functional drawback to the grid is that the solid geometry (of the lines of sight) is fixed, so the source to image (SID) cannot be changed without changing the grid. Several alternatives to the anti-scatter grid are available to the designer for dealing with scatter, some or all of which can be used in combination. These include the use of air gaps between the object and imaging device, the slot scanning technique, and algorithmic correction (including the beam stop and deconvolution methods). Employment of algorithmic correction is especially attractive in digital systems.

Image Receptors

Although digital detector usage is increasing greatly, conventional film and film-screen systems are still the most widely used of all radiologic image receptors (see SCREEN-FILM SYSTEMS). The radiographic cassette contains a relatively high density and high atomic number scintillating screen for converting X-ray energy to visible light. Visible light provides better film exposure than the direct interaction of X rays in the silver halides embedded in film. When irradiated, the screen fluoresces and exposes the film to light. Most film blackening results from this fluorescent light. A screen is held in close contact with the film in a light tight cassette so that there is an optimal transfer of the light to the film, with minimal resolution blur caused by the bloom of light generated in the scintillator. Modern film-screen systems have a detective quantum efficiency (DQE) around 50% (DQE is a measure of the ability to convert SNR presented to the film into recorded SNR and includes metrics of resolution, noise, and efficiency). This means that about half of the ultimate information in the modulated X-ray beam is detected by the system. The sensitivity (speed) of film-screen systems may be chosen by selection of screen and film types. Systems that provide proper film blackening at low dose either exhibit a great deal of quantum noise or mask the noise by blurring both the noise and the image detail. This is determined by selection of screen type. Scintillators in the screen can be amorphous (the majority of cases) or highly structured in finely grown pillars. The shape of the gray scale transfer function of the film-screen system is determined by the choice of film. Ideally, the optimum visible absorption efficiency of the film corresponds to the optimum light wavelength output of the screen, although each of these absorption and emission functions vary with wavelength. Different film characteristics are often needed for the

optimal performance of different radiographic examinations. For example, a slow film speed film with finer spatial resolution may be more useful for extremity imaging of fine bone fractures, whereas a faster speed film with coarser resolution is more useful for chest imaging where stopping or minimizing the influence of cardiac motion is desired.

There are both advantages and disadvantages to the development and use of digital X-ray detectors, but a primary advantage is that there is a decoupling of the image capture and image display process. In addition to separating image capture from image display, the digital representation of the radiographic image is key to the successful implementation of a picture archiving and communications system (PACS) system, which has already shown to have a beneficial impact on the delivery of health care. With advances in large-scale miniaturization and packaging, and production of large-area electronics structures with high yield, there are continual advances in production and manufacture of digital detectors with increasingly finer spatial resolution. Indeed, there is a projected 600% growth in demand of digital radiography and digital mammography systems by 2008, along with declining demand for screen-film and computed radiography (CR) systems sales. Digital systems are expected to surpass other film-screen based X-ray imaging systems in the near future. Nevertheless, a large number of these systems currently exist and are part of contemporary radiography.

Photostimulable phosphor systems were introduced several years ago and remain popular in radiographic practice. In a CR system, an image storage plate "traps" an image of the attenuated X-ray distribution with excited state electrons. When such a plate is scanned with a pencil-tip-sized laser beam, the electrons are de-excited and return to their ground state with the emission of visible, phosphorescent radiation. This phosphorescence can be measured, digitized, and subsequently used to produce an image (fluorescent scintillation systems and phosphorescent systems differ in the decay time τ of the scintillation event, where fluorescence occurs in $\tau \sim 10^{-9}$ s, and phosphorescence can be considerably longer, lasting $\tau \sim$ hours or days). Such CR systems are capable of reproducing >1 ; 5 line per millimeter with an acceptable DQE. The phosphors used in these systems have a linear dose-to-photoluminescence response extending over several orders of magnitude of absorbed dose. With proper reading technique, this intrinsic linearity permits a decoupling of dose from film blackening. Intentional or inadvertent exposure errors can be compensated for by the reading electronics, thus reducing retakes. Dose may be selected with regard to the image quality requirements of the individual examination.

The X-ray-sensitive image intensifier, using charge coupled devices (CCDs), is currently the universal image receptor for fluoroscopy and fluorography (see IMAGE INTENSIFIERS). This device converts the modulated X-ray beam into a minified visible light image projected onto a small, fine resolution (cooled) CCD. The conversion factor (image blackening per unit of X-ray input) of modern image intensifiers is high enough that the quantum sink in most imaging chains is the X-ray intensity detected and photoelectrons created at the tube's input screen. The DQE of

these detectors is also in the neighborhood of 50%. Most image intensifier-based image receptor systems use optical diaphragms between the output of the image intensifier tube and the input of the CCD. This diaphragm is used to restrict the light intensity reaching the CCD, thereby forcing enough X-ray intensity through the patient so as to produce a statistically meaningful image. In some systems, this diaphragm is externally adjustable, permitting the operator to set the dose to a level that is consistent with the allowable X-ray quantum noise for the examination.

Image intensifier systems commonly use video as the primary fluoroscopic display and recording medium. If the video is used only for fluoroscopic monitoring or for simple playback applications, normal broadcast video standards are employed. For systems that use the video signal for fluorographic applications, such as digital subtraction angiography (DSA) (see DIGITAL ANGIOGRAPHY), better quality nonstandard video formats may be used. A variety of photofluorographic cameras can be used for image capture and the production of hardcopy images (see CINE AND SPOT FILM CAMERAS).

Flat panel detectors are becoming increasingly popular for digital radiography (DR). Although they are more expensive than CR systems and may not be able to be retrofitted into existing gantry's, they provide much faster (i.e., instant) digital data acquisition and higher resolution (now on the order 50 μm or 20 lp/mm) than CR systems. DR detectors are generally divided into indirect and direct detector categories. With indirect detection, a scintillator (e.g., CsI, BGO, $\text{Gd}_2\text{O}_2\text{S}$, CdWO_4) is used to convert X rays into photons in the visible spectrum that are then detected by a thin-film transistor (TFT)-based photodiode array. With direct detection, X rays are detected and converted directly into electric charge by the detection layer (e.g., amorphous-Se, CdZnTe, amorphous-HgI₂) without the need for an intermediate scintillation event. There is an ongoing debate pertaining to the superiority of one approach versus the other. Suffice to say here that direct detectors can have finer spatial resolution leading to a better MTF, and until very recently, indirect detectors with higher overall stopping power had better detection efficiency and hence DQE.

With digital detectors of any kind, one must be concerned with image lag or ghosting characteristics that are specific to the type of detector chosen. Acquisition and/or correction techniques may have to be employed to minimize these residual image effects and generally do not affect image quality for planar projection images in the clinical setting. Tomographic systems that require multiple rapid image acquisitions are more likely to suffer from these degrading effects.

Control and Supervisory Logic

Radiological equipment produces X rays with tube voltages of 25 to 150 kV at power levels extending from less than 100 W to more than 100 kW. Exposure times range from a millisecond to several minutes. A wide voltage range is required to produce the required signal characteristics in the final image. Wide power and exposure time ranges are needed to deliver the appropriate dose rate and total dose

to the image receptor. In addition, digital detection systems require careful synchronization such that frames are not exposed during the frame readout period. High-speed frame-grabbing hardware is also required in specialized applications, such as tomography, where frame rates can be very high. Control, synchronization, regulation, and automation of such elements necessitate the introduction of control and feedback elements into X-ray systems (Fig. 1). In many cases, installed radiographic systems have their control primarily associated with the generator, especially in screen-film systems. For newer digital systems, including special applications such as tomography, the generator becomes a component under the logical control of the overall system host computer, which is responsible for controlling and managing all components of the system.

One example of such synchronization and control is illustrated by a timing diagram (Fig. 7). The diagram shows multiple exposure cycles as would be typical in a tomography application, using a digital detector, rotating anode X-ray tube, and movable gantry, although other implementations may exist. A signal must first be sent to the generator starter to initiate rotation of the anode. Once the anode has reached maximum speed, the detector is checked for status availability. Exposures can be initiated only if the detector is not in the process of reading out the panel. The period between readouts is known as the vertical blanking period. X rays can be exposed during this time (the length of this period depends on the frame rate of the detector). When the detector ready signal is verified, a signal is sent to the X-ray generator to expose X rays. After the X-ray pulse is complete, a signal is sent to the gantry to move the assembly into position for the next image, and simultaneously, a signal is sent to the frame grabbing circuit to acquire the image from the detector controller. Frame grabbers are specialized circuits responsible for quickly obtaining or "grabbing" the exposed frame from the digital detector.

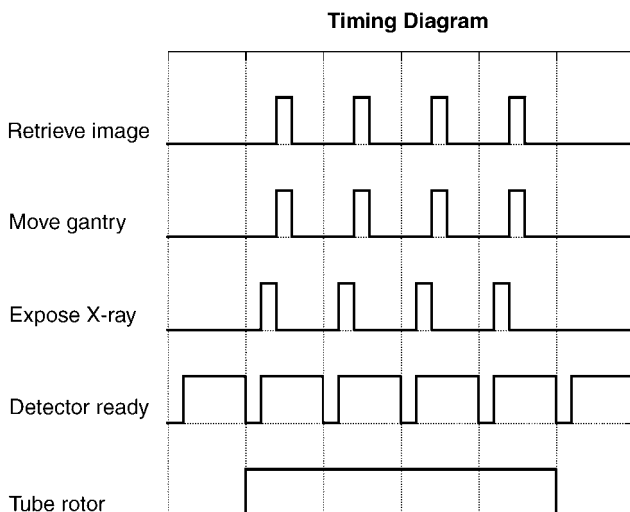

Figure 7. Timing diagram illustrating the necessity for synchronization when implementing an automated system that involves many different system components, including X-ray generator, digital detector, motion control devices, and frame grabbing devices.

The previous scenario gives maximal flexibility to the system designer. Many other options are also available. For example, the detector ready signal could be wired directly to the generator so that exposures are initiated automatically whenever the detector goes into a ready state. In addition, some tomography applications have the X-ray beam constantly on during the multiple acquisitions for tomography and, instead, use a timed, physical shutter for initiation of exposures.

The above scenario also assumes that exposure times are predetermined and will take place at the preset values when an expose signal is initiated. Another control option available on many systems is that of automatic exposure control (AEC). This involves the measurement of X-ray transmission and is used as a control element for generator switching. The commonly used feedback loop, which switches the X-ray beam at a predetermined dose, remains essentially the same as Morgan's original phototimer. Most AEC systems offer the choice of several different measuring fields, with the selection of active fields being examination and projection dependent. With proper positioning, this ensures proper exposure of critical anatomical detail. Modern systems adjust sensitivities within the AEC system to accommodate different film screen systems, compensate for reciprocity loss in radiographic film, select different measuring fields for different examinations and for other control functions. This provides a high degree of uniformity and image consistency via the automatic termination of an exposure for a predetermined desired effect. So the overall hope is that with AEC, the number of reshoots and/or call backs for additional exposures is reduced. The most common transmission measurement device used is an ionization chamber interfaced to the phototiming circuit.

The radiographic technique is the selection of appropriate X-ray exposure factors, taking into consideration patient size, shape, and physical condition, the examination and projection to be performed, and the available choice of radiological materials and supplies. This may, of course, all be done properly by a technologist using his or her own judgment with a manually controlled generator. However, this process has become less a matter of technologist preference and more a part of a departmental standard protocol, both in terms of required radiographic projections and technique factors. Many modern systems also provide anatomical programmed radiography (APR). APR typically provides the technologist with dozens of examination views for each of several different anatomical regions in a menu at the controller. By selecting a particular mode, APR automatically sets the required technique factors, including kVp, mA, time, focal spot, film speed, SID, and imaging receptor. In addition, the operator may input the actual patient thickness providing the optimal technique parameters for that examination.

Patient Support Structures

Patient safety, handling, and comfort are critical elements in the design of medical imaging equipment. The needs of the physician or technologist must also be taken into account. These are not trivial design problems. The engineer must consider, among other things, the patient's

physical condition, attached life support systems, required accessory devices (i.e., traction slings or intravenous bottles), and the patient's mental attitude. In addition, the ergonomics of the equipment should promote the expeditious performance of the examination. For example, the examination table should permit easy patient transfer with a minimum amount of staff assistance. The key component of each radiographic examination is the image receptor. To this end, the technologist must have direct and unimpeded access to the patient from a variety of directions. Nearly all of the technologist's tasks, with the exception of patient handling and positioning, can be automated. The technologist's ability to interact with a sick patient while obtaining the desired imaging results is a fine art. Equipment design and selection must be conducive to this process.

As many rooms often contain Potter-Bucky diaphragms (they are referred to as table and wall Bucky's, respectively), the room must be designed to carry such devices. A variant on the radiographic room is the use of a tilting table in place of the flat (nontilting) table. The X-ray tube is usually mounted on a ceiling suspension. A special-purpose apparatus may be used to improve the efficacy of positioning for complex examinations such as skull radiography and trauma-related procedures. C-arms may also be used and must be accommodated.

Another major requirement in room design is that of safety. Rooms must be shielded to prevent radiation from reaching unintended areas while allowing visibility between the operator, who is generally outside the permanent room or behind some radiation shielding, and the patient and scanner. Mobile leaded shields with various sized lead-doped glass are available, and some dedicated systems (e.g., in mammography) have attached operator shielding to minimize exposure from the multiple studies coordinated by the technologist. Thus, rooms must be designed to accommodate both the general requirements common to radiographic systems as well as special requirements for custom applications.

Custom Applications and Equipment Selection

The design of a radiology department in terms of the number and type of procedure rooms and the selection of equipment is an important consideration. The amount to which equipment can be differentiated depends on the size of the institution and the nature of its workload. It is a rare department that can maintain an even patient flow throughout the day. Most departments have a sharp peak early in the morning and a secondary peak in the early afternoon. Sufficient staff and equipment must be provided to handle these peaks.

Radiologic equipment is classified by its technical composition and its clinical function. The simplest apparatus is the dental, mobile, or portable generator. This consists only of the means for X-ray generation and beam control. Patient support, grids, image receptors, and so on, are not included.

In fluoroscopy, the rooms are almost universally equipped with radiographic components, a tilting table, an under-table X-ray tube, and an image intensifier. The under-table tube and image intensifier are linked together and mounted on a

spot film tower. The spot film device, located between the patient and the image intensifier, is a specialized cassette holder. Radiographic spot films, obtained during fluoroscopic examinations, are captured using the spot film device and conventional cassettes. The radiologist usually views the fluoroscopic image by means of closed-circuit television or on a computer screen. Fluorographic images are recorded using camera systems directly focused on the output of the image intensifier. The increasing use of fluoroscopic cameras makes the conventional spot film device obsolete.

Angiographic and other interventional or special-procedure laboratories are highly specialized rooms with film changers and cameras adapted to the needs of rapid imaging. Special procedures require especially easy access to the patient by the staff as well as the capability for multiple projection angles of the X-ray beam. The patient's medical condition and any attached life support devices dictate that these examinations be performed with as little patient handling as possible. In addition, the equipment should provide adequate radiation protection for the staff. The patient table and other mechanical equipment in these rooms are therefore highly specialized to meet the needs of different examinations. Under many circumstances, the apparatus permits simultaneous radiography from two directions (i.e., biplane imaging).

Tomographic imaging is another mechanically complex procedure found in radiographic rooms. In a historical tomographic apparatus, the film and X-ray tube were synchronously moved so that overlapping structures in the patient are removed. Tomographic apparatus ranged from attachments to simple Bucky tables to dedicated equipment capable of producing a wide variety of motions. Contemporary computed tomography is still mechanically complex, although manufacturers have gone to great lengths to enable easy patient and technologist access in a clutter-free system (see COMPUTED TOMOGRAPHY).

In radiotherapy, very high (MeV) tube potentials are used for radiation of tumors. These systems may include a separate but integrated keV imaging system for scouting the area for treatment planning before irradiation. MeV imaging systems are also being investigated for their ability to produce their own image without the need for a separate keV system. In the past, direct film detection was used because the incident energy and flux was high enough to sufficiently expose film, but newer flat panel digital devices are rapidly being adapted for this portal imaging, MeV application. Designers must take these into consideration.

Several other emerging areas including tomosynthesis, small animal imaging, computed mammotomography, and other dedicated or application-specific imaging technologies are developing rapidly. Thus, it behooves the designer to keep in mind potential future applications when considering equipment selection options. The primary changes have been rapidly occurring in imaging (i.e., detector) technologies, in moving from analog to digital systems, and the Internet technology associated with their image processing, sharing, and transfer. There are several initiatives to modify the X-ray sources for both improved focal spot characteristics (e.g., smaller, faster, switching capabilities) and target and filtration materials (i.e., for more optimal spectra used

in application specific imaging paradigms). To most appropriately synchronize and use these emerging, digitally based technologies, computer-based, centralized data control and acquisition technologies need to keep pace with these other emerging technologies. Only through properly using and synchronizing these various necessary X-ray system components can the lowest ionizing radiation doses be applied to obtain images that provide the most information content available to the clinician, whose proper interpretation will affect the patient under observation.

X-RAY QUALITY CONTROL PROGRAM

EDWARD L. NICKOLOFF
Columbia University
New York City, New York

INTRODUCTION

In order to improve or maintain an optimal achievable level of healthcare, most medical facilities usually have some type of quality assurance program. The quality assurance programs encompass a variety of functions, such as development of comprehensive safety rules, establishment of infection control guidelines, provisions for the efficient management of critically ill patients, establishment of accurate record-keeping functions, and the development of adequate educational training for the staff (1). In radiology, a portion of the overall quality assurance program is devoted to a quality control program for the X-ray equipment. The American College of Radiology (ACR) defines quality control (QC) programs as a periodic monitoring of aspects of the precision or accuracy of the X-ray equipment pertaining to the successful performance of the equipment, techniques, or tests rather than to the clinical decision making (2). In general, QC involves equipment rather than patient care.

Most X-ray QC programs have several very specific goals toward which they are directed. The list merely enumerates these items. (1) Image quality, (2) patient radiation doses, (3) safety, (4) consistency, (5) economic factors, (6) Regulatory requirements.

The type of QC testing performed is often dependent on the particular goals that are being evaluated. Usually, state or local regulatory agencies require that a QC program for X-ray equipment be conducted on a routine basis. Some regulatory agencies have very specific items that must be measured by a qualified expert or licensed medical physicist at least annually. These items may include typical patient doses (doserate) and generator calibrations. Moreover, the Federal government has published many documents in which suggested survey procedures for X-ray equipment are discussed (3–5). In 1992, the Federal government enacted the Mammography Quality Standards Act (MQSA), which requires: the accreditation of all mammography units, U.S. Food and Drug Administration (FDA) certification of mammography facilities, and at least annually physics QC testing of mammography equipment. In addition, the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) mandates an adequate QC program that has qualified staff and maintains patient safety. Hence, QC programs for X-ray equipment are mandated by various regulatory agencies and accreditation organizations like the American College of Radiology (ACR) and JCAHO.

Some of the regulatory requirements, however, do not have a major impact upon image quality or economic factors. For example, one regulatory restriction requires that X-ray and light field be congruent with each other to within 2% of the source to image receptor distance (between the X-ray tube focal spot and the image receptor) (SID). Another regulatory requirement is directed toward checking the various interlocks in the X-ray system. Although these regulatory requirements affect radiation protection, they have little impact upon the operation of the equipment or upon image quality. Hence, some of the various QC tests mandated by regulatory agencies, and the results must comply with legal standards of performance.

Another reason for performing QC tests is to assess mechanical, electrical, and radiation safety of the X-ray equipment. These evaluations include inspections directed toward eliminating any electrical shock hazards or the failure of cables, locks, mechanical supports, or counterbalances that could result in the injury to patients or staff. The mechanical inspections require that the system components be both visually inspected and the components be manipulated to test their integrity. Radiation levels to the patients and staff must be measured to determine that there is adequate radiation safety and that radiation levels are not excessive.

Another feature of QC programs is to determine the functional performance of an X-ray system. Various controls, switches, and function buttons must be tested to make certain that they are operating properly. These tests are directed toward making certain that the equipment functions as it was designed. A common malfunction of X-ray equipment is a selector switch that indicates some change has been made when in actuality nothing happens.

The optimization of the image quality in radiology procedures is one of the most important reasons for QC programs. The QC programs establish a test procedure by which the image quality can be measured and establish a standard level of image quality one attempts to maintain (6). Thereafter, the image quality can be measured on a regular basis and corrective actions are taken as necessary. Degraded image quality can often hamper the proper clinical diagnosis and thereby have a severe negative impact on patient care. One would not like to deliver radiation doses to the patients that result in limited or no diagnostic information. Hence, a major goal of QC programs in diagnostic radiology departments would be the assessment of image quality.

Quality control programs must also attempt to maintain a consistent level of equipment performance. X-ray outputs that are not reproducible from one exposure to the next will result in over- and under-exposed images. Unusable radiographs result in unnecessary patient radiation dosages, delays in diagnosis and treatment, and economic losses in terms of technologist's and physicians time and film. Similarly, the technologists should be able to expect that adjacent rooms with similar X-ray equipment will have similar X-ray outputs and similar calibrations within reasonable tolerances attributed to differences in the models and manufacturer's designs of the equipment. Automated film processors should be adjusted to produce similar radiographs regardless of where the films are developed. Similarly, digital X-ray imaging like Computed Radiography (CR) and Digital Radiography (DR) must have consistent X-ray exposures, image processing, and display of images. Consistency of a given X-ray room and consistency in comparing the various X-ray equipment is essential to maintaining a standard level of radiographic image quality for the entire facility.

Finally, economic considerations are a major impetus for having an effective QC program. It has been estimated that each radiographic film that must be repeated costs the facility ~\$35 (1986 prices) (7). The cost of repeated films include items such as film prices, X-ray tube usage, X-ray equipment depreciation, chemistry usage, processor depreciation, technologist's and physician's time, and facilities cost (rent, heat, and electricity). A study performed by the federal government indicated that repeat rates can often be decreased by a factor of two by effective QC programs (8,9). Without QC programs, repeat rates can be expected to be 10–16%; with QC programs, repeat rates can be expected to be 5–8%. These repeat rates are due to patient motion, positioning errors, or other technologists' errors. Repeat rates can often be drastically reduced by the usage of charts in which the technical factors to be selected are listed for a variety of patient procedures and patient sizes. The development of these technique charts should be considered to be part of a good QC program. Furthermore, a good QC program often identifies and corrects equipment malfunctions before they become serious and result in excessive downtime of the equipment. Thus, a good QC program usually provides cost savings to a X-ray facility that can offset the cost of the program (10,11).

In summary, there are a number of good reasons for the establishment of a QC program for a medical X-ray facility.

First, a number of regulatory agencies mandate the need for a QC program. Second, a QC program is necessary to ensure adequate mechanical, electrical, and radiation safety. The QC program may decrease the legal problems that can be encountered from various malpractice suits. In addition, the QC program should result in a good and consistent quality of the diagnostic information obtained from the radiological procedures. Finally, an economic benefit should be realized in terms of reduced repeat rates and diminished equipment downtime.

Even though the justification for, and the goals of, the QC program can be easily identified, the description of the measurement procedures for the program is difficult for a number of reasons. First, there are often several different ways by which a given measurement can be performed with varying amounts of accuracy. The methodology chosen will often depend on the kind of test equipment available and the training of the QC personnel. A rudimentary QC program that would be restrained to have limited expenditures might utilize very basic tools that could be readily operated by inexperienced QC personnel. This type of program would utilize items, such as pocket ionization chambers, step wedges, digital kVp meters, and pennies for field alignment locators (12). A more sophisticated QC program might utilize items, such as oscilloscopes, digital exposure-exposure rate detectors with waveform outputs, high voltage bleeder units for peak kilovoltage measurement, and special test stands. The level of the QC program is usually determined by the size of the X-ray facility, the complexity of the X-ray equipment, the goals of the QC program, the funding for the QC program, the training of the QC personnel, and the caliber of the support provided by the X-ray service organizations. In the material that follows, the parameters that should be measured and acceptable levels of tolerance will be indicated. Although a method for performing the measurements may be indicated, the reader should be aware that there may be several alternative means for performing the measurements. The author has not attempted to list all QC measurement modalities (13–17).

Furthermore, there is a large diversity of X-ray equipment. Each type of X-ray installation requires certain specialized tests unique to that type of installation. In general, diagnostic radiology equipment can be categorized into the following groups: (1) simple radiographic (rad units), (2) chest radiography units, (3) mammographic units, (4) body section tomographic units, (5) dental units, (6) portable radiographic units, (7) portable C-arm fluoroscopic units, (8) ultrasound units, (9) combined radiographic and fluoroscopic (R & F) units, (10) special procedure rooms (with digital and/or cine), (11) computerized axial tomographic (CT scanners), (12) magnetic resonance imaging (MRI), (13) automated film processors, (14) CR and DR units, (15) video display terminals (monitors or VDTs), (16) picture archiving and communications systems (PACS).

Even though there is a diversity in the types of diagnostic X-ray installations there are some common components of all units; for example, all X-ray installations (regardless of their type) have an X-ray tube, collimator system, control panel, and an X-ray generator. If the QC program were described in terms of the types of X-ray units, the tests for the various components would be

repeated many times. Instead, it is more efficient to describe the QC testing in terms of the components that would be common to many different types of installations (e.g., the X-ray tube). Items that are unique to a given type of installation are listed separately.

Finally, the level of what is deemed as acceptable performance for the equipment can vary. Older equipment cannot be expected to perform as well as newer equipment. Equipment manufactured after August 1974 is required by Federal regulation to meet certain performance levels and have certain special features. This equipment is designated as compliant equipment. Automatic collimation to the cassette size (PBL, positive beam limitation) was previously required; although this requirement is no longer mandatory, many modern X-ray units still employ PBL (18). Equipment manufactured prior to this date is not as strictly regulated. Moreover, equipment that is well maintained and routinely calibrated should be expected to perform better than equipment not receiving this attention. Hence, performance standards must have some leeway for interpretation. The performance standards that will be quoted here are for newer compliant equipment that is properly maintained.

An evaluation of the performance of X-ray equipment should involve an understanding of the accuracy of the measurements, the condition and age of the X-ray equipment, and its usage. Having stated the various caveats and limitations, the material that follows provides a basic QC outline for various components in the X-ray system.

X-RAY TUBE

The X-ray tubes are the source of the X rays produced in the X-ray equipment. Figure 1 shows a sketch of the X-ray tube. Without exposure initiation, there is usually a

standby current passing through the filament. This current is sufficient to keep that filament warm, but it should be less than that necessary for thermionic emission. There are two or more different filaments. The larger filament is used when more thermionic electrons are needed for increased X-ray production. The use of larger filaments, however, results in a larger area on the anode where the electrons collide with the target; this area, as seen from the position of the image receptor, is called the effective focal spot. Large focal spot sizes can result in the degraded image quality due to geometric blur. An important part of a QC program, therefore, is the measurement of effective focal spot size.

Just prior to making an X-ray exposure, the rotor preparation switch is depressed. This switch increases the current through the filament so that sufficient electrons are boiled off in order to yield the correct amount of electron flow (tube current) between the cathode (filament) and the anode (target). Simultaneously, the anode begins to rotate, increasing to its correct speed. The rotation is needed to distribute the heat created by electron bombardment of the target. Upon depression of the exposure switch, the selected high voltage in kilovolts (kVp) is applied between the cathode and the anode. This voltage accelerates the thermionic electrons from the filament and causes them to hit the anode with high speed. The collisions result in X-ray production. The lead lining attenuates X rays in all directions except in the region of the tube port where the lead is missing. Some of the X rays do penetrate through the lead shielding and they are called leakage radiation. This radiation must be measured to determine if it is within legal limits. At the end of the exposure, the high voltage is removed. The filament current then returns to the standby level, and electromagnetic braking is provided to slow the anode to a stop (19–21).

Figure 1. Diagram of an X-ray tube assembly that depicts the major components.

Several types of X-ray tube malfunctions can occur that should be assessed through QC testing. An X-ray tube that has a vacuum leak is known as a "gassy" tube. Gassy tubes have a decreased X-ray output, show spikes in the milliampere and radiation waveforms, and show decreased penetration. A tube that has been overheated repeatedly may cause metal pitting in the anode; the rough anode surface decreases X-ray output (22). The overheating of the anode can also cause metal to evaporate and desposit inside the glass envelop of the X-ray tube; this phenomenon is known as metalization. Metalization can result in electrical arcs which produce spikes in kilovolts, milliamperes, and radiation waveforms. Overheating the filament results in a thinner filament due to evaporation of the metal. This increases the resistance of the filament. Without a tube current feedback circuit, the X-ray production can be decreased. If the filament becomes too thin, the filament will break and X-ray production will cease. Another X-ray tube malfunction is destruction of the bearings upon which the anode rotates due to excessive heat and mechanical wear. As the bearings fail, the anode does not rotate at the proper speed and the heat destroys the target. Bearing problems create excessive noise during anode rotation. Improper warm-up procedures can crack the anode and cause noise during anode rotation. The QC procedures should be able to detect these malfunctions.

MECHANICAL INSPECTION

The X-ray tube housing should be inspected visually for physical damage and/or oil leakage. The alignment of the X-ray tube in the support rings (trunions) should be checked.

ELECTRICAL INSPECTION

All cables into the X-ray tube should be visually inspected for damage to the insulation. The high voltage cables should be checked to make certain that connectors are properly tightened in the X-ray tube housing.

BEARING ROTATION

There are both optical and vibration sensors that can determine the anode speeds. The typical anode speeds are 3600 rpm on low speed and 10,000 rpm on high speed. The best method for checking the bearings is to listen to the sounds made during preexposure boost and slow down. The pitch of the sound should increase for 1–2 s and stabilize as a steady, even hum. During braking, the sound should be rapid 5–10 s deceleration. A metallic clinking sound and other irregular metallic sounds are indicative of bearing failures.

CENTRAL BEAM ALIGNMENT

An X-ray tube can be misaligned in its mountings or the insert can move inside the housing. To check the central beam alignment, a Lucite block with holes drilled in it (or a

Figure 2. A radiograph of a device utilized to locate the central axis of the X-ray beam.

special hollow plastic cylinder with a central hole on both the top and bottom surface) can be used. The device is placed on a image receptor cassette. The center of the block is positioned at the center of the central beam as shown by the collimator cross-hair. The hole that appears most circular in the film image is at the central axis of the X-ray beam. Off-axis positions have oblong images on the film. This is illustrated in the X-ray image shown in Fig. 2.

X-RAY OUTPUT

The X-ray output could decrease significantly for a number of different reasons. Some sources of a decreased output include excessive X-ray beam filtration, low kilovoltage calibration, low milliamperage calibration, damage to the anode from overheating, a pitted anode, or gassy X-ray tube. To test the X-ray output, a radiation detector is placed at 1 m from the X-ray tube focal spot and suspended several centimeters above the table top to decrease backscatter. The output should be measured at 100 kVp with a large-focal-spot milliamperage setting and exposure times $>1/10$ s. The measured air radiation dose in milligray (mGy) is divided by the mAs used to make the exposure; the measurement can then be converted to a standardized output by expressing the value as mGy per 100 mAs. For a three-phased, 12 pulse X-ray unit, or a high frequency X-ray generator, the X-ray output should be between 7–10 mGy per 100 mAs at 100 kVp and a distance of 1 m. A single-phase, full-wave rectified unit would measure $\sim 50\%$ less. X-ray outputs that are outside these limits by more than $\pm 15\%$ should be considered to be abnormal unless the X-ray tube has significant filtration (>3 mm Al equiv or >0.1 mm Cu).

RADIATION WAVEFORM

Irregularities in the radiation waveform can be indicative of severe problems with the X-ray tube, cables, and/or X-ray generator. Some sources of irregularities in the radiation waveform include gassy X-ray tubes, pitting of

Figure 3. Equipment used to display radiation waveforms. The radiation detector has an output terminal that is connected with a coaxial cable to a storage oscilloscope in order to display the waveform.

the X-ray tube anode, arcing cable connections, malfunctioning milliamperage stabilizer, phase imbalance in the power line, rectifier failure, and other generator problems. Modern radiation detectors usually have a BNC or computer output by which the radiation waveform can be monitored. A coaxial cable can be connected to a storage oscilloscope to record the radiation waveform (see Fig. 3). A three-phase, 12-pulse X-ray tube unit usually exhibits a 5–10% ripple in the wave form; high frequency units have a variable ripple (that depends on kVp and mA used) of 3–20%; a three-phase, 6 pulse unit usually exhibits 20–25% ripple; single-phase units exhibit 100% ripple. The peak values of each of the pulses in the waveform, however, should be relatively constant; the peak values should not change by >7%. The display of spikes or dropouts in the waveform are indicative of problems.

FOCAL SPOT SIZES

Focal spot measurements are usually only performed for new X-ray tubes; focal spot measurements are not routinely performed during QC: unless some spatial resolution problems are being investigated. The size of the X-ray tube focal spots can have a significant influence upon the radiographic image quality. Objectional bur can be introduced by excessively large focal spots. One way to measure focal spots is to use a leaded star pattern that is taped to the center of the collimator face plate. For focal spots >0.6 mm, a 2° star pattern is adequate; <0.6 mm focal spot sizes, a 1° pattern should be utilized. Typically 75–80 kVp should be used along with a milliamperage value that is midrange for the focal spot size being measured. Focal spot sizes decrease as peak kilovoltage increases and milliamperage decreases. Imaging of the star pattern should use plain film in a paper cassette (without intensifying screens that is called direct film exposures). The magnification factor should be small enough that the outermost interference pattern should appear in the film image (see Fig. 4). In general, a magnification factor of ~1.5× should be utilized

Figure 4. The radiograph of a 2° star pattern used to measure focal spot sizes. The radiograph was taken at 120 kVp and 100 mA with a magnification factor of 2.9. The manufacturer's specified focal spot size was 0.60 mm. The measured focal spot was 0.83 × 0.90 mm.

with a 1.2 mm focal spot, and a magnification factor of ~2.5× should be utilized with a 0.6 mm focal spot. The distance, d , between the outermost interference patterns is measured on the film. The effective focal spot size, α , can be calculated from the following equation (23,24)

$$\alpha = \frac{\pi\theta}{180} \frac{d}{(m-1)}$$

where θ is the number of degrees in the star pattern and m is the magnification factor. The measured focal spot sizes should be within -0 to +50% of the manufacturer's stated specifications in the small dimension (width) and within -0 to +100% in the long (length) directions. Small focal spots (<0.4 mm) often have a -0 to + 50% tolerance in both orthogonal directions.

LEAKAGE RADIATION

Since the X rays produced in the anode of the X-ray tube are nearly isotropic in direction, the lead lining within the X-ray tube housing is intended to reduce leakage radiation to acceptable levels. In order to measure the leakage radiation, the highest peak kilovoltages utilized clinically are selected. To accommodate the relatively slow response time of many exposure rate detectors, a relatively long exposure time is required (2–6 s). Federal regulations specify that the leakage radiation be measured at several locations 1 m from the focal spot and averaged; leakage techniques are specified as the highest peak kilovoltage with the highest continuous tube current. The X-ray tube can only be operated continuously at very low tube currents. These currents are typical of those used during fluoroscopy. Unfortunately, radiographic units usually cannot be operated at low currents in a continuous manner; radiographic units are designed for pulsed operations at high currents with short exposure times. To measure leakage radiation with radiographic units, a high peak

kilovoltage and low milliamperage are selected with a several-second exposure time. The adjustable collimators are closed completely and an additional lead sheet (at least 3 mm thick) is placed to block the primary X-ray beam; in this way, only leakage radiation is measured. Readings are taken with an exposure rate meter at several locations 1 m from the other focal spot and averaged. The average value is scaled down to a value corresponding to a low milliamperage continuous tube current (typically 5–10 mA). Federal regulations required that the average leakage exposure rate measured at a distance 1 m from focal spot at leakage techniques be $<100 \text{ mR}\cdot\text{h}^{-1}$ ($0.87 \text{ mGy}\cdot\text{h}^{-1}$). Higher readings are indicative of problems with the lead lining inside the X-ray tube housing. Excessive leakage radiation levels are rare occurrences. Moreover, these measurements need only be performed after X-ray tube replacement; they should not be a part of the routine QC program.

COLLIMATOR ASSEMBLY

The collimator assembly has variable lead shutters that define the size of the X-ray field. The assembly also contains a light bulb and mirror that are used to project a light field identical in size and location to the X-ray field. Collimator assemblies usually contain metallic filters (usually composed of aluminum or maybe also a thin layer of copper) that remove low energy X rays that are not very penetrating. These low energy X rays do not have sufficient energy to penetrate through the patient anatomy that is being

radiographed in sufficient quantity to influence the imager quality; these low energy X rays, however, can contribute significantly to the patient radiation dose. Therefore, the X-ray tube plus collimator assembly should contain sufficient metallic filtration to remove the very low energy X rays and harden the X-ray spectra. Figure 5 shows a typical collimator assembly. The QC procedures should evaluate the X-ray field–light field congruency and the penetration of the X-ray beam (19–21).

X-RAY FIELD–LIGHT FIELD ALIGNMENT

If the localizer light is misaligned with the X-ray field, the radiographic image can be too small, too large, or miscentered on the X-ray field. The alignment can be checked by placing a image receptor cassette at a given distance from the focal spot. The typical SID utilized in diagnostic radiology is 1 m. With the light localizer turned on and pointed at the cassette, metal markers are used to delineate the periphery of the light field; pennies are often used for the markers. A radiographic exposure of the film is made. The misalignment of the metal markers with the edge of the X-ray field is determined from the developed image. Figure 6 is an example of a misaligned X-ray–light field. Federal regulations specify that the misalignment in any one orthogonal direction should not exceed 2% of the SID. For automatic collimation (PBL), the error in any one direction must be $<3\%$ and the sum of the errors in two orthogonal directions must be $<4\%$.

Figure 5. Diagram of an X-ray collimator assembly that depicts major components.

Figure 6. Radiograph of the markers used to measure X-ray–light field congruence. The fields were severely misaligned in this image.

HALF-VALUE LAYER DETERMINATION

The half-value layer (HVL) for each X-ray unit is a measurement of the penetration of the X-ray beam. The HVL is the thickness of aluminum necessary to reduce the X-ray beam intensity by 50%. The HVL is measured in order to determine whether there is sufficient filtration in the X-ray beam. Insufficient filtration will result in increased patient dose. Excessive filtration results in extra stress on the X-ray tube, a loss in radiographic contrast, and increased exposure time. Increased exposure times can result in blur due to patient motion.

The HVL is measured by placing a radiation detector in the X-ray field. Although any selection of peak kilovoltage and mAs can be chosen, usually 80 kVp at 200–400 mA and 0.10 s is selected on the X-ray control. Two exposures are taken with no added filtration in front of the detector; the average value of these two readings represents 100% transmission through the X-ray tube and collimator assembly. Sheets of 1100 aluminum (mammography uses extra high purity aluminum filters) are then placed (one at a time) between the X-ray tube and the detector. The aluminum should be placed closer to the X-ray tube, allowing at least a 30 cm air gap between the aluminum and the detector to minimize scatter effects.

After each new piece of aluminum is added, an exposure is taken and the radiation measured is recorded. When the exposure measured is <50% of the baseline value, the data are plotted on semilog paper and the HVL determined. For

80 kVp, the Federal regulations require the HVL to be >2.3 mm of aluminum equivalent (3). The following table provides the minimum acceptable HVL values for different modalities as a function of the kVp used:

Modality	Equation for Minimum HVL
Mammography	$>(\text{kVp}/100) + 0.03 \text{ mm Al}$ $<(\text{kVp}/100) + C \text{ mm Al}$ Where $C = 0.12 \text{ Mo/Mo}, 0.19 \text{ Mo/Rh},$ and 0.22 Rh/Rh
Radiograph and routine fluoro	$>[2.26 (\text{kVp}/100)] + 0.48 \text{ mm Al}$
Angiography and cardiac fluoro	$>[3.5 (\text{kVp}/100)] + 0.08 \text{ mm Al}$

The maximum HVL should not be >6 mm Al equiv at 80 kVp for routine fluoroscopic, and radiographic units nor >9 mm Al equivalent at 80 kVp for angiography and cardiac fluoroscopy. For CT scanners at 120 kVp, typical values of the HVL are between 6 and 10 mm Al equiv.

ILLUMINATION OF THE LIGHT LOCALIZER

It is important that the collimator light be bright enough to visualize the borders of the light field during normal light conditions in an X-ray room. Otherwise, the X-ray field would not be properly determined and collimated. A visual inspection of the collimator localizing light can be conducted under normal room lighting. If a light meter is available, the intensity of the collimator light should be measured with the room lighting turned off. Federal regulations require that the light intensity of the collimator localizer >160 lux (15 ft·C) at a distance of 100 cm.

POSITIVE BEAM LIMITATION

Some X-ray equipment has an automatic collimation system for the X-ray beam. This automatic collimation system is designated as PBL. The PBL restricts the X-ray field size to the size of the cassette placed into the bucky tray. If this system malfunctions, the X-ray field size could be larger than the cassette and result in unnecessary X-ray dose to the patient. A smaller field size due to malfunctions could result in a loss of diagnostic information toward the periphery of the film. If the PBL system is present, some state regulatory agencies have performance criteria for the collimation accuracy.

To test the PBL system, two identical cassettes can be used. The collimator field size is opened to its maximum extent, and one cassette is placed into the bucky tray. The localizer light is turned on in the collimator, and the tray is inserted into position. One should visually observe the light field decrease to the approximate size of the cassette. The second cassette is placed upon the table and centered in the light field. The light field should be slightly inside all borders of the cassette on the tabletop. In fact, for a 1 m SID and an 8 cm distance between the cassette in the bucky tray, and the tabletop, the light field should be 7.5% smaller

than the cassette in each of the two orthogonal directions. A typical criteria for the PBL collimation is an accuracy of $\pm 3\%$ of the SID error in either orthogonal direction and $\pm 4\%$ of the SID sum error without regard to sign for both directions.

MINIMUM SOURCE-TO-SKIN DISTANCE

In order to prevent placement of the X-ray tube too close to the patient, the federal regulations specify the minimum distance that the bottom of the collimator must be from the focal spot. This regulation usually does not apply to overhead X-ray tubes where the patient would never be placed next to the collimator under routine clinical conditions. This distance can be determined from geometric magnification effects. If an object of known size (OS) is placed at the bottom of the collimator and radiographed, the image size (IS) will be magnified. The distance from the object to the film should be measured (OFD). The source-to-skin distance (SSD) can be determined from the measurements.

$$SSD = [OFD(OS/IS)]/[1 - (OS/IS)]$$

For radiographic units, the federal regulations specify that the SSD be >30 cm (12 in.) for mobile systems. For fluoroscopic units, the Federal regulations specify that the minimum SSD should be >38 cm (15 in.) for stationary certified fluoroscopic units, 30 cm (12 in.) for mobile fluoroscopic units, 19 cm (7.5 in.) for mobile fluoroscopy c-arm with an SID = 45 cm that are used for extremity imaging and 20 cm (8 in.) for image intensifier fluoroscopic units used for specific surgical applications. In general practice, the minimum SSD for stationary certified fluoroscopic units is usually 45 cm (17.7 in.).

X-RAY GENERATOR

The X-ray generator controls X-ray production. The timer circuit determines the duration of the X-ray exposure. The milliamperage selector determines the number of electrons per second that bombard the anode. Hence, the product of milliamperage and time determines the number of X rays produced; this product is known as mAs. kVp selector provides the high voltage between the cathode and anode that accelerates the electrons in an X-ray tube. The peak kilovoltage determines both the energy spectrum and the number of X-ray produced. As peak kilovoltage increases, the penetration of the X-ray beam increases (19–21).

In order to be able to consistently take acceptable radiographs, it is important the X-ray generators be properly calibrated. Moreover, the exposure should be reproducible and the various X-ray equipment should be calibrated to the same standard. In order to meet these criteria, the QC procedures should carefully evaluate the generator performance. Most extremity imaging and some other projections are performed using manual X-ray generator settings.

X-RAY REPRODUCIBILITY

If an X-ray generator is operating properly, the amount of radiation produced for a given selection of technique

factors should be constant. If there is a problem with milliamperage stabilization, peak kilovoltage waveform, arcing in the X-ray tube, and/or timer viability, the measured X-ray output at any fixed location will vary. A radiation detector should be placed in the central ray ~ 30 – 70 cm from the bottom of the collimator. Five-to-ten separate X-ray exposures are recorded for some fixed selection of technique factors (e.g., 80 kVp, 300 mA, and 0.10 s). The average value and the standard deviation for these exposures is calculated. The ratio of one standard deviation divided by the average exposure is also computed. The ratio is called the coefficient of variation (CV). Federal regulations require that the CV be <0.050 for compliant X-ray units and it is desirable that this value really be <0.02 for properly functioning X-ray generators.

TIME ACCURACY

Since the exposure duration timer circuitry partly determines the mAs used, inaccuracy in the timer could result in variations in the radiographic density for film images and mottle for digital images. The duration of X-ray exposures can be easily measured by either special electronic X-ray timers or some digital exposure detectors. One merely places these devices in the X-ray beam and reads the measured exposure time. Other methods utilize the display of a radiation waveform on an oscilloscope and determining the exposure time from the width of the displayed waveform full width at half-maximum (fwhm). It is recommended that the timers be accurate to within $\pm 5\%$ or ± 1 ms, whichever is larger at all timer settings on the control panel; Single-phase equipment should only be accurate to 1 pulse or ± 8.3 ms. Instead of testing all the timer settings, however, 5–10 timer settings from the shortest to the longest should be checked. The X-ray tube chart should be consulted to avoid exposures that would overheat the tube.

TIMER REPRODUCIBILITY

One reason for the lack of exposure reproducibility is an inconsistently functioning X-ray timer circuit. The time for five identical exposures should be measured. Federal regulations require that average exposure time (T) for any fixed selection of technique factors be greater than five times the worse excursion in the exposure duration

$$[5(T_{\max} - T_{\min})]$$

MILLIAMPERAGE ACCURACY

Another factor that influences the selected mAs is the milliamperage calibration. Again, inaccuracies among the milliamperage stations can result in improper radiographic densities on the film. Moreover, it is desirable that various rooms in a large X-ray department have a similar calibration. Therefore, technique charts for procedures throughout the department can be standardized.

Figure 7. Equipment used to measure and display milliamperage of the generator. The noninvasive probe shown on the X-ray cable measures the milliamperage indirectly by sensing the induced magnetic field around the cable. The storage oscilloscope is used to display the milliamperage waveform.

Several different ways to measure the milliamperage accuracy are available. A simple method is the use of noninvasive current probes (25). These probes clamp around the high voltage cables to the X-ray tube and measure milliamperes indirectly by sensing the induced magnetic field around the cable. Figure 7 shows this equipment. This method is usually better for measurement of the larger milliamperage settings. It is recommended that all milliamperage stations be calibrated to within $\pm 5\%$ or ± 1 mA (whichever is larger) of the indicated value on the control panel. Furthermore, the shape of the milliamperage waveform should be observed on an oscilloscope to detect problems, such as arcing, loading, lack of stabilization, rectification problems, and excessive ripple. The waveform should be regular and the peaks in the milliamperage waveform should not vary by $>7\%$.

MILLIAMPERE LINEARITY

The assessment of the relationship between the various milliamperage settings and their corresponding measured X-ray output is called milliamperage linearity. If the milliamperage is increased by a factor of 2 with all other settings unchanged, the X-ray output should also increase by a factor of 2. If the milliamperage settings on the control are miscalibrated, the actual milliamperage will not increase linearly with the selected values.

In order to make milliamperage linearity measurements, one merely places a radiation detector in the X-ray field along the central ray. The detector is kept at a fixed location. One peak kilovoltage and time setting is selected (e.g., 80 kVp and 0.1 s). A series of fixed exposures are measured for each of two (or more) different milliamperage settings (e.g., 200 and 400 mA). The average exposure value for each of the 2 mA stations is calculated (E_1 and E_2). The average exposures are divided by the mAs values used to produce the exposures mGy per 100 mAs (or mR mAs⁻¹). The term ($X_1 = E_1 \cdot \text{mAs}^{-1}$) should be the same for

all selections of milliamperage employed. A linearity factor (LF) is then calculated as follows:

$$LF = |X_1 - X_2| / |X_1 + X_2|$$

Federal regulations require that the LF to be <0.10 . Actually, most X-ray generators are capable of LF values <0.05 for the 2 mA settings with the largest discrepancies (if properly calibrated and functioning correctly).

PEAK KILOVOLTAGE CALIBRATION

Improper peak kilovoltage calibration of the X-ray generator has major influences upon image quality and patient dose. High peak kilovoltages reduce patient contrast, increase scatter, and increase subject latitude; they also result in reduction of patient dose. Low peak kilovoltages have the opposite effect. Moreover, miscalibration results in non-uniform X-ray quality throughout a large X-ray department. Thus, a standard for the determination of peak kilovoltage accuracy is important.

There are a number of methods by which peak kilovoltage calibration can be measured. These methods include high voltage bleeder resistor networks and noninvasive kVp meters (26–29). A simple method often utilized is noninvasive kVp meters, such as one shown in Fig. 8. These meters are placed in the X-ray beam and display a digital number for the measured peak kilovoltage. The meters contain several solid-state radiation detectors, each with different amounts of copper filtration. By measuring the amount of penetration of X-ray beam through these filters the peak kilovoltage can be computed. These noninvasive peak kilovoltage meters are usually accurate to within ± 2 kVp. Even though more accurate peak kilovoltage instrumentation exists, the relative ease with which is noninvasive peak kilovoltage measurements can be made is their principal advantage. It is recommended that peak kilovoltage calibration be accurate to within $\pm 5\%$ or ± 2 kVp, whichever is larger at all milliamperage

Figure 8. Equipment used to measure and display to peak kilovoltage of the generator. The device shown below the X-ray tube is a noninvasive peak kilovoltage meter. The storage oscilloscope is used to display the peak kilovoltage waveform.

stations for a range of peak kilovoltage settings. For radiographic units, the checks are usually made at 60, 90, and 120 kVp, using a variety of milliamperage settings. The shape of the kVp waveform can also be observed by a BNC output connection from the noninvasive kVp meter to an oscilloscope. The peak kilovoltage waveform is monitored to detect problems with arcing, excessive or irregular ripple, stabilization problems, rectification failures, phase imbalances, and noise. The peaks in the kVp waveform should not vary by $>7\%$.

OPERATOR'S CONTROL PANEL

The control panel contains the selection switches that determine the technique factors for the X-ray exposure. The QC program should determine that selection switches function properly and that regulatory requirements are met.

FUNCTION CHECKS

The various selection switches should be tried; it needs to be determined that the switches actually function. Furthermore, all lights, meters, and digital displays should be checked to make certain they are operational.

EXPOSURE CONTROL

Recommendations suggest that the exposure control should be secured at least 40 in. (1 m) from the edge of the secondary radiation protection barrier. It should not be possible to carry the exposure switch into the room and/or make an exposure while inside the X-ray room.

REGULATORY CHECKS

The operator's control panel is required to have certain features. The QC procedures should check for these regulatory items. There must be a warning label with a caution about the hazards of X-ray irradiation. The technique factors must be indicated on the control panel prior to an exposure. During an exposure, there should be a visible beam-on indicator and an audible indicator of exposure termination. Following the exposure, there should be an automatic resetting of the exposure termination timer. For fluoroscopic units, there should be a 5 min timer; after 5 min of fluoroscopy, there must be an audible indicator at the end of each 5 min of fluoroscopy. The 5 min timer alarm must continue to sound until the timer is reset (18). However, the reset of the alarm must not affect the cumulative timer that accumulates the total fluoroscopy time during each study.

TABLE AND TUBE STAND

Foremost, the mechanical functions of the table and tube stand motion should be checked. All typical positions utilized clinically should be tried. The accuracy of distance

indicator for the SID should be determined; a tape measure can be used to check the SID indicator. The mechanical safety of the table and tube stand should be visually inspected. Anticollison devices should be checked.

AUTOMATIC EXPOSURE TERMINATION

Automatic Exposure Control (AEC) or phototiming utilizes a radiation detector to measure the amount of X-ray radiation incident upon the film-screen or CR cassette. When the detector measures sufficient radiation to produce adequate density on the image or a level of mottle on digital image receptors that is deemed appropriate, the detector sends an electronic signal to the X-ray generator, which terminates the exposure. In this manner, with properly functioning phototimers, radiographs should have satisfactory density (film) or minimally acceptable noise (CR/DR) to prevent degradation of image quality. In order to check the AEC system, the phototimer tracking should be measured.

PHOTOTIMER TRACKING

An accurate AEC circuit can result in a decrease in the repeat rate and a consistent image quality for a variety of patient sizes. However, phototimer circuits can be susceptible to variations with changes in the peak kilovoltage, non-linear responses of film-screen systems, a limited range of patient sizes, or a lack of reproducibility. The best method to check the phototimer is to use acrylic plastic sheets to stimulate the patient and to take radiographs of the plastic. The acrylic sheets are placed in front of the phototimer to simulate various patient sizes. For various peak kilovoltage settings or changes in the plastic thickness, the density of the exposed and developed film (as determined with a densitometer) or Exposure Index Number for CR or DR cassettes should remain constant. If the phototimer circuitry is performing properly, it is recommended that the measured film density be within ± 0.15 du at one standard deviation (or $\pm 10\%$ for digital system index number) of the average value for all variations in peak kilovoltage or simulated patient thickness. Furthermore, for conditions of fixed peak kilovoltage and thickness, reproducibility of the measured film density should be within ± 0.05 du (one standard deviation) or $\pm 5\%$ for the digital system index number.

BUCKY TRAY

The tray into which the film-screen or CR cassette is inserted is called the bucky tray. Above the tray, there is usually a moving grid that is used to remove some of the scattered X rays. It is important that the grid moves properly during the exposure and that it does not contain any defects. A common problem is that the wrong grid is inserted into the table. The detente mechanism that positions the X-ray tube over the cassette may also not be properly centered. The QC tests should attempt to investigate for possible problems.

VISUAL INSPECTION

If possible, the grid should be removed from the bucky assembly on an annual basis. It should be visually inspected for damage and for spills of contrast material. The focal distance and grid ratio marked on the grid should be checked to determine if they are appropriate for the intended radiographic procedures. It should also be determined that the correct side of the grid faces the X-ray tube; inverted grids result in cutoff of image density toward the edges.

GRID UNIFORMITY

In order to ascertain that there are no defects in the grid and that there are no irregular cutoffs, a cassette should be placed in the bucky tray and a rapid exposure made to result in a film density of ~ 1.20 du (or appropriate digital image index number). Exposure times should be < 20 ms in order to stop grid motion. The developed film should have uniform density throughout and the grid lines should be visible. Irregularities in the grid lines or nonuniform density may be indicative of a grid problem.

BUCKY MOTION

Sometimes, the device that causes the grid to oscillate during the exposure malfunctions or is not properly synchronized with the X-ray exposure. To test for bucky motion, a cassette is placed in the bucky tray and an exposure is taken with a longer exposure time selected. Exposure times should be > 100 ms. The developed image should have a uniform density and grid lines should not be visible. The bucky motion should blur all the grid lines on the image. If the grid lines still appear, there is a problem with the bucky motion.

CENTERS ALIGNMENT

The miscentering of the X-ray field and the center of the image receptor cassette could result in the loss of diagnostic information. For this test, the detente and collimator light systems are used to position the X-ray tube assembly over the film–screen cassette that has been placed in the bucky tray. The X-ray field size must be smaller than the cassette. An X-ray exposure of the cassette is made and the centers of both the X-ray field and the image are determined. The misalignment of the center of the cassette with the center of the X-ray field must be $< 2\%$ of the distance between the X-ray tube focal spot and the cassette (SID).

FLUOROSCOPIC X-RAY EQUIPMENT

Some of the components in fluoroscopic X-ray equipment are similar to those in radiographic equipment. The same X-ray generators are often used to operate several X-ray tubes in a single radiology room; often a fluoroscopic and radiographic X-ray tube are connected to the same X-ray generator. However, in addition to the standard radio-

graphic components, fluoroscopic X-ray equipment usually includes additional components, such as image intensifier, cassette spot film devices, television systems, 100 mm (or digital) fluoroscopic spot film cameras, and a tilting table. The fluoroscopic system is designed to operate as a real-time dynamic imager. The X-ray tube operates with low milliamperage values for continuous fluoroscopy so that X-ray production can continue for minutes without overheating the X-ray tube. Pulsed fluoroscopy utilizes large milliamperage values (> 100 mA), but the duty cycle (actual X-ray production) is $\sim 5\text{--}30\%$. The image intensifier stops the X rays transmitted through the patient and converts them to a light image. The light from the image intensifier can then be recorded by the television system, cassette spot film, or the spot film camera. The QC tests should also include those components that are specific to fluoroscopic systems. The QC procedures for the X-ray generator and tube have been described previously (30).

TRACKING TEST

The image-intensifier assembly (IIA) on fluoroscopic X-ray systems can be positioned at various heights above the table. It is important that the collimator on the X-ray tube adjusts to track the image receptor properly, otherwise, the X-ray field size could possibly exceed the image receptor size. This function is observed by placing an object in the fluoro field and moving the IIA up and down. The collimator should adjust automatically. Federal regulations require compliant fluoro systems to have tracking with SID adjustment.

INTERLOCK TEST

When the IIA is placed in the park position, fluoroscopic X-ray production should be inhibited. If fluoroscopic X-ray production were not inhibited, the patient could receive a radiation dose without any image being recorded (i.e., unnecessary dose). The test is performed by placing the IIA in the park position and then placing a radiation detector on the table surface. The fluoroscopic “on” switch is depressed and the detector indicates whether X rays were produced. IIA interlocks are required for compliant units.

PRIMARY BARRIER TRANSMISSION

The IIA acts as a primary radiation barrier. Any X ray impinging upon it should be drastically attenuated. Transmission of the X rays should be minimal. The test is performed by placing a 1.5 in. (3.8 cm) aluminum penetrometer on the table surface in the primary X-ray beam and depressing the fluoro switch. The entrance radiation exposure rate into the penetrometer is measured as well as the exposure rate of the radiation transmitted through the IIA. Federal regulations require that the exposure rate transmitted through the IIA should not exceed $2 \text{ mR}\cdot\text{h}^{-1}$ at 10 cm above the IIA surface for each roentgen per minute of entrance exposure.

MAXIMUM ENTRANCE EXPOSURE RATE

In order to limit the patient dose, the federal government has established regulations to limit the maximum fluoroscopic entrance exposure rate. The measurement can be performed with no backscatter material according to regulatory specifications; however, more realistic conditions can be simulated by placing a 1.5 in. (3.8 cm) aluminum penetrometer on the table with a radiation detector next to the penetrometer on the side toward the X-ray tube. Once the detector is centered in the X-ray beam, a lead sheet (3 mm thick) is placed on the penetrometer side toward the IIA. Both the Automatic Brightness Control (ABC) and the manual adjustments are used serially to obtain the highest X-ray radiation levels. The radiation detector is used to measure the exposure rate. Federal regulations require that the entrance rate at the point where the center of the useful beam enters the patient shall not exceed $87 \text{ mGy}\cdot\text{min}^{-1}$ in air ($10 \text{ R}\cdot\text{min}^{-1}$) in the ABC mode, except during the recording of the fluoroscopic image (cassette or spot exposures) or when provided with an optional high level control. When provided with the optional high level control, the equipment shall not be operable at any combination of tube potential and current that will result in any exposure rate in excess of $87 \text{ mGy}\cdot\text{min}^{-1}$ in air ($10 \text{ R}\cdot\text{min}^{-1}$) at the point where the center of the useful beam enters the patient unless the high level control is activated. In the higher level fluoroscopy mode, a special buzzer or chime must sound and the maximum patient entrance exposure rate must be $<174 \text{ mGy}\cdot\text{min}^{-1}$ in air ($20 \text{ R}\cdot\text{min}^{-1}$). Furthermore, equipment that does not employ ABC shall not be operable at any combination of peak kilovoltage or milliamperage that will result in an exposure rate in excess of $43 \text{ mGy}\cdot\text{min}^{-1}$ in air ($5 \text{ R}\cdot\text{min}^{-1}$) at the point where the center of the useful beam enters the patient, except during recording of the fluoroscopic images or when provided with an optional high level control.

TYPICAL PATIENT ENTRANCE EXPOSURE RATES

In order to assess the normal operation of fluoroscopic or cine equipment, typical patient entrance exposure rates should be measured. These rates can be influenced by the improper functioning of the equipment and by adjustments made by the service personnel. A 3.8 cm (1.5 in.) aluminum penetrometer to which 0.5 mm copper has been added can be utilized to simulate an average male patient of $\sim 75 \text{ kg}$ weight; the measurement procedure is the same as that for maximum dose rate, except that the lead is not placed in the X-ray beam. It is recommended that the simulated patient entrance exposure at the point the X-ray beam enters the phantom should not exceed $8.7\text{--}26.1 \text{ mGy}\cdot\text{min}^{-1}$ in air ($1\text{--}3 \text{ R}\cdot\text{min}^{-1}$) in the 23 cm (9 in.) Field-of-View (FoV) with ABC. During these measurements, the indicated fluoroscopic peak kilovoltage should $>55 \text{ kVp}$ and $<90 \text{ kVp}$. During digital cine recording in the 23 cm (9 in.) mode, the measured entrance exposure should be less than $200 \mu\text{Gy}$ per frame (23 mR per frame) with the same phantom of 3.8 cm (1.5 in.) of aluminum plus 0.5 mm of copper. Some local regulatory agencies require that

typical patient radiation levels be measured annually for all X-ray equipment.

LIMITATION OF THE X-RAY FIELD TO THE IMAGE RECEPTOR SURFACE

The intent of this test is to limit the X-ray field size to the IIA surface such that the patient is only irradiated over a surface for which a TV image can be seen. If the X-ray field size were larger, the patient would be unnecessarily receiving a radiation dose over an area that would not be imaged. In order to perform the measurement of X-ray field size, a leaded ruler is placed in two orthogonal directions upon a film in a cardboard cassette. The film with the ruler can be placed in the X-ray beam anywhere between the tabletop and the IIA surface. The film and ruler are then fluoroscoped. The TV image is viewed to determine the amount of the scale that is visible on the TV monitor. The exposed film is then developed and the size of the fluoro X-ray field is indicated by the darkened portion on the film. Federal regulations specify that the misalignment between the X-ray field size and the image receptor in the fluoroscopic mode must be $<3\%$ of the SID in either orthogonal direction and less than a sum of 4% of the SID for the two orthogonal directions combined.

FLUOROSCOPIC X-RAY OUTPUT

The fluoroscopic X-ray output is valuable information utilized in several ways. These data can then be used to yield patient dose estimates. Furthermore, miscalibrations in peak kilovoltage and/or milliamperage and filtration problems would become apparent in the fluoroscopic X-ray output measurements. Additionally, malfunctions in the X-ray tube, such as anode deterioration, should cause drastic changes in the fluoroscopic output. The measurement is performed by placing an X-ray detector on the table surface (without backscatter) in the X-ray beam to measure the air dose rate in $\text{mGy}\cdot(\text{mA}\cdot\text{min})^{-1}$ [or exposure rate in $\text{R}\cdot(\text{mA}\cdot\text{min})^{-1}$] during fluoroscopy for various peak kilovoltage settings. It is recommended that the fluoroscopic X-ray output measured at the table surface ($\sim 46 \text{ cm}$ or 18 in.) from the focal spot should be between 13 and $22 \text{ mGy}(\text{mA}\cdot\text{min})^{-1}$ [or 1.5 and $2.5 \text{ R}\cdot(\text{mA}\cdot\text{min})^{-1}$] at 100 kVp , except for heavily filtered X-ray beams.

RADIATION INTO INPUT RECEPTOR(S)

The operation of fluoroscopic X-ray equipment is closely aligned to levels determined by feedback control loops that measure parameters associated with the input radiation exposure levels. Thus, proper equipment performance necessitates that the levels be adjusted appropriately. Within the guidelines listed below, the levels should be high enough to limit fluoroscopy image noise to tolerable levels, but low enough to limit patient dose and contrast losses associated with the ABC driving to high peak kilovoltage settings. These tests are performed with a 3.8 cm (1.5 in.) aluminum plus 0.5 mm copper in the

X-ray beam and the brightness being controlled by the ABC mode. The IIA should be placed high above the aluminum and copper attenuator in order to limit scattered X-rays from being measured. The radiation detector should be placed at the IIA surface with the grid removed (on some units the grid cannot be easily removed). It is recommended that the following radiation levels for input exposure rates the image receptor be established:

1. Fluoroscopy for 23 cm (9 in.) mode (no grid) $\leq 6 \text{ mR}\cdot\text{min}^{-1}$ ($100 \text{ R}\cdot\text{s}^{-1}$ or $0.9 \text{ Gy}\cdot\text{s}^{-1}$)
2. Fluoroscopy for 15 cm (6 in.) mode (no grid) $\leq 12 \text{ mR}\cdot\text{min}^{-1}$ ($200 \text{ R}\cdot\text{s}^{-1}$ or $1.8 \text{ Gy}\cdot\text{s}^{-1}$)
3. Digital cine recording for 23 cm (9 in.) mode (no grid) $\leq 20 \text{ R/frame}$ or $0.17 \text{ Gy}\cdot\text{f}^{-1}$
4. Digital subtraction angiography radiographic exposures (no grid) $\leq 1.0 \text{ mR}$ per image or 8.7 Gy per image for 23 cm (9 in.) mode

Excessive input radiation levels are indicative of problems, such as the selection of too small an aperture (a diaphragm placed behind the objective lens of the IIA) or deterioration of the image intensifier.

SPATIAL RESOLUTION MEASUREMENTS

The image quality analysis of fluoroscopic X-ray systems requires the measurement of the spatial resolution capabilities of the various imaging modalities. Unfortunately, the TV chain usually degrades the spatial resolution available from the output phosphor of the image intensifier (II). Hence, measurements of II spatial resolution require the removal of the TV camera; direct observation of the II output phosphor with a special telescope is necessary. This measurement is rarely done. Furthermore, the spatial resolution is dependent upon: the magnification mode for the II [6 or 9 in. (15 or 23 cm) field size], the use of a grid, amount of scatter, the type of test pattern, the location of the test pattern on the II surface, the peak kilovoltage employed, and the focal spot size. Focal spot influences are minimized by the placement of the bar test pattern as close as possible to the II input surface; however, clinical usage has the object of interest displaced away from the II input surface. Therefore, a second test should be performed with the test pattern located at a position corresponding to the patient's location. In this case, the combined effect of focal spot and II distortion is included in the spatial resolution measurement.

A variety of measurement procedures for assessing the spatial resolution of the II are utilized; the following methodology, however, is suggested. A 3.8 cm (1.5 in.) aluminum penetrometer should be placed on the tabletop at the center of the X-ray beam. A 0.10 mm lead bar pattern (0.5–5.0 line pairs per millimeter) should be taped at the II surface with the grid removed. The equipment should be operated in the ABC mode with 60–80 kVp. The output phosphor of the II should be observed through a special telescope. An alternative procedure would be to record the image of the bar pattern with the fluoroscopic spot film camera. The mea-

asured spatial resolution for the II should be > 3.8 – 4.0 line pairs per millimeter in the 15 cm (6 in.) mode and 2.5–2.7 line pairs per millimeter in the 23 cm (9 in.) mode. The TV camera should then be reattached and the spatial resolution on the TV monitor should be examined. The lead bars should be oriented at 45 degree to the raster lines on the TV system. For a 525 line TV system, the spatial resolution should be at least 1.8–2.0 line pairs per millimeter in the 15 cm (6 in.) mode and at least 1.2 line pairs per millimeter in the 23 cm (9 in.) mode. For 1023 line TV units, the measured spatial resolution is typically 50–80% better. Flat panel image receptors typically have resolutions of 2.2–2.8 line pair millimeters in all FoV.

CONTRAST RATIO

Due to light scattering from adjacent areas (veiling glare) in the fluoroscopy image, contrast can be degraded. It is therefore important to measure the maximum contrast achievable. To perform this measurement, a lead disk [at least 0.32 cm (1/8 in.) thick] is placed at the center of the input surface. The diameter of the disk should be 10% of the II input area selected. It is suggested that a thin penetrometer be placed in the X-ray field. For modern digital systems (without film recording) a light meter can measure the intensity levels behind the lead disk and the surrounding background on the display monitor using standardized contrast and brightness control settings. The contrast ratio is a ratio of the light intensity in the area surrounding the disk to the area directly under the disk. For satisfactory fluoroscopy image receptors, the contrast ratio measured with a light meter should be $>40:1$ – $60:1$. For film type measurements, the ratio should be $>20:1$.

CONVERSION GAIN

The conversion gain of an II defines the efficiency by which the device can convert incident X-ray radiation at the II entrance into light output at the output phosphor of the II. Conversion gain (G_x) is measured in units of nit ($\text{cd}\cdot\text{m}^{-2}$) of light output per $\text{mR}\cdot\text{s}^{-1}$ of X-ray radiation input. The conversion gain degrades with age and usage; typical amounts for the decrease in conversion gain are 5–10% year^{-1} .

As the II conversion gain decreases the patient radiation dose will increase and the X-ray tube heat loading will increase. Although II conversion gain measurements can be performed by medical physicists, it is usually better to request the manufacturer's service personnel to do the measurement (31,32). Conversion gain should be measured immediately after installation when the II is new. By the time that the conversion gain drops to 50–60% of its initial value, replacement of the II would be recommended.

SCATTERED RADIATION LEVELS

Information about the scatter radiation levels is relevant to the assessment of radiation protection criteria for radiology

personnel. In order to limit the radiation to the radiologists to 870 Gy (100 mR) per week, the measured levels should be $<170\text{--}220\text{ Gy}\cdot\text{h}^{-1}$ ($20\text{--}25\text{ mR}\cdot\text{h}^{-1}$) for an estimated maximum of 4–5 h of actual fluoro time per week.

The scatter radiation measurements are performed by placing 25 cm of acrylic in the fluoro beam with the collimator wide open. The ABC is used to control the radiation levels. A portable survey meter is used to measure the scatter radiation levels. It is assumed that protective curtains and flaps will be utilized where they are available. Radiation levels are measured for eye, chest, and gonadal levels at standard positions of staff in the fluoroscopic rooms.

MAMMOGRAPHIC X-RAY EQUIPMENT

Mammographic equipment is a special category of X-ray units. These units can either be used with special film-screen cassettes or as digital units. Mammographic units intended for both types of units typically have a molybdenum X-ray tube target with a beryllium window and either a molybdenum or rhodium X-ray beam filter. (Some mammography units are available with either rhodium or tungsten X-ray tube targets.) Digital units typically contain an image receptor with a scintillator phosphor coupled to photodiode array or a direct conversion amorphous selenium radiation detector array. Both types of mammography units operate at low peak kilovoltages usually with X-ray tube potentials of 25–35 kVp. The measured HVLs will depend on the type of unit being tested. Federal regulations specify that the HVL at 30 kVp must be at least 0.33 mm of aluminum equivalent using ultra pure aluminum filters (not 1100 Al) (see table in Half Value Layer Determination).

At these low peak kilovoltages, small irregularities in the compression plate, grid, or cassette can produce artifacts on the radiographs. Even a small piece of tape (or dirt) inadvertently placed on the compression plate can create objectional artifacts. Another consideration is that the female breast is radiation sensitive. Therefore, the radiation dosage during mammography should be kept as low as reasonably possible (ALARA). Finally, mammography strives to achieve better spatial resolution than other types of film-screen radiographs. To achieve these goals, an X-ray tube with a small focal spot size is used to minimize geometric blur. The film-screen cassette is also designed to provide excellent film-screen contact. Beyond the aforementioned factors, the mammographic equipment has many features in common with the standard radiographic units. The QC procedures for mammographic equipment must be expanded to encompass their special features. Specialized tests required for mammographic units are listed below (33–35)

TYPICAL PATIENT DOSE

There are a number of methods to specify the patient dose. One can either measure a skin entrance dose, a mid-breast dose, or an average glandular dose; the average glandular dose is being recommended due to its biological significance

(34). Because of the ease of measurement, however, the skin entrance exposure value is most often determined. The measurement is dependent on breast size, breast composition, peak kilovoltage used, anode and filter combination used, and the type of image being recorded (digital or film-screen). To simplify the measurement, 4–5 cm of BR-12 plastic or acrylic plastic can be used to represent a typical breast. The exposure should be taken to obtain normal densities or digital exposure settings for the image. The skin entrance exposure is then measured with a radiation detector that has a good low energy response. The measured radiation with grid should be 5.2–13 mGy (600–1500 mR) dependent on: the type of mammography unit, film-screen or digital selection, image processing conditions, film density, anode type, filtration type, and kVp used. The average glandular radiation dose for a 4.2 cm compressed breast must be $<3.0\text{ mGy}$ (300 mrad). Typical values for both film-screen and digital units with a 4.2 cm ACR phantom are $\sim 1.5\text{--}2.0\text{ mGy}$ (150–200 mrad). Although the use of grids increases the measured exposure values by 2.0–2.5 times, grids are essential to obtain good image contrast.

SPATIAL RESOLUTION

To assess the spatial resolution of the imaging system, a bar pattern (same one described previously in radiography and fluoroscopy section) should be placed on top of a 4–5 cm plastic block (BR-12 or acrylic) that simulates a typical breast. An image should be recorded and the spatial resolution seen on the image should be determined. This measurement combines the effects of the focal spot and image system blur. In general, the spatial resolution of most mammography systems is excellent. It should be anticipated that the measured spatial resolution should be >13 line pairs per millimeter with bars along the anode-cathode direction and 11 line pairs per millimeter with bars in the perpendicular direction for film-screen systems. The spatial resolution for digital systems is limited by the detector pixel size; and it is usually in the 5–10 line pairs per millimeter range for current technology.

ARTIFACTS

To identify artifacts, an image of the 3–5 cm acrylic sheets should be imaged. The density should be appropriate and uniform across the surface. Any changes in density are indicative of potential artifacts.

IMAGE QUALITY

Good mammographic image quality involves an assessment of numerous factors. The QC procedures should require that a radiographic image of a phantom that includes several different types of test objects be taken. Figure 9 is an image of the ACR phantom that contains fibrils, calcium specks, simulated masses, and a plastic disk for contrast assessment. For film-screen units, at least 4 fibrils, 3 speck groups, and 3 masses must be clearly

Figure 9. CT image of ACR CT phantom showing plastic rods for CT number linearity and wire for slice thickness evaluation.

visible for a total score of 10 objects (according to ACR and MQSA standards). Digital mammography systems should be able to visualize even more objects in the phantom. The ACR Mammography Accreditation Manual should be consulted for details about many of the mammography equipment tests.

TRAY TRANSMISSION

Since the patient's lap is often situated beneath the cassette tray, it is important that the back surface have sufficient lead lining to significantly attenuate or block the X-ray beam. A radiation detector should be used to measure the amount of radiation transmitted during typical mammographic exposures. It is recommended that the transmission be <0.01% of the primary beam.

BODY-SECTION TOMOGRAPHIC EQUIPMENT

The purpose of the equipment is to image thin planar sections through the patient's anatomy using film-screen or CR cassettes. The X-ray tube and cassette move in opposite directions about a pivot (or focal) plane to blur objects outside this focal plane. The motion is done such that the anatomy at a preselected depth in the patient will remain in focus on the image receptor cassette. All other anatomy outside the focal plane will be blurred by the motion.

The QC procedures of these tomographic units should include additional tests directed toward analyzing the tube motion and the planar radiographs (36).

PINHOLE IMAGES

The angle through which the X-ray exposure is made influences the thickness of the imaged tomography planar sections. Moreover, it is important that the motion be uniform and symmetric about a central point. All these factors can be assessed through a pinhole image.

To do this test, a lead sheet with a small hole [$\sim\frac{1}{8}$ in. (0.32 cm)] drilled in it should be suspended several inches above the tabletop at the height of the focal plane. A film-screen cassette should be placed on the table top beneath the hole in the lead sheet. With the X-ray tube at zero degree tomo angle, the pinhole should be placed along the central ray and a short exposure taken with no tomo motion to mark this position. Then, a routine tomographic exposure should be made and the cassette film developed. The track on the film should be of uniform density and symmetrical about the zero tomo angle point. The tomographic angle can be computed from the height of the pinhole above the cassette (h) and the width of the track on the film (W). For linear tomography, the tomographic angle is given by the following equation:

$$\theta = 2 \tan^{-1} \frac{W}{2h}$$

The measured exposure angle should correspond to the selected angle within $\pm 1^\circ$.

SLICE THICKNESS

A standard tomographic phantom has been designed to measure the slice thickness and image quality for the body section units (37). The phantom is merely placed on the table and a preselected depth is chosen. A routine tomographic scan is taken and the image developed. Figure 10 shows a tomographic image through this phantom. Examination of the portion of the image that is not blurred yields the depth accuracy, slice thickness, and image quality. It is recommended that both the location of focal plane depth and the slice thickness be accurate to within ± 1.0 mm.

COMPUTED TOMOGRAPHY

Computed tomography scanners are composed of many major subsystems. The hardware contains a variety of complex equipment, such as the X-ray source, the rotating mechanical assemblies in the gantry, radiation detectors, signal-processing electronics, computer systems, display systems, and input-output devices (38). The X-ray source consists of a standard X-ray tube and generator. This portion of the equipment can be tested in the routine manner to check the peak kilovoltage, milliamperage, and time calibration. Because it is difficult to evaluate each of the other CT subsystems individually, the QC tests assess the overall image quality through the use of phantoms. Other tests are directed toward measurement of the patient dosimetry, slice geometry, and table motion. There are several different types of CT phantoms that can be used for QC testing (39-42). The procedures that will be described here are based upon use of the ACR CT Accreditation

Figure 10. Radiograph of a tomographic phantom used to assess performance of linear tomographic units.

phantom. Similarly, there are many methods by which the CT dosimetry can be performed; however, most often a specialized CT ionization chamber with 100 mm length is used. The chamber is placed in holes drilled in cylindrical acrylic phantoms with a 16 cm diameter cylindrical head and 32 cm diameter body phantom are used for this purpose.

CT NUMBER LINEARITY

The CT numbers of a computerized axial tomographic unit represent the effective linear attenuation coefficients of the various materials being analyzed. In order to be able to differentiate various kinds of body tissues, the CT scanner must be able to measure the effective linear attenuation coefficients correctly for a wide range of materials from air to compact bone, that is, the CT scanner must be able to detect small differences in the way different substances stop X-rays. Usually, the CT numbers (in Hounsfield units) represent the difference in the linear attenuation coefficients between air and water as 1000 units. The CT number linearity is determined by plotting the CT numbers for known materials (usually plastics) versus their effective linear attenuation coefficients, as published in the literature. Linear attenuation coefficients are a function of the photon energy, as well as the X-ray beam filtration. A

typical average energy for a well filtered 120 kVp X-ray beam is ~ 70 keV; this effective energy is often used for this assessment.

One section of the CT phantom contains various rods of plastic embedded in a water equivalent plastic cylinder that has a diameter of 20 cm. The rods consist of air, polyethylene, acrylic, and simulated bone. The anticipated CT numbers for these materials at 120 kVp are approximately -1000 , -95 , 120 , and 955 Hounsfield Units (HU), respectively. Water (or water equivalent plastic) has a reference value of zero. The CT numbers for the various substances are plotted against their attenuation coefficients. The linear regression fit to the data should have a correlation coefficient of >0.99 . In order to compare different types of tissue by their CT numbers, it is important to eliminate both CT number offsets and/or slope differences in the linearity scale.

CONTRAST SCALE

The contrast scale for any given CT scanner can be arbitrary. If calibrated properly, however, the CT number of air should be -1000 and the CT number of water should be zero. Compact bone should have a large positive value near $+1000$ or more. In this manner, an acceptable gray scale will be established for the various anatomical substances shown in scans of patients.

The contrast scale is the change in the effective attenuation coefficient per CT number unit. Usually, measurements are performed with reference to plexiglass and water. The contrast scale (CS) is represented by the following equation:

$$CS = \frac{\mu_{\text{plex}} - \mu_{\text{water}}}{(\text{CT No.})_{\text{plex}} - (\text{CT No.})_{\text{water}}}$$

For most CT energies, the numerator of the equation is equal to $\sim 0.024 \text{ cm}^{-1}$. The CS value should be ~ 0.0002 .

In order to determine whether the contrast scale is suitable, one must compute the anticipated CT numbers for air and compact bone based upon the contrast scale measurements.

$$(\text{CT No.})_x = \frac{\mu_x - \mu_{\text{water}}}{CS}$$

A number of references list the linear attenuation coefficients for air and compact bone. For 120 kVp, $\mu_{\text{air}} = 0.000208 \text{ cm}^{-1}$ and $\mu_{\text{bone}} = 0.414 \text{ cm}^{-1}$. For water, μ_{water} is usually taken to be 0.190 cm^{-1} . Hence, based upon the measurement of CS, the CT numbers of air, water, and bone can be estimated. Usually the CT units set air at -1000 and compact bone at $+1000$ HU. (Bone actually has a wide range of CT number values due to the various densities it may have in the human body.) A comparison of the measured values with the ideal values indicates whether the CS is satisfactory.

COMPUTER TOMOGRAPHY NOISE LEVELS

When one images a uniform material in a CT scanner, the CT numbers for a localized region should all be the same. In

practice, the CT numbers vary around some average value. The reason for these variations are changes in the X-ray output, small differences and drifts in the detectors, extraneous electronic noise, and small errors in the computer processing algorithm. All of these parameters introduce variations in the CT numbers. The variations are lumped collectively into a term called the noise of the CT system.

The noise is determined by scanning a uniform water-bath section of the CT phantom and evaluating all the different CT numbers in a small region. The mean value (X) and the standard deviation (σ) of the CT numbers are computed. The CT noise is then expressed as a percentage variation of the linear attenuation coefficient of water.

$$\% \sigma_{\text{water}} = \frac{(100 \sigma \text{CS})}{\mu_{\text{water}}}$$

The noise value should be measured at various locations in the phantom; both the average noise value for the various locations and the worst case value should be quoted (see Fig. 11).

The noise values for CT scanners are very important performance parameters. The difference in the attenuation coefficients between normal and pathological tissue is small. High CT noise values tend to obscure small tissue differences. For example, differences in the CT values between white and gray matter in the brain are $\sim 0.5\text{--}0.6\%$ relative to water (1% on most CT scanners are ~ 10 CT numbers). In fact, most body tissues have CT numbers of nearly the same value, $\pm 8\%$ (except for bone). Furthermore, the use of lower peak kilovoltages also tends to differentiate tissue better. CT noise levels for a 10 mm slice thickness with 0.50 mm pixel sizes should be below 0.5% of the linear attenuation value of water.

Figure 11. Society of Motion Picture and Television Engineers (SMPTE) test pattern for the evaluation of VDTs used with digital imaging systems.

The measured CT noise levels, however, are a function of many parameters. The noise level decreases as the radiation dose is increased. As the slice thickness is increased, the noise level decreases. The noise levels are also higher for large patients. The relationship to the various factors to the noise level is usually given as the following equation:

$$\% \sigma_{\text{water}} \propto [B/(HW^3D)]^{0.5}$$

where B is percentage attenuation, H is slice thickness, W is pixel width size, and D is patient dose per scan. In many modern CT units, the noise changes little with pixel size. CT noise is also closely related to the type of reconstruction kernel chosen. The CT noise is greater for edge enhancement kernels, and CT noise is less for smoothing kernels. To maintain quality control of the CT scanner, noise levels should be monitored on a regular basis. An increase in the noise level is indicative of a developing problem in the CT scanner.

SPATIAL UNIFORMITY

It is extremely important that the response of a CT scanner be uniform across the field being scanned. A CT scan of a uniform material should only exhibit random fluctuations due to system noise. No areas of nonuniform response nor artifacts should be appearing in the scan. This feature is tested by scanning uniform water equivalent plastic section in the CT phantom and examining the CT numbers in different portions of the image. The mean CT numbers should be the same in all portions of the scan. The difference between the average CT number in the various portions of the image should not differ by $> 2\text{--}3 \times$ values the standard deviation of the CT numbers (or ~ 10 CT numbers).

HIGH CONTRAST SPATIAL RESOLUTION (HOLE PATTERN)

One of the performance criteria of CT scanners is their ability to image small objects. The ability of the scanner to image small objects depends on the subject contrast. The CT scanners have the best spatial resolution with high subject contrast. The ability of the CT scanner to image small, high contrast objects can be measured by a section of the ACR CT phantom; this section has many plastic bars and spaces of different sizes. These bars are of vastly different CT number from the plastic in the spaces to create high contrast, spatial resolution test objects. For each set of bars, a spatial frequency in line pair per cm can be assigned. The frequency ranges from 4 to 12 line pairs per cm. The CT display window and level settings are adjusted to best display bars and spaces. The just barely discernable bar pattern is identified and recorded. It has been suggested that a scanner be capable of resolution approximately twice its smallest pixel size (for pixel-limited resolution). With a 512×512 matrix and a 25 cm FoV, the spatial resolution would be limited by pixel size to ~ 10 line pairs per cm. For small FoV, the spatial resolution is limited by factors, such as the focal spot size, detector size, and reconstruction algorithms. The modern CT units are capable of spatial resolution of $\sim 8\text{--}10$ line

pairs per cm for high contrast objects using image zoom display features.

HIGH CONTRAST SPATIAL RESOLUTION (IMPULSE RESPONSE)

Another way of determining scanner resolution is the scanning of a metal pin in a water bath. This scan will produce a point spread response function (PSF). One usually plots the numbers and draws a smooth curve. The point spread for a CT unit can usually be fit with a Gaussian function given below:

$$F(x) = A \exp[-\alpha^2(x - \epsilon)^2]$$

This equation can be rearranged in order to determine the value of α and ϵ . The modulation transfer function (MTF) can be computed directly using the value α (43).

LOW CONTRAST RESOLUTION

The CT scanner must not only be able to detect small objects with high contrast, but it must also be able to image small objects with low subject contrast. The difference between normal tissue and pathology is usually small differences in subject contrast (1–2% differences). A good CT scanner should be able to detect small low contrast lesions, that is, low contrast is more important than high contrast resolution.

In order to test low contrast resolution, CT scans are taken through a section in the phantom composed of a plastic with CT numbers only slightly different from water. This section contains various size holes of a slightly different plastic than the surrounding material. The contrast between the plastic and the water is usually 0.4–0.6%. The detectability is dependent upon the radiation dose used, but it would be desirable to have low contrast discrimination of 4–6 mm holes at 0.5–0.6% contrast.

BEAM HARDENING

X-ray beams are polychromatic. Therefore, filtration changes the X-ray spectrum and its effective energy. When CT scanner X-ray beams pass through a lot of bone or long paths through tissue, the X-ray spectrum is altered. The effective linear attenuation coefficients for these hardened X-ray beams change because attenuation is a function of X-ray energy. Therefore, the CT numbers of tissue behind extensive sections of bone may decrease appreciably due to beam hardening. These effects are highly undesirable as some tissues appear abnormal in CT number. This beam hardening artifacts in CT numbers are undesirable.

In order to evaluate beam-hardening effects, 1 in. (2.5 cm) diameter plastic rods with high attenuation coefficients are taped on the opposite sides of the surface of the water section of a CT phantom. This section is scanned, and the CT numbers along the line between the rods are measured. CT scanners should be designed in a manner that the water values are not depressed more than three times the noise standard deviation.

IMAGED CT SLICE THICKNESS

The CT image slice thickness (i.e., sensitivity profile) is measured by scanning a section of the phantom that contains small wires that are displaced along the longitudinal axis of the phantom by a 0.5 mm distance and angled. By counting the number of wires visible in the image, the image slice thickness can be assessed. The measured sensitivity slice thickness should be within ± 0.50 mm of the selected slice values.

PATIENT TABLE TOP INDEXING

It is extremely important that the patient table top moves by the selected distance, otherwise either clinical information or the patient radiation exposure is compromised. This motion is tested by taping a radiation therapy verification film to the outside surface of a cylindrical phantom. Afterward, a series of scans are taken. Each slice thickness setting should be tried; the table motion should be equal to the slice thickness. Three or more consecutive scans should be taken for each collimator setting; the table should index at least 20 mm between different slice thickness settings. Following these scans, the film is developed and examined. There should neither be gaps nor overlaps for consecutive scans. Moreover, the table motion should be accurate to within 1.0 mm for 100 mm of motion in 10 or more steps.

ARTIFACTS

Artifacts can be misinterpreted as anatomical abnormalities in patient scans. Various software and scan techniques should be used to scan the water section of the CT phantom. Since water equivalent plastic should be homogeneous, any artifacts should be clearly visible in the CT image. The various window level and width settings should be utilized to view the image.

PATIENT DOSIMETRY

A special CT ionization chamber (100 mm long) is inserted into cylindrical acrylic phantoms designed to simulate a typical head and body of a patient. The head CT phantom has a 16 cm diameter and the body phantom has a 32 cm diameter. Each phantom has holes drilled at the center and at other locations with different distances from the surface of the phantom. At least one hole is 1 cm inside the outer surface. The ionization chamber is placed in both the center hole and later at the periphery hole. Empty holes are filled with acrylic rods. A single, axial CT slice is taken in the middle of the cylinder, and the exposure measured by the ionization chamber (E_m) is recorded. The radiation dose is then computed by the following equation:

$$CTDI = (C \times f \times E_m \times 100 \text{ mm}/XW)$$

where C = calibration factor for detector, f = exposure to absorbed dose conversion factor, E_m = measure exposure, XW = X-ray beam width specified.

The f -factor for acrylic is $0.78 \text{ cGy}\cdot\text{R}^{-1}$, and the f -factor for tissue is about $0.92 \text{ cGy}\cdot\text{R}^{-1}$. The f -factor for air is $\sim 0.87 \text{ cGy}\cdot\text{R}^{-1}$. A weighted CTDI (CTDI_W) is calculated using (1/3) of the center value and (2/3) of the peripheral value.

For these data, the actual radiation dose values can be scaled using clinical setting of kVp, milliampere-second, and pitch. Pitch is the table movement between rotation of the X-ray tube divided by the width of the X-ray beam. The $\text{CTDI}_{\text{volume}}$ is equal to the CTDI_W divided by the pitch. It is recommended that the $\text{CTDI}_{\text{volume}}$ for clinical head CT scans of patients be $<6.0 \text{ cGy}$ (rad) and that the body value is $<3.5 \text{ cGy}$ (rad).

FILM PROCESSORS

Because the film processing affects the end product of film-screen radiographic images, this is one of the most important aspects of the QC program for diagnostic radiology. Film processing conditions can affect film contrast, the speed of the film-screen system, and base plus fog levels. Indirectly, inadequate processing usually causes the technologist to alter kilovoltage or mAs that could result in an increased dose to the patient.

In general, a 1°F (0.6°C) temperature change in the developer chemistry produces a $0.03\text{--}0.07$ density change in the developed radiograph. The film density decreases for a decrease in the developer temperature. For an $8\text{--}18^\circ\text{F}$ ($4.4\text{--}10^\circ\text{C}$) decrease in the developer temperature, a 50% increase in the patient exposure is necessary. Similarly, increasing the developer temperature by 5°F (2.8°C) can cause a latitude film to appear to have increased contrast. Contamination of the processing chemistry also causes changes in the film density and contrast. The magnitude of the effects are dependent on the type of film, the kind of chemistry, and the processor design.

In order to maintain consistency in the film development, a routine maintenance program for the processor should be established. The replenishment rates should be adjusted properly for the workload. The rollers should be cleaned and inspected on a regular basis and the chemistry should be changed as required. Moreover, steps should be taken to minimize inconsistencies in the chemistry. Within reason, all processors should operate from the same batch of fixer and developer; this can be accomplished by mixing large batches for delivery or using electronic mixers with modular chemistry canisters.

The QC program for processors should utilize daily sensitometry strips that are run through each processor (44). In conjunction with the sensitometry, the processor replenishment rates and temperatures should be checked. Light sensitometers are recommended for making the sensitometry strips (45,46) (see Fig. 12). The film used for sensitometry should be the fastest high contrast film routinely used in the facility. Since variations can be found in different film emissions batches of the same kind of film, strips from both old and new emulsion batches should be run simultaneously during transition periods. The processed sensitometry strips should have the densities measured with a densitometer. A sensitometer step

Figure 12. A reproduction of a developed sensitometry strip that is used to evaluate processor performance. The steps used for speed point and contrast index are shown on the strip.

with a density ~ 1.0 du above the base plus fog level should be selected as the speed point. The difference in densities of two points in the linear portion of the characteristic curve should be used to determine a contrast index. The base plus fog level on the sensitometry strips should also be measured. These three parameters should be compared to optimal values supplied by the film manufacturer and average values should be established for the facility. The speed point should not be allowed to change by more than ± 0.15 du about the average value. The contrast index should not change more than ± 0.15 units. Since the base plus fog is not very sensitive to variations, a small change is indicative of significant abnormalities in the processing. With good maintenance and QC procedures, the film processors should be very stable and consistent.

DIGITAL IMAGE RECEPTORS

Digital image receptors could be either CR Cassettes with their electronic readers or DR image receptors (47). With both systems, a QC program should be routinely implemented to ensure consistency, identify artifacts and evaluate physicians display monitor (48). Most CR and DR

Figure 13. Radiographic image of an ACR Mammography phantom showing fibrils, calcium, speck group, and simulated masses.

systems have an index number to ensure sufficient radiation is utilized to avoid excessive quantum mottle. The QC program should assess that the AEC is properly adjusted to maintain proper radiation exposure. For CR systems, cassette should be exposed to measure spatial linearity, spatial resolution, uniformity of density and proper size and collimation. Both CR and DR units should be evaluated for artifacts and dirt. The physicians' review video monitor should be checked with a video pattern such as the SMPTE (Society of Motion Picture & Television Engineers) for low contrast visibility, spatial linearity, spatial resolution and a reasonable contrast scale. A light meter can then be employed to ensure that maximum luminance and contrast scale are adjusted similarly on all video monitors (Fig. 13).

SUMMARY

There are numerous reasons for providing a QC program in diagnostic radiology. Quality control is mandated by several regulatory agencies; hence a radiology facility must demonstrate that some type of QC is being performed. Another reason for QC programs is to ensure electrical, mechanical and radiation safety for patients and staff. Moreover, the QC program should provide better image quality and a consistency in the radiographs. Finally, the QC program should result in financial savings and improved equipment performance.

The effectiveness of the QC program will depend on the extent of testing performed. A cursory QC program is usually conducted to just meet minimum regulatory requirements. A more extensive program will attempt to establish and maintain a high standard for equipment performance.

Because of the diversity in the diagnostic equipment, the QC program should be directed toward evaluating the special features of each type of equipment. Hence, there are

many specialized aspects to QC testing. Although other testing could be used to supplement and strengthen the QC procedures described, the information given in this article provides a basis for establishing an effective QC program for diagnostic radiology equipment.

X-RAY THERAPY EQUIPMENT, LOW AND MEDIUM ENERGY

C-M CHARLIE MA
Fox Chase Cancer Center
Philadelphia, Pennsylvania

INTRODUCTION

X-rays were used to treat cancer patients within a year of their discovery by Wilhelm Roentgen in November 1895 (1). However, it was not until the invention of the hot cathode tube by Coolidge in 1913 that X-ray beams could be delivered in a stable manner and, hence, the output controlled and measured with any precision. Further improvements in the accuracy of X-ray beam dosimetry occurred with the publication of the first central-axis depth dose tables in 1922 (2) and with the definition of the Roentgen and its use as a standard unit for X-ray dosage in 1928 as recommended by the Second International Congress of Radiology in Stockholm, Sweden.

In those early years, the energy of X-ray beams was limited to 140 kV, and therefore only relatively superficial lesions could be successfully treated. The situation was improved in the early 1920s as higher energy (up to 400 kV) X-ray units became available to permit the treatment of deep-seated lesions (3). Since cobalt-60 treatment units (average γ -ray energy = 1.25 MeV) came into use in the late 1950s and electron linear accelerators capable of producing high energy (≥ 4 MeV), X rays in the early 1960s, the use of kilovoltage X-rays in radiation therapy has drastically declined for deep-seated tumors.

The use of low energy X rays for the treatment of superficial lesions is still popular, even though the use of electrons has replaced them for treating such lesions in

many cancer clinics. Electron beams have finite ranges that are ideal for treating shallow tumors to spare distal normal tissues. However, clinical accelerators that produce electron beams for radiation therapy are more expensive than X-ray units. There is an increased use of low energy X-rays for intraoperative radiation therapy, such as for stereotactic brain irradiation or treatment of the dura, for endocavitary irradiation of rectal cancers, and treatment of other malignant skin lesions. The depth-dose properties of X-rays are considered by some oncologists to be more favorable than electron beams for adequate surface coverage and for treating macroscopic diseases at depths. Medium energy X-rays still play a role in many developing countries, where the technology is easier to support and maintain than electron linear accelerators and safer than cobalt-60 teletherapy units. Medium energy X-rays are also widely used in radiation biology research for *in vitro* cell irradiation or *in vivo* animal experiments.

X-RAY DEVICES FOR RADIATION THERAPY

Medium energy X-rays (also called *orthovoltage* X-rays) are generated by X-ray devices at an accelerating potential between 150 and 500 kV. Low energy X-rays (also called *superficial* X-rays) are generated by X-ray devices at an accelerating potential between 50 and 150 kV. Very low energy X-rays that are generated at an accelerating potential <50 kV have mainly been used in *contact* therapy.

The manner in which X-rays are generated is similar between therapeutic and diagnostic X-rays. Electrons emitted from a heated filament are accelerated in an evacuated tube onto a tungsten anode (also called target), producing bremsstrahlung photons with peak energy up to the accelerating voltage. Because of the intended applications, however, therapeutic and diagnostic X-ray tubes have some very different design features as discussed below.

One difference is the target design for heat dissipation. Diagnostic tubes are generally run for shorter times (from

a fraction of a second to several seconds) at high current (up to 500 mA) leading to high instantaneous rates of heat production. Tungsten is used as the target material since it has a high melting point (3370°C). In addition, rotating targets are used in diagnostic tubes to spread the heat deposition over a large area, thereby increasing the maximum permissible loading of the tube. Therapeutic tubes are often run for longer times (several minutes being common) at relatively low currents (5–30 mA). The instantaneous rate of heat production is low for therapeutic tubes, but the total amount of heat generated during a therapy session can be quite high. Therefore, therapeutic tubes use stationary targets that can be cooled by oil or water. The target is often made of tungsten and is mounted on a massive copper stem that serves as a good heat conductor.

The second difference is the target angle, which effectively defines the X-ray source size. Small target angles in the range of $6\text{--}20^{\circ}$ are used in diagnostic tubes in order to produce small focal spots that will result in a small geometric penumbra of the image. In therapeutic tubes, however, geometric penumbra is not of primary concern. Therefore, therapeutic tubes can use larger target angles in order to produce radiation beams with large field sizes (up to 20×20 cm) at target-to-surface distances (SSD) that are usually much shorter than the SSDs employed in diagnostic tubes. The resultant X-ray source size of a therapeutic tube may be as large as 1.0 cm in diameter.

Another difference is the target shielding for secondary electrons. For therapeutic tubes running at an accelerating potential >200 kV, damages to the tube may result if secondary electrons from the target are allowed to reach the glass envelope. The target in a therapeutic tube is often surrounded by a double-layered shield as shown in Fig. 1 (4). The inner layer is made of copper that stops most electrons while its low atomic number ($Z = 29$) minimizes bremsstrahlung production. The outer layer is made of tungsten ($Z = 74$), which absorbs most stray bremsstrahlung photons produced in the copper layer. A thin beryllium ($Z = 4$) window in the shield below the target absorbs most secondary electrons, but allows the useful X-ray beam

Figure 1. An X-ray tube for radiation therapy constructed with a hooded anode design.

to pass through with little attenuation. This type of shielding design for therapeutic tubes is called a hooded anode. The X-ray tube is enclosed in an oil shield that serves two purposes: (a) to cool the tube and (b) to attenuate stray X rays.

Many major manufacturers have ceased manufacturing kilovoltage X-ray therapy units (5). The three currently available orthovoltage treatment units are Therapax DXT300 manufactured by Pantak, Inc. (East Haven, CN) and Gulmay D3300 and Gulmay D3225 manufactured by Gulmay Medical Ltd. (Mississauga, ON). The same two vendors also produce two superficial therapy units, Therapax HF 150 and Gulmay D2000. Some kilovoltage units are no longer available, but are still in wide use, such as the Philips RT-250 and RT-305 units and the Siemens Stablipan. The most popular contact unit still in clinical use is the Philips RT-50, formerly manufactured by Philips Medical Systems (Shelton, CN). A new, and novel, contact therapy device available is the Photon Radiosurgery System, Model PRS400, manufactured by Photoelectron Corp. (Lexington, MA).

Orthovoltage Units

Most orthovoltage units operate at 200–300 kV with a tube current of 10–20 mA and have various filters to provide beams with half value layers (HVL) between 1 and 4 mm Cu. The X-ray generators used in these units may be single phase, that is, self-rectified or half-wave rectified, or may employ a Villard-type voltage-doubling circuit or a constant potential circuit (6). The constant potential circuit maintains the accelerating potential at a nearly constant value so that X rays can be produced continuously rather than in pulses. This type of circuit allows for treatments at a shorter treatment time with a higher average X-ray energy.

The energy absorbed by the anode of an X-ray tube is proportional to the product of tube current, accelerating potential, and operating time. For orthovoltage units, which may be operated continuously at high tube voltages, the anode must be cooled efficiently. The copper anodes of orthovoltage units are usually massive to serve as heat conductors. Oil circulated cooling is used instead of water circulated cooling, as shown in Fig. 2 (7), where a hollowed-out anode

Figure 2. The anode of an orthovoltage X-ray tube. The back of the anode is hollowed out to permit oil circulation.

Figure 3. The Therapax DXT300 orthovoltage unit manufactured by Pantak.

provides efficient oil circulation for heat dissipation. The oil then flows through a reservoir where heat is removed by either circulating water or forced-air cooling. Orthovoltage units usually require a warm-up time of several minutes, which allows the tube potential to increase gradually in order to minimize the strain of high voltage on the tube.

Figure 3 shows a currently available microprocessor-controlled orthovoltage treatment unit, Therapax DXT300 (5). This unit features a dual channel dosimetry system in which the primary means of termination of treatment dose can be either a timer or the integrated signal from a transmission ionization chamber. It features a metal ceramic tube, a control panel that incorporates microprocessor technology, a Diamentor dose monitor, and a Cockcroft–Walton multiplier generator that gives a very stable output. The unit can be ceiling or stand mounted. The Therapax DXT300 unit offers energies and filtrations from 300 kV (3 mm Cu) down to 30 kV (0.1 mm Al). The treatment field shape and size can be defined by a variable collimator (rectangular or square fields up to 20 cm × 20 cm defined at 50 cm SSD) or by fixed square or circular cone-type applicators: open-ended cones (30 cm SSD) or close-ended cones (50 cm SSD).

Superficial Units

Superficial units operate at an accelerating potential 50–150 kV with a tube current 5–15 mA. The X-ray generators in these units are generally half-wave rectified. The X-ray tube has a hooded anode and is enclosed in an oil shield that is constructed with expansion bellows to allow oil to expand as temperature increases. Superficial units may also operate continuously for long treatment times, and therefore require additional cooling in parallel to heat conduction by the copper anode stem and

Figure 4. The cooling system for superficial X-ray tubes. Water circulates through the pipe N–N' to remove the heat from the oil.

convection and absorption by the oil shield. Figure 4 shows a cooling system that employs circulating water to remove heat from the oil continuously (7).

Orthovoltage tubes can also produce X-ray beams in the superficial energy range with matching HVLs. The principal difference between a superficial unit and an orthovoltage unit is that a superficial unit typically has shorter SSD cone applications and, consequently, higher dose rates (5). For example, the Therapax HF150 (Fig. 5) is the companion device to Therapax DXT300 and produces X rays in the range 20–150 kV with HVLs from 0.1 to 10.78 mm Al. The DXT300 can also produce X rays down to 30 kV with an HVL of 0.1 mm Al. The HF150 has 15 cm SSD cone applicators while the DXT300 has 30 and 50 cm SSD cone applicators.

Figure 5. The Therapax HF150 superficial unit manufactured by Pantak.

Contact Units

Both orthovoltage and superficial units can produce X-ray beams in the contact X ray range with complete overlap of available energies and HVLs. The Philips RT-50 unit is strictly a contact therapy unit, operating at energies between 10 and 50 kV. This unit has a slim, long body measuring 43 cm in length and 6 cm in diameter, tapering down to 3 cm at the tip. The SSD is only 4 cm and its dose rate in air is up to $20 \text{ Gy} \cdot \text{min}^{-1}$. These features make it especially suitable for endocavitary irradiation (e.g., for treating rectal cancers).

The Photon Radiosurgery System (PRS) is a special treatment unit (Fig. 6) consisting of an X-ray source, a control console, and associated calibration devices (8). The X-ray source is small, measuring $17.5 \times 11 \times 7 \text{ cm}$ and weighing 1.6 kg, with X rays being produced at the tip of a 10 cm long, 3.2 mm diameter probe. A plastic, biocompatible sheath covers the probe tip to avoid direct tissue contact when used interstitially. The X-ray energy can be 30, 40, or 50 kV with a tube current of 5, 10, 20, or 40 μA . The whole unit is small enough to be hand-held, though it is designed to work in conjunction with a conventional stereotactic head frame. The system has a built-in internal radiation monitor to measure the output of the beam and to determine the length of the treatment. Additional monitors include a timer and an external radiation monitor that has to be calibrated at the start of each treatment since its output is geometry dependent. Other dosimetry devices are provided to measure the isotropy of the beam, the straightness of the probe, and the relative in-air output of the beam during routine calibration and in the operating room immediately prior to the procedure.

X-RAY BEAM QUALITY

X-ray beams with different energy spectra will differ in their ability to penetrate in a medium such as tissue. The quality of an X-ray beam refers to its penetrating power, with high beam quality indicating deeper penetration. The exact knowledge of beam quality plays an important role in clinical radiotherapy to ensure proper treatment target coverage and adequate skin sparing. It is desirable to use more than one beam quality parameter to specify an X-ray beam (9). The usual quantities used are the accelerating potential and the HVL. However, most dosimetric data for kilovoltage X rays have been given using one beam quality parameter, usually HVL.

The peak voltage across the X-ray tube determines the maximum photon energy in an X-ray spectrum. The accelerating potential is expressed in kilovolts for a kilovoltage X-ray beam to indicate that the X-ray beam actually has an energy spectrum with its maximum energy up to its accelerating potential. Higher accelerating potentials produce more penetrating X-rays and, therefore have a direct effect on the beam quality.

The HVL is defined as the thickness of an absorber that reduces the air kerma rate of a narrow unidirectional X-ray beam at a point distant from the absorber to 50% of that of the nonattenuated beam (9). For orthovoltage X rays, both aluminum (Al) and copper (Cu) can be used as the

Figure 6. A schematic diagram showing the Photon Radiosurgery System for interstitial treatment.

absorbing material for the determination of HVL although Cu is more frequently used. The beam quality is expressed in mm Al or mm Cu. For superficial and contact X-ray beams, only mm Al is used to express HVL.

The HVL is measured using an ionization chamber with a narrow beam setup, in which a collimating aperture is placed half-way between the X-ray target and the measurement chamber. The field size is reduced just enough to encompass the chamber. The absorbing materials are placed at least 50 cm from the measurement chamber and close to the collimating aperture. The absorber should be made of high purity material and the thickness of the absorber should be measured accurately. The thickness that reduces the air kerma value to one-half is obtained by interpolation. A monitor detector is used to correct fluctuations of air kerma rate. The measurement chamber must have limited beam quality dependence (within 5% between 40–300 kV) for accurate HVL measurements. Thin-walled chambers are used for lightly filtered beams to measure the low energy X-ray components accurately (HVL errors of up to 10% were observed for a lightly filtered 100 kV beam using a Farmer-type cylindrical chamber).

DOSIMETRY CALIBRATION

Methodology

For kilovoltage X-ray beams, the absorbed dose to water is usually determined with an ionization chamber calibrated in air in terms of either exposure or air kerma. The commonly used ionization chambers are generally considered to be “photon detectors” as the well-known Bragg-Gray cavity theory no longer applies to this energy range (10). To determine the dose to water, the measured air kerma is converted to water kerma using the ratio of mass energy absorption coefficients for water to air, evaluated using the energy spectrum at the position of interest. The dose to water is considered to be the same as water kerma for this energy range due to the negligible difference between kerma and collision kerma (electrons have very small ranges) assuming that quasicharged particle equi-

librium exists. This is generally true for measurement points at depths equal to or greater than the depth of maximum dose for kilovoltage X rays.

Two different methods have been recommended for kilovoltage X-ray dosimetry calibration by national and international dosimetry protocols (11–14). The in-air method measures the air kerma free in air and then converts it to dose to water with the ratio of mass energy absorption coefficients for water to air and a backscatter factor. The in-phantom method measures the air kerma at the reference depth in water under reference conditions and then converts it to the absorbed dose at the depth of the center of the chamber in undisturbed water using the ratio of mass energy absorption coefficients for water to air and other beam quality- and chamber-dependent correction factors.

The ICRU Report 23 was the first to recommend the in-phantom method for orthovoltage X-ray beams since it was difficult to make accurate measurements in regions at or close to the surface of a phantom, and the dose distribution there, unlike at greater depths, was considerably affected by the details of the beam collimation system (11). For this reason, the *British Journal of Radiology Supplement 11* gave two distinct sets of depth-dose tables for close-ended applicators and open diaphragms, respectively (15). It was also clear that by normalizing the depth-dose curves at a depth rather than at the surface the differences in the recommended depth-dose curves would be virtually eliminated. The dose values at greater depths were more clinically relevant since orthovoltage X-ray beams were primarily used for treating deep-seated tumors in the 1970s.

Several more recent dosimetry protocols still recommended the in-phantom method for reference dosimetry for orthovoltage X-ray beams, but used a reference depth of 2 rather than 5 cm (12–14). This was aimed at reducing the measurement uncertainty at lower X-ray energies. However, the in-air method has been the commonly used method for the whole kilovoltage energy range in clinical radiotherapy, especially in North America (16). This may be explained by the fact that nowadays orthovoltage beams

are mainly used for treating tumors close to the skin. The primary point of interest is the dose near the surface rather than at greater depths. Another reason is that it is more convenient to perform routine beam calibration free in air than in a water phantom.

The American Association of Physicists in Medicine (AAPM) recommended that both methods be used for absorbed dose determination for orthovoltage X-ray beams depending on the measurement point of interest (9). To improve measurement accuracy, the in-air method should be used if the primary point of interest is at the phantom surface. On the other hand, if one is more interested in the dose at large depths than at the surface, the in-phantom method should be used. Better agreement in measured PDD curves at depth = 1 cm and greater can be achieved when they are normalized to the values at the 2 cm reference depth than normalized to the surface values. The AAPM recommended that only the in-air method be used for superficial X-ray beam dosimetry (9).

Measurement Equipment

Phantoms. Water is the recommended phantom material when the in-phantom method is used in orthovoltage X-ray beam dosimetry (9). Conversion factors are used to convert from the air kerma in the sensitive chamber cavity to the dose to water. Plastic phantoms are not recommended for in-phantom reference dosimetry for orthovoltage X rays as the chamber correction factors and conversion factors to derive dose at a depth in water for these phantoms are poorly known. Some water equivalent plastics are commercially available for orthovoltage X-ray measurements. However, their properties must be investigated before they can be used as water substitutes.

Dosimeters. Air-filled ionization chambers are recommended for kilovoltage X-ray beam reference dosimetry (9). Measurements for orthovoltage X rays are performed either free in air (in cases where the surface dose is the primary concern) or at a 2 cm depth in water (dose at greater depths is the primary concern). Cylindrical chambers that have a calibration factor varying with the beam quality by <3% in this energy range are recommended for the beam output measurement. For superficial X rays, only the in-air method is used. Cylindrical chambers that have a calibration factor varying with the beam quality by <5% between 50 and 150 kV are recommended. Extensive studies have been carried out on the correction factors for the commonly used Farmer-type chambers for the in-phantom measurement (16–21). Other cylindrical chambers may also be used. However, correction factors must then be determined by comparing these chambers with a chamber with known correction factors. If measurements are performed in water, a thin waterproofing sleeve should be used and appropriate correction factors should be applied depending on the material and thickness used. If measurements are made in air, the thimbles of cylindrical chambers are thick enough, so no build-up cap is required. For X-ray energies <70 kV, calibrated parallel-plate chambers with a thin entrance window are recommended. Thin plastic build-up foils should be added to the entrance window, if

Table 1. Thickness of Build-Up Material for Thin Window Parallel-Plate Chambers Used for In-Air Calibrations with X-Ray Energy <100 kV

Generating Potential, kV	Thickness of Foil, mg cm ⁻²

80	6.6
90	8.7
100	10.9

necessary, to provide full electron buildup and to eliminate electron contamination (see Table 1). All measurements should be corrected for temperature, pressure, ion recombination, and polarity effect.

Electrometers. Electrometers for kilovoltage X-ray therapy measurements should be capable of reading currents on the order of 0.1 nA, with an accumulated charge of 50–100 nC. They are calibrated by a standards laboratory with proper correction factors applied in the measurement. These correction factors are generally close to 1.000; but can occasionally be 5% different from 1.000. Electrometers and ionization chambers can be calibrated either together or sometimes separately and if so their calibration factors must be combined.

Detector Calibration

Modern dosimetry protocols for kilovoltage X rays are based on the air kerma, K_{air} , which is defined as the kinetic energy, ΔE , transferred from X rays to charged particles per unit air mass, Δm (i.e., $K_{\text{air}} = \Delta E/\Delta m$). Assuming that K_{air} is the air kerma at the reference point in air for a given beam quality and M the reading (corrected for temperature, pressure, recombination, and polarity effect) of an ionization chamber to be calibrated with its center at the same point, the air kerma calibration factor, N_K , for this chamber at the specified beam quality is defined as

$$N_K = \frac{K_{\text{air}}}{M} \quad (1)$$

Previous dosimetry protocols for kilovoltage X rays were based on the exposure, X , which is defined as the total electric charge, ΔQ , of all ions of one sign (e.g., electrons), produced in air by X rays in a unit mass of air, Δm (i.e., $X = \Delta Q/\Delta m$). A similar equation can be used to derive the exposure calibration factor, N_X :

$$N_X = \frac{X}{M} \quad (2)$$

The relation between the air kerma calibration factor and the previous exposure calibration factor is given by

$$N_K = N_X \left(\frac{W}{e} \right)_{\text{air}} (1 - g)^{-1} \quad (3)$$

where $(W/e)_{\text{air}}$ has the value 33.97 J/C (or 0.876 cGy·R⁻¹) for dry air, $(1 - g)$ corrects for the effect of radiative losses by charged particles to bremsstrahlung photons (g is the

fractional energy lost to bremsstrahlung photons in air, which is practically zero for X-ray beams below 300 kV).

The N_K or N_X factors can be obtained from a standards laboratory for a number of available X-ray beam qualities to match the beam energies in a clinic. In the calculation of dose to a patient for a kilovoltage X-ray beam, the accuracy of the chamber calibration determines the final accuracy. Each chamber involved in reference dosimetry of the clinical kilovoltage setup should be calibrated, since there can be up to 8% differences between the calibration factor, N_K , for different chambers of the same type. In addition, each chamber should be calibrated at a number of beam qualities to determine the energy dependence of its response. One generally expects this energy dependence to be at most 6% between 40 and 300 kV for well-designed chambers.

Determination of Absorbed Dose

Formalism for the In-Air Method. The in-air method can be used for both superficial and orthovoltage X-ray dose determination. If the point of interest is at the phantom surface the in-air method is more accurate than the in-phantom method. In this method, the measurement is performed with the chamber free in air and the dose to water at the phantom surface (theoretically, this only applies for depths beyond the range of the contaminant electrons and where quasicharged particle equilibrium has been established) can be calculated by

$$D_w = MN_K \left(\frac{\bar{\mu}_{en}}{\rho} \right)_{air}^w B_w P_{stem,air} \tag{4}$$

where M is the corrected ionization chamber reading, N_K the chamber air kerma calibration factor at the user’s beam quality, $(\bar{\mu}_{en}/\rho)_{air}^w$ the ratio of mass energy absorption coefficients for water to air, evaluated over the X-ray energy spectrum free-in-air, in the absence of a phantom, B_w the backscatter factor that accounts for the effect of the phantom (water) scatter, and $P_{stem,air}$ the chamber stem correction factor that accounts for the change in photon scatter from the chamber stem between the calibration and measurement (mainly due to the change in field size). Here, $(\bar{\mu}_{en}/\rho)_{air}^w$ is independent of the field size used since it is evaluated over the primary beam only (22). The AAPM recommended values of $(\bar{\mu}_{en}/\rho)_{air}^w$ and B_w for some typical beam qualities are given in Tables 2 and 3 (taken from Ref. (9)). The parameter $P_{stem,air}$ is taken as unity for a calibrated chamber if, for a given beam quality, the same field size is used in the calibration and the measurement. Otherwise, the $P_{stem,air}$ factor can be measured by inter-comparing the chamber with unknown $P_{stem,air}$ with a reference chamber for which $P_{stem,air}$ is known (9). A Farmer-type cylindrical chamber with flat response can be used as a reference chamber for the measurement of $P_{stem,air}$ of another chamber since its stem effect varies little with field size (<1%).

Formalism for the In-Phantom Method. For orthovoltage X rays, the in-phantom method is recommended (9) if the point of interest is at a depth in the patient. For the 2 cm reference depth in water the dose to water for orthovoltage

X rays can be calculated using

$$D_w = MN_K P_{Q, cham} P_{sheath} \left(\frac{\bar{\mu}_{en}}{\rho} \right)_{air}^w \tag{5}$$

where M is the corrected ionization chamber reading, N_K the chamber air kerma calibration factor at the user’s beam quality, and $(\bar{\mu}_{en}/\rho)_{air}^w$ the ratio of mass energy absorption coefficients for water to air, evaluated over the X-ray energy fluence at 2 cm depth in water, in the absence of the chamber. The overall chamber correction factor $P_{Q, cham}$ accounts for the effect of the change in chamber response due to photon energy and angular variation between chamber calibration in air and measurement in water, the effect of chamber stem between calibration in air and measurement in water and the effect of displacement of water by the chamber in the measurement in water. The sheath correction factor P_{sheath} is needed when a waterproofing sheath is used (23), which is not directly related to the individual chamber type. The values of $P_{Q, cham}$, P_{sheath} and $(\bar{\mu}_{en}/\rho)_{air}^w$ for some typical beam qualities are given in Tables 4–6. The values were taken from Ref. 9.

CLINICAL DOSIMETRY

Percentage Depth Dose

Percentage depth dose (PDD) and lateral dose profiles are difficult to measure for kilovoltage X rays because of the significant variation of X-ray energy (especially for lightly filtered beams) and angular distribution with depth and field size. Detectors for the PDD and dose profile measurement should have high spatial resolution and constant energy and angular response. Solid detectors, attractive because of the small size of their sensitive volume (diode detector, TLD, film), usually show significant beam quality

dependence or large experimental uncertainties. Well-designed cylindrical chambers have nearly constant energy response in this beam quality range and are suitable for in-phantom measurements. However, the mea-

surement depth is limited to no less than the outer radius of the chamber. Parallel-plate chambers have been used for measurements at smaller depths. Those chambers designed for electron beams usually have a calibration

5.0	20.3	1.105

factor varying with beam quality by 20–40% for kilovoltage X rays. Significant corrections with depth may be required for the PDD measurement with these chambers. Specifically designed parallel-plate chambers for low energy X rays usually have a flat energy response in air but not at a depth in a phantom. For example, >10% variations in chamber response have been observed for the Capintec PS-033 chambers. Thus, a depth-related correction factor may be required for these chambers to be used in accurate PDD measurements.

The suitability of X-ray detectors for relative dosimetry measurement has been evaluated extensively (16,24,25). As a general requirement for the evaluation of a specific detector, the relative in-air chamber response and the relative in-phantom response should be compared with a well-behaved cylindrical chamber at depths, where reasonable measurements with the cylindrical chamber can be performed. Diamond detectors and the NACP parallel plate chamber (type) have been found to require relatively small depth-dependent correction factors for orthovoltage X-ray beams (16).

Care must be exercised in the measurement of PDD and dose profiles for kilovoltage X-ray beams because of their significant depth and field size dependence. A water tank with a small-volume scanning ionization chamber is ideal for the PDD and profile measurement. A monitor chamber is often needed to eliminate the effect of erratic fluctuations in dose rate. If a thin window parallel plate chamber is used, the chamber must have sufficient buildup material placed over its entrance window (see Table 1). Because of the finite size of the ionization chamber in the beam direction, it is necessary to extrapolate the dose to the surface. Since the dose distribution may be nonlinear near the phantom surface, caution should be exercised in extrapolating over the last few millimeters (24,25).

If desired, the depth-dose distribution can be measured by placing thin sheets of water-equivalent material over

5.0	20.9	1.000	1.000	1.000	1.000

^aThe data applies to 2 cm depth in water and a 100 cm² field.

the chamber in a phantom and moving the chamber back by the same amount to maintain a constant SSD. The water-equivalence of the material in the energy range of interest must be verified. The Poly (methyl methacrylate) (PMMA) is not suitable for this purpose. Strictly speaking, an ion chamber measures the depth-ionization distribution rather than the depth-dose distribution. However, the difference between them is small (16). If a suitable detector for relative dosimetry cannot be identified in the clinic it is recommended to use the data from the *British Journal of Radiology Supplement 25* (26) or published data that match the kV and HVL values of the user's beams (27–31).

Output Factors

Output factors are required for all combinations of SSD and field size used for kilovoltage X-ray treatment. The output factor is defined as the surface dose value for a given SSD and field size relative to that under the reference conditions. Since the scatter contribution from the inside of a cone applicator may be significant, it is not sufficiently accurate to estimate output factors for different applicators using the ratio of the backscatter factors corresponding to the respective field sizes. The output factor for each individual applicator must be measured at each beam quality. If the in-phantom calibration method has been used for orthovoltage X rays it is necessary to obtain the PDD in order to determine the dose at the surface. Note that this may result in large uncertainties in the output factors since the uncertainties are generally high in the PDD values near the surface.

Isodose Curves

Isodose curves are obtained by joining together the points, which have the same dose values. This can be done using the depth dose and lateral profile data if they already exist. A water tank with a small volume ionization chamber is recommended for the dose distribution measurement. A monitor chamber is needed to eliminate the effect of dose rate fluctuations. Dose values at various depths across the beam are measured and the points of equal dose are connected to give the isodose curves. Published dose distributions may be used as reference if a suitable detector for relative dosimetry cannot be identified in the clinic. However, the published data must have the same kV and HVL values as those of the clinical beams.

Quality Assurance

A well-established quality assurance (QA) program will ensure the safe and accurate delivery of radiation therapy treatments using kilovoltage X rays. The safe delivery of radiation therapy is ensured by machine interlocks and strategically placed emergency-off buttons. Accurate delivery of radiation treatment is ensured by maintaining the mechanical accuracy within the specification of treatment unit, maintaining the beam quality in its original condition, and maintaining the accuracy of dosimetry calculation and measurements for treatment planning and plan verification. All dosimetry data and mechanical

limits are established during the initial machine commissioning period before the system is first used for treating a patient and thereafter annually, or after any change which may significantly alter the dosimetry data and the mechanical limits. Once the baseline is established, maintaining the baseline data becomes the mission of the dosimetry QA program. Documentation for each full yearly calibration is maintained for 5 years after the completion of calibration. Documentation of weekly and monthly spot check measurements is maintained for 2 years.

The test frequency of each mechanical component and dosimetry data for a treatment machine is determined by the significance of the tests that indicate beam dosimetry changes and mechanical tolerance changes within the limited amount of time. Unlike clinical linear accelerators, the number of combinations of energy and filter for a kilovoltage X-ray machine are high, but only a few combinations are used on a routine basis. The number of patients that are treated using kilovoltage X-ray beams are much less than for megavoltage radiotherapy. Therefore, the check of the beam dosimetry should depend on the frequency of the beam usage. The dosimetry QA items and their frequencies are summarized below:

Daily Checks.

- Beam output constancy for energy and filter combinations in use.
- Functionality of the audiovisual monitor.
- Door and energy interlock circuits and emergency stops.

Monthly Checks.

- Items included in the daily checks.
- Beam flatness and symmetry.
- Timer operation.
- Light-radiation congruence.

Annual Checks.

- Items included in the monthly checks.
- Dose rate for all energy and filter combinations.
- Output factors for each of the applicator (cone).
- Timer accuracy (verification of the timer error).
- Accuracy of the light localizer system.
- Accuracy of distance measuring devices.
- Beam quality.
- Accuracy of depth dose data and isodose charts.
- Accuracy of field size dependence data.
- Agreement of dose rate with distance from target.
- Attenuation in lead for patient block thickness.

X-RAYS: INTERACTION WITH MATTER

ANIL SETHI
Department of Radiation
Oncology Loyola University
Medical Center
Maywood, Illinois

INTRODUCTION

X-ray interaction with matter forms the backbone of medical physics. The basic interaction and its applications can be found in many subfields of medical physics. Some of the more common examples are applications in diagnosis and treatment of cancer, shielding design of accelerators, radiation detectors, biological response to radiation, and radiation protection. A thorough understanding of the interaction process is therefore mandatory to appreciate many exciting phenomena encountered in medical physics. Although the title of this article refers to X-ray interaction with a medium, the physics of the process applies equally well to gamma (γ) rays. Furthermore, in this article, all electromagnetic radiation is referred to as photons regardless of whether their origin is atomic (X rays) or nuclear (γ rays). How a given photon will interact with matter depends on the energy of the photon and not on its birth-place.

When a beam of X rays passes through the medium, it undergoes attenuation or loss of intensity. In other words, some photons are removed from the beam. This attenuation may be due to either absorption or scattering of photons by the medium. In absorption, the energy of the photon is completely transferred to the atoms, whereas in scattering, the X-ray beam undergoes a change in direction that may be accompanied by a change in its energy. In both absorption and scattering, the net result is the transfer of energy to the medium. The amount of energy deposited per unit mass of the medium is called dose (measured in the SI

unit, gray, $1 \text{ Gy} = 100 \text{ cGy}$), which is an important quantity in radiotherapy applications. How much energy will be transferred to the medium depends on the medium composition and the energy of X rays.

X-ray energy transfer to the medium is a two-step process. First, incident photons interact with the medium and release electrons. Next, in traveling through the medium, these electrons lose their energy via excitation or ionization of atoms. Therefore, photons are labeled as “indirectly ionizing” radiation, in contrast to charged particles, such as, electrons that are “directly ionizing.” It is the latter that act as a vehicle for photon energy transfer to the medium. If the electrons have sufficient energy, they may also eject secondary electrons from atoms that form their own tracks known as δ rays.

MODES OF PHOTON INTERACTION

A photon can interact with the medium in any one of several competing but independent processes. The main modes of interaction are as follows:

1. Coherent (or Rayleigh) scattering
2. Photoelectric effect
3. Compton scattering
4. Pair production or triplet production
5. Photodisintegration

Each of the above processes is characterized by the photon interacting with a different subatomic particle in the medium. For example, the photon interaction may be with the entire atom (as in photoelectric effect, coherent scattering), atomic electrons (Compton scattering), atomic nucleus (photodisintegration), electric field of electrons (triplet production), or nuclear field (pair production). As a result, the photon may undergo elastic (coherent) scattering, inelastic (incoherent) scattering, or complete absorption. For a beam of photons emanating from a linear accelerator and having a mixture of energies (polyenergetic beam), all of these interactions may be taking place simultaneously. Which interaction process will dominate and govern the fate of most photons in the beam depends on the energy of photons and the type (atomic number, Z) of attenuating material.

The interaction processes listed above are in an increasing order of importance as the photon energy increases. For example, coherent scattering is the most important interaction at very low photon energies, whereas photodisintegration occurs only at very high photon energies. In the energy domain most common in medical physics (few Kiloelectronvolts to several Megaelectronvolts), the interactions of greatest interest are photoelectric effect, Compton scattering, and pair production. It is these interactions that will be the primary focus in this article.

SOME DEFINITIONS OF INTEREST

Before describing each interaction in further detail, it is useful to define terms that are commonly used in describing a photon beam.

Photon Fluence (Φ)

The photon fluence of an X-ray beam is the number of photons crossing a unit area. If we find that N photons pass through an area A perpendicular to the beam, then the photon fluence through the medium is

$$\Phi = \frac{N}{A}$$

Fluence Rate (Flux Density, ϕ)

The rate at which photons pass through an area is called fluence rate. If N photons pass through an area A in time t , then the fluence rate is

$$\phi = \frac{N}{At}$$

Energy Fluence (Ψ)

If the energy of each photon is $h\nu$ (where ν is the frequency and h is Planck's constant, $h = 4.135 \times 10^{-31} \text{ MeV/s}$), then the energy fluence is

$$\Psi = \frac{EN}{A} = \frac{dE}{dA} = h\nu \frac{dN}{dA}$$

Energy Fluence Rate (ψ)

Also called the intensity of the beam, and it is defined as ψ (or I)

$$I = \frac{EN}{At} = \frac{d\Psi}{dt}$$

Photon Attenuation

Linear Attenuation Coefficient (μ). Suppose that a monoenergetic beam consisting of N_0 photons is incident on an attenuator of thickness x (Fig. 1). The number of photons N that will pass through the attenuator and get registered by the detector may be written as

$$N = N_0 e^{-\mu x} \quad (1)$$

where μ is known as the *linear attenuation coefficient* of the attenuator and represents the fraction of incident photons that interact in a unit thickness of the medium. Therefore, μ represents the probability that a photon will

Figure 1. Experimental setup to determine photon beam attenuation in an absorbing medium.

interact in the absorber medium. The attenuation coefficient is a function of both the absorber material and the incident photon energy. As the incident beam is assumed to be monoenergetic, μ is a constant. Because μx must be a dimensionless number, when x is expressed in centimeters, the linear attenuation coefficient μ has units of 1/cm.

Equation 1 may also be written in terms of the beam intensity:

$$I = I_0 e^{-\mu x} \tag{2}$$

where I_0 is the intensity of incident photons and I is the transmitted intensity. The plot of intensity (I) versus thickness of absorber (x) is an exponential curve on a linear graph or a straight line on a semilogarithmic graph (Fig. 2). The plot shows that the percentage of photons removed from the photon beam is the same with each unit increase in absorber thickness.

Half-Value Layer. The thickness of the absorber that will attenuate a photon beam to 50% intensity is known as the half-value layer (HVL). It can be shown from equation 2 that

$$\text{HVL} = \frac{\ln 2}{\mu} = \frac{0.693}{\mu} \tag{3}$$

Figure 2. A graph of number (%) of photons transmitted through an absorber versus absorber thickness. Each HVL of absorber reduces the incident number of photons by half.

HVL is a measure of the penetrability of the beam: a high-energy X-ray beam (with low μ) will have a large HVL.

Tenth Value Layer. The tenth value layer (the thickness of the absorber required to reduce the transmitted intensity to one tenth of the original intensity) or TVL can be written as

$$\text{TVL} = \frac{\ln 10}{\mu} = \frac{2.302}{\mu} = 3.323(\text{HVL}) \tag{4}$$

The beam generated from an X-ray tube or a linear accelerator is not mono-energetic, but it is composed of a spectrum of energies. The average energy of such a beam of photons is approximately one third of the maximum photon energy. When this poly-energetic beam passes through the absorber, it is the low-energy X rays that are absorbed or filtered out first. After the low-energy photons have been removed, the filtered beam becomes more energetic or “harder.” As the filter thickness increases, the average energy of the beam increases. Therefore, for an X-ray beam, the plot of beam intensity *versus* absorber thickness is not quite a straight line (Fig. 3). Instead, we see that the first HVL in the absorber is smaller than the second HVL; the second HVL is smaller than the third HVL, and so on.

Figure 3. Transmitted intensity for a polyenergetic X-ray beam incident on an absorber. As the beam gets “harder” in passing through the absorber, the corresponding HVL gets larger.

Mean Free Path. As stated above, μ is the probability that a photon will undergo an interaction in a unit thickness of the absorber; therefore, $1/\mu$ can be thought of as the average distance a photon will travel between two successive interactions. Hence, the mean free path (MFP) is

$$\text{MFP} = \frac{1}{\mu} \quad (5)$$

It can be observed from equation 1 that approximately 37% of photons are left in the photon beam after traveling one MFP in the absorber.

Mass Attenuation Coefficient (μ/ρ). The linear attenuation coefficient (μ) varies with the density of the medium. As an example, water, water vapor, and ice have the same atomic composition, but their linear attenuation coefficients are all different due to the difference in physical density. However, if we divide the linear attenuation coefficient μ by the density ρ of the medium, we get a more fundamental quantity, known as the mass attenuation coefficient (measured in squared centimeter/gram):

$$\mu_m = \mu/\rho \quad (6)$$

The absorber thickness, in this case, is ρx and has the units of gram/squared centimeter (i.e., mass of the absorber per unit area). Here the density dependence of the attenuation coefficient has been removed and μ_m is a function of the material composition only. In the aforementioned example, water, water vapor, and ice all have the same mass attenuation coefficient μ_m .

The attenuation coefficient of a mixture of elements (such as water) can be calculated from the attenuation coefficients of individual elements:

$$\left(\frac{\mu}{\rho}\right) = \sum_i w_i \left(\frac{\mu}{\rho}\right)_i \quad (7)$$

where w_i is the fractional weight of the i th element in the mixture.

As photon beam attenuation depends on the number of electrons and atoms in the path of the beam, the corresponding attenuation coefficients can be defined as follows.

Electronic Attenuation Coefficient. When the absorber thickness is expressed as electrons/squared centimeter, the corresponding attenuation coefficient is the electronic attenuation coefficient. If N_e is the number of electrons/gram, then

$$\mu_e = \frac{\mu}{\rho} \left(\frac{1}{N_e}\right) = \frac{\mu}{\rho} \left(\frac{A}{N_A Z}\right) \quad (8)$$

where A is the atomic mass number, Z is the atomic number, and N_A is the Avogadro's number = 6.02×10^{23} atoms per atomic weight in grams. The electronic attenuation coefficient, μ_e (expressed in squared centimeter/electron) represents the probability that an incident photon will have an interaction with an electron in the absorber. As $Z/A \cong 0.5$ for all materials (except hydrogen), the number of electrons/gram is a constant for all materials: $N_e = (N_A Z/A) = 3 \times 10^{23}$ (Table 1). As we will see

Table 1. Number of Electrons Per Gram

Material	Density (g/cm ³)	Atomic Number (Z)	Number of Electrons/Gram
Hydrogen	0.0000899	1	6.00×10^{23}
Carbon	2.25	6	3.01×10^{23}
Oxygen	0.001429	8	3.01×10^{23}
Aluminum	2.7	13	2.90×10^{23}
Copper	8.9	29	2.75×10^{23}
Lead	11.3	82	2.38×10^{23}
<i>Effective Z</i>			
Fat	0.916	5.92	3.48×10^{23}
Muscle	1	7.42	3.36×10^{23}
Water	1	7.42	3.34×10^{23}
Air	0.001293	7.64	3.01×10^{23}
Bone	1.85	13.8	3.00×10^{23}

From Johns and Cunningham, *The Physics of Radiology*.

later, the near constancy of N_e across the periodic table has important implications for the Compton effect.

Atomic Attenuation Coefficient. Similarly, the atomic attenuation coefficient may be defined as the probability that the photon will have an interaction with an atom in the absorber. The coefficient is related to linear attenuation coefficient via

$$\mu_a = \frac{\mu}{\rho} \left(\frac{Z}{N_e}\right) = \frac{\mu}{\rho} \left(\frac{A}{N_A}\right) \quad (9)$$

The atomic attenuation coefficient μ_a is expressed in squared centimeter/atom, when the absorber thickness is in the units of atoms/squared centimeter.

We now look at each interaction in more detail.

COHERENT OR RAYLEIGH SCATTERING

Coherent scattering refers to the elastic scattering of a photon beam with atomic electrons, in which no energy transfer to medium takes place. The incident photon interacts with bound electrons as a whole (hence called coherent scattering). The electrons are temporarily set in motion (or oscillation) by the photon's electromagnetic field, and they return back to their original state by emitting a photon with the same energy as the incident photon (Fig. 4). The incident photon energy is too small to break free any electron from its shell. The scattered photon is emitted at a small angle relative to the incident photon. When a single electron from an atom participates in the process, the reaction is called Thomson scattering.

Figure 4. Illustration of coherent scattering: A photon with energy $h\nu$ scatters off an atom without transferring any energy. The scattered photon has the same energy as the incident energy.

Figure 5. Photoelectric effect: A photon incident on an atom is absorbed with the emission of photoelectron. In the process, characteristic X rays and Auger electrons may also be emitted.

The probability of coherent scattering (σ_{coh}) is highest when photon energy is very small and the medium atomic number Z is very large. Likewise, the probability of coherent scattering is lowest when Z of the medium is small and the photon energy is large. Consequently, coherent scattering is not very likely to occur in tissue and therefore is not of much interest in medical physics.

PHOTOELECTRIC EFFECT

In the photoelectric effect, the incident photon interacts with an atom and ejects one of the bound electrons (from K, L, M, or N shells) (Fig. 5). The photon disappears by transferring all of its energy to the atom. Some of the photon's energy is used to overcome the binding energy of the electron, and the rest changes into the kinetic energy of the electron:

$$K.E. = h\nu - E_b \quad (10)$$

where $h\nu$ is the incident photon energy and E_b is the binding energy of the electron. For the photoelectric effect to take place, the energy of the incident photon *must* be larger than the binding energy of the bound electron.

For example, suppose that the incident photon ejects an electron from the K-shell. After the photoelectron is ejected, a vacancy is created in the electron shell and the atom goes into an excited state. The vacancy left by the electron is filled by an outer shell electron (say, from an L-shell) with a lower binding energy. This leads to emission of characteristic X rays with energy $= E_K - E_L$. If the characteristic X rays have sufficient energy, they may also knock out electrons (called Auger electrons) from the surrounding shells. These Auger electrons leave behind more vacancies that in turn leads to generation of more X rays. The cycle is repeated until all of the photon energy is absorbed by the medium. In the tissue, the binding energies of electron shells are very small. Therefore, the characteristic X rays released in tissue are of very low energy and hence are locally absorbed. In the photoelectric energy range, all incident radiation on tissue is locally absorbed with no scatter radiation. In contrast, the characteristic radiation produced in high Z material (e.g., lead) is more energetic and is absorbed some distance away from the site of photoelectric effect.

Figure 6. Variation of photoelectric mass attenuation coefficient with incident photon energy. Curves shown are for water ($Z = 7.82$) and lead ($Z = 82$).

The probability that a photon will undergo photoelectric effect depends strongly on its incident energy $E = h\nu$ and the atomic number Z of the absorbing material. In fact, the photoelectric mass attenuation coefficient τ/ρ varies directly as the cube of atomic number and inversely as the cube of photon energy (Z^3/E^3). Figure 6 shows a plot of τ/ρ versus energy for water ($Z = 7.5$) and lead ($Z = 82$). Due to the Z^3 dependence, a photon is 1000 times more likely to undergo photoelectric interaction in lead than in a water-like medium (e.g., tissue). Also, if it has sufficient energy to knock out an electron, a low-energy photon is more likely than a high-energy photon to participate in the photoelectric effect. It can be observed from the figure that as the photon energy increases, the probability of photoelectric interaction decreases rapidly (as $1/E^3$). The curve for lead also shows sharp discontinuities for incident photon energies of 15 keV and 88 keV. These peaks correspond to the binding energies of L- and K-shells, respectively, for lead and are called absorption edges. A photon having energy less than the electron's binding energy cannot undergo a photoelectric effect with electrons in that shell. However, as soon as the photon energy exceeds the binding energy of the electron, the probability of the photoelectric effect increases dramatically (like a resonance) and a sudden jump (or discontinuity) is observed in the plot of photoelectric attenuation coefficient versus energy. The discontinuity is greatest for the K-shell and becomes weaker for higher shells (L, M, N, etc.). Therefore, it is noticed that the most tightly bound

electrons have the greatest chance of undergoing photoelectric interaction. For water, the plot of τ/ρ again shows the same steady decline with energy, although the curve is much smoother. As the K-shell binding energy for a low Z medium is only about 0.5 keV, no discontinuities are observed.

The above behavior of the photoelectric effect has many important applications in medical physics:

1. Due to the Z^3 dependence, differential absorption of photons by bone, muscle, and fat is exaggerated and provides excellent X-ray film contrast in mammography and other diagnostic applications.
2. High Z materials, such as, BaSO_4 and Hypaque, are ideally suited for contrast enhancement in CT scanning.
3. As lead is a good absorber of low-energy photons, it is commonly used for shielding in diagnostic radiology procedures (for example, lead aprons).

The angular dependence of emitted photoelectron is a function of the photon's energy. For a low-energy photon, the electron has small kinetic energy and is emitted at 90° relative to the direction of the incident photon. As the photon energy increases, the photoelectrons also have higher energy and are emitted in a more forward direction.

COMPTON SCATTERING

As the incident photon energy increases (beyond 30–40 keV in tissue-like medium), the probability that it will undergo photoelectric effect decreases and the Compton effect becomes the dominant mode of interaction. This is the most important mode of interaction for tissue like materials.

In Compton scattering, the incident photon with energy $h\nu_0$ interacts with a loosely bound (or "free") electron from an outer shell and transfers some of its energy to it. The photon is scattered at a lower energy ($h\nu'$) and scattering angle θ , and the recoil (or Compton) electron is ejected with an energy E at an angle ϕ relative to the incident photon's direction (Fig. 7). From conservation of energy and momentum, the following relations

Figure 7. Compton effect: Incident photon scattering off a free electron.

can be obtained:

$$E = h\nu_0 \frac{\alpha(1 - \cos \theta)}{1 + \alpha(1 - \cos \theta)}$$

$$h\nu' = \frac{1}{1 + \alpha(1 - \cos \theta)}$$

$$\cot \phi = (1 + \alpha)\tan \theta/2$$
(11)

where $\alpha = h\nu_0/m_0c^2$ and $m_0c^2 = 0.511$ MeV is the rest mass energy of the electron.

In terms of a photon's wavelength, after undergoing a Compton interaction, the scattered photon has a longer wavelength λ' than that of the incident photon λ . The change in wavelength or "Compton shift" is independent of the incident photon energy and depends only on the scattering angle θ :

$$\Delta\lambda = \lambda' - \lambda = h/m_0c(1 - \cos \theta) = \lambda_C(1 - \cos \theta)$$
(12)

where $\lambda_C = h/m_0c = 0.02426 \text{ \AA} = 2.426 \times 10^{-10} \text{ m}$ is the Compton wavelength, or the wavelength of a photon whose energy is just equal to the rest mass energy of the electron.

The scattered photon's energy, and therefore how much energy is imparted to Compton electron, depends on the scattering angle and incident photon energy. Let us first consider the dependence of transferred energy on the photon's scattering angle θ (Fig. 8). If the photon undergoes a "head-on" collision with the electron, the photon is scattered backward ($\theta = 180$) and the electron moves forward ($\phi = 0$). In this case, the photon transfers most of its energy to the electron ($h\nu' = h\nu'_{\min}$ and $E = E_{\max}$). If the photon makes a "glancing" hit with the electron ($\theta = 0$), the electron receives very little energy and the scattered photon continues forward with the same energy as the incident photon ($h\nu' = h\nu$ and $E = 0$). In summary, when a photon is scattered at small angles ($\theta \rightarrow 0$), very little of its energy is transferred to the electron. However, as the photon scattering angle increases ($\theta = 0 \rightarrow 180$), a greater fraction of the incident energy is imparted to the electron.

Figure 8. Compton scattering: Relationship between energy transferred to Compton electron and the scattering angle.

Unlike the photoelectric effect, however, the photon does not give all of its energy to the electron. The directional dependence of scattered electron and photon is governed by equation 11.

We next study the dependence of Compton effect on incident photon energy. For a low-energy photon, only a small portion of its energy is imparted to the electron. The scattered photon's energy is almost the same as the incident photon. Note that in the limiting case ($h\nu_0 \rightarrow 0$), this reduces to Rayleigh scattering where the incident photon suffers no loss of energy. As the photon energy increases, the fraction of energy transferred to the electron increases. For a very high-energy photon, the photon loses almost all of its energy to the electron and is emitted with a low energy.

It can be shown that a photon scattered at 90° can have energy of no more than 0.511 MeV regardless of the incident photon energy. If the photon is scattered backward, its maximum energy is only 0.255 MeV. These results are independent of the incident photon energy and have important consequences in the shielding design for treatment rooms in radiotherapy. For example, for side-scattered radiation (90° scatter), one needs to only shield for 0.511 MeV photons, and for backscattered radiation (180° scatter), the maximum required shielding is for 0.255 MeV photons. However, a photon scattered in the forward direction can have any energy up to that of the incident photon. As the incident photon energy increases, the recoil electron angle ϕ becomes smaller; i.e., the electron is more likely to be ejected in the forward direction.

As the Compton interaction involves a free electron, it is independent of the atomic number Z of the medium and depends only on the number of electrons per gram, which is constant for almost all materials (Table 1). Thus, the Compton mass attenuation coefficient σ/ρ is the same for all materials. In other words, gram for gram all materials will undergo the same Compton interaction. However, the linear attenuation coefficient σ will be larger for denser materials: In the Compton energy range, 1 cm of bone will attenuate more than 1 cm of tissue. The inherent contrast in the Compton range is due to density difference and not due to Z dependence as observed in the photoelectric effect. This fact, coupled with the presence of scattered photons, causes the mega-voltage X ray film quality to be inferior to that of kilovoltage films. In the soft tissue, the Compton effect is most important for photons with incident energy 0.1–10 MeV. As the photon energy increases, the probability of Compton interaction decreases.

PAIR PRODUCTION

A photon with energy more than 1.02 MeV may interact with the medium through pair production. In this reaction, the photon interacts with the field of the nucleus and disappears with the creation of a positive and negative electron (e^+/e^-) pair (Fig. 9). This reaction is an example of energy converting into mass. As the rest mass energy for electron or positron is $m_0c^2 = 0.511$ MeV, the threshold for pair production is 1.022 MeV. The total kinetic energy of the electron–positron pair is

$$h\nu - 1.022 = E^+ + E^- \quad (13)$$

The excess energy is generally shared equally between e^+ and e^- ; however, any ratio is possible. As the products have equal and opposite charge, the net charge is conserved in the reaction.

The above reaction can also take place in the presence of an electron: a process known as triplet production (e^+/e^- pair and the interacting electron). The threshold energy for triplet production is 2.04 MeV. However, the likelihood of triplet production is small compared with pair production.

The electron and positron formed in the pair- (or triplet-) production lose their energy in passing through matter via ionization and excitation of atoms, until they come to rest. Near the end of its track, a positron combines with an available electron to produce two annihilation photons, each with an energy of 0.511 MeV (Fig. 9). The photons are emitted in opposite directions (180 degrees apart) to conserve momentum. This reaction is opposite to the pair production in that matter is now converted into energy.

The likelihood of pair production is very small when the photon energy is about 1–2 MeV. However, it increases rapidly with energy and becomes the dominant interaction for photons with an incident energy above 10 MeV. This behavior is in contrast to the other photon interaction processes considered so far that decrease in likelihood with increasing photon energy. The pair production interaction also increases with Z of the atomic nucleus.

It varies as Z^2/atom or Z/g . This implies that high-energy X rays will be readily absorbed in high Z materials, leading to “beam-softening.” For this reason, lead is not recommended as a flattening filter in high-energy linear accelerators. For the same reason, HVL is not a useful concept in specifying beam quality of high-energy X rays. This can be explained by recalling that HVL is related to the attenuation coefficient as $\text{HVL} = 0.693/\mu$. In the high-energy range, μ increases (or HVL decreases) as the photon

Figure 9. Illustration of pair production process and subsequent production of annihilation radiation.

energy increases. Therefore, HVL is not a meaningful quantity in describing a beam of high-energy photons.

PHOTODISINTEGRATION

A photon with still higher energy may penetrate the nucleus and knock out one of its constituents: a proton, neutron, or alpha particle along with more gamma rays. The incident photon is absorbed, and the nucleus is transformed into an unstable reaction product. The latter next returns back to a stable state via radioactive decay of a nuclear particle, for example, as in (γ, p) and (γ, n) reactions.

The threshold for the photodisintegration reaction is essentially the binding energy of nucleons in the nucleus. For low Z nuclei, this is above 10 MeV (except for Be: 2 MeV and ^2H : 1.5 MeV). For heavy nuclei, the nuclear binding energy is about 7 MeV. Due to Coulomb repulsion, the threshold for (γ, p) is lower than that for the (γ, n) reaction. Beyond the threshold energy, the probability for photodisintegration increases rapidly with increasing incident photon energy, reaches a maximum value, and then drops with further increase in energy. This peak is referred to as the *nuclear giant resonance* and is due to the electric dipole absorption of the incident photon.

Compared with the other reactions described above, the probability for photodisintegration is small and hence does not contribute significantly to photon attenuation. However, the interaction has great importance in shielding considerations for radiotherapy room design.

RELATIVE IMPORTANCE OF VARIOUS TYPES OF INTERACTIONS

Up to now we have considered how a monoenergetic beam of photons interacts with a medium having an atomic number Z . However, an X-ray beam from a radiotherapy machine is not monoenergetic, but it consists of a mixture of photons with various energies. Such a beam, in passing through an absorber, will undergo all of the above interactions to various degrees. The *total linear attenuation coefficient* may be written as the sum of the photoelectric, coherent, Compton, and pair production coefficients:

$$\mu_{\text{total}} = \tau + \sigma_R + \sigma_C + \kappa \quad (14)$$

Figure 10 shows a plot of μ_{total} versus photon energy along with contributions from individual component interactions.

The *total mass attenuation coefficient* may be written as

$$\frac{\mu_{\text{total}}}{\rho} = \frac{\tau}{\rho} + \frac{\sigma_R}{\rho} + \frac{\sigma_C}{\rho} + \frac{\kappa}{\rho} \quad (15)$$

The relative probability of various interactions depends on the incident photon energy and the Z of the material. In general, the photoelectric interaction is most common at low photon energies; the Compton effect dominates at intermediate energies and the pair production at high energies. As explained above, as coherent scattering is significant for low-energy photons (<10 keV) incident on high Z materials, it may be ignored.

Figure 10. A plot of total linear attenuation coefficient that is composed of Rayleigh, photoelectric, Compton, and pair production processes.

Let us consider the plot of total mass attenuation coefficient as a function of photon energy for water and lead, which, respectively, represent a low Z and high Z material (Fig. 11). At low energies (≥ 10 keV), the photoelectric effect is dominant. The attenuation coefficient displays Z^3/E^3 behavior in this region. Therefore, μ is much higher for lead (10^3 times) compared with water and decreases rapidly with increasing photon energy.

As the photon energy exceeds electron binding energy (~ 100 keV and higher), the Compton effect takes over. As the Compton interaction is independent of Z of medium, lead and water have practically the same attenuation. As the photon energy is further increased, the attenuation coefficient decreases until the pair production becomes the dominant mode of interaction (for photon energies higher than 1 MeV).

In the pair production range, the attenuation coefficient increases with energy as $\log E$. Also, the likelihood of interaction is higher in lead than in water because of the Z dependence of pair production interaction. The above behavior of various modes of interactions is summarized in Table 2 for tissue-like material.

Another way to discuss the relative importance of various interactions is to look for them as regions of dominance in the plot of $h\nu$ versus Z (Fig. 12). The curves display points in the $h\nu$ and Z space for which the Compton effect equals the photoelectric effect and pair production. The Compton effect is most dominant between 1 and 5 MeV

Table 2. Relative Importance of Photoelectric, Compton, and Pair Production Processes in Water

Energy	Photoelectric	Compton	Pair Production
10 keV	95	5	0
25 keV	50	50	0
150 keV	0	100	0
4 MeV	0	95	5
24 MeV	0	50	50
100 MeV	0	16	84

Figure 11. A plot of total mass attenuation coefficient as a function of incident photon energy for lead and water.

regardless of the type of material. According to this figure, for low Z (tissue-like materials), the Compton effect is the main interaction over a much wider energy range. For high Z materials, however, the photoelectric effect is dominant at low photon energies and pair production is the main interaction at high energies.

ENERGY TRANSFER AND ENERGY ABSORPTION COEFFICIENTS

When a beam of photons passes through an attenuator, either part or all of its energy is transferred to the medium (Table 3). The exact fraction of energy transferred depends on the incident photon energy and Z of the medium. If part of the incident energy is transferred, then the remaining photon energy is emitted as scattered photons. The scattered photons may further interact with the medium and lose some or all of their energy. Thus, a photon may undergo *multiple* interactions with electrons in the medium before it is absorbed or escapes out. Suppose $h\nu$ is the

incident photon energy, out of which, \bar{E}_{tr} is the average energy transferred to the medium. Let E_{scat} be the energy of scattered photons; then

$$h\nu = \bar{E}_{tr} + \bar{E}_{scat} \tag{16}$$

The fraction of photon energy transferred to electrons kinetic energy per unit absorber thickness can be written as

$$\mu_{tr} = \frac{\bar{E}_{tr}}{h\nu} \mu \tag{17}$$

where μ_{tr} is the linear energy transfer coefficient. The corresponding mass energy transfer coefficient is μ_{tr}/ρ .

Most of the energy transferred to the electrons is deposited in the medium at the site of interaction via ionization and excitation of atoms and is referred to as the absorbed energy E_{ab} (related to radiation dose delivered). However, a portion of the transferred energy is radiated away in the form of bremsstrahlung radiation (E_{rad}):

$$\bar{E}_{tr} = \bar{E}_{ab} + \bar{E}_{rad} \tag{18}$$

Therefore, the energy absorption coefficient may be written as

$$\mu_{ab} = \frac{\bar{E}_{ab}}{h\nu} \mu \tag{19}$$

Figure 12. Relative importance of the three major types of X-ray interactions. The curves show the values of Z and $h\nu$ for which two neighboring effects are equal.

Table 3. Depth of Maximum Dose and Percent Depth Dose at 10 cm Depth for Megavoltage Photon Beams

Photon Beam Energy	Depth of Maximum Dose (cm)	Percent Depth Dose at 10 cm depth (%)
1.25 MV (^{60}Co)	0.4	58.7
4 MV	1	63

X-RAY BEAM ENERGY PARAMETERS

As we have noted, the type of interaction an X-ray beam will undergo with a medium depends on its energy. This section presents some ways of defining energy of incident radiation.

The most comprehensive description of an X-ray beam is obtained via spectral energy distribution, i.e., a graph showing the relative population of different energy photons in the beam. The spectral distribution can be measured by several methods, including magnetic spectrometry, photoactivation, Cerenkov detection, and total-scintillation spectrometry, or it can be approximated by computational techniques based on bremsstrahlung interaction in a target. Although useful, the exact determination of the spectra is labor intensive. In addition, the spectral distribution consists of a vast amount of information that makes it difficult to compare two X-ray beams using this information. Instead, alternative simpler methods may be used to describe the quality of the X-ray beam and its spectra.

Beam Energy, Maximum Energy, or Peak Energy

Typical X-ray spectrum consists of photons with energy ranging from 0 to a maximum energy (E_{\max}). X-ray energy as nominally specified by the manufacturer is generally the energy of the peak intensity. This energy is the energy of the most probable electrons incident on the patient. The peak energy, however, is not a good indication of the X-ray spectrum, as two beams with same peak energy may have different spectrum.

Effective Energy

The X-ray beam is usually composed of photons of a mixture of energies. These will attenuate differently in matter. The effective energy of such a heterogeneous beam is defined as the energy of a monoenergetic beam that has the same HVL as the beam in question.

Half-Value Layer

HVL is the thickness of the absorber required to attenuate the beam intensity to half its original value.

Weighted Mean Energy

The weighted mean energy of a heterogeneous X ray beam is found from the mean mass-attenuation coefficient weighted by the energy fluence of the photons. The mean energy of the heterogeneous beam is approximately one third of the peak energy.

X-RAYS, PRODUCTION OF

BRUCE HORN
Kaiser Permanente
Los Angeles, California

INTRODUCTION

Soon after Wilhelm Roentgen discovered X rays in 1895, scientists recognized their usefulness to visualize the internal anatomy of humans. For a number of years, X-ray tubes that radiologists used for this purpose were unreliable and produced low X-ray output. In 1913, William Coolidge invented the forerunner of the modern X-ray tube. Unlike earlier designs, this tube featured a heated tungsten filament as the source of electrons and utilized a high quality vacuum instead of the low gas pressure previously employed. The result was a reliable X-ray tube whose X-ray output could be reproducibly controlled over a wide range. Today's wide range of X-ray imaging techniques, from a simple chest radiograph to a multislice computed tomogram, still depend on an X-ray tube to produce X rays. Recent developments in X-ray tube design include improved heat handling capability, increased X-ray output, and reduced focal spot size.

PRODUCTION OF X RAYS

X rays, like radio waves, light, γ rays, and other types of electromagnetic radiation, are defined by their energy and source. X rays are produced by two methods involving the interaction of electrons with matter. In the first method, a stream of electrons directed at a target is decelerated by forces between the incident electrons and the atomic nuclei of the target material. Since a deceleration implies that kinetic energy is lost, one of the ways in which electrons lose energy is by creating photons of electromagnetic energy equal in energy to the kinetic loss. This process is called bremsstrahlung, or "braking radiation". The photons produced by this interaction are commonly called X rays. If a large number of electrons, all having the same initial kinetic energy, interact with a target material, the resulting bremsstrahlung consists of photons, or X rays, with a continuum of energies from zero to a maximum equal to the initial electron kinetic energy. This range of energies is called the X-ray spectrum. The shape of the spectrum remains the same regardless of the kinetic energy of the electrons. Although X rays are produced by this mechanism even if the target consists of a gas, the efficiency of X-ray production by bremsstrahlung is directly proportional to the product of the atomic number (Z) of the target

material and the kinetic energy of the electrons. Since the portion of the kinetic energy of the incident electrons that is not converted to X rays results in heating the target material, it is desirable to utilize high energy electrons and target materials of high atomic number to increase the efficiency of bremsstrahlung production as much as possible. However, in either therapeutic or diagnostic medical applications, X-ray beam penetration is controlled by selecting the initial kinetic energy of the electrons, which is controlled by the electrical potential difference between the electron source (cathode) and the target (anode). Although other considerations may dictate the choice of target material when designing X-ray tubes for some diagnostic applications, such as mammography (molybdenum or rhodium), the target material remains as the variable that can be optimized to provide the most efficient X-ray production. Due to its high atomic number, relative high melting point, good heat-transfer characteristics, and low cost, the best target material for use in diagnostic imaging applications is tungsten. At energies commonly employed in medical applications, approximately $\sim 1\%$ of the kinetic energy of the electrons is converted to bremsstrahlung by interaction with a tungsten target. The remaining 99% of the incident energy results in heating of the target. As will be discussed later, the primary challenge of X-ray tube design is how to most effectively handle heat generated by the X-ray production process.

In the second method, electrons impinging on the target also interact with the orbital electrons of the atoms in the target. If the incident electron has a kinetic energy greater than or equal to the binding energy of an orbital electron, the bound electron may be ejected from the atom as a result of the interaction. The resulting vacancy is then filled by one of the other orbital electrons falling into the potential well of the vacancy. This transition results in the release of a photon with an energy equal to the difference between the electronic states of the vacancy and the orbital electron that fills the vacancy. The released photon is called a characteristic X ray. Due to the quantized energy levels of orbital electrons, characteristic X rays have specific energies independent of the original kinetic energy of the accelerated electrons. For tungsten, the *K*-shell binding energy is 69 keV, and the *L*-shell binding energy is 11 keV. Characteristic X rays resulting from interactions with *L*-shell electrons are not important for medical applications since the resulting low energy photons are not useful and are severely attenuated by the encapsulating materials used in a practical X-ray tube. As a result, for practical purposes, the X-ray spectrum from a tungsten target produced by electrons with kinetic energies < 69 keV will not exhibit characteristic X-ray production. X-ray spectra produced by electrons with kinetic energies > 69 keV will have a series of narrow peaks of increased X ray production at photon energies corresponding to the energy differences for the possible *K*-shell orbital transitions superimposed on the bremsstrahlung spectrum. Figure 1 illustrates the typical shape of bremsstrahlung spectra, as well as the difference in characteristic X-ray production between two accelerating potentials. The existence of characteristic X rays in the spectra is relatively unimportant for most medical diagnostic imaging procedures. On the other hand,

Figure 1. Diagnostic X-ray spectra.

the characteristic X rays produced by a molybdenum target X-ray tube are important to the process of image formation for film-screen mammography.

CONSTRUCTION OF X-RAY TUBES

An X-ray tube consists of a cylindrical envelope (tube insert) that contains the primary components necessary to produce X rays in a controlled manner. This envelope is contained within a tube housing that provides physical protection of the tube insert, stray radiation protection and a means of transferring heat generated during the X-ray production process from the insert to the surrounding environment. The insert contains an electron source (filament), a means of directing the electrons in the intended direction (focusing cup), and a target (anode). A typical X-ray tube insert is shown in Fig. 2. Unlike radiation emitted by radioactive material, X-ray production can be electrically switched on and off by controlling the voltage applied to the X-ray tube.

Envelope

The envelope housing the X-ray generating components is usually constructed of blown glass. However, some specialized X-ray tubes have metal or ceramic envelopes to improve the tube's heat handling capabilities. Air is evacuated from the envelope until an acceptable vacuum is achieved so that the electrons used in the X-ray generation process will not interact with gas molecules.

Filament

A small helical coil of tungsten wire, similar to the filament in an ordinary light bulb, is used to produce the electrons needed for the X-ray generation process. Passing an electric current through this tungsten filament, heats it to the point where free electrons are sufficiently energized to escape from the filament. This process is called thermionic emission. The freed electrons form a cloud, or space charge, around the filament. A separate filament is provided for each focal spot size, usually two per tube. During the X-ray generation process, a large negative electrical potential difference is applied to the filament relative to the anode

Figure 2. Typical medical X-ray tube insert.

so that electrons supplied by the cloud are repelled by the filament and attracted by the anode. If large quantities of electrons (high X-ray output) are needed at low accelerating potentials, the repulsive force of the space charge may inhibit thermionic emission and reduce the rate at which electrons are released.

Focusing Cup

A metal focusing cup (cathode) surrounds the filament on all sides, except that facing the anode. Figure 3 shows a typical focusing cup and filaments. During the X-ray generation process, the same large negative potential difference that is applied to the filament is also applied to the focusing cup. The surface of the focusing cup adjacent to

Figure 3. Focusing cup and filaments.

the filament is shaped in such a way as to focus the beam of accelerated electrons onto the anode. Therefore, the size of the filament and shape of the focusing cup control the size of the focal spot on the surface of the anode.

Anode

The anode (target) is the medium with which the electrons interact to produce X rays. In a typical X-ray tube used for medical applications, the anode is constructed of tungsten or an alloy of rhenium and tungsten. In the case of film-screen mammography, molybdenum or rhodium is often used for X-ray tube anodes because its characteristic X rays are better suited for breast imaging than the spectrum of X rays from tungsten. It is not necessary that the entire anode be constructed of the target material. Since the interactions of the electrons with the target take place near the surface, the target can be relatively thin and backed by a material that exhibits better heat-transfer characteristics, such as copper or graphite. During the X-ray generation process, a large positive electrical potential difference is applied to the anode to attract electrons emitted by the filament. As a result, the electrons are accelerated during their passage from the filament to the anode by the potential difference between the filament (cathode) and the anode, typically 20,000–150,000 V. Because the voltage supplied to the X-ray tube from a single-phase, full-wave-rectified source varies from zero to maximum and back to zero every 8.3 ms, this accelerating voltage is specified by its maximum value in units of peak kilovolts (kVp). Although three-phase or high frequency voltage sources exhibit considerably less voltage variation, their voltage waveforms are also described in terms of peak voltage. An X-ray tube with an anode-to-cathode potential difference of 100 kVp produces a spectrum of X rays with a maximum energy of 100 keV.

The surface of the anode is angled slightly from perpendicular with the electron beam. This angle is referred to as the target angle. The area on the anode where the electrons interact to produce X rays is called the focal spot or focus. The geometry of the X-ray tube components is designed so that the X-ray beam exits the tube at a 90° angle with respect to the electron beam inside the tube. The effective size of the focal spot is the size of the spot on the anode projected along the central axis of the X-ray beam. Since the width of the focal spot is the dimension along the axis perpendicular to both the electron beam and the X-ray beam central axis, only the length of the focal spot is affected by the target angle. The effective focal spot size is important because it determines an X-ray tube's ability to image small objects. The focal spot area in the plane of the surface of the anode is important because it limits the number of electrons per unit time that can impinge on the target without overheating. The relationship between the effective focal spot size and the actual size on the anode is given by the following formula:

$$f = F \sin \alpha$$

where f is the length of the focus effective size, F is the length of the actual focus on the anode, and α is the target angle. The concept of having a large focal area, over which

Figure 4. Line-focus principle.

to distribute heat while maintaining a small focal area for imaging by use of an angled target, is called the line-focus principle and is demonstrated in Fig. 4. For example, a 12° target angle with an effective focal spot of 1.0 × 1.0 mm has an actual focus size of 4.8 × 1.0 mm.

As illustrated in Fig. 5, the maximum X-ray field size is the largest field size that can be produced by the tube at a specified distance from the focal spot. Since X rays emitted by the focal spot at an angle greater than the target angle will be absorbed by the anode, the maximum field size (centered on the X-ray beam) along the dimension parallel to the anode–cathode axis of the X-ray tube is dependent on the target angle as follows:

Figure 5. Maximum X-ray field size.

where S is the maximum size of the X-ray beam, d is the distance from the focal spot along the central axis of the X-ray beam, and α is the target angle. Therefore, although a larger target angle will result in a larger maximum field size, it will also result in lower heat loading capability. Conversely, a smaller target angle will result in a higher heat loading capability, but a smaller maximum field size. Simple algebra using the formula for maximum field size results in the conclusion that a target angle of at least 12° is required to cover the typical diagnostic imaging maximum field size of 43 cm at the commonly used distance of 100 cm. Diagnostic X-ray tube target angles typically are in the range of 12–15°, with a few special-purpose X-ray tubes having target angles as small as 9°. The intensity distribution of X rays along the direction parallel with the anode–cathode axis of the X-ray tube is not uniform. As shown in Fig. 6, comparison of the intensity at points equidistant from the central axis of the X-ray beam and equidistant from the focus indicates that the intensity of points toward the anode is less than that of corresponding points toward the cathode. This effect is called the heel effect. Since the X rays are generated from interactions of

Figure 6. Heel effect.

the electrons slightly below the surface of the anode, X rays at the anode end of the field will have had to travel through additional anode material when compared with the cathode end. This attenuation of the X rays by the anode material produces a reduced intensity at the anode end. It also selectively reduces the number of low energy photons, which causes the spectrum of X-ray energies at the anode end of the X-ray field to have relatively more high energy photons and fewer low energy photons than the cathode end. As a result, the X rays at the anode end have a higher average penetrating power.

Due to the limiting effect of target angle on field size and the desire for higher heat loading capabilities, the rotating anode was developed. Rather than continuously directing the electron beam toward the same area on the anode throughout an X-ray exposure, directing the electron beam to different areas on the anode during the exposure will produce higher heat loading capability. By using a disk-shaped anode and rotating the disk about its central axis, the focus traces a circular path, or focus track, on the anode during an exposure. Since heat is distributed over a larger area, the X-ray tube's heat loading capability is greatly increased. For example, a rotating anode with a 10 cm diameter focus track and a 1.0 mm focal spot is capable of a heat loading >300 times that of the same anode held stationary during the exposure. Due to their exceptional heat loading advantage, essentially all X-ray tubes used for medical imaging have rotating anodes. On the other hand, fixed-anode tubes are used for dental radiography since the techniques employed do not produce enough heat to require the use of a rotating anode. Typical rotating-anode diameters are 7.5–10 cm, with some special purpose X-ray tubes employing anodes that have a diameter of 12.5 cm.

The tungsten disk in a rotating-anode X-ray tube is supported on its central axis by a molybdenum stem that is concentrically connected to a copper cylinder, or rotor. The rotor is supported internally on ball bearings to allow the entire anode/stem/rotor assembly to rotate. Figure 7 shows a typical tungsten rotating-anode assembly. Unlike a fixed-anode tube in which heat is transferred from the anode by conduction, the mounting of a rotating anode is designed to insulate the bearing from the heat contained in

the anode and, as a result, to prevent damage to the bearings. Heat transferred to the bearings decreases their lubrication, resulting in premature bearing failure. A rotating anode transfers heat to the surrounding tube housing by radiation, rather than by conduction.

Although the electrons are focused to a specific area on the anode, they may rebound from the focus with sufficient energy to interact at other positions on the anode to generate X rays. This off-focus radiation produces imaging artifacts. Generally, rotating-anode tubes generate more off-focus X rays than fixed-anode tubes because they have larger tungsten surfaces with which to interact. Although a significant amount of the output of an X-ray tube may be due to off-focus radiation, a well-designed collimator attached to the tube will reduce the affect of this radiation on clinical imaging.

Focus

As stated previously, a typical diagnostic X-ray tube has two focal spots, one approximately half the size of the other, with nominal sizes ranging from 0.3 to 2.0 mm. The larger focus is used for clinical applications that demand the shortest possible exposure time (consequently maximum heat generation). Conversely, the smaller focus is used for applications that require the capability to resolve the smallest anatomical features. X-ray tubes incorporating two focal spot sizes are usually built so that their foci are superimposed on the surface of the anode, even though two separate filaments are used to produce the two focal spots. This design alleviates alignment problems that would occur if the foci were not superimposed. However, X-ray tubes have been manufactured that employ a biangular anode so that the focus tracks of the two focal spots are on separate areas of the anode with different target angles. This design allows optimization of the target angle for each of the foci, but also causes some alignment problems.

When selecting an X-ray tube, one of the important factors to consider is the size of the focal spot. In order to have a standardized method of defining focal spot size, the National Electrical Manufacturers Association (NEMA) in the United States and the International Electrotechnical Commission (IEC) in Europe have each developed standards that address focal spot size specification and measurement. Since the X-ray tube manufacturing process is somewhat imprecise, the labeled focus size is a useful nominal value when comparing the relative sizes among different tubes. However, the actual focal spot size may vary considerably from the nominal size. In fact, measured focus length as much as 100% greater than the nominal size are considered to be within the tolerance specified by the standards. For example, a nominal 1.0 mm focus may have a measured length as large as 2.0 mm. Several methods of characterizing the focal spot have been developed: (1) slit method, (2) resolution or star pattern method, and (3) pinhole method.

The slit method employs a rectangular slit 10 μm wide and at least 5000 μm long used at enlargement factors of 1.0–3.0. The long axis of the slit is placed perpendicular to the axis of the focal spot whose dimension is desired. The resulting image on the film is a one-dimensional (1D)

Figure 7. Rotating anode assembly.

distribution of the focal spot intensity along the chosen axis. Two images are therefore necessary to measure both the width and length of the focal spot. Both NEMA and the IEC specify the slit method as the method to be used for measuring the dimensions of focal spots. However, while the NEMA standard specifies measurement by eye using a 5–10X magnifying glass that has a built-in calibrated graticule, the IEC standard specifies the use of a scanning microdensitometer to obtain the line-spread function (LSF) of the width or length of the focal spot. The dimension of the focal spot is specified as the full width at 15% of maximum of the LSF.

The resolution method measures the ability of the focal spot to spatially resolve small objects and specifies the results in terms of spatial frequency (e.g., line pairs per mm), but does not provide a measurement of the dimensions of the focal spot. In this method, a line-pair resolution phantom is placed on the central axis of the X-ray beam between the focal spot and a single-emulsion film. The line-pair phantom consists of alternating lines of absorbing material (usually lead) and spaces, where adjacent lines and spaces have the same width. The width of the line pairs varies systematically over the face of the phantom to provide a range of line-pair sizes. The largest line-pair width, for which the line pair is completely blurred, is proportional to the focal spot size along the X-ray tube axis perpendicular to the line pairs. In order to facilitate the measurement of focal spot sizes by this method, a specialized phantom, commonly called a star pattern, which consists of alternating wedges of absorbing material and spaces in a circular configuration, was developed. Star pattern line-pair widths vary continuously from the outside edge to the center of the phantom. Using this phantom, both dimensions of the focal spot can be characterized from the same exposure. Since the phantom is circularly symmetric, the orientation of the phantom relative to the axes of the X-ray tube is unimportant. The image of the phantom on the film is analyzed by finding the points closest to the outside edge of the phantom for which the line pairs are completely blurred. The focal spot resolution can then be calculated using the following formula:

$$R = 180M/\pi\theta D$$

where R is the focal spot resolution in line pairs per millimeter, θ is the angle in degrees of a single wedge of absorbing material, D is the diameter of the blur on the film in millimeters, and M is the magnification factor of the phantom image. For the typical star pattern phantom with 2° wedges, this formula reduces to

$$R = 28.65M/D$$

The diameter corresponding to the resolution of the focal spot parallel with the anode–cathode axis of the X-ray tube (length) is the blur diameter that is perpendicular to this axis. Likewise, the diameter corresponding to the focal spot resolution perpendicular to the anode–cathode axis (width) is the blur diameter that is parallel with the anode–cathode axis. The principal advantage of the star pattern method of characterizing focal spots is its

ease of use. It does not require long exposure times and evaluates both the width and length of the focal spot from one exposure. The disadvantage of this method is that it does not provide an indication of the shape or intensity distribution of the focal spot.

The pinhole method utilizes a small circular pinhole 30–100 μm in diameter to image the focal spot onto a single-emulsion X-ray film for the purpose of determining its overall shape, orientation, intensity distribution and relative location. Although this method was used in the past to measure the dimensions of the focal spot, it is no longer considered suitable for doing so. The pinhole must be carefully aligned with the central axis of the X-ray beam. The distances between the focal spot and pinhole and between the pinhole and the film are adjusted so as to provide an enlargement factor of 1.0 or 2.0, depending on the nominal focus size. The film is exposed for a sufficient amount of time to produce an image of the focal spot with a density of 0.8–1.2 O.D. above base plus fog. Figure 8 illustrates the measurement geometry. The pinhole image is examined by eye using a magnifying glass, or by use of a scanning microdensitometer to quantitatively characterize the focal spot.

The focal spot size depends on the technique factor used during an exposure. Generally, the size of the focus increases as the tube current (mA) increases, and slightly decreases as the tube potential (kVp) increases. An increase in X-ray tube current means that more electrons travel from the filament to interact with the anode. The self-repulsion of the electrons causes the electron beam to slightly defocus, thereby interacting with a larger area on the anode. Since neighboring electrons in the beam are closer and more plentiful for larger tube currents, the effect of self-repulsion increases the focus size. An increase in

Figure 8. Focal spot size measurement geometry.

X-ray tube potential means that the electrons that travel from the filament to the anode are more energetic, and therefore have higher velocities. In addition, since neighboring electrons experience self-repulsion for a shorter period of time, the effect of self-repulsion is diminished and the focus size decreases. It is because of the effect of tube potential and current on focus size that both NEMA and the IEC specify the exposure factors for which focal spot sizes are measured. For a typical diagnostic X-ray tube, factors of 75 kVp, 50% of the maximum rated tube current at this tube potential, and 0.1 s exposure duration are employed.

Due to the line-focus principle, the projected focal spot size is dependent on the position in the X-ray field from which the actual focus on the anode is viewed. The observed target angle from a point at the cathode end of the X-ray field is larger, thereby producing a larger focal spot. Conversely, the observed focal spot size at the anode end is smaller. For example, the projected focus size at the cathode edge of a 40-cm field is 1.9 mm for an X-ray tube with a 12° target and a nominal focus size of 1.0 mm. All focal spot sizes are therefore specified relative to the central axis of the X-ray beam.

Stator

By surrounding the neck of the X-ray tube with a coil of wire in combination with a copper rotor attached to the anode inside of the tube forms an electric motor that rotates the anode. Exciting the coil with 60 Hz alternating current (ac) results in the anode being rotated at 3600 rpm, or one revolution every 16.7 ms, since it acts as a synchronous motor. However, this rotation speed is insufficient to avoid overheating the focal spot while meeting the clinical need for short, intense X-ray exposures of only a few milliseconds duration. For example, a 3 ms exposure would use only 18% of the available focal track. By applying 180 Hz ac to the stator windings so that the anode is accelerated to $\sim 10,000$ rpm within 1–2 s, heat will be spread over a greater percentage of the focal track (e.g., 50% of the track for a 3 ms exposure). The delay while the anode accelerates to the desired speed is called the “prep” time. During the prep time, the filament circuit is boosted so that the filament will have already reached its operating temperature by the time the X-ray exposure is initiated (when the anode has reached its desired speed). As soon as the exposure is completed, the accelerating voltage is removed from the stator. Due to mechanical resonances in the anode bearings, it is necessary to apply a braking voltage to the stator windings to decelerate the anode from 10,000 to 3,600 rpm within ~ 20 s. This action prevents destruction of the bearings by mechanical resonances. The anode is allowed to coast to a standstill once its speed is < 3600 rpm. Maintaining the anode speed at 10,000 rpm for long periods of time causes the bearings to wear out quickly.

Window. In most diagnostic X-ray tubes, the glass envelope of the tube insert serves as a window through which the X-ray photons pass. However, for X-ray tubes designed for applications requiring low energy photons, a

beryllium window is used because beryllium, unlike glass, does not significantly attenuate low energy photons.

Tube Housing

The X-ray tube insert must be contained within a metal tube housing, shown in Fig. 9, which provides a number of functions: mechanical protection against breakage of the glass envelope, an electrically grounded enclosure for safety, lead shielding against stray radiation emitted by the X-ray tube, a means to transfer heat from the anode to the outside environment, connections for the electrical cables from the high voltage power supply or generator, as well as a mechanical mounting for attachments. A glass or plastic window in the tube housing that is aligned with the central axis of the X-ray beam serves as a means for the useful X-ray beam to exit the tube. It also offers a means for directly viewing the anode to determine its physical condition. The volume between the insert and the tube housing is filled with oil to aid the transfer of heat deposited in the anode from the insert to the housing.

Although the X-ray photons emitted toward the window are desired, X-rays are also produced in many other directions. For this reason, the tube housing must contain sufficient lead shielding to reduce this “leakage” radiation to acceptable levels, since it does not serve a useful purpose. The allowable amount of X-ray tube leakage radiation is controlled by government regulations that specify that the maximum magnitude of the leakage radiation shall not exceed 100 mR in 1 h at any point 1 m from the focal spot when the X-ray tube is operated at its maximum continuous rated tube current and maximum

Figure 9. Typical medical X-ray tube housing.

tube potential. Although an X-ray tube may be capable of operating at tube currents as high as 1000 mA for brief periods, the maximum continuous rating for a typical diagnostic X-ray tube is 150 kVp and 3–6 mA. All manufacturers of diagnostic X-ray tubes, both dental and medical, must certify that their tube housings provide the required degree of shielding. In practice, tube leakage rates are significantly lower than required by regulations.

Most X-ray systems balance the tube potential difference between the anode and cathode so that the voltage difference between anode and ground is equal to the voltage difference between ground and the cathode. In other words, a 100 kVp tube potential means that the anode is 50 kVp positive with respect to ground, and the cathode is 50 kVp negative with respect to ground. For this reason, special high voltage connectors are required for both the anode and cathode. The standard high voltage connector contains three receptacles, each insulated from ground. In the anode connector, all three receptacles are electrically connected together, as well as to the anode. In the cathode connector, one receptacle is connected to the cathode, one receptacle is connected to the small focus filament, and one receptacle to the large focus filament. The receptacle connected to the cathode also acts as the common connection for the small and large filaments. In this way, the filaments are maintained at the same potential difference from ground as the cathode or focusing cup. The exceptions are X-ray tubes that utilize a biased focusing cup to shape the focal spot distribution, necessitating a cathode high voltage connector with four receptacles instead of three. The fourth receptacle is used to apply a bias voltage between the focusing cup and the filaments. Since the connectors are standardized, X-ray tubes from different manufacturers can be easily used with an X-ray system.

As discussed previously, X-ray photons emitted by the tube have a spectrum of energies. Since lower energy photons have little penetrating power, they tend to be absorbed near the skin surface of a patient undergoing a diagnostic exam and do not contribute to the X-ray image. For patient protection purposes, it is therefore desirable to eliminate or filter these low energy photons before they reach the patient. By reducing the low energy content of the beam, the materials used in the construction of the tube insert and tube housing that are in the path of the useful X-ray beam serve this purpose. Aluminum permanently mounted in the tube housing window provides additional filtration. All of the filtration that is permanently in the useful beam is referred to as the inherent filtration. Government regulations specify the minimum amount of inherent filtration that must be present in the X-ray beam as a function of the maximum tube potential at which the tube is operable.

HEAT DISSIPATION IN X RAY TUBES

Much of the design of an X-ray tube is predicated on the heat generated by the inefficiencies of the X-ray production process. Although the use of a rotating anode increases the ability of the focal spot to handle the instan-

taneous heat load during the short period of X-ray generation, there are limitations as to the total amount of heat that the anode and tube housing can each store. Basically, there are five parameters that describe the heat dissipation characteristics of an X-ray tube: (1) focal spot loading, (2) anode heat capacity, (3) anode cooling rate, (4) housing heat capacity, and (5) housing cooling rate.

These heat characteristics are described in terms of one of two units, heat units or watt-seconds. In the United States, heat parameters are specified in heat units (HU). The number of heat units generated by an X-ray exposure is given by the following formula:

$$HU = CVA t$$

where HU is the number of heat units, C is a waveform factor, V is the tube potential in peak kilovolts, A is the tube current in milliamperes, and t is the exposure duration in seconds. The waveform factor corrects for the differences in heating effect resulting from differences in average power of different high voltage waveforms. For a full-wave-rectified, single-phase waveform, the waveform factor is 1.0. For a 12-pulse, three-phase waveform, the waveform factor is 1.35. For example, an X-ray exposure of 100 kVp, 500 mA, 0.2 s using a single-phase generator would result in 10,000 HU. The same technique using a three-phase generator would result in 13,500 HU.

In Europe, heat parameters are expressed in watt-seconds (W·s) or joules (J). The heat generated by an X-ray exposure is given by the following formula:

$$E = KVA t$$

where E is the heat in watt-seconds or joules, K is a waveform factor, V is the tube potential in peak kilovolts, A is the tube current in milliamperes, and t is the exposure duration in seconds. In this case, the waveform factor for a full-wave-rectified, single-phase waveform is 0.74 and for a 12-pulse, three-phase waveform is 1.0. Therefore, the quantity of heat represented by one heat unit is 26% less than the quantity represented by 1 W·s or joule. Using the technique factors of the previous example (100 kVp, 500 mA, 0.2 s) results in 10,000 J of heat generated.

Focal Spot Loading

The heat handling characteristic of the X-ray tube focal spot is expressed in terms of kilowatts for an exposure duration of 0.1 s. The kilowatt loading of the focal spot is equal to the product of the tube potential in peak kilovolts and the tube current in milliamperes divided by 1000. It is the amount of power, or energy per second, deposited as heat in the anode. Typical X-ray tube inserts used in diagnostic radiology for high power procedures have focal spot loading capabilities of 30–40 kW for a small focus of 0.6 mm, and 100 kW for a large focus of 1.2 mm. The small focus of such a tube could not be used for the example technique of 100 kVp, 500 mA, because the focal spot loading would be exceeded. This demonstrates the trade-off between focal spot size and heat loading capability. A focal spot of 0.3 mm may have a maximum heat loading of as little as 9 kW. A tube insert with this rating could not be

used with a tube current >90 mA at 100 kVp, or >125 mA at 72 kVp, for an exposure duration of 0.1 s.

Anode Heat Storage Capacity

The maximum amount of heat that can be stored in the anode at any one time is its heat capacity. Depending on the manufacturer, the heat capacity is specified in terms of heat units or joules. The size and construction of the anode determine its heat capacity. Rotating anodes 3 in. (7.6 cm) in diameter have less heat storage capacity than anodes 4 in. (10.2 cm) in diameter. The typical "high power" diagnostic X-ray tube has a heat capacity of 300,000–400,000 HU. This is equivalent to the heat generated by 22–29 three-phase exposures of 100 kVp, 500 mA, 0.2 s each. Since the heat storage capacity is defined by the amount of energy deposited in the anode that raises its temperature from some reference temperature to the maximum operating temperature of the anode, the specified heat storage capacity will depend on the choice of reference temperature. For example, the storage capacity of an insert may be 400,000 HU when referenced to a "warm" anode, but is 600,000 heat units when referenced to ambient room temperature, that is, a "cold" anode. For this reason, it is important to be aware of the corresponding reference temperatures when comparing anode heat storage capacities of tube inserts of different manufacturers.

Anode Cooling Rate

Heat deposited in the anode is transferred to the tube housing. The rate at which the anode cools is dependent on the temperature difference between the anode and the tube housing. When the maximum rated amount of heat is stored in the anode, the cooling rate will be maximum; when the anode is cold, the cooling rate will be minimum. For this reason, the cooling rate of the anode is given as a cooling curve of heat stored in the anode as a function of time, with no additional heat deposited, as illustrated in Fig. 10. For an X-ray tube with a maximum anode cooling rate of $72,000 \text{ HU}\cdot\text{min}^{-1}$, at least 11 s would be required to transfer the heat generated by a 100 kVp, 500 mA, 0.2 s three-phase exposure from the anode to the tube housing. Since the maximum continuous heating rate is equal to the maximum cooling rate, the anode of this tube could be subjected to $1200 \text{ HU}\cdot\text{s}^{-1}$ continuously (e.g., 100 kVp, 8.9 mA).

Tube Housing Heat Capacity

Just as the anode is limited as to the amount of heat that can be stored in it at any one time, the heat capacity of the tube housing is also limited. Since the housing has a much larger mass than the anode, its heat capacity is significantly greater. The typical diagnostic X-ray tube housing has a heat storage capacity of 1,500,000 HU. This is equivalent to the heat generated by 111 three-phase exposures of 100 kVp, 500 mA, 0.2 s each.

Tube Housing Cooling Rate

Heat deposited in the tube housing is transferred to the surrounding ambient environment. The maximum housing

Figure 10. Anode cooling/heating curves.

cooling rate occurs when the housing is heated to its maximum capacity; the minimum cooling rate occurs when the housing contains little heat. The maximum cooling rate of a typical tube housing is $\sim 15,000 \text{ HU}\cdot\text{min}^{-1}$, unless additional measures have been taken to increase the cooling rate. A typical tube housing that has a fan to increase air flow over the housing has a maximum cooling rate of $\sim 24,000 \text{ HU}\cdot\text{min}^{-1}$. Another method of increasing the cooling rate is to constantly circulate the oil contained in the housing through an external heat exchanger. This method results in a maximum cooling rate of $\sim 50,000 \text{ HU}\cdot\text{min}^{-1}$. For high work load applications where X-ray exposures occur frequently enough that the heat generated by the exposures will not be totally dissipated from the X-ray tube before the next exposure, the cooling rate of the housing determines the rate at which heat can be generated in the tube. It is for this reason that manufacturers use the additional cooling measures discussed. For example, at least 54 s would be required to transfer the heat generated by a 100 kVp, 500 mA, 0.2 s three-phase exposure from a housing with a cooling rate of $15,000 \text{ HU}\cdot\text{min}^{-1}$. The addition of a fan would reduce this cooling time to 34 s.

Tube Rating Chart

To allow X-ray equipment users to easily determine whether a desired exposure technique exceeds the heat characteristics of an X-ray tube, all tube heat parameters are combined into one chart called a tube rating chart. A chart is provided by the manufacturer for each focal spot size and anode rotation speed. Each chart consists of a set of curves of tube potential versus exposure duration for different tube currents that defines the maximum single exposure capability of the X-ray tube when the tube is cold. An exposure technique that falls "below" the corresponding

Figure 11. Tube rating chart.

curve on the chart is allowed; a technique that is “above” the corresponding curve is not allowed.

Using the tube rating chart shown in Fig. 11, the point corresponding to a technique of 100 kVp, 500 mA, 0.2 s is above the curve for 500 mA. Therefore, this technique exceeds the heat capabilities of this particular X-ray tube and is not allowed. Examination of this 500 mA rating curve reveals that a tube potential of 100 kVp is not allowed, regardless of the duration of the X-ray exposure. The point corresponding to 100 kVp and 0.2 s indicates that a maximum tube current of ~280 mA is obtainable for 100 kVp and 0.2 s exposure duration. Similarly, the point where the 500 mA rating curve intersects 0.2 s indicates that a maximum tube potential of 54 kVp is obtainable for a 500 mA and 0.2 s exposure technique. Since the amount of film blackening is proportional to the product of the tube current and exposure duration, the technique of 100 kVp, 500 mA, 0.2 s could be changed to 100 kVp, 250 mA, 0.4 s without affecting the resulting diagnostic image. The point on the tube rating chart for this latter technique is below the 250 mA rating curve and the technique is therefore allowed. Some manufacturers provide tube rating charts that provide rating curves of tube current versus exposure duration for different tube potentials, but these can be utilized in a similar manner.

Single-exposure tube rating charts are not useful for determining the feasibility of multiple radiographic exposures (or radiographic exposures combined with fluoroscopic exposures) that may come close to exceeding a tube’s heat capabilities. The appropriate cooling and heating curves, combined with direct calculation of heat units produced, must be used in these cases. The data sheets for X-ray tubes designed for serial exposure applications such as cineangiography often include tables of maximum allowable techniques for serial exposures.

X-RAY TUBE FAILURE

Like electric light bulbs, X-ray tubes have a limited length of life. Due to the electrical, mechanical, and heat stresses

that an X-ray tube experiences during its normal use, there are several types of X-ray tube failures.

Bearing Wear

Since the X-ray tube insert is a sealed envelope, the bearings of a rotating anode can only be lubricated at the time of manufacture. Although the insert is designed to prevent heat deposited in the anode from reaching the bearings, sufficient heating of the bearings takes place in the long term to gradually reduce their lubrication. Prolonged operation at high rotor speeds also rapidly decreases the lifetime of the bearings. Eventually, the bearings become noisy and, if the tube insert is not replaced, will seize, thus preventing the anode from rotating.

Filament Evaporation

By design, an electric current is used to heat the filament to produce electrons. If this current is excessive, the filament will melt, resulting in an open filament. In addition, evaporation of the filament material is a natural consequence of filament heating. This may result in a loss of filament material sufficient to cause failure.

Cracked Anode

If an X-ray exposure is made with the anode stationary, the anode may crack due to intense heat build-up at the focal spot. This may be caused by either bearing or stator failure. Even if the problem of the stationary anode is resolved (i.e., the stator repaired) the cracked anode presents a safety problem because it may shatter, implode the glass envelope, and pierce the tube housing. It is also possible to crack a rotating anode if the anode is subjected to a very high heat-generating technique when it is cold. For this reason, some manufacturers recommend that X-ray tubes be warmed up by making several low tube-current, long-duration exposures (70 kVp, 75 mA, 6.0 s) whenever the tube has not been used for 1 h or more.

Tungsten Deposition

The heating of the tungsten filament and tungsten anode during normal operation of the X-ray tube causes some of the tungsten to evaporate and to build up gradually as a deposit on the glass envelope of the tube insert. This deposit causes the glass envelope to be less able to repel electrons reflected from the anode because it reduces the electrical insulating properties of the glass envelope, thereby reducing the magnitude of the induced negative charge on the envelope. The electron bombardment of the glass releases trapped gases that cause the electrical breakdown (arcing) of the tube when the amount of gas released becomes great enough.
